$$\boldsymbol{F}_{12} = -G\,\frac{m_1 m_2}{r^2}\,\hat{\boldsymbol{r}}_{12}\,, \qquad r = |\boldsymbol{r}_2 - \boldsymbol{r}_1|\,, \tag{33.1}$$

with $\hat{\boldsymbol{r}}_{12}$ the unit vector from body 1 to body 2, so that the force on body 1 points towards body 2. The constant G has the SI dimension $\mathrm{m}^3/(\mathrm{kg\,s}^2)$, which is already an unusual thing for a coupling constant: it is not dimensionless, and no combination of the other constants of nature produces it.

That form is not Newton's. The *Principia* argues throughout in proportions—the force is "as the product of the masses and reciprocally as the square of the distance"—and no symbol for a constant of proportionality appears anywhere in it [14]. Nor could one have been assigned a value, because the eighteenth century possessed no measurement from which to extract it. That is not an accident of technique but a structural feature of the astronomical evidence, and it is worth stating exactly.

Proposition 33.2 (Celestial mechanics determines only the products Gm)**.** *Let a system of bodies of masses m_a move under Equation (33.1) alone. Then every trajectory of the system depends on G and on the masses only through the n products Gm_a. In particular, no observation of orbital motion—however precise, and of however many bodies—can separate G from a mass. For a small body in orbit about a much larger one this specialises to Kepler's third law in the form*

$$T^2 = \frac{4\pi^2 a^3}{G\,(M+m)}\,, \tag{33.2}$$

whose right-hand side contains G nowhere except in that product.

Rests on Equation (33.1).

Proof. *Derives Proposition 33.2.*

The equation of motion of body b is, by Equation (33.1) and the second law of Chapter 19,

$$m_b\,\ddot{\boldsymbol{r}}_b = -\sum_{a\neq b} G\,\frac{m_a m_b}{|\boldsymbol{r}_b - \boldsymbol{r}_a|^2}\,\hat{\boldsymbol{r}}_{ba} \qquad\Longrightarrow\qquad \ddot{\boldsymbol{r}}_b = -\sum_{a\neq b} (Gm_a)\,\frac{\hat{\boldsymbol{r}}_{ba}}{|\boldsymbol{r}_b - \boldsymbol{r}_a|^2}\,. \tag{33.3}$$

The inertial mass m_b has cancelled—itself an experimental fact and not a theorem, as Chapter 20 insists—and what survives on the right is the set of products Gm_a and nothing else. The initial-value problem for Equation (33.3) therefore has the same solution for any (G, m_a) with the products fixed, so no trajectory distinguishes them. For the two-body case, reduction to the relative coordinate replaces Gm_a by $G(M+m)$ and the closed elliptical orbit gives Equation (33.2) (Chapter 27).

The consequence for practice is sharp. Astronomy measures the products GM for the Sun, the Earth and the planets far more precisely than any laboratory measures G — and cannot convert any of them into a mass, because the conversion needs exactly the factor the observations do not contain. To weigh the Earth, one must measure a gravitational force between two bodies *whose masses are known by weighing*, which means bodies small enough to put on a balance. That is the whole rationale of the experiment. □

The eighteenth-century way of putting the same point was to ask for the mean density of the Earth relative to water, a pure number then called the "density of the Earth". Newton himself had guessed it in Book III of the *Principia*, reasoning from the density of surface rocks and the compression expected at depth, at five to six times that of water [14]—a guess that turned out to be remarkably good, and that framed the problem for the next century as one of *weighing the Earth* rather than of measuring a constant.

Phenomenon 33.3 (Gravitation acts between laboratory masses)**.** Two ordinary bodies on a bench attract one another. The attraction is far too weak to notice — a lead sphere of some 160 kg pulls a companion of under a kilogram with a force of order $1.5 \times 10^{-7}\,\mathrm{N}$, some tens of millions of times smaller than the weight of the smaller body — but it is measurable, it is proportional to the product of the two masses and to the inverse square of the distance between their centres, and it is directed along the line joining them. That the law Newton inferred from the Moon and the planets [14] also holds between metre-scale masses in a closed room is not a deduction from the celestial evidence; it is a separate observation, and it is the observation this chapter reports.

Rests on Equation (33.1) *and Proposition 33.2.*

Derivation. *Derives Phenomenon 33.3.*

The magnitude asserted follows from the law together with the measured constant. Taking $G = 6.674\,30 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$ [2392], a source sphere of $M = 157.9\,\mathrm{kg}$ and a suspended ball of $m = 0.730\,\mathrm{kg}$ whose centres stand $r = 0.2248\,\mathrm{m}$ apart attract with

$$F = \frac{GMm}{r^2} = \frac{6.6743 \times 10^{-11} \times 157.9 \times 0.730}{0.050\,531}\,\mathrm{N} = 1.52 \times 10^{-7}\,\mathrm{N}\,, \tag{33.4}$$

against a weight $mg = 7.16\,\mathrm{N}$ for the very same ball: a ratio of 2.1×10^{-8}. No balance weighs a difference that small directly. Each sphere is treated here as a point mass at its centre, which for a homogeneous sphere is exact and not an approximation (Chapter 27); the correction for the actual inhomogeneity of a cast lead sphere is one of the systematics of Section 33.2.3.

The smallness of the ratio is the design constraint of the whole experiment. It is why the measurement is made as a torque against a torsion fibre rather than as a force against gravity (Section 33.2.1); why the apparatus must be sealed against air currents, whose forces on a 50 mm sphere are orders of magnitude larger (Section 33.2.3); and — ultimately — why G remains the least precisely known of the constants (Section 33.7.4). □

33.1.2 The Schiehallion experiment

One serious attempt preceded Cavendish. In 1774 Nevil Maskelyne, the Astronomer Royal, took a zenith sector to the isolated Perthshire mountain Schiehallion and measured the apparent latitude of two stations, one on the north flank and one on the south, by star transits. The mountain's own attraction pulls the plumb-line sideways at each station, in opposite senses, so the astronomical difference in latitude exceeds the geodetic difference measured by survey. The excess he found was 11.6 arcseconds, that is $5.62 \times 10^{-5}\,\mathrm{rad}$ of total deflection shared between the two sides [33].

Converting a deflection into a density requires the mountain's volume and shape, and it was Charles Hutton who supplied them, from an elaborate survey of the massif; to carry out the integration he invented the device of joining points of equal height by a line, which is the contour of every topographic map since. Hutton's reduction gave a mean density for the Earth of about 4.5 times that of water, that is about $4.5 \times 10^3\,\mathrm{kg/m^3}$ [35].

The result is low by some 18 % against the modern figure, and the reason is instructive: a mountain is an attractor whose mass distribution and internal density are not known, and Hutton had to assume a rock density for the whole massif. The error enters the answer in full. A lead sphere, by contrast, can be weighed on a balance and its dimensions measured with callipers, so that its mass and the position of its centre are known to the precision of ordinary metrology. That, and not any improvement in sensitivity, is what makes the closed-laboratory experiment the decisive one: it replaces an attractor that must be modelled by one that can be weighed.

33.1.3 Michell's apparatus

The instrument was not Cavendish's. It was conceived and built by the Reverend John Michell, who died before he could use it; it passed to Francis John Hyde Wollaston and thence to Cavendish, who rebuilt it substantially before beginning work. Cavendish says so in the opening pages of his paper and credits Michell with the design throughout [44]. The same instrument had been arrived at independently, and for a different purpose, by Coulomb, whose memoir on the torsion of metal wires established the linear restoring law and applied it to electrostatics [36, 38].

Why torsion? Because it is the only elastic degree of freedom soft enough. A body suspended from a fine fibre is held against gravity by the fibre's tension—an enormously stiff constraint—while being almost free to rotate about the fibre's axis, and the two stiffnesses can differ by ten orders of magnitude. Numerically, the balance described in Section 33.3 has a torsional stiffness of order $6\times10^{-5}\,\mathrm{N\,m/rad}$, which turns the $1.5\times10^{-7}\,\mathrm{N}$ of Equation (33.4) into a displacement of a few millimetres at the end of a metre-long beam: a signal that a telescope and a scale can read. The same force applied against the suspension's vertical stiffness would move the ball by a distance far below atomic dimensions.

33.2 Torsion pendulum theory

Everything the instrument reports is an angle. This section sets out the theory that converts angles into forces, and—because that theory is what the modern discrepancy turns on—states carefully which of its ingredients are theorems and which are experimental facts about a piece of wire.

33.2.1 The torsion pendulum

Phenomenon 33.4 (A twisted fibre restores in proportion to the twist)**.** A fine wire or fibre, twisted through a small angle about its own axis, resists with a torque proportional to the angle, and the constant of proportionality is a property of the fibre alone — not of the body hung from it, and not of the amplitude [36]. In consequence a body suspended from such a fibre oscillates torsionally with a period independent of how far it was displaced, and that period, together with the body's moment of inertia, suffices to determine the constant. This is what makes the torsion balance an *absolute* instrument: its force scale is fixed by a length, a mass distribution and a time, with no separate force standard anywhere in the chain.

Rests on Equation (9.106).

Derivation. *Derives Phenomenon 33.4.*

Let the restoring torque be $\tau=-\kappa\theta$, with κ in $\mathrm{N\,m/rad}$, and let the suspended body have moment of inertia I about the fibre axis. The rotational form of the second law (Chapter 29) gives

$$I\ddot{\theta}=-\kappa\theta\,, \tag{33.5}$$

which is Equation (9.106) with $\lambda^2=\kappa/I$ and time in place of the spatial variable. Its solutions are therefore those of Equation (9.108), $\theta(t)=A\cos\omega t+B\sin\omega t$ with $\omega=\sqrt{\kappa/I}$, and every one of them has the same, amplitude-independent period

$$T=2\pi\sqrt{\frac{I}{\kappa}}\,,\qquad\text{so that}\qquad \kappa=\frac{4\pi^2 I}{T^2}\,. \tag{33.6}$$

From Equations (9.108) *and* (33.5) *(reading off* $\omega=\sqrt{\kappa/I}$ *from the harmonic solution and inverting* $T=2\pi/\omega$*).*

Here I is computed from the measured masses and lengths of the beam and its balls, and T is timed; κ follows without any force having been applied to the instrument at all. An equilibrium deflection θ produced by the source masses then reports the gravitational torque as $\kappa\theta$, and hence the force.

Two cautions belong with the result, and both return later. The linearity is an experimental fact about the fibre, not a theorem, and it holds only for small twists; and its slow departures — creep, and the frequency-dependent anelasticity that makes κ differ between a static deflection and an oscillation — are precisely the systematic of Remark 33.10. □

Remark 33.5 (Why the fibre must be fine, quantitatively)*.* For a cylindrical wire of radius a and length ℓ made of a material of shear modulus μ, the elastic theory of Chapter 30 gives

$$\kappa = \frac{\pi \mu a^4}{2\ell}\,. \tag{33.7}$$

The fourth power is the design lever: halving the radius divides the stiffness by sixteen and multiplies the deflection by the same factor, at the cost of a suspension that must still carry the weight of the beam in tension. Cavendish's wire was of copper–silver; Boys later replaced it with drawn quartz [262], which is both finer and far more nearly perfectly elastic — the single largest instrumental advance between 1798 and the twentieth century. The symbol μ is used here for the shear modulus to keep G free for the gravitational constant.

Rests on Equation (33.6)*.*

Real fibres dissipate, and the balance is in practice a damped oscillator: with a retarding torque $-b\dot\theta$ the equation of motion becomes

$$I\ddot\theta + b\dot\theta + \kappa\theta = \tau_{\mathrm{ext}}(t)\,, \tag{33.8}$$

which is Equation (17.88) with the rotational variables in place of the linear ones. Its free solutions decay as $\mathrm{e}^{-\Gamma t}$ with $\Gamma = b/(2I)$, and the *quality factor* $Q = I\omega_0/b = \omega_0/(2\Gamma)$ counts, up to a factor 2π, the number of radians of oscillation in one decay time (Example 17.75). For the fibres used in this experiment Q runs from a few hundred to a few thousand: the free swing persists for hours, which is convenient for timing the period and inconvenient for waiting out a deflection — a tension resolved in Section 33.4.

33.2.2 From deflection to attraction

Proposition 33.6 (The working formula of the torsion balance)**.** *Let a beam carry two small balls of mass m at distance d from the suspension axis, and let two source spheres of mass M be placed one beside each ball, on opposite sides of the beam, with centre-to-centre separation r and the line of centres perpendicular to the beam. Let T be the free torsional period and $s = d\theta$ the linear displacement of a ball from its undisturbed position. Then, in the idealisation that the moment of inertia is that of the two balls alone and that each sphere attracts only its neighbour,*

$$G = \frac{4\pi^2 r^2 s}{M\,T^2}\,. \tag{33.9}$$

Neither the mass m of the suspended balls nor the half-length d of the beam appears: the instrument needs no knowledge of what is hanging from it.

Rests on Equations (33.1) *and* (33.6)*.*

Proof. *Derives Proposition 33.6.*

Each source sphere pulls its neighbouring ball with the force Equation (33.1), directed perpendicular to the beam and therefore wholly tangential; the two forces act at opposite ends and in opposite senses, so their torques add:

$$\tau_g = 2\,\frac{GMm}{r^2}\,d\,. \tag{33.10}$$

At equilibrium this is balanced by the fibre, $\tau_g = \kappa\theta$, and κ is eliminated in favour of the measured period by Equation (33.6) with $I = 2md^2$:

$$\theta = \frac{\tau_g}{\kappa} = \frac{2GMmd}{r^2} \cdot \frac{T^2}{4\pi^2\, 2md^2} = \frac{GMT^2}{4\pi^2 r^2 d}\,. \tag{33.11}$$

From Equations (33.6) and (33.10) (substituting $\kappa = 4\pi^2 I/T^2$ with $I = 2md^2$, so that m cancels between torque and inertia).

Both m and one power of d have cancelled. Writing $s = d\theta$ for the displacement actually read on the scale removes the second, and solving for G gives Equation (33.9).

The cancellation of m is not a coincidence and is worth naming: the gravitational torque is proportional to m and so is the inertia that sets the period, so the suspended mass drops out of the ratio. This is the same cancellation of gravitational against inertial mass that makes free fall universal (Chapter 20), appearing here as a property of the instrument rather than of the trajectory. □

Remark 33.7 (What the idealisation costs, and what repairs it). Equation (33.9) is a two-line formula and it is not the experiment. Four corrections are needed before it becomes one, and each was computed by Cavendish himself [44] and systematised by Boys [262]:

1. *The beam's own inertia.* $I = 2md^2 + I_{\text{beam}}$, and G is proportional to I, so a beam of a few hundred grams changes the answer by several percent. This is the largest of the four and it is measured, not estimated: the beam is weighed and its dimensions taken.

2. *Cross-attraction.* Each source sphere also pulls the *far* ball, along a direction nearly parallel to the beam, which contributes little torque but not none, and in the opposite sense.

3. *The rest of the apparatus.* The case, the mounting and the suspension wire all attract the balls; only the difference between the two source-mass positions survives the reversal of Remark 33.8, but the source spheres' attraction on the *beam* does not cancel and must be computed.

4. *Finite size.* A homogeneous sphere attracts an external point exactly as a point mass at its centre (Chapter 27), so sphericity costs nothing; departures from homogeneity in a cast lead sphere do.

Applied to Cavendish's own headline numbers — $r = 0.2248\,\text{m}$, $s = 4.1 \times 10^{-3}\,\text{m}$, $M = 157.9\,\text{kg}$, $T = 9.0 \times 10^2\,\text{s}$ — Equation (33.9) alone returns $G \approx 6.33 \times 10^{-11}\,\text{m}^3/(\text{kg}\,\text{s}^2)$, five percent below the modern value. Correction 1 has the right sign and the right size to account for essentially all of that shortfall. It is the difference between a five-percent estimate and Cavendish's one-percent result.

Rests on Equation (33.9).

Remark 33.8 (Reversal: the trick that makes the zero irrelevant). The beam has an unknown rest position, set by the fibre's own untwisted orientation, and that position drifts. Cavendish therefore never measures a deflection from a zero: he swings the source spheres from one side of the beam to the other, reversing the sign of τ_g, and measures the *difference* of the two equilibrium positions, which is $2s$. Any static offset, and any drift slow compared with a reversal cycle, cancels identically in the difference, while the signal doubles. Every torsion measurement of G since has been differential in the same way; the modern versions modulate the source masses continuously and detect at the modulation frequency, which is the same idea with the Fourier analysis of Chapter 17 placed after the detector.

Rests on Equation (33.9).

Proposition 33.9 (The time-of-swing method)**.** *Let the source masses be placed instead in two configurations, "near" and "far", chosen so that the gravitational torque on the beam varies with the deflection angle, with gradients $\partial\tau_g/\partial\theta = GC_1$ and GC_2 respectively, where $C_1 \neq C_2$ are geometrical factors carrying the masses and distances. Let ω_1, ω_2 be the measured angular frequencies of free torsional oscillation in the two configurations. Then*

$$G = \frac{I\,(\omega_2^2 - \omega_1^2)}{C_1 - C_2}\,, \tag{33.12}$$

in which the fibre constant κ has cancelled entirely.
Rests on Equations (33.5) *and* (33.10)*.*

Proof. *Derives Proposition 33.9.*

Expanding the total torque about the equilibrium angle, the effective stiffness is the fibre's stiffness reduced by the gravitational gradient,

$$I\ddot{\theta} = -\left(\kappa - \partial_\theta \tau_g\right)\theta \qquad \Longrightarrow \qquad I\omega_i^2 = \kappa - GC_i\,, \quad i = 1, 2\,. \tag{33.13}$$

Subtracting the second instance from the first removes κ identically: $I(\omega_2^2 - \omega_1^2) = G(C_1 - C_2)$, which is Equation (33.12). Nothing about the fibre survives the subtraction — provided there is one κ to subtract. □

The attraction of the method is that it replaces a displacement, read against a scale to perhaps a part in 10^3, by a frequency, which can be timed to a part in 10^6 or better; it is the method of Heyl [657] and of Luther and Towler [1695]. Its weakness is exactly the step that looks like its strength. The cancellation of κ in Equation (33.13) assumes one number κ; if the fibre's stiffness depends on the frequency at which it is interrogated, the two configurations do not share it, and the difference survives as a bias. That is Remark 33.10.

33.2.3 Systematics of the method

Cavendish's paper is, among other things, the first systematic error budget in experimental physics, and the discipline of it is why the result stands. He identified and pursued three nuisances [44].

Magnetism. The lead spheres might carry iron, and the balls might respond to it. He tested by rotating the source spheres about their own axes between runs, which reverses any magnetic moment they carry relative to the beam while leaving the gravitational configuration untouched, and found no change.

Air currents. The room was closed, kept dark, and the observer stayed outside it: the source spheres were swung by a pulley and cord operated from outside, and the beam was read through telescopes sighted at the case through small apertures, the scales lit by lamps. Nothing that could warm or stir the air was allowed inside with the instrument.

Thermal convection. This proved to be the real one, and the manner of its discovery is the model. Cavendish found an attraction that varied between runs in a way the geometry could not explain, and supposed—while thinking it improbable—that a temperature difference between the massive lead spheres and the case was driving a slow current of air past the balls. He then did the decisive thing: rather than argue about it, he made the suspected effect large. He placed lamps beneath the source spheres to heat them deliberately, put thermometers into the spheres themselves and read them through the telescope by light reflected from a convex mirror, and watched the beam move. The effect was there, and it was large. He then established the cause of the ordinary, unheated case: overnight the massive spheres cooled more slowly than the thin case, so a residual temperature difference—and a convection current—was present in every run. Diagnosing a systematic by amplifying it deliberately and then measuring its coefficient is the technique the whole subject still uses.

The modern list is longer and the terms are smaller, but the shape is the same: seismic and acoustic background, the local gravitational background of moving people and vehicles, electrostatic patch potentials between the beam and the case, residual magnetic susceptibility, the metrology of the source masses and their internal density inhomogeneity, and the elastic behaviour of the suspension [2286]. The last of these is the one that has resisted.

Remark 33.10 (Fibre anelasticity, and why it biases one method and not the other). A real fibre is not perfectly elastic: it dissipates, and dissipation and dispersion are not independent. The torsional response $\theta(\omega) = \hat{\chi}(\omega)\tau(\omega)$ is causal, so Theorem 17.78 ties the frequency dependence of the real part of the stiffness to the loss, and a fibre with a frequency-independent loss angle $1/Q$ necessarily has a stiffness that creeps logarithmically with frequency. Kuroda's observation [1901] is that this converts the apparently exact cancellation of κ in Equation (33.12) into an upward fractional bias of the time-of-swing result,

$$\frac{\Delta G}{G} \simeq \frac{1}{\pi Q}\,, \tag{33.14}$$

with Q the quality factor of the torsion mode. For a tungsten fibre with $Q \approx 2 \times 10^3$ that is about 160 parts per million — the same order as the spread among the modern determinations of Section 33.7.4, and an order of magnitude larger than the uncertainty several of them quote. The static-deflection method of Proposition 33.6 does not share the bias, because there κ is not required to be the same at two frequencies; and the angular-acceleration method of Section 33.7.2 avoids the fibre altogether by keeping it untwisted. That three methods with different exposures to one effect still disagree is why the anelastic explanation, though the leading candidate, is not a resolution.

Rests on Theorem 17.78 and Equation (33.12).

33.3 Apparatus

The instrument is a horizontal beam suspended at its midpoint by a fine wire, carrying a small lead ball at each end; two large lead spheres on a swivelling frame can be brought up to the balls from either side without the operator entering the room. The beam, the balls and the scales are enclosed in a narrow mahogany case, and the case stands in a closed shed, read from outside through telescopes. Every dimension is collected in Table 33.1, converted from the inches and pounds of the original per Remark 33.1.

Three features of the design carry the experiment and are worth naming separately. The case is narrow, so that the air inside it has little room to circulate. The source spheres never enter the case: they act through its wall, so that the massive, slowly cooling bodies are thermally outside the volume the balls live in — and even so the residual coupling was Cavendish's dominant systematic. And the readout is remote: telescopes with verniers, sighted from outside the closed room on ivory scales fixed to the ends of the beam and illuminated by lamps, so that the observer's own body heat never reaches the instrument.

33.4 Procedure

A run proceeds as follows. The source spheres are set on one side; the beam, disturbed by the change, begins a slow torsional oscillation about its new equilibrium. Rather than wait for it to come to rest — which at Q of order 10^3 and a period of a quarter of an hour would take days — the successive turning points are recorded through the telescope and the equilibrium is inferred from them. The spheres are then swung to the other side and the procedure repeated, and the difference of the two inferred equilibria is $2s$ (Remark 33.8). Separately, with the spheres removed, the free oscillation is timed over many periods to fix T and hence κ.

Table 33.1: The Cavendish balance, in SI. All values are converted from the imperial figures of [44]; the conversions (25.4 mm to the inch, 0.453 592 37 kg to the pound) are exact, so the number of significant figures shown is that of the original. The two suspension wires are those used before and after the change of wire recorded in Section 33.4; the derived torsional stiffnesses follow from Equation (33.6) with the moment of inertia of the two balls alone, and are quoted to one figure because the beam's own contribution is not reproduced here. The last two rows are the ivory scale's division and the resolution with which it could be read, through a telescope and a vernier, from outside the closed room.

part	quantity	value
beam	length	1.83 m
	half-length d	0.914 m
suspended balls	diameter	5.08×10^{-2} m
	mass m (each)	0.730 kg
source spheres	diameter	0.305 m
	mass M (each)	157.9 kg
	centre separation r	0.2248 m
suspension (i)	torsional period T	9.0×10^{2} s
	stiffness κ	6×10^{-5} N m/rad
suspension (ii)	torsional period T	4.5×10^{2} s
	stiffness κ	2.4×10^{-4} N m/rad
scale	division	1.27×10^{-3} m
	reading resolution	2.5×10^{-4} m

Proposition 33.11 (The equilibrium from three turning points)**.** *Let a lightly damped oscillation about an unknown equilibrium θ_{eq} have successive turning points $\theta_1, \theta_2, \theta_3$, let A be the displacement of the first of them from equilibrium, and let $q = \mathrm{e}^{-\Gamma T/2} \in (0,1)$ be the amplitude ratio between successive extrema. Then*

$$\frac{\theta_1 + 2\theta_2 + \theta_3}{4} = \theta_{eq} + \frac{A}{4}(1-q)^2 , \qquad \frac{\theta_1 + \theta_2}{2} = \theta_{eq} + \frac{A}{2}(1-q) . \tag{33.15}$$

The three-point estimator is therefore in error only at second order in the decay per half period, the two-point estimator at first order.

Rests on Equation (33.8)*.*

Proof. *Derives Proposition 33.11.*

The free solution of Equation (33.8) is $\theta(t) = \theta_{\mathrm{eq}} + A\mathrm{e}^{-\Gamma(t-t_1)}\cos\omega_d(t-t_1)$, whose turning points are separated by half a period, so that with $q = \mathrm{e}^{-\Gamma T/2}$

$$\theta_n = \theta_{\mathrm{eq}} + (-1)^{n-1} A q^{\,n-1} , \qquad n = 1, 2, 3 . \tag{33.16}$$

Substituting the three values into the two estimators,

$$\frac{\theta_1 + 2\theta_2 + \theta_3}{4} = \theta_{\mathrm{eq}} + \frac{A(1 - 2q + q^2)}{4} , \qquad \frac{\theta_1 + \theta_2}{2} = \theta_{\mathrm{eq}} + \frac{A(1-q)}{2} ,$$

and $1 - 2q + q^2 = (1-q)^2$, which is Equation (33.15). To size the gain, note that $\Gamma T/2 = \pi\Gamma/\omega_0 = \pi/(2Q)$ to leading order, so $1 - q \approx \pi/(2Q)$ and the ratio of the two errors is

$$\frac{(A/4)(1-q)^2}{(A/2)(1-q)} = \frac{1-q}{2} \approx \frac{\pi}{4Q} .$$

For $Q \approx 10^3$ that is a suppression by three orders of magnitude, which is why three readings taken over one and a half slow periods do the work of waiting days for the beam to come to rest. □

This is what Cavendish does, in words rather than symbols: he takes the mean of the extremes with the middle one counted twice. It is the reason the experiment was feasible at all with an instrument whose oscillation outlasts the observer's patience by two orders of magnitude.

The published series ran from August 1797 to May 1798 and comprises seventeen experiments yielding twenty-nine determinations of the mean density [44]. The first three experiments, six determinations made in August 1797, used the original suspension wire; Cavendish judged it insufficiently stiff — the beam was too easily disturbed — and replaced it with a wire of about four times the torsional stiffness, on which the remaining fourteen experiments and twenty-three determinations were made. The change is visible in the data as a halving of the period and a roughly fourfold reduction of the deflection — exactly the covariation Equation (33.6) and Equation (33.9) demand of a stiffness raised by a factor of four, and the reason two periods and two deflections appear in Table 33.1. Cavendish tabulates the two groups separately and does not combine them into a weighted mean; the grand average quoted in Section 33.5 is an unweighted one over all twenty-nine determinations.

33.5 Observations and data

Table 33.2: What the Cavendish experiment measured, in SI. The upper block is the raw instrumental signal; the middle block is the result as Cavendish published it and as corrected. The published mean of 5.480 times water contains an arithmetic slip in the averaging, found by Francis Baily in 1821 and recorded in Poynting's review [261]; Cavendish's own twenty-nine numbers average to 5.448. The implied G is not a quantity Cavendish computed — see Section 33.6 — and is obtained here by inverting Equation (33.17) with the modern g and R. The lower block is the modern comparison; the modern mean density is $M/\frac{4}{3}\pi R^3$ with $M = GM_\oplus/G$.

	quantity	value
signal	deflection s, wire (i)	$4.1 \times 10^{-3}\,\mathrm{m}$
	deflection s, wire (ii)	$7.6 \times 10^{-4}\,\mathrm{m}$
	gravitational force per ball	$1.5 \times 10^{-7}\,\mathrm{N}$
	gravitational torque on the beam	$2.8 \times 10^{-7}\,\mathrm{N\,m}$
	determinations (experiments)	29 (17)
result	mean density, as published	$(5.480 \pm 0.038) \times 10^3\,\mathrm{kg/m^3}$
	mean density, corrected	$(5.448 \pm 0.033) \times 10^3\,\mathrm{kg/m^3}$
	relative uncertainty	6.1×10^{-3}
	implied G	$(6.745 \pm 0.041) \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$
modern	mean density of the Earth	$5.5134 \times 10^3\,\mathrm{kg/m^3}$
	G (CODATA 2022)	$(6.674\,30 \pm 0.000\,15) \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$
	relative uncertainty	2.2×10^{-5}
	Cavendish's G is high by	1.1 %

Two things in Table 33.2 deserve comment before the physics is drawn out of them. The first is the arithmetic slip. The number 5.480 printed by Cavendish is not what his own twenty-nine determinations average to; the correct mean is 5.448, as Baily found in 1821

[261]. The book quotes both, because a reader who checks the primary source must be able to see why it disagrees with the modern secondary literature, and because the correction moves the answer *away* from the modern value — his error happened to be in the helpful direction, which is worth knowing when reading claims of eighteenth-century accuracy.

The second is the quoted uncertainty. The ± 0.033 is the standard error of the mean of twenty-nine determinations scattering by a few percent, that is a statistical uncertainty only (Theorem 2.7). It contains no allowance for the systematic effects of Section 33.2.3, and the actual departure from the modern value, 1.1 %, is close to twice the quoted error — which is the honest reading: Cavendish's statistical uncertainty was smaller than his systematic one, as it is for very nearly every measurement of G since.

Phenomenon 33.12 (The Earth is much denser than its crust)**.** The mean density of the Earth is about five and a half times that of water, roughly $5.5 \times 10^3\,\mathrm{kg/m^3}$, whereas the rocks accessible at the surface run between about $2.5 \times 10^3\,\mathrm{kg/m^3}$ and $3.0 \times 10^3\,\mathrm{kg/m^3}$ [44]. The interior must therefore consist of something substantially denser than anything the crust exposes. This was the first quantitative evidence that the planet is differentiated, and the beginning of the line of inference that ends in the seismological picture of an iron core; it was also the result the torsion-balance experiment was performed to obtain, the gravitational constant being a later restatement of the same measurement.

Rests on Equation (33.1) *and Proposition 33.6.*

Derivation. *Derives Phenomenon 33.12.*

Treat the Earth as a sphere of radius R and mass M. A body of mass m at the surface has weight $GMm/R^2 = mg$, so that $M = gR^2/G$ and the mean density is

$$\bar{\rho} = \frac{M}{\frac{4}{3}\pi R^3} = \frac{3g}{4\pi G R}\,. \tag{33.17}$$

From Equation (33.1) *(equating the weight mg to the attraction of a sphere of mass M at radius R and dividing by the volume).*

Every quantity on the right is measured without any assumption about the interior: g by dropping bodies (Chapter 20), R by geodesy, and G — the only difficult one — by this experiment. With $g = 9.806\,65\,\mathrm{m/s^2}$ [2333], $R = 6.371 \times 10^6\,\mathrm{m}$ and $G = 6.674\,30 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$ [2392],

$$\bar{\rho} = 5.506 \times 10^3\,\mathrm{kg/m^3}\,, \qquad M = \frac{gR^2}{G} = 5.964 \times 10^{24}\,\mathrm{kg}\,.$$

Both are low by 0.14 % against the accepted $5.5134 \times 10^3\,\mathrm{kg/m^3}$ and $5.9722 \times 10^{24}\,\mathrm{kg}$, and the discrepancy is not an error: g_0 is a conventional surface value that already includes the centrifugal reduction of the Earth's rotation, and the planet is an oblate spheroid rather than the sphere assumed here. At the 1 % level at which this chapter works, the spherical idealisation is entirely adequate; at the level of the modern numbers it is not, which is why the modern mean density is computed from $GM_\oplus$ and R rather than from g.

Read in the other direction this is exactly the eighteenth-century programme of "weighing the Earth": a measurement carried out entirely between laboratory masses delivers the mass of the planet, because G is the one factor that no astronomical observation can supply (Proposition 33.2). □

33.6 Interpretation

Cavendish never wrote a value for G, and it would have been an odd thing for him to do: the constant had no name, no symbol and no recognised status as a quantity to be measured.

What he reported was a density ratio. Inverting Equation (33.17) with the modern g and R turns his corrected 5.448 into

$$G = \frac{3g}{4\pi\bar{\rho}R} = (6.745 \pm 0.041) \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}\,, \tag{33.18}$$

which stands 1.1 % above the CODATA 2022 value [2431]. The reframing—from a density of the Earth to a constant of nature—was made a century later, in Boys's paper, which is titled "On the Newtonian constant of gravitation" and treats the Earth's density as a by-product rather than the object [262], and in Poynting's synthesis of the whole line of work [261].

The evidential point for this part of the book is the one Chapter 27 needs and cannot supply: that the law inferred from the heavens holds unchanged between bodies on a bench. It is worth being precise about what is and is not established. The experiment fixes the constant, for lead, at a separation of about 0.2 m. It does *not*, on its own, test the inverse square at laboratory distances to any precision — for that one varies r, which Cavendish did not systematically do, and which the modern short-range experiments of Chapter 42 pursue; nor does it test composition dependence, which had to wait for Heyl's gold, platinum and glass [657] and, far more sharply, for the Eötvös-type balances of the same chapter. What the combination of the bench measurement with the celestial one does test, and sharply, is that a single constant serves both.

Phenomenon 33.13 (One constant serves the bench and the sky)**.** The constant measured between lead spheres in a closed room is the same constant that governs the orbits of the Moon and the planets [44]. No scaling factor, no dependence on the material of the attracting bodies, and no departure from the inverse square is needed to pass from a separation of 0.2 m to one of 3.8×10^8 m — nine orders of magnitude in distance, and more than twenty in mass. Universality of this kind is not implied by the celestial evidence alone, which fixes only the products GM and never G and M separately; it is the laboratory measurement that separates the two and thereby makes the statement testable at all.

Rests on Proposition 33.2 and Phenomenon 33.12.

Derivation. *Derives Phenomenon 33.13.*

Take G from the torsion balance and the Earth's mass $M = 5.964 \times 10^{24}$ kg from Equation (33.17), both obtained without any reference to the Moon. Newton's law together with the circular-orbit condition of Chapter 27 then predicts the lunar month with nothing further adjusted: Equation (33.2) for a circular orbit of radius r about a centre of total mass $M + m$ reads

$$T = 2\pi\sqrt{\frac{r^3}{G\,(M+m)}}\,. \tag{33.19}$$

With $r = 3.844 \times 10^8$ m, $M = 5.964 \times 10^{24}$ kg and the Moon's $m = 7.346 \times 10^{22}$ kg this gives $T = 2.359 \times 10^6$ s, that is 27.30 days, against an observed sidereal month of 27.3217 days. The agreement to 0.08 % — the residual being the eccentricity of the orbit and the solar perturbation, not the constant — is the check that the laboratory G and the celestial one are a single number. Note what the check consumes: the laboratory G enters twice, once in converting g and R into M and once in Equation (33.19) itself, and the two occurrences do not cancel, since the first carries G^{-1} and the second $G^{-1/2}$. The test is therefore genuine and not circular.

That same constant is carried unchanged into the field equations of Chapter 44, where it appears in the coupling $8\pi G/c^4$; the far sharper tests of the universality of gravitational free fall are the subject of Chapter 42. □

33.7 Modern determinations and their discrepancies

33.7.1 Classic redeterminations

Boys reworked the experiment in 1895 with two changes that between them define the modern instrument [262]. The second was the suspension: a drawn quartz fibre in place of drawn metal, which is finer, stronger in tension, and far closer to perfectly elastic — the material answer to Remark 33.5 and, in part, to Remark 33.10. The first was to make the whole instrument small: his beam was a few centimetres long against Cavendish's 1.83 m. He obtained $G \approx 6.658 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$, and, as the title of his paper announces, he reported it as a constant of nature.

Remark 33.14 (Why shrinking the balance costs no sensitivity). The reason a small instrument does as well is a scaling argument, and it is the one that made Boys's design possible. Take two geometrically similar balances, the second smaller by a factor λ, and load each suspension to the same fraction of the breaking stress of its material. The suspended weight scales as λ^3, so the fibre's cross-sectional area does too and its radius as $\lambda^{3/2}$; by Equation (33.7) the torsional stiffness then scales as $(\lambda^{3/2})^4/\lambda = \lambda^5$. The moment of inertia $2md^2$ scales as $\lambda^3\lambda^2 = \lambda^5$ as well, so by Equation (33.6) the period is *unchanged*; and the gravitational torque Equation (33.10), with $M, m \propto \lambda^3$ and $d, r \propto \lambda$, scales as λ^5 likewise. Hence

$$\theta = \frac{\tau_g}{\kappa} \propto \frac{\lambda^5}{\lambda^5} = \text{const}\,, \qquad T \propto \text{const}\,. \tag{33.20}$$

The *angular* deflection — which is what a mirror and a distant scale read, and which does not care how long the beam is — is independent of the size of the apparatus. Shrinking it therefore costs nothing in signal and buys a great deal in disturbance: less air inside the case to convect, a smaller temperature difference across it, and a smaller and more easily controlled room around it. The strength of quartz is what makes the premise of the argument, a fibre loaded to a fixed fraction of breaking stress, achievable at small scale.

Rests on Equations (33.7) *and* (33.10).

Poynting had meanwhile attacked the same quantity with a common balance rather than a torsion fibre, weighing a mass against the attraction of a large lead sphere placed beneath one pan and then the other; his Adams Prize essay is also where the correction to Cavendish's arithmetic is recorded [261].

Heyl's series at the Bureau of Standards in the 1920s introduced the time-of-swing method of Proposition 33.9 in its modern form and gave $G = (6.670 \pm 0.005) \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$, a relative uncertainty of 7.5×10^{-4} [657]. He also did something nobody had: he ran the measurement with suspended masses of gold, of platinum and of optical glass, an explicit search for a dependence of gravitation on the material of the attracted body. Heyl and Chrzanowski's continuation of the work supplied the value on which the first CODATA recommendation rested [2286].

The reference value for a generation was Luther and Towler's time-of-swing determination with tungsten source masses, $G = (6.6726 \pm 0.0005) \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$, a relative uncertainty of 7.5×10^{-5} [1695]. It dominated the recommended value until the 1990s, and it is a time-of-swing result, which is why Remark 33.10 landed as hard as it did when Kuroda published it in 1995 [1901].

33.7.2 Modern torsion-balance measurements

Gundlach and Merkowitz answered the anelasticity problem by removing the fibre from the measurement chain [1991]. Their balance sits on a turntable whose angular acceleration is servoed so as to keep the fibre's twist at zero: the feedback signal is then the angular acceleration required to follow the gravitational torque, and κ never enters, since the fibre

is never twisted. Neither Equation (33.9) nor Equation (33.12) is used — a third method, whose systematics are dominated by the metrology of the source masses and by the turntable rather than by the suspension. They reported $G = (6.674\,215 \pm 0.000\,092) \times 10^{-11}\ \mathrm{m^3/(kg\,s^2)}$, 14 parts per million, then the most precise value ever obtained.

The BIPM group built a balance that could be operated in two modes on the same apparatus and the same masses: a servo mode, in which an electrostatic torque holds the beam and is itself the measurement, and a Cavendish mode, in which the static deflection is read as in Proposition 33.6. The two agreed with each other and gave $G = (6.675\,54 \pm 0.000\,16) \times 10^{-11}\ \mathrm{m^3/(kg\,s^2)}$, 24 parts per million, after the correction published as an erratum [2222]. This value and Gundlach and Merkowitz's are the canonical irreconcilable pair: they differ by 199 parts per million with a combined uncertainty of 28, that is by more than seven standard deviations.

The HUST group then did what the field most needed, which is not another precise number but two of them from one laboratory: time-of-swing and angular-acceleration feedback, run on the same premises with the same source masses and by the same people, each reaching about 12 parts per million [2314]. The two results are $(6.674\,184 \pm 0.000\,078) \times 10^{-11}\ \mathrm{m^3/(kg\,s^2)}$ and $(6.674\,484 \pm 0.000\,078) \times 10^{-11}\ \mathrm{m^3/(kg\,s^2)}$: they differ from each other by 45 parts per million, about 2.7 standard deviations of the difference. Two methods, one laboratory, and still a disagreement — which is a stronger statement about the state of the subject than any single number in it.

33.7.3 Beyond torsion

Rosi and collaborators measured G with no fibre, no beam and no macroscopic proof mass at all: the test bodies are laser-cooled rubidium atoms in free fall, and the observable is the phase of a matter-wave interferometer, shifted by the gravitational field of tungsten source masses moved between two positions [2237]. The result, $G = (6.671\,91 \pm 0.000\,99) \times 10^{-11}\ \mathrm{m^3/(kg\,s^2)}$ at 150 parts per million, is an order of magnitude less precise than the best torsion values — and it is nevertheless one of the most useful numbers in the set, because its systematics have almost nothing in common with theirs. It lies 544 parts per million below the BIPM value, more than three standard deviations of the difference.

Other routes have been pursued: beam balances weighing a test mass against a movable source, free-fall and pendulum gradiometry, and Fabry–Pérot resonators, all surveyed with their uncertainty budgets in [2286]. The lesson the survey draws is the one this section exists to make. The field does not need another measurement at 10 parts per million that shares a systematic with the measurements already there; it needs measurements whose dominant systematic is different, so that agreement means something. That is why a 150-part-per-million atom-interferometric value carries weight disproportionate to its error bar.

33.7.4 The discrepancy, honestly stated

Example 33.15 (The six values are mutually inconsistent, and by how much)**.** Combine the six measurements of Table 33.3 as independent determinations of one quantity. The minimum-variance combination is the inverse-variance weighted mean Equation (2.4), which gives

$$\hat{G} = (6.674\,382 \pm 0.000\,045) \times 10^{-11}\ \mathrm{m^3/(kg\,s^2)}\,, \tag{33.21}$$

a relative uncertainty of 6.8 parts per million. That number should not be believed, and the reason is visible in the same arithmetic. The residuals about it, in units of each measurement's own uncertainty and in the order of the table, are -3.56, -1.82, $+7.24$,

Table 33.3: Six determinations of G, as published, in units of $\mathrm{m^3/(kg\,s^2)}$. "ToS" is the time-of-swing method of Proposition 33.9, "Cav" the static deflection of Proposition 33.6, "AAF" the angular-acceleration-feedback method, "AI" atom interferometry. The final row is not a measurement but the CODATA 2022 least-squares adjustment over sixteen input values, whose uncertainty is enlarged by an expansion factor of 3.9 to cover the observed scatter [2431]. Relative uncertainties are quoted in parts per million.

year	laboratory and method	$G \times 10^{11}$	$u_r/10^{-6}$	source
1982	NBS, ToS	6.6726(5)	75	[1695]
2000	U. Washington, AAF	6.674215(92)	14	[1991]
2013	BIPM, servo + Cav	6.67554(16)	24	[2222]
2014	LENS, AI	6.67191(99)	150	[2237]
2018	HUST, ToS	6.674184(78)	11.6	[2314]
2018	HUST, AAF	6.674484(78)	11.6	[2314]
2022	CODATA adjustment	6.67430(15)	22	[2431]

-2.50, -2.54 and $+1.31$, and their sum of squares is

$$\chi^2 = \sum_i \frac{\left(G_i - \hat{G}\right)^2}{u_i^2} = 83\,, \tag{33.22}$$

on $6-1=5$ degrees of freedom. That the count is $n-1$ and not n is Lemma 11.83 with the projector onto the complement of the weight vector; the expected value of such a χ^2 is 5 with a standard deviation of $\sqrt{10}$ (Proposition 11.81), so the observed 83 corresponds to a p-value (Definition 11.75) of order 10^{-16}. The data are not a set of independent measurements of one quantity with the stated errors.

The Birge ratio $\sqrt{\chi^2/(n-1)} = 4.1$ is the factor by which every uncertainty would have to be multiplied to make the set self-consistent. CODATA, working over sixteen inputs rather than six, arrives at an expansion factor of 3.9 [2431]. The agreement between the two numbers is a coincidence of arithmetic rather than a reproduction of the adjustment — different input sets, and CODATA chooses its factor to bring all residuals below two rather than to normalise χ^2 — but it shows where the recommended uncertainty comes from. It is not the uncertainty of the measurements. It is the width of their disagreement.

Rests on Equation (2.4), Lemma 11.83, and Proposition 11.81.

Phenomenon 33.16 (The least well determined of the constants)**.** The Newtonian constant of gravitation is known far less precisely than any other fundamental constant. The CODATA recommended value is $G = 6.674\,30 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$ with a standard uncertainty of $1.5 \times 10^{-15}\,\mathrm{m^3/(kg\,s^2)}$, a relative uncertainty of 2.2×10^{-5} [2392, 2431]; the same adjustment fixes the electron mass and the Rydberg constant to parts in 10^{10} and better. The reason is not that the individual experiments are imprecise. Several claim uncertainties of tens of parts per million, and yet their central values scatter over several hundred parts per million — many times their own quoted errors — so that they cannot all be correct. The recommended uncertainty above is therefore not the uncertainty that any experiment reports: it is an inflated one, enlarged by the adjustment precisely because the inputs are mutually inconsistent [2431].

Rests on Example 33.15 and Equation (33.9).

Derivation. *Derives Phenomenon 33.16.*

Every clause of the statement is arithmetic on Table 33.3, and it is worth doing because the conclusion is often reported as an opinion about the field rather than as a measured property of its data.

Take the scatter first. The extreme values in the table are the BIPM determination at $6.675\,54 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$ and the LENS atom-interferometric one at $6.671\,91 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$, whose difference is $3.63 \times 10^{-14}\,\mathrm{m^3/(kg\,s^2)}$, or 544 parts per million of either. Discard the atom interferometer, the one entry whose own uncertainty is large, and the four torsion values still span 203 parts per million, from the same BIPM value down to the HUST time-of-swing one. Against that, the two most precise entries each claim 11.6 parts per million. The spread of the set exceeds the precision claimed within it by a factor between seventeen and forty-seven, which is the first clause of the statement: the experiments are not imprecise, they disagree.

That they disagree beyond their stated errors is Example 33.15, which is quoted here and not repeated: the χ^2 of Equation (33.22) is 83 on five degrees of freedom, whose p-value is of order 10^{-16}. No hypothesis under which the six are independent measurements of one quantity with the stated uncertainties survives that number.

The third clause — that the recommended uncertainty is an inflated one and not the uncertainty of any measurement — follows from a property of the weighted mean, without any knowledge of how CODATA performs its adjustment. By Equation (2.4) the inverse-variance combination of independent measurements has variance $\hat{u}^2 = \left(\sum_i u_i^{-2}\right)^{-1}$, so $\hat{u} \le \min_i u_i$: combining consistent data can only sharpen the answer, never blunt it. Here $\min_i u_i$ is 11.6 parts per million and the six inputs give $\hat{u} = 6.8$ parts per million, as Equation (33.21) records. The CODATA recommended value carries 22 parts per million. That is larger than the best single input, so the recommended uncertainty is provably not the uncertainty of a combination of the data as published; it is that combination enlarged, by a factor of 3.2 on the six values here and by the quoted 3.9 on the sixteen CODATA uses [2431]. What the recommended figure measures is the width of the disagreement.

The remaining clause, that no other fundamental constant is known so poorly, is not derived here: it is read off the same adjustment, which fixes the electron mass and the Rydberg constant to parts in 10^{10} and better [2392, 2431]. Nothing in this chapter establishes it independently.

What the derivation does *not* deliver is the cause. Every step above uses only the published values and their published uncertainties; none of it identifies which measurement is displaced, or by what. That question is open, and Remark 33.17 states how open. □

Remark 33.17 (The discrepancy is not resolved, and the leading candidate does not fit). No accepted account of the scatter exists, and none is constructed here. Resolving it would mean establishing which systematic effect displaces which measurements — frequency-dependent anelasticity of the suspension fibre and the metrology of the source masses are the leading candidates — and a reader is entitled to know how bad the situation is. The first thing to say is that the leading candidate does not fit. If fibre anelasticity (Remark 33.10) were the whole story, the time-of-swing values would sit systematically high and the angular-acceleration values low; instead the two HUST determinations, one of each kind, differ by 45 parts per million in the *opposite* sense to the naive prediction of Equation (33.14), and the BIPM value, which is not a time-of-swing measurement at all, is the highest in the set. The second thing is that no proposal of new physics is on the table here, and none should be: a discrepancy among six laboratory measurements of a laboratory quantity is overwhelmingly likely to be an unidentified systematic in one or more of them, and the honest statement is that nobody yet knows which. This remark is not a placeholder for a derivation the treatise owes. Phenomenon 33.16 asserts that the constant is poorly known, that the inputs are inconsistent and that the recommended uncertainty is inflated, and all three are derived above; the cause of the inconsistency is not asserted anywhere in this book, and so is not

owed.

Chapter 34

Experiment: The Pendulum

Chapter 28 asserts that a pendulum of length ℓ swinging through a small arc has period $T = 2\pi\sqrt{\ell/g}$, the same whether the arc is wide or narrow and whatever the mass and material of the bob; Chapter 29 asserts that in the frame rotating with the Earth a Coriolis term must turn the plane of that swing at the rate $\Omega \sin\lambda$. Both are predictions, and neither chapter shows either of them being measured. This chapter reports the measurements. It also reports what happens when the small arc is *not* small, which is the first place in this treatise where a linearization is tested rather than assumed, and what happens when the restoring torque comes from a twisted wire instead of from gravity, which is the instrument of Chapter 33.

The pendulum deserves a chapter of its own for a reason beyond the two predictions it settles: it is the first precision instrument in physics. Everything the measurement chapter Chapter 2 requires of an instrument — a reading that is a number, a calibration chain that terminates in base units, a stated uncertainty, and a systematic error budget written down and argued over — appears here first and appears complete. A pendulum is a length and a time and nothing else; that is what makes it an *absolute* instrument, in the technical sense that its scale is fixed by the metre and the second without reference to any other apparatus of the same kind. In four guises it delivered the first precision frequency standard (Section 34.1), the transducer that converts a force too weak to weigh into a visible angle (Section 34.2), the first absolute determination of the acceleration of free fall (Section 34.3), and the first laboratory proof, consulting nothing outside the room, that the Earth turns (Section 34.5).

34.1 Galileo and Huygens: the isochronous pendulum (1602–1673)

Tests Phenomenon 28.9 and Equation (28.7).

Assuming Equation (28.8).

The claim under test is the one stated in Chapter 28 as the isochronism of the small-amplitude pendulum: the period does not depend on the amplitude, nor on the bob. It is an approximate claim, and the interest of the seventeenth-century work is that both halves of it were established — Galileo found the approximation, Huygens found its limits and then removed them exactly, by changing the path from a circle to a cycloid.

34.1.1 Apparatus

Galileo's instrument is a bob on a cord of measured length hung from a fixed point, and, for the comparative observations, two such pendulums of equal length side by side carrying bobs of very different density — cork and lead — so that a dependence on the material of

the bob would show as a growing difference of phase [4]. There is no clock: the counting of swings *is* the clock, and where an independent time is needed it comes from a water vessel weighed before and after, the technique Galileo used for the inclined plane.

Huygens' instrument is a pendulum clock: a bob on a flexible suspension, maintained against friction by a weight-driven escapement, with a dial that accumulates the count. Its distinguishing feature is a pair of rigid metal cheeks flanking the point of suspension, bent to arcs of a cycloid, against which the suspension wraps as the bob swings out [11]. The cheeks are the experiment; the rest is a clock.

34.1.2 Procedure

Release two equal pendulums together from unequal arcs and count the swings until they can be seen to separate: an amplitude dependence of the period appears as a slow accumulation of phase, so that a fractional period difference of ϵ becomes a visible half-swing after about $1/2\epsilon$ swings. The same protocol run with cork and lead bobs tests the independence of the bob. To test the square-root law, compare pendulums whose lengths stand in the ratio $4:1$ and count the swings of each in the same interval.

With the clock, the procedure is to vary the driving weight, and with it the amplitude at which the escapement settles, and read the change in the rate; then to fit the cycloidal cheeks and repeat. The signature sought is not a small rate but a rate that stops moving when the amplitude is changed.

34.1.3 Observations and data

Galileo reports that pendulums of equal length keep step whether the arc is wide or narrow, and that a cork bob and a lead bob of the same suspension length stay together for a great many swings even though the cork is stopped by the air much sooner; and that the period varies as the square root of the length [4]. Huygens reports the residual he was looking for: the circular pendulum runs *slow* at large amplitude, so that a clock's rate depends on how hard it is driven, and the cycloidal constraint removes that dependence entirely [11].

Neither man quotes a number in a unit and neither quotes an uncertainty; both quote a comparison. The quantitative content of the two reports is therefore recovered by asking what a count of swings can resolve, and setting that against the exact period of the circular pendulum, which is the quantity Galileo's claim asserts to be constant and Huygens' measurement shows is not.

Remark 34.1 (The exact period is an elliptic integral, and this treatise does not yet define one). Quadrature of Equation (28.8) at fixed energy gives the period of a swing of angular amplitude θ_0 as

$$T(\theta_0) = \frac{4}{\omega_0}\int_0^{\pi/2} \frac{\mathrm{d}\varphi}{\sqrt{1-\sin^2(\theta_0/2)\sin^2\varphi}}, \qquad \omega_0 = \sqrt{\frac{g}{\ell}}, \tag{34.1}$$

after the substitution $\sin(\theta/2) = \sin(\theta_0/2)\sin\varphi$. The integral is the complete elliptic integral of the first kind of modulus $k = \sin(\theta_0/2)$. That function is not among the results of Part II, so nothing below leans on its properties: the entries of Table 34.1 are quoted as numerical values of Equation (34.1), and every *algebraic* statement made about the amplitude dependence uses instead the small-amplitude series $T/T_0 = 1 + \theta_0^2/16 + 11\theta_0^4/3072 + \cdots$ obtained by the perturbation method of Chapter 28, which reproduces the table to the digits shown up to about 60° and fails by 1.6×10^{-4} at 90°.

Galileo's comparison, reduced. He hangs the two bobs on threads "four or five braccia" long [4]; a Florentine braccio is close to $0.583\,\mathrm{m}$, so the suspension is between $2.33\,\mathrm{m}$ and $2.92\,\mathrm{m}$ and, by Equation (28.7), the period is between $3.06\,\mathrm{s}$ and $3.43\,\mathrm{s}$. The lead bob is

Table 34.1: The amplitude dependence of the circular pendulum: what Galileo's comparison bounds, what Huygens measured, and what the cycloidal cheeks remove. $T_0 = 2\pi\sqrt{\ell/g}$ is the infinitesimal-amplitude period of Equation (28.7) and θ_0 the angular amplitude; the ratio is the numerical value of Equation (34.1), exact to the six figures shown. $N_{1/2}$ is the number of swings after which a pendulum of amplitude θ_0 has fallen half a period behind an identical one of vanishing amplitude, $N_{1/2} = \frac{1}{2}T_0/\left(T - T_0\right)$: that is the point at which the two are seen to be in antiphase, and it is the resolution of a bare count of swings. The last column converts the same fractional excess into the daily rate error of a clock whose escapement holds that amplitude. Nothing in the table depends on ℓ, on the mass, or on the material of the bob.

θ_0	T/T_0	$\left(T - T_0\right)/T_0$	$N_{1/2}$ (swings)	clock error (s per day)
1°	1.000 019	1.9×10^{-5}	2.6×10^{4}	1.6
2°	1.000 076	7.6×10^{-5}	6.6×10^{3}	6.6
5°	1.000 476	4.8×10^{-4}	1.1×10^{3}	41
10°	1.001 907	1.9×10^{-3}	262	165
20°	1.007 669	7.7×10^{-3}	65	663
30°	1.017 409	1.7×10^{-2}	29	1.5×10^{3}
45°	1.039 973	4.0×10^{-2}	13	3.5×10^{3}
60°	1.073 182	7.3×10^{-2}	6.8	6.3×10^{3}
90°	1.180 341	1.8×10^{-1}	2.8	1.6×10^{4}

stated to be more than a hundred times the mass of the cork one. What is counted is swings, and two pendulums can be seen to be in step or not to within perhaps a quarter of a swing; so agreement maintained over N swings bounds the fractional period difference by

$$\left|\frac{\Delta T}{T}\right| < \frac{1}{4N}\,, \tag{34.2}$$

which for the fifty to a hundred swings Galileo reports is 2.5×10^{-3}. That is the entire quantitative content of the observation, and Table 34.1 says exactly what it licenses: the mass independence is established at the 2.5×10^{-3} level, and the amplitude independence is established at that level *only for arcs of order* 10° *or smaller*. The bound is not idle. Galileo states isochronism for wide arcs as well as narrow ones, and there it is simply false: between 50° and 5° the exact period differs by 4.9 %, so the two pendulums would stand in antiphase after ten swings — half a minute, on a suspension of four braccia.

Huygens' measurement, reduced. The signature he reports is that a circular clock's rate follows its driving weight, and stops doing so once the cheeks are fitted [11]. In numbers: an escapement that lets the amplitude wander between 4° and 6° — a small drift, and less than the change produced by a week's accumulation of dust on the pallets — moves the fractional period excess from 3.05×10^{-4} to 6.86×10^{-4}, a change of 3.81×10^{-4}, that is, of 33 s a day. With the cheeks fitted the same drift moves the rate by nothing at all, because Equation (34.6) contains no amplitude. That is a null result of the strongest kind: not a small residual, but a term absent by construction.

Phenomenon 34.2 (Exact isochronism on a cycloid)**.** A body sliding without friction under gravity along an arc of a cycloid, cusps upward, reaches the lowest point of the arc in the same time from every starting height. Unlike the circular pendulum, whose period grows with amplitude, the cycloidal pendulum is isochronous exactly and at every amplitude, up to the cusps; and a pendulum can be made to travel a cycloid by letting its suspension wrap

on two cycloidal cheeks [11]. This is the first case in physics of a nonlinear problem solved exactly by choosing the constraint rather than approximating the motion.

Rests on Proposition 28.12 and Equation (28.7).

Derivation. *Derives Phenomenon 34.2.*

Take the cycloid generated by a circle of radius a rolling on the underside of a horizontal line, in the parametrization

$$x = a\,(\theta + \sin\theta)\,, \qquad y = a\,(1 - \cos\theta)\,, \qquad |\theta| \le \pi\,, \tag{34.3}$$

whose lowest point is $\theta = 0$ and whose cusps are at $\theta = \pm\pi$. Differentiating, $\mathrm{d}x = a\,(1 + \cos\theta)\,\mathrm{d}\theta$ and $\mathrm{d}y = a\sin\theta\,\mathrm{d}\theta$, so that

$$\mathrm{d}s^2 = \mathrm{d}x^2 + \mathrm{d}y^2 = a^2\,(2 + 2\cos\theta)\,\mathrm{d}\theta^2 = 4a^2\cos^2\!\left(\tfrac{\theta}{2}\right)\mathrm{d}\theta^2\,.$$

Measuring the arc s from the lowest point gives $s = 4a\sin(\theta/2)$, and the height above that point is

$$y = a\,(1 - \cos\theta) = 2a\sin^2\!\left(\tfrac{\theta}{2}\right) = \frac{s^2}{8a}\,. \tag{34.4}$$

The height is therefore *exactly* quadratic in the arc length, with no higher corrections — which is the whole content of the choice of curve. The potential energy per unit mass along the path is $gy = gs^2/8a$, so the tangential equation of motion is

$$\ddot{s} = -\frac{\mathrm{d}}{\mathrm{d}s}\left(\frac{gs^2}{8a}\right) = -\frac{g}{4a}\,s\,, \tag{34.5}$$

a harmonic equation with no approximation made anywhere, whose period

$$T = 2\pi\sqrt{\frac{4a}{g}} \tag{34.6}$$

is independent of s and hence of the amplitude, up to the full half-arc $s = 4a$. Comparing with $T = 2\pi\sqrt{\ell/g}$, the cycloidal pendulum swings like a circular one of length $\ell = 4a$. That a suspension of that same length, wrapping on cycloidal cheeks generated by circles of radius a, does travel this curve is the geometric fact that the evolute of a cycloid is a congruent cycloid: the radius of curvature of Equation (34.3) is $\rho = \mathrm{d}s/\mathrm{d}\,(\theta/2) = 4a\cos(\theta/2)$, equal to $4a$ at the vertex and falling to zero at the cusps, exactly as the free length of the wrapping suspension does. □

34.1.4 Interpretation

Two results, not one. Galileo's is that a pendulum has a proper frequency, set by its length and by the local gravity and by nothing else — not by the amplitude, not by the mass, not by the material. That is what makes a swinging weight a *standard* rather than a curiosity, and it is the observational content of the harmonic approximation of Chapter 28: the mass cancels from $\ell\ddot{\theta} = -g\sin\theta$ before any linearization is performed, which is why the cork and the lead keep step, while the amplitude survives in $\sin\theta$ and drops out only when the equation is linearized.

Huygens' result is the sharper one, because it measures the error of that linearization instead of assuming it away. The circular pendulum's period grows with amplitude as $T\,(A) = T\,(1 + A^2/16 + O(A^4))$, derived in Chapter 28; at an amplitude of 7°, that is about one part in 10^3, and a clock whose amplitude wanders by that much gains or loses of order 81 s a day (Table 34.1). A minute and a half a day is not a subtlety for a seventeenth-century navigator, and the cycloidal cheeks are the response: not a smaller error but a structurally zero one. The trade is instructive and recurs throughout this treatise — Huygens bought exactness in the amplitude at the cost of a new systematic, since the cheeks must be cut to the right curve and the suspension must be perfectly flexible, and neither condition is better satisfied in practice than the small-angle condition it replaced.

[4, 11]. Huygens' *Horologium Oscillatorium* also contains the theory of the compound pendulum used in Section 34.3 and the proposal for a universal length standard discussed in Section 34.4.

34.2 Coulomb: the torsion pendulum (1784)

Tests Phenomenon 30.60 and Equation (30.55).
Assuming Equations (28.2) *and* (30.21).

Replace gravity by a twisted wire and the pendulum becomes something else: an instrument whose restoring constant can be made as small as the wire is fine, and which therefore responds visibly to forces far below anything a balance can weigh. Coulomb established the law of that restoring torque and the scaling of its constant with the geometry of the wire, in the memoir that also gave him the instrument he used the following year on the electrostatic force.

34.2.1 Apparatus

A fine metal wire, hung vertically from a torsion head at the top of a tall case, carrying at its lower end a horizontal needle or bar of known dimensions — so that its moment of inertia I about the wire axis is computable from measured lengths and masses. The case is graduated in angle and closed against draughts; the torsion head can be turned through a read angle, so that a known twist may be imposed on the wire independently of the needle's position. Wires of several materials, and of systematically varied length L and diameter d, are used in turn [36].

34.2.2 Procedure

Two measurements, run on each wire. First, the free torsional oscillation: displace the needle, release it, and time many periods, repeating at several amplitudes. Second, the static twist: turn the torsion head and read the equilibrium deflection of the needle, comparing the angle applied at the top with the angle taken up at the bottom. Then vary L and d and repeat both. Nothing in either measurement requires a force standard, and that is the point of the instrument.

34.2.3 Observations and data

The restoring torque is proportional to the angle of twist and to nothing else: the torsional period is independent of the amplitude, and the static deflection is linear in the applied twist. The constant of proportionality depends on the wire alone — not on the body hung from it — and varies as the fourth power of the diameter and inversely as the length [36].

Coulomb, like Galileo, states his results as proportionalities rather than as numbers with units. Put into the modern form, they are two: the restoring torque is $-\kappa\varphi$ with κ independent of φ, and $\kappa \propto d^4/L$ with the same two exponents for iron and for brass. Table 34.2 gives the second of these in numbers, and the paragraph after it checks the first against a published instrument; the derivation of both from linear elasticity is Phenomenon 34.3 below, and the two equations used here, Equations (34.8) and (34.9), are established there.

The amplitude independence is the sharper of the two findings, and its reach is worth stating in numbers because it is what separates this instrument from the gravity pendulum of Section 34.1. Table 34.1 shows the gravity pendulum's period rising by 18 % between a vanishing arc and 90°. Over the same range — indeed over several complete revolutions of the needle — Coulomb finds no change in the torsional period at all, and Equation (34.8)

Table 34.2: The torsion constant of a round wire, from Equation (34.8), over the range of geometries a laboratory torsion pendulum uses. The shear moduli are the polycrystalline aggregate values of Chapter 30, $\mu = 81.8\,\mathrm{GPa}$ for iron and 47.3 GPa for copper, each carrying about 1 %, which is the uncertainty on every κ below; the diameters and lengths are exact by construction, being the independent variable. T is the period the suspension would give a needle of moment of inertia $I = 1.7 \times 10^{-5}\,\mathrm{kg\,m^2}$ — a bar of mass 20 g and length 0.10 m — by Equation (34.9). Coulomb's measurement is the statement that the first four rows stand in the ratios 1 : 16 : 256 : 4096 and that rows two and five stand in the ratio 2 : 1: a factor 16 in stiffness for a factor 2 in diameter, and a factor 2 for a factor 2 in length.

material	d (mm)	L (m)	κ (N m/rad)	T (s)
iron	0.05	1.0	5.02×10^{-8}	116
iron	0.10	1.0	8.03×10^{-7}	28.9
iron	0.20	1.0	1.29×10^{-5}	7.2
iron	0.40	1.0	2.06×10^{-4}	1.8
iron	0.10	2.0	4.02×10^{-7}	40.9
copper	0.10	1.0	4.64×10^{-7}	38.0

says why: the constitutive relation is linear in the shear strain, and the strain a torsion pendulum reaches is tiny. Three full turns of the 0.10 mm iron wire of Table 34.2 give a surface shear strain of only $\gamma = (d/2)\,\varphi/L = 9.4 \times 10^{-4}$ — a tenth of a per cent. The angle is enormous and the deformation is not, which is why a wire may be twisted through three revolutions and still answer with a linear torque.

Run the relation backwards and it calibrates. The one torsion instrument in this treatise whose constants are published is Cavendish's: two balls of 0.730 kg on an arm of half-length $a = 0.914\,\mathrm{m}$, so that $I = 2ma^2 = 1.22\,\mathrm{kg\,m^2}$, and torsional periods of $9.0 \times 10^2\,\mathrm{s}$ and $4.5 \times 10^2\,\mathrm{s}$ for the two suspensions he used [44]. Equation (34.9) turns those into $\kappa = 5.9 \times 10^{-5}\,\mathrm{N\,m/rad}$ and $2.4 \times 10^{-4}\,\mathrm{N\,m/rad}$ without any force ever being applied. Inverting Equation (34.8) with the copper modulus asks, for the first of these, a wire of diameter

$$d = \left(\frac{32\kappa L}{\pi\mu}\right)^{1/4} = 0.34\,\mathrm{mm} \qquad \text{at } L = 1.0\,\mathrm{m}\,, \tag{34.7}$$

and the fourth root makes the answer nearly indifferent to the assumed length — halving L gives 0.28 mm. Both are ordinary diameters for drawn wire. The dynamical calibration and the elastic formula therefore agree on the same instrument, which is the consistency Coulomb's memoir asserts and Chapter 33 depends on.

Phenomenon 34.3 (The stiffness of a twisted wire is geometric)**.** A wire twisted about its own axis resists with a torque proportional to the angle, with a constant κ that scales as the fourth power of the wire's diameter and inversely as its length, the remaining factor being a property of the material [36]. Halving the diameter therefore makes the suspension sixteen times softer, which is what allows a torsion pendulum to be tuned over orders of magnitude in sensitivity by a change of wire alone, and what makes it the transducer of choice for forces at the limit of detection.

Rests on Phenomenon 30.60 and Equation (30.55)*.*

Derivation. Derives Phenomenon 34.3.

Twist a circular shaft of radius R, length L and shear modulus μ through a total angle ϕ. Plane cross-sections stay plane and rotate rigidly, so a filament at radius r is sheared

by $\gamma = r\phi/L$ and carries the shear stress $\tau = \mu\gamma = \mu r\phi/L$ — the linear elastic constitutive relation of Chapter 30. Integrating its moment over the section,

$$\text{torque} = \int r\,\tau\,\mathrm{d}A = \frac{\mu\phi}{L}\int r^2\,\mathrm{d}A = \frac{\mu J}{L}\,\phi\,, \qquad J = \int r^2\,\mathrm{d}A = \frac{\pi R^4}{2} = \frac{\pi d^4}{32}\,, \tag{34.8}$$

so that $\kappa = \mu J/L \propto d^4/L$, which is the observed scaling. Two consequences follow at once. The torque is strictly linear in ϕ, so the equation of motion of the suspended body is $I\ddot{\varphi} = -\kappa\varphi$ and the period $T = 2\pi\sqrt{I/\kappa}$ is amplitude-independent, as measured; and, running the argument backwards,

$$\kappa = \frac{4\pi^2 I}{T^2} \tag{34.9}$$

delivers the torque scale of the instrument from a computed moment of inertia and a timed period. No force is ever applied to calibrate it. That is what makes the torsion balance absolute, and it is the reason the same instrument can be turned on gravitation (Chapter 33) and on electrostatics [38] without either measurement borrowing a scale from the other. □

Phenomenon 34.4 (A free torsion pendulum rings for a very long time)**.** Set swinging and left alone, a torsion pendulum on a fine fibre decays far more slowly than any gravity pendulum of comparable period: quality factors of 10^3 and beyond are ordinary for a metal fibre, and much higher values are reached with fused silica. The consequence is practical and dominates the design of every experiment built on the instrument — the equilibrium position cannot be obtained by waiting for the oscillation to stop, because at a period of minutes and a quality factor of 10^3 the amplitude takes of order a day to fall by a factor e. Cavendish already read successive turning points instead of waiting [44], and every later torsion experiment has done some version of the same thing [262, 657, 1991].

Rests on Equation (34.9) *and Definition 28.19.*

Derivation. *Derives Phenomenon 34.4.*

With a linear damping torque the equation of motion is $I\ddot{\varphi} + b\dot{\varphi} + \kappa\varphi = 0$, that is $\ddot{\varphi} + 2\beta\dot{\varphi} + \omega_0^2\varphi = 0$ with $\beta = b/2I$ and $\omega_0^2 = \kappa/I$. The underdamped solution is $\varphi = A\mathrm{e}^{-\beta t}\cos(\omega t + \delta)$ with $\omega = \sqrt{\omega_0^2 - \beta^2}$, so the stored energy, being quadratic in the amplitude, decays as $\mathrm{e}^{-2\beta t}$. Defining the quality factor of Chapter 28 as $Q = \omega_0/2\beta$, the amplitude falls by a factor e in the time

$$\tau_A = \frac{1}{\beta} = \frac{2Q}{\omega_0} = \frac{Q}{\pi}\,T\,, \tag{34.10}$$

that is, after Q/π periods. For a torsion period of a few minutes and $Q \sim 10^3$ this is of order 10^5 seconds, about a day, which is the assertion above. The same Q fixes the sharpness of the resonance, $\Delta\omega \approx \omega_0/Q$. □

It fixes one thing more, and that one decides how a torsion balance should be built. The dissipation that damps the ringdown and the fluctuation that shakes the fibre are the same physical process seen twice, so Q also sets the instrument's noise floor — and the floor is worth having in closed form.

Proposition 34.5 (Thermal torque noise of a torsion pendulum)**.** *A suspension of torsion constant κ, moment of inertia I, resonant angular frequency $\omega_0 = \sqrt{\kappa/I}$ and quality factor Q, in equilibrium at temperature T — the one statement in this chapter in which T is a temperature and not a period — is driven by a fluctuating torque whose one-sided power spectral density is white across the band of the instrument and equal to*

$$S_\tau = 4k_B T b = \frac{4k_B T\kappa}{\omega_0 Q}\,, \tag{34.11}$$

b being the damping coefficient of Equation (34.10). The smallest torque distinguishable in a measurement bandwidth Δf is accordingly

$$\tau_{\min} = \sqrt{S_\tau \, \Delta f} = 2\sqrt{k_B T \, \Delta f} \, \frac{(\kappa I)^{1/4}}{\sqrt{Q}} \, . \tag{34.12}$$

At fixed I and T the floor falls only as the fourth root of the torsion constant, but as the square root of the quality factor: softening the fibre is a weak lever and raising Q is a strong one.

Rests on Equations (34.9) and (34.10).

Derivation. Derives Proposition 34.5.

Add a stochastic torque to the equation of motion used for the ringdown, $I\ddot{\varphi} + b\dot{\varphi} + \kappa\varphi = \tau(t)$. The response to a torque of angular frequency $\omega = 2\pi f$ is $\chi(\omega) = \left(\kappa - I\omega^2 + \mathrm{i}b\omega\right)^{-1}$, so

$$\left\langle \varphi^2 \right\rangle = \int_0^\infty S_\tau \, |\chi(2\pi f)|^2 \, \mathrm{d}f = \frac{S_\tau}{4b\kappa} \, ,$$

the integral being elementary for a quadratic denominator. In thermal equilibrium the suspension holds $\frac{1}{2}\kappa\left\langle\varphi^2\right\rangle = \frac{1}{2}k_B T$ by equipartition (Part XII), that is $\left\langle\varphi^2\right\rangle = k_B T/\kappa$; comparing the two expressions gives $S_\tau = 4k_B T b$. This is the rotational form of Nyquist's relation and an instance of the fluctuation–dissipation theorem [1117]: the coefficient b that damps the ringdown is the same coefficient that drives the fluctuation, because dissipation and fluctuation are one process seen twice. Writing $b = 2I\beta = I\omega_0/Q$ from the definition of Q used in Equation (34.10), and $I\omega_0 = \sqrt{\kappa I} = \kappa/\omega_0$, gives the second form of Equation (34.11) and then Equation (34.12).

Put Cavendish's numbers in it. With $\kappa = 5.9 \times 10^{-5}\,\mathrm{N\,m/rad}$, $I = 1.22\,\mathrm{kg\,m^2}$ and a torsional period of $9.0 \times 10^2\,\mathrm{s}$, so that $\omega_0 = 7.0 \times 10^{-3}\,\mathrm{rad/s}$, and taking $Q = 10^3$ at a room temperature $T = 293\,\mathrm{K}$, Equation (34.11) gives $S_\tau = 1.4 \times 10^{-25}\,\mathrm{N^2\,m^2/Hz}$. Averaging for a day is a bandwidth $\Delta f = 1.2 \times 10^{-5}\,\mathrm{Hz}$, whence $\tau_{\min} = 1.3 \times 10^{-15}\,\mathrm{N\,m}$ — about 5×10^{-9} of the gravitational torque of $2.8 \times 10^{-7}\,\mathrm{N\,m}$ that the instrument had to resolve, as Chapter 33 reconstructs it. Thermal noise was irrelevant to Cavendish by nine orders of magnitude; it is a real limit for the modern instruments [1991, 2135], whose signals are many orders of magnitude smaller. Two cautions belong with Equation (34.11) and are not derived here. It assumes *viscous* damping, a torque proportional to $\dot{\varphi}$; a real fibre dissipates internally, which puts more noise below the resonance than Equation (34.11) predicts and less above it, and is the same physics as the frequency dependence of κ taken up in Phenomenon 34.6. And the relation applies to each dissipation channel separately, with its own b: gas damping, clamp losses and readout damping each contribute a fluctuating torque of their own, so a measured Q that lumps them together is the right number to use only when the fibre dominates. □

34.2.4 Interpretation

The torsion pendulum is the pendulum turned into a force transducer, and Equation (34.9) is why it is an absolute one: a mass distribution, a length and a time fix the torque scale, with no comparison against any other force. That is the property Chapter 33 depends on — Cavendish's gravitational torque is read as $\kappa\theta$ with κ obtained from the instrument's own period — and it is why the same design has served, essentially unchanged, for the electrostatic force law [38], for the gravitational constant [44, 262, 657, 1991], and for the tests of the equality of inertial and gravitational mass [486, 1294, 1469, 2135] that Chapter 42 reports.

The limitation belongs here too, because it is a property of the instrument and not of any one experiment using it.

Phenomenon 34.6 (The torsion constant depends on the frequency)**.** Coulomb's law of torsion is very good but not exact. A real fibre is anelastic: its response lags the applied twist, so that the effective κ measured from a slow static deflection differs from the one inferred from the period of a fast oscillation, by a fractional amount that grows as the quality factor falls. Kuroda showed that this biases the time-of-swing determinations of the gravitational constant upward, by an amount of order $1/\pi Q$ [1901] — some hundreds of parts per million for an ordinary metal fibre, which is the size of the discrepancy that Chapter 33 reports among modern determinations and does not resolve.

Rests on Equations (34.9) *and* (34.10).

Derivation. Derives Phenomenon 34.6.

Only one thing has to be assumed about the material, and it is an observation rather than a model: over the narrow band a torsion balance uses, a metal fibre dissipates with a *loss angle* that is very nearly independent of frequency. Everything else follows from causality.

Let $\hat{\chi}(\omega)$ be the torsional compliance, defined by $\hat{\theta}(\omega) = \hat{\chi}(\omega)\hat{\tau}(\omega)$ with the convention $\theta(t) = \Re\left[\hat{\theta}\,\mathrm{e}^{-\mathrm{i}\omega t}\right]$ of Theorem 17.78, and of SI dimension rad/(N m). The work done per cycle by a torque of amplitude $|\hat{\tau}|$ is $\pi\,|\hat{\tau}|^2\,\Im\hat{\chi}(\omega)$, since the cycle average of $\tau\dot{\theta}$ is $\frac{1}{2}\omega\,|\hat{\tau}|^2\,\Im\hat{\chi}$, so dissipation requires $\Im\hat{\chi} > 0$ for $\omega > 0$; and the loss-angle hypothesis is

$$\frac{\Im\hat{\chi}(\omega)}{\Re\hat{\chi}(\omega)} = \frac{1}{Q}\,, \qquad \omega > 0\,, \tag{34.13}$$

with the same Q as the ring-down of Equation (34.10). To leading order in $1/Q$ the numerator may be evaluated with $\Re\hat{\chi}$ replaced by its value χ_0 at the working frequency, and χ being real in the time domain makes $\Im\hat{\chi}$ odd, so $\Im\hat{\chi}(\omega) = (\chi_0/Q)\,\operatorname{sgn}\omega$.

A constant is not integrable at infinity, so use the once-subtracted form of Equation (17.92), symmetrized over the half line by the parity of the real and imaginary parts. For any reference frequency ω_r,

$$\Re\hat{\chi}(\omega) - \Re\hat{\chi}(\omega_r) = \frac{2}{\pi}\,\mathrm{PV}\!\int_0^\infty \omega'\,\Im\hat{\chi}(\omega')\left[\frac{1}{\omega'^2-\omega^2} - \frac{1}{\omega'^2-\omega_r^2}\right]\mathrm{d}\omega'\,. \tag{34.14}$$

With $\Im\hat{\chi} = \chi_0/Q$ on the half line the substitution $u = \omega'^2$ removes the ω' in the numerator and leaves an elementary integral,

$$\mathrm{PV}\!\int_0^\infty \left[\frac{1}{u-\omega^2} - \frac{1}{u-\omega_r^2}\right]\mathrm{d}u = \left[\ln\left|\frac{u-\omega^2}{u-\omega_r^2}\right|\right]_0^\infty = -2\ln\frac{\omega}{\omega_r}\,, \tag{34.15}$$

the upper limit contributing nothing because the ratio tends to one. Hence $\Re\hat{\chi}(\omega) = \chi_0\,[1 - (2/\pi Q)\ln(\omega/\omega_r)]$, and inverting to the stiffness $\kappa = 1/\Re\hat{\chi}$, to the same order in $1/Q$,

$$\kappa(\omega) = \kappa_r\left[1 + \frac{2}{\pi Q}\ln\frac{\omega}{\omega_r}\right], \qquad \kappa_r = 1/\chi_0\,. \tag{34.16}$$

From Equations (17.92) *and* (34.13) *(a frequency-independent loss angle inserted into the subtracted dispersion relation).*

The fibre is therefore stiffer the faster it is twisted, by $2/\pi Q$ per e-fold of frequency — which is the first assertion of Phenomenon 34.6, with the fractional discrepancy between a static deflection held for a time t_s and an oscillation at ω_0 equal to $(2/\pi Q)\ln(\omega_0 t_s)$: for $Q = 10^3$ and a deflection read after a few hundred seconds, some parts in 10^3.

Now the bias. The time-of-swing determination of G is Equation (33.12): with ω_1 and ω_2 the torsional frequencies in the two source-mass configurations, and $C_1 \neq C_2$ the geometrical gradients, the equation of motion of Equation (33.5) gives $I\omega_i^2 = \kappa - GC_i$ and the fibre

constant cancels in the difference. It cancels, however, only if it is the *same* constant at the two frequencies. With Equation (34.16) it is not, and

$$I\left(\omega_2^2-\omega_1^2\right)=G\left(C_1-C_2\right)+\kappa(\omega_2)-\kappa(\omega_1)\ . \tag{34.17}$$

The two frequencies differ only by the gravitational gradient, a fractional shift of order 10^{-4}, so $\ln\left(\omega_2/\omega_1\right)=\frac{1}{2}\ln\left(\omega_2^2/\omega_1^2\right)\approx\left(\omega_2^2-\omega_1^2\right)/2\omega_0^2$ with $\omega_0^2=\kappa/I$, whence

$$\kappa(\omega_2)-\kappa(\omega_1)=\frac{2\kappa}{\pi Q}\,\frac{\omega_2^2-\omega_1^2}{2\omega_0^2}=\frac{1}{\pi Q}\,I\left(\omega_2^2-\omega_1^2\right)\ , \tag{34.18}$$

which to leading order is $G\left(C_1-C_2\right)/\pi Q$. The experimenter divides the left side of Equation (34.17) by C_1-C_2 and calls the result G, so what is obtained is

$$G_{\text{measured}}=G\left(1+\frac{1}{\pi Q}\right)\ , \tag{34.19}$$

From Equations (34.17) and (34.18) (substituting the residual stiffness difference and dividing by the geometrical factor).

an upward bias, independent of every geometrical factor and of the sense of the difference. That is Equation (33.14), and it is the second assertion of Phenomenon 34.6: at $Q=2\times10^3$ it is 160 parts per million, and at the $Q\approx1\times10^3$ of a bare metal fibre, twice that. □

Remark 34.7 (What is assumed, and what the model cannot be asked). Two things are quoted rather than derived. The first is the loss mechanism: Equation (34.13) is an empirical description of metals over a limited band, and why internal friction in a drawn wire should be so nearly frequency-independent is materials physics that this treatise does not carry. The second is the range of validity of Equation (34.16), which cannot hold down to $\omega=0$: the logarithm diverges, and a genuinely static compliance is finite. What the model is entitled to describe is the *difference* between two frequencies within the band, which is all Equation (34.19) uses, and a static deflection only in the weaker sense of a measurement completed in a finite time t_s, which is why the discrepancy above was quoted with $\ln\left(\omega_0 t_s\right)$ rather than with an infinite one. Kuroda's paper [1901] makes the same restriction.

34.2.5 Primary references

[36]. The instrument's application to the electrostatic force is [38]; its application to gravitation is Chapter 33, following [44]; the anelasticity systematic is [1901].

34.3 Kater: the reversible pendulum (1818)

Tests Equations (28.7) and (28.9).

Assuming Phenomenon 28.9.

A simple pendulum measures g in principle and not in practice: no real pendulum is a point mass on a massless string, and the correction from the actual mass distribution is precisely as uncertain as the mass distribution is. Kater's reversible pendulum removes that difficulty completely, by exploiting a theorem of Huygens to make the awkward quantity drop out of the answer. The result is the first absolute determination of the acceleration of free fall, and the ancestor of every absolute gravimeter since.

34.3.1 Apparatus

A rigid bar, of brass or iron, carrying two knife edges facing each other and separated by a fixed measured distance, with the two edges placed asymmetrically about the centre of

mass; between them, a heavy weight that can be slid along the bar and clamped, and a smaller slider for fine trimming. The bar rests on hard flat planes so that either knife edge in turn serves as the pivot, and the whole hangs from a massive support — the compliance of the support is a systematic in its own right. The comparison clock is an astronomically regulated pendulum clock, and the distance between the knife edges is measured against a length standard [62].

34.3.2 Procedure

Swing the pendulum about one knife edge and time it; invert it, swing it about the other, and time it again. Move the adjustable weight and repeat, iterating until the two periods agree. When they do, the distance between the knife edges — a length that can be measured directly to high accuracy — *is* the length of the simple pendulum having that period, and

$$g = \frac{4\pi^2 L}{T^2} \tag{34.20}$$

follows with no other quantity involved. The period is compared with the clock by the method of coincidences: the experimental pendulum is set swinging in front of the clock pendulum with a mark visible only when the two are aligned, and the slow drift of the coincidences measures the difference of periods far more precisely than either could be timed alone.

One trap must be avoided by construction, and it is the reason the two knife edges are deliberately placed at unequal distances from the centre of mass; the derivation below identifies it.

34.3.3 Observations and data

Kater does not report a value of g. He reports a length: the length of the pendulum vibrating seconds in the latitude of London, reduced to sea level, to vacuum, and to a stated temperature [62]. That is the natural output of the method, since Equation (34.20) with $T = 2\,\mathrm{s}$ makes the two equivalent, and it is the form in which the seconds pendulum was proposed as a length standard — the proposal Section 34.4 takes up. His figure is quoted in inches; editorial rule 3 of this treatise admits SI only, and the conversion at the exact 25.4 mm to the inch gives 0.994 138 m. That is the figure customarily quoted from the memoir, and it is quoted here on that authority: no copy of the 1818 *Philosophical Transactions* paper is held in this treatise's evidence store, so its digits have not been read off the original. Nothing below turns on the last two of them. Table 34.3 carries that through to g and compares it with the modern picture; Table 34.4 is the error budget, rebuilt here in the terms of Chapter 2 and [1945, 2129] rather than reproduced from the memoir.

The gap between the fourth and fifth rows of Table 34.3 is the honest part of the entry. Kater prints seven significant figures, which asserts a resolution of 2.6×10^{-7}; nothing in the apparatus supports that, and the reason is Table 34.4. Every correction he must apply is between 6×10^{-6} and 1.4×10^{-4} of the answer, and a correction is never known to better than a few per cent of itself. The quadrature sum of the corrections is 2.4×10^{-4}; taking the residual uncertainty of each as a tenth of the correction gives an overall $u_g/g \approx 2 \times 10^{-5}$, by Theorem 2.8. That is the number the last row of Table 34.3 should be compared against, and against it the agreement is unremarkable — which is the correct verdict, and a stronger statement about the method than a spuriously perfect one would be.

Phenomenon 34.8 (Suspension and oscillation centres are reciprocal)**.** For any rigid body swinging about a horizontal axis there is a second, parallel axis — on the far side of the centre of mass, along the same perpendicular — about which the body swings with exactly the same period; and the distance between the two axes is the length of the simple

Table 34.3: Kater's determination, in SI. The first block is his result and what Equation (34.20) makes of it; $T = 2\,\mathrm{s}$ is exact by the definition of the seconds pendulum, so $g = 4\pi^2 L/T^2 = \pi^2 L$ and the uncertainty on g is entirely the uncertainty on L. The second block is the comparison. g_n is the conventional standard value, exact by adoption [2431], and carries no claim about London; the reference value against which Kater should be read is the second entry, the two-term latitude formula $g(\lambda) \approx g_{\mathrm{eq}} + (g_{\mathrm{pol}} - g_{\mathrm{eq}}) \sin^2 \lambda$ of Chapter 29 evaluated at Greenwich, $\lambda = 51.48°$, with the equatorial and polar values quoted there. That formula is itself good only to about 1×10^{-5}, which is why the agreement in the last row must not be read as better than that.

	quantity	value
result	length of the seconds pendulum, London	$0.994\,138\,\mathrm{m}$
	period T, exact by definition	$2\,\mathrm{s}$
	implied $g = \pi^2 L$	$9.811\,75\,\mathrm{m/s^2}$
	figures quoted, as a relative resolution	2.6×10^{-7}
	accuracy actually achieved	$\sim 1 \times 10^{-5}$
modern	conventional g_n (exact)	$9.806\,65\,\mathrm{m/s^2}$
	latitude formula at 51.48°	$9.8118\,\mathrm{m/s^2}$
	Kater minus the latitude formula	$-9 \times 10^{-5}\,\mathrm{m/s^2}$
	the same, relative	-9×10^{-6}

Table 34.4: The systematic corrections a reversible-pendulum determination of g must carry, with their sizes recomputed here for Kater's instrument rather than taken from the memoir. Each is quoted as a fractional shift in g; since $g = 4\pi^2 L/T^2$, a fractional error ϵ in the period enters g as 2ϵ and one in the length enters as ϵ (Corollary 2.9). The 1.5° amplitude, the 5 K temperature departure, the 10 µm edge radius and the 20 m elevation are representative working values, not Kater's; brass has a linear expansion coefficient near $1.9 \times 10^{-5}/\mathrm{K}$ and a density near $8.5 \times 10^3\,\mathrm{kg/m^3}$, and air at laboratory conditions $1.20\,\mathrm{kg/m^3}$. Every one of these is larger than the resolution Kater's seven printed figures claim.

correction	mechanism	$\lvert\delta g\rvert / g$
finite arc	period excess $\theta_0^2/16$ at $\theta_0 = 1.5°$, doubled into g	8.6×10^{-5}
air buoyancy	restoring torque reduced by $\rho_{\mathrm{air}}/\rho_{\mathrm{brass}}$	1.4×10^{-4}
entrained air	added moment of inertia of the co-moving air [135]	$\sim 1.4 \times 10^{-4}$
thermal expansion	$\alpha\,\Delta\vartheta$ on the knife-edge separation	9.5×10^{-5}
clock rate	comparison clock in error by 1 s a day	2.3×10^{-5}
knife-edge radius	rolling rather than pivoting, r/L	1.0×10^{-5}
free-air reduction	$2h/R_\oplus$ to sea level	6.3×10^{-6}
in quadrature		2.4×10^{-4}

pendulum that keeps that period. The relation is symmetric: each axis is the other's centre of oscillation. Huygens established it in the *Horologium Oscillatorium* [11], and it converts an otherwise intractable measurement of g into the measurement of one length and one time.

Rests on Equations (28.7) *and* (28.9).

Derivation. *Derives Phenomenon 34.8.*

Let the body have mass m, centre of mass C, and radius of gyration k about the horizontal axis through C parallel to the pivot, so that its moment of inertia about that axis is mk^2. Suspended from a point at distance h from C, it has, by the parallel-axis theorem, moment of inertia $I = m\left(k^2 + h^2\right)$ about the pivot, while gravity exerts the moment $-mgh\sin\vartheta$. The rotational law of Chapter 19 gives $I\ddot{\vartheta} = -mgh\sin\vartheta$, whose small-amplitude period is

$$T = 2\pi\sqrt{\frac{I}{mgh}} = 2\pi\sqrt{\frac{L\left(h\right)}{g}}\,, \qquad L\left(h\right) = \frac{k^2 + h^2}{h} = h + \frac{k^2}{h}\,. \tag{34.21}$$

So the body swings exactly like a simple pendulum of length $L\left(h\right)$, the *equivalent length*. Now ask which pairs of suspension distances give equal periods. Setting $L\left(h_1\right) = L\left(h_2\right)$ and clearing denominators,

$$\left(h_1 - h_2\right)\left(1 - \frac{k^2}{h_1 h_2}\right) = 0\,, \tag{34.22}$$

so either $h_1 = h_2$, or $h_1 h_2 = k^2$. In the second case, with the two pivots on opposite sides of C, their separation is

$$h_1 + h_2 = h_1 + \frac{k^2}{h_1} = L\left(h_1\right)\,, \tag{34.23}$$

which is the assertion: the two axes are conjugate, and the distance between them is the equivalent length. Note what has vanished. Neither m nor k appears in Equation (34.23); the mass distribution of the bar, its knife edges, its adjustable weight and its clamps have all dropped out, and Equation (34.20) needs only the measured separation and the measured period.

The first root of Equation (34.22) is the trap. Two knife edges placed at equal distances from the centre of mass also give equal periods, for a trivial reason, and their separation $2h$ is *not* the equivalent length — using it in Equation (34.20) yields a value of g that is simply wrong, with nothing in the data to signal the error. This is why the two distances are made deliberately unequal, so that the observed equality of periods can only be the conjugate root. □

34.3.4 Interpretation

Equation (34.20) contains a length and a time, and nothing else. That is the whole claim, and it is a strong one: the measurement is *absolute*, in the same sense as the torsion calibration Equation (34.9) — it does not compare the local g against g somewhere else, and it needs no previously calibrated instrument of any kind. The reversible pendulum accordingly became the standard of absolute gravimetry for more than a century, and the worldwide network of g values it established is the empirical base for the latitude dependence that Chapter 29 derives from the centrifugal term and the flattening of the Earth.

The residual difficulties are all systematic and all mechanical: knife edges are not lines, supports are not rigid, air is neither absent nor inert, and the bar is not at the temperature at which it was measured. Each is a correction of the same order as the accuracy sought, which is the recurring shape of a precision measurement and the reason Chapter 2 insists that an uncertainty statement is part of a result rather than a comment on it. The method

was displaced only when a genuinely different one became available: dropping a corner cube in vacuum and reading its fall interferometrically, which replaces the mechanical corrections with optical ones and reaches some $2 \times 10^{-8}\,\mathrm{m/s^2}$ [1906]. The free-fall instrument is treated with the kinematics it tests, in Chapter 20.

34.3.5 Primary references

Kater's memoir on the length of the pendulum vibrating seconds in the latitude of London, read to the Royal Society in 1818, is the primary source for this experiment [62]. The theorem the method rests on is Huygens' [11]; the modern successor instrument is [1906].

34.4 The seconds pendulum and the metre

Before it was an instrument for measuring g, the pendulum was a candidate for defining the metre. The proposal is Huygens' — a universal measure taken from the length of the pendulum that beats seconds, so that any observer anywhere could reconstruct the unit from a clock [11] — and it is the earliest attempt at what Chapter 2 calls a definition by reproducible procedure rather than by artefact. It was not adopted, and the reason it was not adopted is a measurement made with pendulums.

Phenomenon 34.9 (The seconds pendulum is nearly, but not exactly, a metre)**.** A pendulum beating seconds — one swing per second, hence a period of 2 s — is about 0.9936 m long at the conventional acceleration $9.806\,65\,\mathrm{m/s^2}$, within about 0.7 % of the metre. But it is not the same length everywhere: because g runs from about $9.780\,\mathrm{m/s^2}$ at the equator to about $9.832\,\mathrm{m/s^2}$ at the poles, as Chapter 29 derives from the centrifugal term and the flattening of the Earth, the seconds pendulum is some 5 mm longer at the pole than at the equator, a spread of about one part in 190. A length unit defined this way would therefore have depended on where it was realized.

Rests on Equation (28.7) *and Axiom 2.2.*

Derivation. *Derives Phenomenon 34.9.*

Inverting $T = 2\pi\sqrt{\ell/g}$ with $T = 2\,\mathrm{s}$ gives

$$\ell = \frac{gT^2}{4\pi^2} = \frac{g}{\pi^2}\,, \tag{34.24}$$

numerically $\ell = 0.993\,62\,\mathrm{m}$ at $g = 9.806\,65\,\mathrm{m/s^2}$, and $\ell = 0.990\,92\,\mathrm{m}$ and $\ell = 0.996\,19\,\mathrm{m}$ at the equatorial and polar values quoted above — a difference of 5.3 mm. The near-coincidence with the metre is a historical accident of the same kind as the near-coincidence of the metre with the ten-millionth of the meridian quadrant, and carries no physical content; the spread does. Latitude dependence of this size was well established by pendulum surveys before the metre was defined, so the defect was known in advance rather than discovered afterwards. □

The metre was defined instead from the Earth's meridian, then from a platinum–iridium artefact, then from a krypton wavelength, and now from the speed of light and the second [2333]. The pendulum's descendant in the modern system is not the metre but the second: a counted oscillation of a system whose frequency is a property of nature rather than of an artefact. What changed between Huygens' proposal and the present definition is not the idea but the oscillator — from a weight on a wire, whose frequency depends on where you stand, to an atomic transition, which does not.

34.5 Foucault: the pendulum at the Panthéon (1851)

Tests Phenomenon 29.61.

Assuming Equations (28.7) *and* (29.66).

That the Earth rotates was, by 1851, not in doubt; but every argument for it was astronomical, and therefore rested on observations of things outside the laboratory. Foucault produced the missing argument: an experiment performed in a closed room, consulting nothing beyond its walls, whose result is the rotation rate of the Earth.

34.5.1 Apparatus

A heavy sphere — of order 28 kg, of lead clad in brass — hung on a fine steel wire some 67 m long from the crown of the dome of the Panthéon in Paris, at a latitude close to 48.85°. The suspension is designed to be as nearly isotropic as possible, since any asymmetry in the support gives the two horizontal directions slightly different frequencies and thereby drives the swing off a straight line. A pointer fixed to the bob writes in a low ring of damp sand laid on the floor beneath, so that successive extremes of the swing are recorded as a physical mark. Foucault had already run the experiment twice on a smaller scale, first privately in a cellar with a wire of a couple of metres and then publicly at the Paris Observatory, before moving it to the Panthéon where the long wire makes the effect unmistakable within a single session [134].

34.5.2 Procedure

The release is the delicate part, and it is done with a cord: the bob is drawn aside, tied off to a fixed point with a light thread, the system is allowed to come completely to rest, and the thread is then burned through. Pulling the bob aside by hand and letting go imparts an uncontrolled sideways impulse, which turns the intended straight swing into a narrow ellipse; and an elliptical swing precesses on its own account, at a rate set by the area of the ellipse and the anharmonicity of the motion, which is indistinguishable in the data from the effect being sought. Burning the thread releases the bob from rest along the line of the thread, with no transverse velocity. Thereafter the experiment is left alone and the direction of the swing plane is read off the sand at intervals.

34.5.3 Observations and data

The plane of the swing turns steadily, and it turns clockwise seen from above — the same sense in every trial, in Paris. The rate is close to 11.3° an hour, so that a full circuit takes about 31.8 h [134]. The sense reverses in the southern hemisphere and the rate falls to zero on the equator, both of which follow from the derivation below and neither of which is a free parameter.

Table 34.5 collects the apparatus, the prediction and the reading, and then does with them the thing that makes this an absolute measurement: it inverts the observed rate for Ω and recovers the length of the sidereal day from a weight, a wire and a floor.

Two features of the table carry the argument. The predicted and observed rates agree, and the recovered sidereal day sits within a fifth of its own uncertainty of the astronomical value — which is a weak test of the astronomy and a strong one of the mechanics, since nothing astronomical entered the measurement. And the numbers are small: 2.7 mm of advance per swing at the working amplitude, on a trace made in sand. That is why the wire had to be 67 m long. Shorten it and the rate is unchanged — the precession does not know ℓ — but the swings come faster, and the advance per swing shrinks with the period, so the effect stays detectable only for as long as the pendulum keeps swinging. The advance per swing is $A\,\Omega \sin\lambda\, T_0$ and therefore grows as $A\sqrt{\ell}$: a 2 m pendulum turns its plane by

Table 34.5: The Panthéon pendulum: apparatus, prediction and result. The apparatus figures are Foucault's [134]; g at the station is the two-term latitude formula of Chapter 29 at $\lambda = 48.85°$, and the swing period follows from Equation (28.7). The sidereal angular velocity used for the prediction is $\Omega = 2\pi/86\,164\,\mathrm{s}$, the sidereal day being the solar day divided by 366.2422/365.2422 — one extra rotation per orbit. Foucault quotes no uncertainty; the value assigned to the measured rate here is what a sand trace read to about 1° gives over a ten-hour run, and it propagates into the recovered day by Corollary 2.9. The last two rows are the point of the experiment: the rotation period of the Earth, obtained inside a closed building.

	quantity	value
apparatus	wire length ℓ	67 m
	bob mass	28 kg
	latitude λ	48.85°
	swing amplitude (working)	3 m
predicted	g at the station	$9.8095\,\mathrm{m/s^2}$
	swing period $T_0 = 2\pi\sqrt{\ell/g}$	16.42 s
	Ω (sidereal)	$7.2921 \times 10^{-5}\,\mathrm{rad/s}$
	precession rate $\Omega \sin\lambda$	$5.491 \times 10^{-5}\,\mathrm{rad/s}$
	the same, in degrees per hour	11.32°
	one full turn	$1.144 \times 10^{5}\,\mathrm{s}$
	the same, in hours	31.79 h
	plane turned per swing period	$9.0 \times 10^{-4}\,\mathrm{rad}$
	advance of the trace per swing period	2.7 mm
observed	precession rate	11.3° per hour
	one full turn	31.8 h
	assigned uncertainty on the rate	1.2 %
recovered	sidereal day, from the rate and λ	$(8.64 \pm 0.10) \times 10^{4}\,\mathrm{s}$
	sidereal day, adopted	$8.6164 \times 10^{4}\,\mathrm{s}$

11.3° in an hour just as the Panthéon one does, but at a 0.2 m amplitude each of its 2.8 s swings advances the trace by 31 µm — ninety times less — and it is stopped by air in an hour or two.

The one systematic that can imitate the effect is not air, and not the support: it is the shape of the orbit.

Proposition 34.10 (An elliptical swing precesses on its own account)**.** *Let a pendulum of length ℓ traverse, in a frame that is* not *rotating, an ellipse of semi-axes a and b about the vertical, with $a, b \ll \ell$. Then the anharmonicity of the suspension alone makes the ellipse precess, in the sense in which it is traversed, at*

$$\Omega_{ell} = \frac{3}{8}\,\frac{ab}{\ell^2}\,\omega_0\,, \qquad \omega_0 = \sqrt{\frac{g}{\ell}}\,, \tag{34.25}$$

while the frequency of the motion around the ellipse is $\omega = \omega_0\left[1 - \left(a^2+b^2\right)/16\ell^2\right]$. Both reduce to known results at the two ends of the family. $b \to 0$ recovers the arc correction $\omega = \omega_0\left(1 - \theta_0^2/16\right)$ of Table 34.1, with $\theta_0 = a/\ell$. And $a = b$ recovers the conical pendulum: the bob's total angular rate about the vertical is then $\omega + \Omega_{ell} = \omega_0\left(1 + a^2/4\ell^2\right)$, which is the expansion of the exact conical relation $\omega_{con}^2 = g/\left(\ell\cos\vartheta\right)$ at $a = \ell\sin\vartheta$.

Rests on Equations (28.8) and (34.38).

Proof. Derives Proposition 34.10.

Let x and y be horizontal Cartesian coordinates of the bob with origin at the lowest point of the sphere, $\rho^2 = x^2 + y^2$, and $\omega_0^2 = g/\ell$. The constraint puts the bob at height $z = \ell - \sqrt{\ell^2 - \rho^2} = \rho^2/2\ell + \rho^4/8\ell^3 + O(\rho^6)$, and differentiating it gives $\dot z = S/\ell + O(\rho^3)$ with $S := x\dot x + y\dot y$. Both pieces are needed: the quartic term of the potential and the $\dot z^2$ the constraint generates are of the same order, and keeping only one of them is the commonest way to get the coefficient wrong. To fourth order in the displacement,

$$\mathcal{L} = \frac{m}{2}\left(\dot x^2 + \dot y^2\right) + \frac{m}{2\ell^2}S^2 - \frac{m\omega_0^2}{2}\rho^2 - \frac{m\omega_0^2}{8\ell^2}\rho^4\,. \tag{34.26}$$

The Euler–Lagrange equation for x has $\partial\mathcal{L}/\partial\dot x = m\dot x + \left(m/\ell^2\right)Sx$ and $\partial\mathcal{L}/\partial x = \left(m/\ell^2\right)S\dot x - m\omega_0^2 x - \left(m\omega_0^2/2\ell^2\right)\rho^2 x$; the term $\left(m/\ell^2\right)S\dot x$ cancels between the two sides, and with $\dot S = \dot x^2 + \dot y^2 + x\ddot x + y\ddot y = v^2 - \omega_0^2\rho^2$ to the order retained, both coordinates obey the *same* equation,

$$\ddot x + \left[\omega_0^2 + \varepsilon(t)\right]x = 0\,, \qquad \varepsilon = \frac{1}{\ell^2}\left(v^2 - \frac{\omega_0^2}{2}\rho^2\right)\,, \tag{34.27}$$

and likewise for y, with $v^2 = \dot x^2 + \dot y^2$.

Insert the unperturbed ellipse $x = a\cos\omega t$, $y = b\sin\omega t$ with $\omega \approx \omega_0$. Then $\rho^2 = \left(a^2+b^2\right)/2 + \left[\left(a^2-b^2\right)/2\right]\cos 2\omega t$ and $v^2 = \omega_0^2\left\{\left(a^2+b^2\right)/2 - \left[\left(a^2-b^2\right)/2\right]\cos 2\omega t\right\}$, so

$$\varepsilon = \varepsilon_0 + \varepsilon_2\cos 2\omega t\,, \qquad \varepsilon_0 = \frac{\omega_0^2\left(a^2+b^2\right)}{4\ell^2}\,, \qquad \varepsilon_2 = -\frac{3\omega_0^2\left(a^2-b^2\right)}{4\ell^2}\,. \tag{34.28}$$

The perturbation is thus a constant plus a modulation at twice the frequency, and the modulation acts differently on a cosine and a sine. Removing the secular term as in Theorem 28.72: with $x_0 = a\cos\omega t$ the resonant part of $-\varepsilon x_0$ is $-a\left(\varepsilon_0 + \varepsilon_2/2\right)\cos\omega t$, because $\cos 2\omega t\cos\omega t = \frac{1}{2}\left(\cos\omega t + \cos 3\omega t\right)$; with $y_0 = b\sin\omega t$ it is $-b\left(\varepsilon_0 - \varepsilon_2/2\right)\sin\omega t$, because $\cos 2\omega t\sin\omega t = \frac{1}{2}\left(\sin 3\omega t - \sin\omega t\right)$. Hence

$$\omega_x^2 = \omega_0^2 + \varepsilon_0 + \frac{\varepsilon_2}{2}\,, \qquad \omega_y^2 = \omega_0^2 + \varepsilon_0 - \frac{\varepsilon_2}{2}\,. \tag{34.29}$$

From Equations (34.27) and (34.28) (removing the secular terms of the two components separately).

The two components keep their amplitudes — the vertical angular momentum $m\,(x\dot{y}-y\dot{x})$ is conserved exactly, because Equation (34.26) is axisymmetric, and at this order it is $mab\omega$, so the perturbation can redistribute phase but not amplitude — and acquire a growing phase difference.

That difference is a rotation of the axes. Put $\psi=\omega_x t$ and $2\delta=(\omega_y-\omega_x)\,t$, so that $x=a\cos\psi$ and $y=b\sin(\psi+2\delta)$ with δ small over any interval short compared with its own growth time. The same ellipse turned bodily through a small angle Θ and traversed with phase $\psi'=\psi+\eta$ has components $x=a\cos\psi'-\Theta b\sin\psi'$ and $y=\Theta a\cos\psi'+b\sin\psi'$; expanding both to first order in Θ and η and matching the coefficients of $\cos\psi$ and $\sin\psi$ in each component gives $a\eta+\Theta b=0$ from the first and $\Theta a+b\eta=2\delta b$ from the second, whence

$$\Theta=\frac{2\delta\,ab}{a^2-b^2}\,,\qquad \eta=-\frac{\Theta b}{a}\,. \tag{34.30}$$

Now put in the numbers. From Equation (34.29), $\omega_y^2-\omega_x^2=-\varepsilon_2=3\omega_0^2\,(a^2-b^2)\,/4\ell^2$, so $\omega_y-\omega_x=3\omega_0\,(a^2-b^2)\,/8\ell^2$ and $2\delta=(\omega_y-\omega_x)\,t$; substituting in Equation (34.30),

$$\Omega_{\text{ell}}=\dot{\Theta}=\frac{3\omega_0\,(a^2-b^2)}{8\ell^2}\,\frac{ab}{a^2-b^2}=\frac{3}{8}\,\frac{ab}{\ell^2}\,\omega_0\,, \tag{34.31}$$

which is Equation (34.25). The difference of squares cancels, so the rate depends on the *area* of the ellipse alone, and it changes sign with b, that is with the sense of traversal.

The frequency around the ellipse is the rate of ψ', namely $\omega=\omega_x+\dot{\eta}=\omega_x-\Omega_{\text{ell}}b/a=\omega_x-3\omega_0 b^2/8\ell^2$. With $\varepsilon_0+\varepsilon_2/2=\omega_0^2\,(5b^2-a^2)\,/8\ell^2$ from Equation (34.28), so that $\omega_x=\omega_0\,[1+(5b^2-a^2)\,/16\ell^2]$,

$$\omega=\omega_0\left[1+\frac{5b^2-a^2}{16\ell^2}-\frac{6b^2}{16\ell^2}\right]=\omega_0\left[1-\frac{a^2+b^2}{16\ell^2}\right]\,, \tag{34.32}$$

the second statement of the proposition. Both limiting checks are now computations rather than assertions. At $b=0$, Equation (34.32) is $\omega_0\,(1-\theta_0^2/16)$ with $\theta_0=a/\ell$, and Ω_{ell} vanishes: a plane swing does not precess. At $a=b$ the modulation ε_2 vanishes identically, the two components share the frequency $\omega_x=\omega_0\,(1+a^2/4\ell^2)$, and that single number is the whole angular rate of the bob about the vertical, which is what the proposition asserts as $\omega+\Omega_{\text{ell}}$ — Equations (34.31) and (34.32) sum to it. The matching Equation (34.30) is singular at $a=b$, as it must be, since a circle has no axes whose orientation could be tracked; the rate Equation (34.31) is not, and the circular case is settled by the direct computation just given. □

Equation (34.25) is what the burnt thread is for. At the Panthéon, $\omega_0=0.3827\,\text{rad/s}$ and $\ell^2=4489\,\text{m}^2$, so an ellipse of semi-major axis 3 m precesses at the Foucault rate itself once its minor semi-axis reaches

$$b=\frac{8\ell^2\Omega\sin\lambda}{3a\,\omega_0}=0.57\,\text{m}\,, \tag{34.33}$$

and contributes 1 % of it at $b=5.7\,\text{mm}$. Since $b\simeq v_\perp/\omega_0$ for a release from the end of the swing, holding the systematic at 1 % means releasing the bob with a transverse velocity below 2.2 mm/s, against a peak speed of $a\omega_0=1.15\,\text{m/s}$: a fractional tolerance of 2×10^{-3} on the release. No hand meets that, and a burnt thread does. Two further properties of Equation (34.25) are what let the residue be diagnosed rather than merely feared. It is proportional to the *area* of the ellipse, so it decays as the swing decays, while the Foucault rate does not; and it changes sign with the sense in which the ellipse is traversed, while the Foucault rate is clockwise in Paris whatever the release. Repeating the run with the swing started along a different azimuth, and fitting the rate against amplitude rather than quoting a single number, separates the two.

Phenomenon 34.11 (The swing plane precesses at the vertical component of the Earth's rotation)**.** A long pendulum, released from rest and left undisturbed, does not keep its plane of swing with respect to the room. The plane turns at the rate $\Omega \sin\lambda$, where Ω is the Earth's sidereal angular velocity and λ the latitude: clockwise seen from above in the northern hemisphere, anticlockwise in the southern, one turn per sidereal day at either pole, and not at all on the equator. The room may be sealed and nothing outside it consulted, so the experiment measures Ω from within the laboratory [134]. The rate depends on the latitude and not at all on the length of the pendulum, on its mass, or on the amplitude of the swing — which is what distinguishes the effect from every mechanical imperfection that could mimic it.

Rests on Phenomenon 29.61 and Equation (28.7).

Derivation. *Derives Phenomenon 34.11.*

Work in the frame rotating with the Earth at angular velocity $\boldsymbol{\Omega}$, and use local axes at latitude λ with x east, y north and z up, so that $\boldsymbol{\Omega} = \Omega\,(0, \cos\lambda, \sin\lambda)$. The centrifugal term is time-independent and merely redefines the local vertical and the effective g, as Chapter 29 shows; absorbing it, the equation of motion of the bob is

$$\ddot{\boldsymbol{r}} = \boldsymbol{g}_{\text{eff}} + \frac{\boldsymbol{F}_{\text{tension}}}{m} - 2\,\boldsymbol{\Omega} \times \dot{\boldsymbol{r}}\,. \tag{34.34}$$

For small horizontal excursions the vertical velocity is second order, so $\dot{\boldsymbol{r}} \simeq (\dot{x}, \dot{y}, 0)$ and

$$-2\,\boldsymbol{\Omega} \times \dot{\boldsymbol{r}} = 2\Omega\,(\sin\lambda\,\dot{y}, -\sin\lambda\,\dot{x}, \cos\lambda\,\dot{x})\ .$$

The vertical component is taken up by the tension and does not move the bob; only the vertical component of $\boldsymbol{\Omega}$ survives in the horizontal motion. Writing $\Omega_z = \Omega\sin\lambda$ and using the restoring acceleration $-\omega_0^2\,(x, y)$ with $\omega_0^2 = g/\ell$ from Chapter 28,

$$\ddot{x} = -\omega_0^2 x + 2\Omega_z \dot{y}\,, \tag{34.35}$$

$$\ddot{y} = -\omega_0^2 y - 2\Omega_z \dot{x}\,. \tag{34.36}$$

Combine them into $\zeta = x + \mathrm{i}y$:

$$\ddot{\zeta} + 2\mathrm{i}\Omega_z \dot{\zeta} + \omega_0^2 \zeta = 0\,. \tag{34.37}$$

Now substitute $\zeta = \mathrm{e}^{-\mathrm{i}\Omega_z t}\eta$, which is precisely the statement that η is the motion referred to axes turning at the rate Ω_z. Differentiating, $\dot{\zeta} = \mathrm{e}^{-\mathrm{i}\Omega_z t}\,(\dot{\eta} - \mathrm{i}\Omega_z \eta)$ and $\ddot{\zeta} = \mathrm{e}^{-\mathrm{i}\Omega_z t}\,(\ddot{\eta} - 2\mathrm{i}\Omega_z\dot{\eta} - \Omega_z^2\eta)$; substituting into Equation (34.37), the terms in $\dot{\eta}$ cancel identically and there remains

$$\ddot{\eta} + \left(\omega_0^2 + \Omega_z^2\right)\eta = 0\,. \tag{34.38}$$

In the rotating axes the bob is an ordinary plane pendulum, of frequency $\sqrt{\omega_0^2 + \Omega_z^2}$, which for $\Omega_z \ll \omega_0$ is ω_0 to a fractional accuracy of $(\Omega_z/\omega_0)^2/2$ — for the Panthéon pendulum, of order 10^{-9}. Its plane is fixed in those axes; therefore in the room the plane turns at $-\Omega_z$, that is, at $\Omega\sin\lambda$ in the clockwise sense seen from above when $\lambda > 0$. Numerically, with the sidereal day $86\,164\,\mathrm{s} = 2\pi/\Omega$ and $\lambda = 48.85°$, the period of one full turn is

$$\frac{2\pi}{\Omega\sin\lambda} = \frac{86\,164\,\mathrm{s}}{\sin 48.85°} \approx 1.14 \times 10^5\,\mathrm{s}\,, \tag{34.39}$$

about 31.8 h, or 11.3° an hour — the observed value. Two features of the result carry the physical weight. First, ℓ, m and the amplitude are absent, so the effect cannot be confused with a property of the particular pendulum. Second, only $\sin\lambda$ enters: the horizontal component of $\boldsymbol{\Omega}$ drops out entirely, having been absorbed by the tension, which is why the experiment reports the component of the Earth's rotation along the local vertical and not the whole of it. □

34.5.4 Interpretation

The measurement is local in the strict sense: the apparatus is a weight, a wire and a floor, and the result is the rotation rate of the planet they stand on. This is the sharpest available form of the statement of Chapter 29 that rotation, unlike uniform motion, is detectable from inside a sealed laboratory; and it is evidence about the Earth obtained without astronomy, which is what made the public demonstration decisive for people whom the astronomical argument had not moved.

There is a second reading of the same data, and it is the one that matters later in this treatise. The swing plane is not held fixed by any force — Equation (34.38) contains no torque about the vertical — yet after one sidereal day, during which the station has been carried once around its latitude circle, the plane has turned through $\Omega \sin\lambda \times 2\pi/\Omega = 2\pi \sin\lambda$ and not through 2π. The deficit is

$$\Delta = 2\pi - 2\pi \sin\lambda = 2\pi\,(1 - \cos\vartheta)\;, \qquad \vartheta = \frac{\pi}{2} - \lambda\,, \tag{34.40}$$

which is exactly the solid angle subtended at the centre of the Earth by the spherical cap the latitude circle bounds — a purely geometric quantity, independent of ℓ, of m, of g and of Ω itself. That the deficit *is* the holonomy of the Levi-Civita connection of the sphere, so that the pendulum is performing parallel transport (Definition 13.146) rather than merely producing the same number, is a theorem this treatise does not yet carry: it needs the identification of the holonomy around a closed curve with the integral of the Gaussian curvature over the region enclosed, which Chapter 13 does not prove. Taken with that theorem, the Foucault pendulum is the oldest laboratory measurement of a geometric phase and belongs with the fibre-bundle language of Chapter 14; taken without it, Equation (34.40) is an arithmetical coincidence that this chapter has checked and not explained.

Foucault himself drew the operational conclusion and built the instrument that follows from it: if a swinging mass keeps its plane against a rotating frame, a spinning mass will keep its axis, which is the gyroscope [136]. The optical descendant is Sagnac's interferometer [410], in which the rotation appears as a fringe shift rather than a slow turning; ring-laser and fibre gyroscopes are its industrial form, and they measure $\Omega \sin\lambda$ in seconds where the pendulum needs hours.

34.5.5 Primary references

[134]. The gyroscope sequel is [136]; the Coriolis term whose consequence this is was published by Coriolis in 1835 [100]; the optical successor is [410].

34.6 The pendulum as the first precision instrument

Table 34.6 makes the common structure visible. In each case a quantity that cannot be weighed, timed or seen directly — an elastic constant, the strength of gravity, the rotation of a planet — is converted into the period or the azimuth of an oscillation, and the oscillation is counted. Counting is the one laboratory operation that can be done without error, which is why every subsequent increase in precision in this treatise has taken the same form: the Josephson and quantum-Hall standards of Chapter 128, the atomic clocks behind Chapter 90, and the fringe counting of Chapter 47 are all frequency measurements wearing different hardware.

The lineage is also literal. The suspension that isolates a gravitational-wave interferometer's mirrors is a pendulum, chosen for exactly the reason Coulomb's wire was chosen — a low resonant frequency decouples the mass from ground motion above it — and its thermal noise is governed by the quality factor of Equation (34.10) through the same fluctuation–dissipation argument [1117] that gives Equation (34.12), which is why such suspensions are

Table 34.6: The four pendulum experiments of this chapter. Every one of them is *absolute*: its calibration chain terminates in the metre and the second, and it borrows no scale from another instrument of the same kind. That is the property that made the pendulum the first device in physics whose reading could be quoted with an uncertainty.

Experiment	Measures	Result
Galileo, Huygens 1602–1673	period	the period is set by the length and by g alone, to 2.5×10^{-3} in the seventeenth-century data; the amplitude dependence is removed exactly on a cycloid (Table 34.1)
Coulomb 1784	torque	restoring torque linear in the twist, with $\kappa \propto d^4/L$; the torque scale follows from a moment of inertia and a period (Table 34.2)
Kater 1818	g	an absolute value of the local free-fall acceleration from one length and one time: $9.811\,75\,\mathrm{m/s^2}$ at London, good to about 2×10^{-5} (Table 34.3)
Foucault 1851	$\Omega \sin \lambda$	the swing plane turns at about 11.3° an hour at Paris, one circuit in about 31.8 h, whence a sidereal day of $(8.64 \pm 0.10) \times 10^4$ s (Table 34.5)

made of fused silica and not of metal: the lever that matters is Q. The torsion pendulum of Section 34.2 remains the instrument of choice for gravitation at laboratory scale [1991, 2135] and hence for the least well determined of the constants, as Chapter 33 reports. And the reversible pendulum's successor, the free-fall gravimeter, still measures g the way Kater did in principle: a length and a time [1906].

Chapter 35

Experiment: Waves and Acoustics

Chapter 28 reduces a large part of classical wave physics to four sharp claims. A string clamped at both ends sustains a discrete harmonic series $f_n = nf_1$ with $f_1 = (1/2L)\sqrt{T/\mu}$. A bounded elastic sheet has its own discrete spectrum, whose modes are surfaces rather than curves and whose overtones are *not* integer multiples of a fundamental. A compressible fluid carries non-dispersive waves at the speed $\sqrt{\mathrm{d}p/\mathrm{d}\rho}$, whose value depends on which thermodynamic path the compressions follow. And a source in motion through the medium is heard at a shifted frequency. This chapter reports the measurements that established all four.

They are old — 1636 to 1866 — and they are, for that reason, unusually clean. Each is a *counting* experiment: a number of loops on a thread, a number of nodal lines on a plate, a spacing of dust ridges, a musical interval. Ratios of small integers and ratios of lengths are what the apparatus delivers, and ratios are exactly what the theory predicts without adjustable parameters. Two of the experiments do more than confirm: the sound-speed measurement of Section 35.4 exposed a 15 % discrepancy that stood for one hundred and twenty-nine years and was resolved only by recognizing the compressions as adiabatic, so that an acoustic measurement became a thermodynamic one; and the Doppler test of Section 35.6 is the case in which the medium is real and at rest in the laboratory, which makes the source–observer asymmetry a physical fact here and its absence in optics (Chapter 37) a genuine surprise.

35.1 Mersenne: the laws of the vibrating string (1636)

Tests Equation (35.1).

Assuming Equation (28.46).

The pitch of a stretched string was the first quantitative law of acoustics, and it was found a century before there was a wave equation to explain it. Its interest here is not only historical: the three proportionalities are precisely the content of the formula $f_1 = (1/2L)\sqrt{T/\mu}$ that Chapter 28 derives, and they were measured against an instrument of remarkable precision — the trained ear, which judges frequency *ratios* and not frequencies.

35.1.1 Apparatus

A monochord: one string of gut or of drawn brass stretched over a graduated soundboard between a fixed bridge and a movable one, tensioned by a weight hanging over a pulley at one end, so that the tension is known as a weight and not as a turn of a peg. A set of strings of several materials and several diameters, otherwise identical, allows the mass per unit length to be varied at fixed length and tension. For the absolute measurement a second apparatus is needed: a long, heavy cord, metres in length and slack enough that its

fundamental period is a substantial fraction of a second, stretched horizontally between fixed supports.

35.1.2 Procedure

Three comparisons, each holding two of the three variables fixed. Displace the movable bridge and compare the pitch of the shortened string with that of the whole; the comparison is made by ear against the consonances, whose ratios are known in advance and are exact by definition — the octave $2:1$, the fifth $3:2$, the fourth $4:3$. Hang different weights on the same length and find the loads at which the pitch rises by a known interval. Substitute strings of different diameter at the same length and tension and do the same.

The absolute measurement is a separate operation and is the more ingenious of the two. The long cord vibrates slowly enough that its swings can be counted directly against a pendulum or a pulse, giving one frequency in absolute terms. The three laws are then used in the reverse direction, as a transfer standard, to carry that number up to the audible range: shorten the length and reduce the diameter by measured factors, and the frequency scales by factors that a ruler determines.

35.1.3 Observations and data

The three ratio laws, stated without any absolute frequency. Halving the length raises the pitch by an octave, and thirds and quarters of the length give the twelfth and the double octave, so that $f \propto 1/L$ exactly over at least two octaves. Quadrupling the hanging weight raises the pitch by an octave, so that $f \propto \sqrt{T}$. Doubling the diameter of a string of the same material at the same length and tension lowers the pitch by an octave, so that $f \propto 1/d$, and since $\mu \propto d^2$ for a cylinder of fixed density this is $f \propto 1/\sqrt{\mu}$ [2, 4].

Phenomenon 35.1 (Mersenne's laws of the stretched string)**.** The fundamental frequency of a uniform string clamped at both ends varies inversely as its sounding length, as the square root of its tension, and inversely as the square root of its mass per unit length; all three hold as exact proportionalities, over the full range of a musical instrument, before any theory of the vibration exists [2, 4]. The higher partials that the same string sounds together with its fundamental stand to it in the ratios of the whole numbers.

Derivation. *Derives Phenomenon 35.1.*

Take from Chapter 28 the clamped-string spectrum

$$f_n = \frac{n}{2L}\sqrt{\frac{T}{\mu}}\,, \qquad n \in \mathbb{N}\,. \tag{35.1}$$

Holding any two of L, T, μ fixed and varying the third reads off the three laws directly, and setting $n = 2, 3, 4$ at fixed L, T, μ gives the whole-number partials. What must be derived *here* is the transfer, because the absolute measurement is made on one string and reported for another. Let a cord of length L and diameter d be compared with a string of the same material and the same tension, of length L' and diameter d'. Since $\mu = \tfrac{1}{4}\pi\rho d^2$ for a cylinder of density ρ, Equation (35.1) gives

$$\frac{f_1'}{f_1} = \frac{L}{L'}\,\frac{d}{d'}\,, \tag{35.2}$$

in which the tension, the density and the numerical factors have all cancelled. Every quantity on the right is a length measured with a ruler. A frequency of a few hertz, counted by eye on a cord metres long and a millimetre thick, therefore fixes the frequency of a string centimetres long and a tenth of a millimetre thick — three orders of magnitude away — with no clock faster than a pulse and no calibration of the material at all. □

35.1.4 Interpretation

Two things are established, and they are of different kinds. The first is the empirical law itself, which any theory of the vibrating string was thereafter obliged to reproduce; d'Alembert's wave equation [25] and Bernoulli's modal superposition [28] were tested against it a century later, and it is the reason the eigenvalue problem of Chapter 9 was posed at all. The second is methodological, and is the reason this experiment opens the chapter: Equation (35.2) shows that the whole of acoustics can be done in ratios. The ear is a poor absolute instrument and an excellent comparator, resolving a mistuned unison of a fraction of a per cent; the theory predicts ratios; and the apparatus is built so that what is read off is a ratio of lengths. The same discipline governs every experiment below.

One caution belongs with the result. The absolute frequency obtained by the transfer is only as good as the assumption that Equation (35.1) extrapolates unchanged across those three orders of magnitude — that is, that the string is non-dispersive and the vibration linear. That assumption is itself a prediction of the theory, and it is tested independently in Section 35.2, where the same law is checked at fixed frequency across a whole family of modes.

35.1.5 Primary references

[2, 4]. Galileo's *Discorsi* states the same three rules, arrived at independently and published two years later; the two accounts are usually cited together and are so cited here.

35.2 Melde: standing waves on a driven string (1860)

Tests Equation (35.3).

Assuming Equation (35.1).

Mersenne's laws are read from the sounding pitch of a freely vibrating string. Melde inverted the arrangement: drive the string at a *fixed, known* frequency and vary the tension instead, and the standing-wave pattern becomes visible, countable, and present only at discrete settings of the load. The experiment thereby shows the eigenvalue structure of the boundary-value problem directly, in a form that needs no ear at all.

35.2.1 Apparatus

A tuning fork of known frequency, maintained electromagnetically so that it runs continuously at constant amplitude. A light silk or cotton thread tied to one prong, led horizontally over a smooth pulley at a measured distance, and terminated in a scale pan carrying weights, so that the tension is a known weight. The fork is mounted on a rotatable block, so that its prong can be set to vibrate either perpendicular to the thread or along it.

35.2.2 Procedure

With the prong vibrating transversely, the thread is driven at the fork's frequency. Weights are added to the pan and the thread watched; at most loads it thrashes without pattern, but at particular loads it settles into a stationary figure of n clean loops separated by points that do not move. The load is recorded for each n. Because the prong's excursion is a small fraction of the loops' amplitude, the driven end is a node to good approximation, and the thread behaves as if clamped at both ends.

The fork is then rotated through a right angle, so that it pulls the thread *along* its own length, periodically modulating the tension rather than displacing the end. Standing waves appear again, at different loads, and a direct comparison shows the thread completing one transverse cycle for every two cycles of the fork.

35.2.3 Observations and data

Discrete loads, and a pure-number law relating them. The pattern of n loops appears at a tension T_n, and the tensions found for successive n fall as the inverse square of the number of loops, so that four loops require one quarter the load of two and nine loops one ninth the load of three [155]. In the second, longitudinal configuration the response is at half the driving frequency.

Phenomenon 35.2 (Standing waves appear only at discrete tensions)**.** A string of fixed length and mass per unit length, driven transversely at a fixed frequency f, shows a stationary pattern of n loops only at the discrete tensions

$$T_n = \frac{4L^2 f^2 \mu}{n^2}\,, \qquad n \in \mathbb{N}\,, \tag{35.3}$$

and shows no stationary pattern between them; the loads at which successive patterns appear stand in the ratios $1 : \frac{1}{4} : \frac{1}{9} : \ldots$ [155].

Rests on Equation (35.1).

Derivation. *Derives Phenomenon 35.2.*

A stationary pattern with n loops on a string of length L whose ends are both nodes requires $L = n\lambda/2$, so $\lambda = 2L/n$. The wave travels at $v = \sqrt{T/\mu}$ and the pattern oscillates at the driving frequency, so $v = \lambda f$. Eliminating λ and v,

$$\sqrt{\frac{T_n}{\mu}} = \frac{2Lf}{n}\,, \tag{35.4}$$

which on squaring is Equation (35.3). Two features make this a stringent test rather than a demonstration. First, the ratios $T_n/T_1 = 1/n^2$ contain none of L, f or μ: the experiment can be run without knowing the fork's frequency, the thread's mass or even the distance to the pulley, and it still tests the theory, because a scale pan measures a ratio of loads directly. Second, the prediction is as much about the loads at which *nothing* happens as about those at which something does. A continuum of admissible frequencies would give a pattern at every load; the discreteness is the observable, and it comes from the boundary conditions, not from the wave equation. □

Phenomenon 35.3 (Half-frequency response to a modulated tension)**.** When the same string is driven not by displacing its end but by periodically varying its tension at frequency f, standing waves are again established, but the string oscillates at $f/2$ — one transverse cycle for every two cycles of the drive [155]. The response is absent for weak modulation and sets in above a threshold that increases with the damping.

Rests on Equations (35.1) *and* (35.3).

Derivation. *Derives Phenomenon 35.3.*

Rotating the fork removes the transverse drive altogether: the prong now moves *along* the thread, stretching and relaxing it, so the end is not displaced sideways at all and what the drive modulates is the tension,

$$T(t) = T_0\,(1 + \epsilon \cos \omega t)\,, \qquad \omega = 2\pi f\,, \quad 0 < \epsilon \ll 1\,, \tag{35.5}$$

with ϵ the fractional swing of the load and f the fork's frequency. The length, the density and the end conditions are untouched, so the transverse displacement may still be expanded in the clamped-string modes, $y(x,t) = \sum_n q_n(t) \sin(n\pi x/L)$. Substituting that expansion into $\mu\,\partial_t^2 y = T(t)\,\partial_x^2 y$ and using the orthogonality of the sines, each mode separates:

$$\ddot{q}_n + \omega_n^2\,(1 + \epsilon \cos \omega t)\,q_n = 0\,, \qquad \omega_n = \frac{n\pi}{L}\sqrt{\frac{T_0}{\mu}} = 2\pi f_n\,, \tag{35.6}$$

From Equations (35.1) *and* (35.5) *(inserting the modal expansion into the string equation and projecting on* $\sin(n\pi x/L)$*).*

with f_n the free frequency of Equation (35.1) at the mean tension T_0. Each mode of the thread is therefore an oscillator whose stiffness — not whose applied force — is modulated, and Equation (35.6) is Mathieu's equation [173]. That is exactly the system solved in Chapter 28, and its two conclusions may be taken over unchanged: the amplitude grows exponentially in a band of drive frequencies centred on $\omega = 2\omega_n$, so that the response is at half the drive; and, once the mode's damping is restored, the growth occurs only above the threshold $\epsilon > 2/Q_n$, with Q_n the quality factor of that mode. Both features asserted in the phenomenon follow — the half-frequency response by construction, since a term $\cos\omega t$ multiplying q_n feeds back on itself only through its half-frequency component, and the threshold because the modulation multiplies the amplitude instead of adding to it.

The reduction also yields a prediction that a scale pan tests directly. Under the transverse drive the n-loop pattern needs $f_n = f$, which is Equation (35.3); under the longitudinal drive it needs $f_n = f/2$, so that $(n/2L)\sqrt{T_n'/\mu} = f/2$ and

$$T_n' = \frac{L^2 f^2 \mu}{n^2} = \frac{T_n}{4}\,. \tag{35.7}$$

From Equations (35.3) *and* (35.6) *(imposing* $f_n = f/2$ *in place of* $f_n = f$ *and dividing).*

Turn the fork through a right angle and the same figure of n loops reappears at one quarter of the load that held it before. The ratio contains neither the fork's frequency nor the thread's mass, so it is another pure number read off a set of weights — and it is a prediction, not a datum: the loads for the longitudinal configuration are not quoted in the source, which reports the halving of the frequency. □

Remark 35.4 (What the reduction does not settle). Equation (35.6) is linear, so it predicts unbounded exponential growth above threshold and nothing about the steady amplitude actually seen. What arrests the growth is the stretching of the thread by its own transverse excursion, which raises T_0 with amplitude and detunes the mode out of the unstable band; that saturation, and the further instabilities beyond it, belong to Chapter 32. The linear analysis also locates only the principal band; the full tongue structure in the (ω, ϵ) plane is Floquet's theorem, which Chapter 28 records as a result Part II does not yet carry. Nothing above uses it.

Rests on Equation (35.6).

35.2.4 Interpretation

The transverse configuration makes the discreteness of the spectrum visible to the eye and countable, and it does so at fixed frequency, which is the complement of Mersenne's fixed-mode, variable-frequency measurement: between them the law $f_n = (n/2L)\sqrt{T/\mu}$ is checked along both of its independent directions. The nodes, in particular, are not an artefact of the ear or of any interpretation; they are points of a taut thread that visibly do not move while their neighbours a centimetre away sweep through centimetres, and their number is an integer that anyone in the room can count.

The longitudinal configuration is a different phenomenon, and it is the reason this experiment retains a place in modern physics. Driving a system by modulating one of its *parameters* rather than by applying an external force produces a response at half the drive frequency, above a threshold — the mechanical prototype of parametric amplification, and the classical ancestor of the parametric oscillators of Chapter 122. Melde was not the first to see it: Faraday had already reported a half-frequency response in the "crispations" of liquid on a vibrating plate [88], thirty years earlier and in a two-dimensional system. Melde's string is the case in which the mechanism is transparent, because the modulated parameter is a single measurable number, the tension.

35.3 Chladni: the nodal figures of a vibrating plate (1787)

Tests Equation (35.12).
Assuming Equation (35.9).

A string has nodes at isolated points; a plate has them along curves, and the curves can be made to draw themselves. Chladni's figures are the first direct images of the eigenfunctions of a two-dimensional boundary-value problem, and they are still the standard demonstration that a bounded elastic body has a discrete spectrum whose modes have shape.

35.3.1 Apparatus

A flat plate of brass or of glass, square or circular, of the order of a tenth of a millimetre to a millimetre thick and some tens of centimetres across, held rigidly at its centre by a clamp on a stand so that the whole boundary is free. Fine, dry, sifted sand. A violin bow, well rosined.

35.3.2 Procedure

Sand is sprinkled evenly over the upper surface. One point of the rim is damped with a fingertip, which forces a node there, and the bow is drawn downwards across the rim at another point, which forces an antinode there. The plate sounds, and within a second or two the sand migrates off the regions in motion and settles in sharp ridges along the curves that are at rest. Changing the damped and bowed points selects a different mode, and the figure and the pitch change together. Each figure is recorded by drawing, and its pitch is recorded by comparison with a monochord or an organ pipe.

35.3.3 Observations and data

A catalogue of figures, each with its own pitch. The nodal sets are curves — for a circular plate, a family of diameters and concentric circles; for a square plate, systems of lines and hyperbola-like arcs that are not the modes of a rectangular membrane and are strikingly harder to guess. The number of nodal diameters m and nodal circles n labels the mode, and the frequencies of the circular plate were found to rise roughly as the square of $m + 2n$ [39]. Crucially, the pitches are *not* in whole-number ratios: a plate has a discrete spectrum, like a string, but an inharmonic one, which is why a struck plate has no definite musical pitch.

Phenomenon 35.5 (Two-dimensional normal modes have shape)**.** A bounded elastic plate vibrates freely only at a discrete set of frequencies; each is accompanied by a stationary pattern whose nodal set is a system of curves on the surface, determined by the shape of the plate and by the boundary conditions and not by how the plate is excited. The frequencies are not integer multiples of the lowest, and for a circular plate labelled by m nodal diameters and n nodal circles they increase approximately as $(m + 2n)^2$ [39].

Derivation. *Derives Phenomenon 35.5.*

Chapter 30 establishes the equation governing the transverse deflection w of a thin plate of density ρ, thickness h and flexural rigidity D, together with the two conditions a free edge imposes; free harmonic motion $w = W\mathrm{e}^{-\mathrm{i}\omega t}$ reduces it to

$$\nabla^4 W = k^4 W\,, \qquad k^4 = \frac{\rho h \omega^2}{D}\,. \tag{35.8}$$

Everything asserted follows from that eigenvalue problem.

Discreteness and shape come first, and they are the cheapest. The operator in Equation (35.8) is self-adjoint on the plate's own domain under the plate's own edge conditions, so its spectrum is a discrete increasing sequence and each eigenvalue carries an eigenfunction determined by the domain and the boundary alone. The bow selects which eigenfunction is excited and how strongly; it has no other freedom. That is exactly the observed independence of the figure from where and how hard the plate is bowed.

The inharmonicity is read off the dispersion relation. Substituting a plane wave $W \propto \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}$ in Equation (35.8),

$$\omega = k^2 \sqrt{\frac{D}{\rho h}}\,, \tag{35.9}$$

From Equation (35.8) (taking ∇^4 of a plane wave, which multiplies it by k^4, and solving for ω).

quadratic in the wavenumber where the string of Equation (35.1) is linear. That single difference is the whole of the inharmonicity: a clamped string has $k_n = n\pi/L$ in exact arithmetic progression, and a dispersion linear in k carries an arithmetic progression of wavenumbers into an arithmetic progression of frequencies — the harmonic series. Squaring destroys it. Whatever sequence $k_1 < k_2 < \dots$ the boundary conditions select, the frequencies go as k^2, so equally spaced wavenumbers give ever-widening frequency intervals and no ratio of small integers survives.

The square law in the labels needs the geometry of the disc. Since $\nabla^4 - k^4 = (\nabla^2 + k^2)\,(\nabla^2 - k^2)$, every solution of Equation (35.8) is the sum of a propagating part solving the Helmholtz equation and an evanescent part solving the modified one. Separating both in polar coordinates on a disc of radius a and discarding what is singular at the centre,

$$W = [A\,J_m(kr) + B\,I_m(kr)]\cos m\,(\theta - \theta_0)\;, \qquad m \in \mathbb{N} \cup \{0\}\,, \tag{35.10}$$

with J_m the Bessel function of Definition 9.93 and I_m its modified counterpart; m is the number of nodal diameters, and the two free-edge conditions fix B/A and quantize k. Because $I_m(kr)$ grows monotonically, roughly as $\mathrm{e}^{kr}/\sqrt{2\pi kr}$, the evanescent term is confined to within a few $1/k$ of the rim once $ka \gg 1$, and the nodal circles in the interior are those of $J_m(kr)$, at $r = j_{m,s}/k$ with $j_{m,s}$ the s-th positive zero. Exactly n of them lie inside the plate when $j_{m,n} \lesssim ka < j_{m,n+1}$, so the mode carrying n interior circles has $ka \approx j_{m,n}$, up to a shift of order unity fixed by the edge condition. The large zeros of J_m are asymptotically spaced by π,

$$j_{m,n} = \left(n + \frac{m}{2} - \frac{1}{4}\right)\pi + O\!\left(\frac{1}{n}\right)\,, \tag{35.11}$$

whence $ka \approx (\pi/2)\,(m + 2n)$ and, by Equation (35.9),

$$\omega_{mn} \approx \frac{\pi^2}{4a^2}\sqrt{\frac{D}{\rho h}}\,(m + 2n)^2\;, \tag{35.12}$$

From Equations (35.9) and (35.11) (substituting $k \approx \pi(m + 2n)/2a$ into the dispersion relation).

which is the measured law. The combination $m + 2n$ is not a coincidence of bookkeeping: Equation (35.11) says a nodal circle advances ka by a full π while a nodal diameter advances it by $\pi/2$, because the angular index enters as the order of the Bessel function and each unit of order displaces the zeros by half a period. Note also that the prefactor of Equation (35.12) carries the thickness and the inverse square of the diameter, which is the scaling Chapter 30 obtains for geometrically similar plates without solving for any mode at all. □

Remark 35.6 (Part II owes the asymptotics of the Bessel zeros). Equation (35.11) is the one step above that is neither physics nor a computation special to this plate: it is a statement about J_m, and it belongs beside the Bessel material of Chapter 9, which at present carries

the series, the recurrences, the generating function and the orthogonality relation but says nothing about where the zeros lie. The missing statement is that the substitution $u = \sqrt{r}\,R$ puts the Bessel equation in the form $u'' + \left[k^2 - \left(m^2 - \tfrac{1}{4}\right)/r^2\right] u = 0$, whose potential term is negligible for $kr \gg m$, so that the zeros are eventually spaced by π/k with the offset quoted. It is used here only for the asymptotic form of Equation (35.12), which is itself asserted as an approximation and is compared with an experiment that reports pitches to a fraction of a tone; nothing in this chapter would change if the offset $-1/4$ were carried differently.

Rests on Equation (35.11) *and Definition 9.93.*

Remark 35.7 (What is not computed here)*.* The exact eigenvalues are not. Imposing the two free-edge conditions on Equation (35.10) gives a transcendental determinant in ka whose roots depend on Poisson's ratio, and neither those roots nor the nodal figures of the *square* plate — which are not separable and which are the harder and more famous half of Chladni's catalogue — follow from the argument above. What is established is the structure the experiment actually reports: a discrete spectrum, figures owned by the plate rather than by the bow, an inharmonic sequence, and the approximate square law in $m + 2n$.

Rests on Equation (35.10)*.*

Phenomenon 35.8 (The figure depends on the tracer)**.** Fine, light powder such as lycopodium does not settle where sand settles. Sprinkled on the same plate sounding the same mode, it collects at the *antinodes* — the regions of greatest motion — producing the photographic negative of the sand figure [88].

Rests on Phenomenon 35.5.

Half of this is already accounted for. Chapter 30 derives the sand figure from a threshold: a grain leaves the surface wherever the peak acceleration $\omega^2 A$ of the plate exceeds g, is thrown, lands, and is thrown again until it reaches a neighbourhood of a node where the local amplitude is too small to eject it. That argument is about a grain coupled to the *plate*, and it predicts the sand figure and nothing else. The lycopodium figure is the complementary case, in which the grain is coupled to the *air*; what carries it is the steady second-order flow that an oscillating boundary drives in the fluid above it, and that flow is not obtained from any first-order acoustic quantity.

Full derivation: Appendix A.66 (p. 3154).

Derives Phenomenon 35.8.

The argument there is a second-order one throughout, and that is the whole reason it does not fit here. Every first-order acoustic quantity oscillates with zero mean, so the steady transport of a tracer cannot appear until the viscous equations of Chapter 31 are expanded to second order in the amplitude. What emerges is Rayleigh's result: the oscillating viscous layer against the plate rectifies the flow above it into a steady slip velocity proportional to the gradient along the surface of the squared first-order amplitude, directed from the antinodes towards the nodes inside the layer and back the other way in the bulk above it. A grain that the plate never throws is carried by the outer branch of that circulation, and collects where the sand does not.

Remark 35.9 (The discriminator between the two powders)*.* It is tempting to separate sand from lycopodium by the ratio of the grain's Stokes relaxation time to the acoustic period, and that is wrong: at audio frequencies the ratio exceeds unity for both powders, so neither follows the oscillating air. The discriminator is whether the surface ejects the grain at all — the threshold $\omega^2 A > g$ of Chapter 30 — and, for a grain it does not eject, which of the steady streaming drag and the residual contact friction wins. That comparison involves the grain's adhesion to the plate, a quantity this treatise does not model, so what the appendix derives is the streaming flow and the direction of its outer branch, not a predicted threshold radius separating the two powders.

35.3.4 Interpretation

The figures are the observational content of the statement that a two-dimensional wave problem has eigenfunctions. A string can be described without that vocabulary; a plate cannot, because its modes have to be drawn. What the sand traces is a level set of the eigenfunction, namely its zero set, and the fact that this set is independent of how hard the plate is bowed, and of where, so long as the same mode is selected, is precisely the statement that the mode belongs to the plate and not to the excitation.

The inharmonicity matters as much as the discreteness, and it is the sharpest way to see that "discrete spectrum" and "harmonic series" are different claims. The clamped string's exact integer ratios are a special consequence of its linear dispersion relation $\omega = vk$; the plate's governing equation is fourth order in space, its dispersion relation is quadratic in k, and the overtones drift away from whole-number ratios. The same distinction returns in the lattice of Chapter 125, where the departure from linearity in $\omega(k)$ is the physical content of dispersion.

Chladni's plates also forced a theory into existence, which is the cleanest possible illustration of the relation this treatise asserts between experiment and derivation. The figures were exhibited across Europe and could not be explained; the Paris Academy set them as a prize problem; and the answer, Sophie Germain's equation for the elastic surface [70], later put on a consistent footing by Kirchhoff [130], is the plate theory used in Chapter 30 to this day.

Finally, Phenomenon 35.8 is retained here as a standing warning about visualization. The sand figure is not the mode; it is what one particular tracer does in the presence of the mode, and a lighter tracer, coupling to the air rather than to the plate, reports the complementary set. An experiment that images a field through a tracer measures the tracer as well as the field.

35.4 Newton, Laplace and the speed of sound (1687–1822)

Tests Equations (35.13) *and* (35.16).
Assuming Equation (35.14).

This is the experiment in which a measurement of a mechanical speed turned out to be a measurement of a thermodynamic quantity. Newton derived the speed of sound in the *Principia* from the elasticity of the air and obtained a value well below what the field measurements gave; the discrepancy was not an experimental error, and it did not go away for one hundred and twenty-nine years.

35.4.1 Apparatus

Two stations on a surveyed baseline of the order of ten kilometres, each with a gun and an observer; chronometers, or in the earliest work a seconds pendulum; thermometer, barometer and hygrometer at each station. Newton's own attempt used no baseline at all: he timed the returning echoes from the far end of the cloister of Neville's Court at Trinity College against a pendulum, adjusting the pendulum until its swing kept step with the echoes.

35.4.2 Procedure

The observer at each station records the interval between seeing the flash of the distant gun and hearing its report. Light crosses the baseline in a time utterly negligible on this scale,

so the interval is the transit time of the sound and the speed follows from the surveyed distance. The essential refinement is *reciprocal* firing: guns are discharged alternately from the two ends and the two transit times are averaged, which cancels the component of the wind along the line to first order — the dominant systematic error, and one that no amount of repetition from a single end will remove [71]. Temperature, pressure and humidity are logged so that the result can be reduced to a standard state, and the whole procedure is repeated on several nights.

35.4.3 Observations and data

The speed of sound in dry air at 0 °C is close to 331.3 m/s, rising to about 343 m/s at 20 °C. It is independent of the amplitude of the sound at ordinary intensities, independent of its frequency across the audible band, and — at fixed temperature — independent of the pressure of the air. Newton's theoretical value, computed from the same measured pressure and density, is 279.9 m/s: low by more than 15 %, a discrepancy some fifty times any plausible error in a ten-kilometre baseline [14].

Table 35.1: The sound speed in dry air, and the two theoretical values it is to be compared with. No uncertainty is attached to any entry because none of them is a measurement reported by a source verified for this treatise: the first two rows are the standard state, the middle rows are computed in the derivation below from those two numbers alone, and the last two are the reference values for dry air, quoted to the precision shown. They are given so that the reader can repeat the arithmetic, not so that a fit can be claimed.

Quantity	Value	Origin
Pressure p_0 of the standard atmosphere	101 325 Pa	exact by definition
Density ρ_0 of dry air at 0 °C and p_0	1.293 kg/m^3	reference value
Ratio of specific heats γ of a diatomic gas	1.400	theory
Newton's isothermal speed $\sqrt{p_0/\rho_0}$	279.9 m/s	computed
Laplace's adiabatic speed $\sqrt{\gamma p_0/\rho_0}$	331.2 m/s	computed
Speed of sound, dry air at 0 °C	331.3 m/s	reference value
Speed of sound, dry air at 20 °C	343.2 m/s	reference value

Phenomenon 35.10 (The speed of sound is set by the adiabatic compressibility)**.** Sound propagates through a gas at the speed

$$c = \sqrt{\frac{\gamma p_0}{\rho_0}}\,, \tag{35.13}$$

with $\gamma = c_p/c_V$ the ratio of the specific heats and not, as Newton assumed, at $\sqrt{p_0/\rho_0}$ [59]. Because $p_0/\rho_0 = RT/M$ for an ideal gas, the speed rises as the square root of the absolute temperature, does not depend on the pressure at fixed temperature, and carries no dispersion.

Derivation. *Derives Phenomenon 35.10.*

Chapter 28 linearizes the equations of a compressible fluid about rest and obtains a wave equation with speed $c^2 = \mathrm{d}p/\mathrm{d}\rho$, the derivative to be taken along the thermodynamic path the gas actually follows. Newton took it at constant temperature. For dry air at 0 °C, with

$p_0 = 101\,325\,\mathrm{Pa}$ and $\rho_0 = 1.293\,\mathrm{kg/m^3}$, the isothermal path $p \propto \rho$ gives

$$c_T = \sqrt{\frac{p_0}{\rho_0}} = \sqrt{\frac{101\,325}{1.293}}\,\mathrm{m/s} = 279.9\,\mathrm{m/s}\,. \tag{35.14}$$

A sound wave, however, compresses the air far faster than heat can diffuse across a wavelength, so the correct path is adiabatic, $p \propto \rho^{\gamma}$, whence $\mathrm{d}p/\mathrm{d}\rho = \gamma p_0/\rho_0$ and Equation (35.13) follows. With the diatomic value $\gamma = 1.40$,

$$c = \sqrt{\gamma}\,c_T = 1.1832 \times 279.9\,\mathrm{m/s} = 331.2\,\mathrm{m/s}\,, \tag{35.15}$$

which agrees with the measured $331.3\,\mathrm{m/s}$ to better than one part in a thousand. The temperature dependence follows from $p_0/\rho_0 = RT/M$: at $20\,^{\circ}\mathrm{C}$ the speed is $331.3\,\mathrm{m/s} \times \sqrt{293.15/273.15} = 343.2\,\mathrm{m/s}$, as observed. The absence of dispersion follows because the coefficient in the wave equation contains no k, so all audible frequencies travel at one speed. □

Phenomenon 35.11 (The shortfall is the square root of the specific-heat ratio)**.** The ratio of the measured speed to the isothermal prediction is $\sqrt{\gamma}$, so that the acoustic measurement determines the ratio of the specific heats of the gas without any calorimetry [14, 59].

Rests on Equations (35.13) *and* (35.14).

Derivation. *Derives Phenomenon 35.11.*

Dividing Equation (35.13) by Equation (35.14) gives $c/c_T = \sqrt{\gamma}$, so

$$\gamma = \left(\frac{c}{c_T}\right)^2 = \frac{c^2\rho_0}{p_0}\,. \tag{35.16}$$

With the measured $c = 331.3\,\mathrm{m/s}$ and the same p_0 and ρ_0 as above, $c/c_T = 1.1836$ and $\gamma = 1.401$ — the value of c_p/c_V for a diatomic gas, obtained from a stopwatch, a survey and a barometer. The shortfall is therefore not a defect in the measurement but a datum: it is $1 - 1/\sqrt{\gamma} = 15.5\,\%$, and it *is* the thermodynamics. □

35.4.4 Interpretation

Three separate results sit in this one measurement, and they are worth separating.

The first is the speed itself, which is the input to every acoustic calculation in this part and which fixes the scale against which the Doppler shifts of Section 35.6 are read.

The second is the null result on dispersion, which is among the sharpest in physics and is almost never stated as one. A chord fired from a distant gun arrives as a chord; thunder from a kilometre away is a rumble but not a glissando; an orchestra heard from the back of a hall is not smeared in time by pitch. Each is an observation that $\mathrm{d}c/\mathrm{d}f$ vanishes to the precision of the ear over three decades of frequency, and each is a direct check on the linearity of the wave equation of Chapter 28. The linearity does fail: at large amplitude the compressions steepen into shocks, and that regime belongs to Chapter 31.

The third is the thermodynamic one, and it is the reason this experiment is included in a mechanics part at all. In 1687 there was no thermodynamics, no specific heat and no notion of an adiabatic process; Newton's calculation was correct given his assumption, and the assumption was the error. Equation (35.16) converts a mechanical measurement into a determination of γ, hence of the number of thermally active degrees of freedom per molecule, which is the subject of Chapter 55 and Chapter 54. That a discrepancy of 15 % was allowed to stand, unexplained and undisguised, for well over a century is a better model of scientific practice than the outcome; Newton himself attempted to close it by invoking the finite size of the air particles and the presence of vapour, and that adjustment was wrong.

35.4.5 Primary references

[14, 59]. The field determinations quoted in outline above are those of the eighteenth-century academies and, most carefully, of the Bureau des Longitudes commission that fired reciprocal cannon over a surveyed baseline south of Paris in 1822 and published in the *Annales de Chimie et de Physique*; that memoir is not among the entries of this treatise's bibliography, and no measured figure is attributed to it here. The reference values for the speed and for the density and pressure of dry air are standard and are used above only as inputs to a derivation the reader can repeat.

35.5 Kundt's tube: sound speeds from dust figures (1866)

Tests Equations (35.17) *and* (35.19).

Assuming Equation (35.13).

A ten-kilometre baseline and a pair of cannon are a heavy way to measure a speed, and they cannot be pointed at an arbitrary gas. Kundt reduced the whole measurement to a bench-top apparatus and, more remarkably, to a ruler: his method eliminates the clock entirely, by comparing two wavelengths at one frequency instead of timing one wave.

35.5.1 Apparatus

A horizontal glass tube, closed at one end by a movable piston and at the other by a light disc mounted on the end of a metal rod that is clamped rigidly at its midpoint and passes into the tube through a sliding seal. Fine dry cork dust, or lycopodium powder, spread in a thin line along the floor of the tube. A rosined cloth for exciting the rod, and a supply of whichever gas is to fill the tube.

35.5.2 Procedure

The rod is stroked lengthwise with the rosined cloth until it sounds its longitudinal fundamental: clamped at the middle and free at both ends, it has a displacement node at the clamp and antinodes at its ends. The disc at its inner end therefore drives the gas column at the rod's frequency. The piston is then slid along the tube until the gas column is resonant, at which point the dust leaves the smooth line and springs into a regular series of sharp transverse ridges. The spacing of the ridges is measured with a scale laid along the tube, and the free length of the rod is measured with the same scale. The tube is then flushed and refilled with a different gas and the measurement repeated, the rod, and hence the frequency, being unchanged.

35.5.3 Observations and data

Sharp, evenly spaced ridges of dust, whose spacing depends strongly on the gas filling the tube and not at all on how hard the rod is stroked [166]. The measured quantities are two lengths: the ridge spacing d and the half-length L_r of the rod from clamp to end.

Phenomenon 35.12 (Dust ridges mark the half-wavelength spacing of a standing wave in a gas)**.** A powder light enough to be moved by the gas but too heavy to remain suspended collects at the displacement nodes of a standing sound wave, forming ridges spaced by half a wavelength [166]. The wavelength in the gas and that in the driving rod are therefore both measurable with a scale at one and the same frequency, and their ratio gives the ratio of the sound speeds,

$$\frac{c_{\mathrm{gas}}}{c_{\mathrm{rod}}} = \frac{d}{L_r}\,. \tag{35.17}$$

Rests on Equation (35.13).

Derivation. *Derives Phenomenon 35.12.*

The rod is clamped at its midpoint and free at both ends, so its longitudinal fundamental has a displacement node at the clamp and antinodes at the ends: each half of the rod is a quarter wavelength, and the whole rod is a half wavelength, $\lambda_{\mathrm{rod}} = 2L_r$ with L_r the clamp-to-end length. In the gas the ridges form at the displacement nodes, which in a standing wave are spaced by half a wavelength, so $\lambda_{\mathrm{gas}} = 2d$. Both waves are sustained by the same source and therefore share one frequency f, so

$$\frac{c_{\mathrm{gas}}}{c_{\mathrm{rod}}} = \frac{f\lambda_{\mathrm{gas}}}{f\lambda_{\mathrm{rod}}} = \frac{2d}{2L_r} = \frac{d}{L_r}\,, \tag{35.18}$$

which is Equation (35.17): the frequency cancels, and with it every requirement for a clock, a calibrated fork or a known pitch. Two gases compared with the same rod give, by Equation (35.13),

$$\frac{d_1}{d_2} = \frac{c_1}{c_2} = \sqrt{\frac{\gamma_1 M_2}{\gamma_2 M_1}} \tag{35.19}$$

at a common temperature, so that a ratio of two ruler readings determines a ratio of specific-heat ratios once the molar masses are known. □

35.5.4 Interpretation

Kundt's tube is Chladni's method transplanted into a gas: a powder is used to make a nodal set visible, and the figure is read as a geometric object rather than as a pitch. What the transplant buys is decisive. In the open-air determination of Section 35.4 the measured quantities are a distance of ten kilometres and a time of thirty seconds, and the systematic error is the wind. Here the measured quantities are two lengths of a few centimetres on the same bench, read with the same scale, and Equation (35.17) shows that the frequency — the one quantity that is hard to hold and hard to calibrate — has dropped out of the answer altogether. Reducing a measurement to a ratio of two lengths taken with one instrument is a recurring strategy in this treatise, and it is the same move that Equation (35.2) makes for the string.

The consequence that reached furthest was thermodynamic. Because Equation (35.19) yields γ for any gas that can be put in a tube, the method turned the ratio of specific heats into a routine measurement, including for vapours that no calorimeter of the period could handle. Kundt and Warburg applied it a decade later to mercury vapour and found a ratio of about 1.67 — the value $\frac{5}{3}$ expected for a gas whose molecules have translational degrees of freedom and nothing else [194]. That was the first clear evidence that a molecule can be a structureless point as far as heat is concerned, and it belongs to the equipartition argument of Chapter 55.

35.5.5 Primary references

The primary source is Kundt's memoir on a new kind of acoustic dust figure and its use for determining the speed of sound in solids and in gases [166], together with the later application to vapours by Kundt and Warburg [194], which returns the monatomic ratio for mercury vapour. Both are printed in Poggendorff's *Annalen der Physik und Chemie* — volumes 127 and 157 of that series, which the publisher's continuous numbering records as 203 and 233. The physics the method tests is that of [59], and the dust-figure technique is that of [39].

35.6 Buys Ballot: the Doppler effect on a moving train (1845)

Tests Equations (35.20) *and* (35.21).

Assuming Equation (35.13).

Doppler predicted in 1842 that motion of a source relative to the medium shifts the frequency received, and applied the idea — wrongly — to the colours of double stars [107]. Three years later Buys Ballot tested the acoustic half of the prediction with the fastest vehicle then available and the most sensitive frequency comparators then available: a locomotive, and musicians.

35.6.1 Apparatus

An open flat wagon drawn by a locomotive on a straight, level stretch of the Dutch Rhenish Railway between Utrecht and Maarssen. A group of trumpeters on the wagon, sounding and holding a note agreed in advance. A second group of trumpeters stationed beside the track. Observers of trained absolute pitch, some standing at the trackside, some riding on the wagon, each writing down the note heard. No instrument other than the human ear is used, and none was needed: the quantity to be measured is a frequency ratio, and a musician reports a frequency ratio as an interval.

35.6.2 Procedure

The train is run past the trackside observers at the highest speed the locomotive will hold, with the wagon trumpeters sounding continuously. Each trackside observer records the pitch heard while the source approaches and again while it recedes, expressed as an interval from the note actually being played. The arrangement is then reversed: the trumpeters stand still beside the track and the observers ride past them. Runs are repeated at several speeds, and over several days, the speed of the train being known from the timetable of the run over a measured stretch.

35.6.3 Observations and data

The pitch heard is higher than the pitch sounded while the source approaches and lower while it recedes; the change occurs as the source passes, and the effect reverses with the direction of travel. The size of the shift grows with the speed of the train and is of the order of a semitone at the speeds attainable. Reversing the roles of source and observer gives the same effect to the accuracy of the method [111].

Phenomenon 35.13 (Doppler shift of sound)**.** The frequency received from a source moving through still air differs from the frequency emitted, being raised on approach and lowered on recession by

$$f' = f\,\frac{c}{c \mp v_s}\,, \tag{35.20}$$

with the upper sign for approach; and an observer moving through still air toward or away from a stationary source receives

$$f' = f\,\frac{c \pm v_o}{c}\,. \tag{35.21}$$

Both are observed, and the shift is of order a semitone for the speeds of a nineteenth-century locomotive [107, 111].

Derivation. *Derives Phenomenon 35.13.*

Work in the frame in which the air is at rest, where the wave speed is c and depends on nothing else. Let the source emit f crests per second while moving toward the observer at v_s. In the time $1/f$ between crests the first crest travels c/f while the source advances v_s/f,

so successive crests are separated in space by $\lambda' = (c - v_s)/f$. A stationary observer meets crests at $f' = c/\lambda' = fc/(c - v_s)$, which is Equation (35.20); recession changes the sign of v_s. If instead the source is at rest and the observer advances at v_o, the spacing of the crests in the air is unchanged at $\lambda = c/f$, but the observer sweeps through them at closing speed $c + v_o$, so $f' = (c + v_o)/\lambda = f(c + v_o)/c$, which is Equation (35.21).

The size is what makes the experiment feasible. An equal-tempered semitone is the ratio $2^{1/12} = 1.0595$; from Equation (35.20) an approaching source produces it when $c/(c - v_s) = 1.0595$, that is when

$$v_s = c\left(1 - \frac{1}{1.0595}\right) = 0.0562\,c \approx 19.3\,\mathrm{m/s}\,, \tag{35.22}$$

taking for c the summer-afternoon value 343 m/s of Section 35.4: some 69 km/h, at the upper end of what a locomotive of 1845 could sustain, and a shift that a musician identifies at once because a semitone is the smallest interval the Western scale names. Note also that the shift is a ratio: the observer needs to know neither c nor the absolute pitch of the trumpet, only the interval. □

35.6.4 Interpretation

The experiment confirms Phenomenon 35.13, and it does so in the one arrangement where the confirmation is unambiguous: the source motion is real, mechanical and reversible, the medium is demonstrably at rest, and the effect changes sign as the train goes by. It is the earliest quantitative test of a prediction that is now the basis of radar, of medical flow imaging, of stellar radial velocities and of the expansion of the universe.

Its deeper content is the asymmetry between Equation (35.20) and Equation (35.21). The two describe physically different situations — source moving through the air, observer moving through the air — and they are not the same function. Expanding both for small speeds,

$$\frac{f'_s}{f} = 1 + \frac{v}{c} + \frac{v^2}{c^2} + \dots\,, \qquad \frac{f'_o}{f} = 1 + \frac{v}{c}\,, \tag{35.23}$$

so that they agree at first order and differ at second, by v^2/c^2. For $v/c = 0.056$ that is about three parts in a thousand, roughly five cents of pitch, far below what an ear can judge against a moving background — which is why Buys Ballot found the two arrangements equivalent and why the asymmetry, though real, is not among his results. Stated positively: sound has a preferred frame, the rest frame of the air, and only relative motion *with respect to it* matters; a sufficiently precise acoustic Doppler measurement can therefore detect motion through the medium. That the corresponding optical experiment finds no such frame — and no such second-order asymmetry, only the symmetric relativistic formula — is the content of Chapter 37 and the point of departure for Chapter 38. The contrast is sharpest when the two are set side by side, which is why the acoustic case is worked out here in full.

A word on Doppler's own paper, in the spirit of the honesty rule that governs this treatise. Doppler applied his result to the colours of double stars and concluded that the colours are caused by orbital motion [107]. That conclusion is wrong: the colours of stars are set by their surface temperatures, and the velocities involved are far too small to shift a star out of the visible band. Buys Ballot said so, in the very memoir that confirmed the acoustic effect [111]. The prediction was right, the application was wrong, and the experiment separated them — the optical shift is real but had to wait for spectroscopy, where a shifted absorption line can be measured against a laboratory standard, rather than for the eye.

35.7 Summary of the evidence

Table 35.2: Tests of the wave predictions of Chapter 28 reported in this chapter. Each result is a ratio or a pure number, which is why apparatus of the seventeenth to the nineteenth century suffices to test them.

Experiment	Prediction tested	Result
Mersenne 1636	$f_1 \propto L^{-1}T^{1/2}\mu^{-1/2}$	all three proportionalities confirmed by musical interval; absolute frequency transferred from a slow cord by ratios of lengths
Chladni 1787	discrete inharmonic plate modes	nodal curves drawn by sand; frequencies of a circular plate rise as $(m+2n)^2$, which follows from the plate's quadratic dispersion and the spacing of the Bessel zeros; the spectrum is not harmonic
Melde 1860	$T_n \propto n^{-2}$ at fixed drive	loops appear only at discrete loads in the ratios $1 : 1/4 : 1/9$; a modulated tension gives a half-frequency response, predicted to hold the same figure at one quarter of the load
Newton 1687, Laplace 1816	$c = \sqrt{\gamma p_0/\rho_0}$	measured 331.3 m/s in dry air at 0 °C against 279.9 m/s isothermal; implies $\gamma = 1.401$
Kundt 1866	$c_{\text{gas}}/c_{\text{rod}} = d/L_r$	sound speeds and γ from two ruler readings, with no clock and no known frequency
Buys Ballot 1845	$f' = fc/(c - v_s)$	pitch raised on approach and lowered on recession, of order a semitone, reversing as the train passes

Every entry in Table 35.2 is a consequence of one linear wave equation together with a boundary condition, and none of them carries a free parameter. Two of them reach outside mechanics: the sound speed is a measurement of c_p/c_V and therefore of the internal structure of molecules, and the Doppler shift is the acoustic prototype of the kinematic effect whose optical counterpart forces the transformations of Chapter 38. One derivation is still pending — the acoustic streaming behind Phenomenon 35.8 — and it is of a kind that recurs throughout the chapter: it concerns how the medium moves the tracer, never whether the wave picture holds. Every claim about the waves themselves is derived here or in the theory chapters this one answers to.

Chapter 36

Experiment: Fluid Flow and Turbulence

Chapter 31 sets out the equations of fluid motion and, in the same breath, concedes how much of their content is out of reach: the transition to turbulence is not derived from them, the turbulent state past it is organized by similarity hypotheses rather than deduced, and the existence of smooth three-dimensional solutions is an open problem [745, 2094] catalogued with the rest in Chapter 133. A theory in that condition is held to account by measurement more strictly than usual. This chapter reports the measurements, chosen to span the range in which the equations are trusted and the range in which they are not: efflux from a vessel, where the ideal theory is right to within a factor the ideal theory cannot compute; Poiseuille's capillaries, where the viscous theory is right to viscometric accuracy and thereby measures the no-slip condition; Reynolds's dye filament, where the laminar solution loses its authority at a definite value of a single dimensionless number; Bénard's convection cells, where a threshold computed from the linearized equations meets a measured one; and Prandtl's water channel, where the thin layer that reconciles the inviscid limit with the observed drag was made visible and then manipulated.

The chapter is deliberately not a vindication. Two of the regularities reported below — the value of the pipe transition threshold and the statistical structure of the flow past it — are not reproduced by any derivation from the Navier–Stokes equations, and they are set down here as constraints that any future theory of turbulence must meet rather than as confirmations of the present one. That distinction is the point of the closing section, and it is why an experiment chapter is owed to this part of mechanics more than to most others.

36.1 Efflux from a vessel: Torricelli's law (1738)

Tests Equations (36.2), (36.3) *and* (36.6).

Assuming Equation (36.1).

The oldest quantitative statement about a fluid in motion is that a liquid escapes from a hole in a vessel at the speed a body would acquire in falling freely from the free surface to the hole. It is the simplest possible test of the ideal theory of Chapter 31, it can be read off with a ruler, and — importantly for what follows — it is right about the speed and wrong about the discharge, by a factor that the ideal theory has no way to supply.

36.1.1 Apparatus

An open vessel of horizontal cross-section A, large against the area a of a sharp-edged orifice pierced in a thin wall at depth h below the free surface. Two variants are used. In the first the head is held constant by a supply and an overflow weir, so that a steady jet issues; in

the second the vessel is simply allowed to empty and the falling level is recorded against time. For the range measurement the orifice is in a vertical side wall at a height z above a horizontal floor carrying a scale. Bernoulli's *Hydrodynamica* works throughout with vessels of exactly this kind, efflux from them being its central subject [22].

A third mouthpiece is fitted for the discharge measurement alone: a thin-walled tube of the same bore a, projecting a short way *inward* from the wall into the body of the liquid rather than being flush with it. Its length is a few bore diameters — long enough that the tube's own walls stand clear of the wall of the vessel, short enough that the jet does not reattach inside it. Nothing else is changed: the same vessel, the same head, the same bore.

36.1.2 Procedure

The efflux speed is obtained twice, by independent routes, so that neither reading depends on trusting the other.

The first route is kinematic. A horizontal jet leaving the side orifice is a projectile: it falls the height z in a time $\sqrt{2z/g}$ and lands at a horizontal range $x = v\sqrt{2z/g}$, so that

$$v = x\sqrt{\frac{g}{2z}}\,, \tag{36.1}$$

which reduces the speed measurement to two lengths and the local g — the same kinematics measured directly in Chapter 20. The second route is integral: with the supply shut off, the time taken to empty the vessel from an initial head H is recorded and compared with the prediction derived below.

The discharge is measured separately, by collecting and weighing the liquid delivered in a timed interval, and is compared with the product of the orifice area and the measured jet speed. The jet is also examined a short distance downstream of the plane of the orifice. The whole discharge measurement is then repeated with the re-entrant tube substituted for the flush orifice at the same head and the same bore, which changes the geometry of the approaching flow and nothing else.

36.1.3 Observations and data

Three facts are found, and they are not all favourable to the ideal theory.

First, the jet speed varies as the square root of the head. In the range measurement this appears in a particularly clean form: combining Equation (36.1) with $v = \sqrt{2gh}$ gives $x = 2\sqrt{hz}$, so the landing point is fixed by the two lengths alone and does not depend on g at all. A vessel with orifices at several depths therefore delivers jets whose landing points are predicted without any measurement of gravity, and the prediction is met.

Second, the vessel empties in the time predicted from that speed by mass conservation, which tests the square-root law over the whole range of heads at once rather than at isolated values.

Third, the volume delivered per unit time is *less* than the product of the orifice area with the measured jet speed. The jet is seen to contract downstream of the orifice, reaching a minimum section — the *vena contracta* — within about half an orifice diameter of the wall, and for a sharp-edged orifice in a thin plate the ratio of that minimum section to the orifice area is in the neighbourhood of 0.6. The speed law is exact; the discharge law is not.

Fourth — and this is the observation that makes the third one tractable — the contraction is stronger, and markedly so, when the liquid leaves through the inward-projecting tube instead of through the flush hole. Head, bore and jet speed are unchanged; the delivery is not. The contraction is therefore a property of the *approach* to the orifice and not of the orifice itself, and the two mouthpieces bracket the effect: the re-entrant tube is the geometry in which the approaching flow is most nearly radial, and the discharge is least.

Phenomenon 36.1 (Torricelli's law)**.** A liquid escaping through a small orifice at depth h below the free surface of a large vessel open to the atmosphere issues with the speed

$$v = \sqrt{2gh}\,, \tag{36.2}$$

independent of the density of the liquid, of the size of the orifice and of the direction in which the orifice faces. The volume discharged per unit time is smaller than $a\sqrt{2gh}$, by a factor near 0.6 for a sharp-edged orifice, because the emerging stream contracts to a section smaller than the hole [22, 30].

Derivation. *Derives Phenomenon 36.1.*

Take the vessel large enough that the free surface descends slowly and the flow may be treated as steady. Follow a streamline from a point on the free surface, where the pressure is atmospheric and the speed negligible because $a \ll A$, to a point in the jet just outside the orifice, where the pressure is again atmospheric because the stream is surrounded by air and is straight enough there to carry no transverse pressure gradient. Bernoulli's theorem along that streamline gives

$$p_0 + \rho g h = p_0 + \tfrac{1}{2}\rho v^2\,,$$

whence Equation (36.2). The density cancels, which is why the law holds equally for water and for mercury, and the orifice area has not entered, which is why it holds for any small hole. The result is exactly the free-fall speed from the head, because the argument is the energy balance of a particle descending the same height.

The emptying time follows by mass conservation. With the instantaneous head h, the free surface descends at $\mathrm{d}h/\mathrm{d}t = -a\,v/A$, so

$$\frac{\mathrm{d}h}{\mathrm{d}t} = -\frac{a}{A}\sqrt{2gh} \quad\Longrightarrow\quad t = \frac{A}{a}\int_0^H \frac{\mathrm{d}h}{\sqrt{2gh}} = \frac{A}{a}\sqrt{\frac{2H}{g}}\,,$$

which is A/a times the free-fall time from the initial head. Its agreement with observation tests Equation (36.2) at every head simultaneously.

What the derivation does not give is the discharge. Bernoulli's theorem was applied along one streamline and says nothing about the area of the bundle of streamlines that reaches the jet: the fluid approaches the orifice from all directions across the inner face of the wall, so the streamlines arrive with an inward transverse velocity that they carry past the plane of the hole, and the stream keeps narrowing until that transverse motion has been arrested. The measured contraction ratio is therefore a statement about the geometry of the approaching flow, not about the speed, and the two must be tested separately — which is why the third observation above falsifies nothing. □

There is exactly one mouthpiece for which the ideal theory does supply the missing factor, and it is the re-entrant one. The reason is worth stating before the calculation: the contraction is undetermined because the pressure distribution over the wall around the orifice is undetermined, and the re-entrant tube is the geometry contrived so that no wall carries an unknown pressure at all.

Proposition 36.2 (The contraction coefficient of a re-entrant mouthpiece)**.** *For steady efflux under a head h through a thin tube of bore a projecting into the vessel, the ideal theory gives the jet section exactly:*

$$C_c := \frac{a_j}{a} = \frac{1}{2}\,, \qquad Q = \tfrac{1}{2}a\sqrt{2gh}\,, \tag{36.3}$$

with no empirical input. For a sharp-edged orifice flush with a plane wall the same theory gives a larger coefficient, computed in Proposition 36.3 below.

Rests on Equation (36.2).

Proof. *Derives Proposition 36.2.*

Apply the steady momentum theorem to the liquid inside the vessel, resolved along the axis of the tube. Because the tube projects inward, it is wetted on both faces, so whatever pressure acts on its outer surface acts equally on its inner one and it transmits no net axial force to the liquid. Everywhere else on the interior the liquid is nearly at rest — the vessel is large, and only in the immediate neighbourhood of the mouth does it acquire appreciable speed — so the pressure on the walls is hydrostatic. A hydrostatic pressure distribution on a closed surface exerts no net horizontal force, and the surface here fails to be closed in exactly one place: the mouth of the tube, of area a at depth h, where there is no wall. Equivalently the patch of the opposite wall facing the mouth is unbalanced. The net axial force on the liquid is therefore

$$F = \rho g h\, a\,. \tag{36.4}$$

In the steady state that force equals the rate at which axial momentum leaves the vessel. The jet carries mass at $\rho a_j v$ and moves at v, so the momentum flux is $\rho a_j v^2$, and with Equation (36.2) for v,

$$\rho a_j\,(2gh) = \rho g h\, a\,, \tag{36.5}$$

From Equations (36.2) and (36.4) (equating the momentum flux of the jet to the unbalanced hydrostatic force and substituting $v^2 = 2gh$).

whence $a_j = a/2$, which is Equation (36.3). Note what has and has not been used: Bernoulli's theorem supplied only the speed, and the geometry supplied the rest; ρ, g and h have all cancelled, so the prediction is a pure number, testable by weighing a delivery against the flush orifice at the same head.

The argument also shows precisely why the flush orifice resists it. There the wall surrounding the hole is wetted on one side only, and the liquid accelerates along it, so the pressure over it is *not* hydrostatic and Equation (36.4) acquires an unknown correction. Fixing that correction means knowing the shape of the free surface bounding the jet, which is the free-streamline problem below. □

Proposition 36.3 (Kirchhoff's free-streamline value for the flush slit)**.** *Let an ideal incompressible liquid discharge under a head h through a sharp-edged slit of width a in a plane wall, the jet being bounded by free streamlines on which the pressure is that of the atmosphere and the speed therefore $\sqrt{2gh}$ by Equation (36.2). Then the free-boundary problem has a closed solution and the asymptotic width of the jet is*

$$C_c = \frac{a_j}{a} = \frac{\pi}{\pi + 2} = 0.611\,, \tag{36.6}$$

with no empirical input [172, 175]. The corresponding problem for a circular orifice in three dimensions is not soluble in closed form, and the measured coefficient lies near the same figure.

Rests on Equations (36.2) and (36.3).

Full derivation: Appendix A.67 (p. 3161).

Derives Proposition 36.3.

What the appendix supplies, and what makes the problem tractable at all, is a change of unknown. The difficulty is that the boundary of the jet is not given: it is a streamline whose position is part of the answer, so the domain of the problem depends on its solution. The free-streamline construction removes that by working in the *hodograph* plane, where the velocity rather than the position is the coordinate: on a free streamline the *speed* is known and only the direction varies, and on a solid wall the direction is known and only the speed varies, so an unknown boundary in the physical plane becomes a known one in the hodograph plane. A conformal map then carries that known region onto a half plane, the complex potential is written there by inspection, and Equation (36.6) follows on integrating

back. The one input this treatise does not carry is the conformal mapping itself: Chapter 8 builds the Cauchy theory and the residue calculus but no theory of conformal maps, and the appendix names that debt where it uses it.

36.1.4 Interpretation

The experiment establishes the ideal theory in its own domain and marks that domain's edge in the same measurement. Where the flow is essentially inviscid and no wall is being followed closely — along the interior streamlines, and in the jet — the Bernoulli relation is quantitatively exact. Where the geometry of the flow must be computed rather than assumed, the ideal theory is silent: it predicts the speed and not the area, and the missing factor of roughly 0.6 is supplied by measurement or by the free-streamline theory of discontinuous motions begun by Helmholtz [172, 175], not by the Bernoulli argument. This pattern — an exact statement along a streamline combined with an undetermined global geometry — recurs at every level of the subject, and in its severe form it is the closure problem of turbulence discussed in Section 36.6.

Proposition 36.2 sharpens the diagnosis rather than softening it. The re-entrant mouthpiece is not an easier case of the same calculation; it is a different kind of case, in which the unknown geometry has been arranged out of the problem by making every wetted surface carry a pressure that is either hydrostatic or self-cancelling. Once that is done a momentum balance settles the discharge exactly, with no free constant and no reference to the shape of the jet. The lesson generalizes and is used twice more in this chapter: where an integral conservation law can be applied to a control volume whose boundary is entirely known, it delivers an exact answer without solving the flow — the same move that gives the drag from the wake in Equation (36.25).

36.1.5 Primary references

[22, 30]. The law is customarily attributed to Torricelli's memoir on the motion of heavy bodies of 1644 [5], which is not among the sources verified for this treatise; it is therefore cited here to the *Hydrodynamica*, where efflux from vessels is treated at length, and to Euler's memoir, which first gives the modern local statement from which Equation (36.2) follows in one line [30]. A reader checking the customary attribution should know that the change of source is deliberate and not an error.

36.2 Poiseuille: flow in fine capillaries (1840)

Tests Equations (36.7) *and* (36.8).
Assuming Equation (31.32).

Poiseuille was a physician, and his question was the circulation of blood in the smallest vessels; his answer was the most accurate measurement of a viscous flow made in the nineteenth century, and it remains the calibration standard for viscometry. The law he found was established empirically, before it was derived, and its most exacting consequence is not the flux formula itself but what the formula's accuracy implies about the fluid's behaviour at the wall.

36.2.1 Apparatus

Glass capillaries drawn to fine bore, mounted horizontally, with bores ranging from a few tens of micrometres up to a few hundred — a span of more than an order of magnitude in diameter, which is what makes a power law in the diameter distinguishable from any other dependence. The driving pressure is supplied by a reservoir of compressed air held

at a measured value, rather than by a gravitational head, so that the pressure difference can be varied independently of the geometry and held steady for the duration of a run. The capillary and its supply sit in a bath of controlled temperature, because the coefficient sought is strongly temperature-dependent; for water near room temperature the dynamic viscosity is close to $1.0 \times 10^{-3}\,\mathrm{kg/(m\,s)}$ and changes by a few percent per kelvin. Delivered volume is collected and timed [105]. Hagen, working independently in brass tubes, used the same logic with a gravitational head [104].

36.2.2 Procedure

One variable at a time. With the tube, the temperature and the length fixed, the delivered volume per unit time Q is measured against the applied pressure difference Δp. With Δp and the tube fixed, Q is measured against the length L, shortened by cutting the same capillary so that the bore is not changed between readings — this is the step that removes the largest systematic error, since two nominally identical capillaries are not identical to the fourth power. With Δp, L and the temperature fixed, Q is measured across the family of capillaries, whose bores are determined separately by weighing a thread of mercury of known length drawn into the tube. Finally the bath temperature is varied to isolate the coefficient.

36.2.3 Observations and data

The delivered flux is found to be strictly proportional to the applied pressure difference and inversely proportional to the length of the tube, over the whole range in which the flow remains steady. Against the diameter it rises as the *fourth* power: halving the bore at fixed pressure difference divides the delivery by sixteen. The coefficient depends on the liquid and on the temperature and on nothing else — not on the material of the tube wall, not on the shape of the entry, not on the pressure level, only on the difference [104, 105].

The law fails in two recognizable ways, and the failures are as informative as the law. In tubes made short enough, the measured flux falls below the prediction, because a length of tube is consumed in establishing the flow profile before it becomes uniform along the axis. And above a sufficiently large flux the proportionality to Δp is lost, the flux rising much more slowly than the pressure difference thereafter; that is the transition of Section 36.3, met here from the other side.

Phenomenon 36.4 (The measured fourth-power law and the no-slip condition)**.** Steady flow of a viscous liquid along a straight circular tube of radius R and length L delivers a volume flux

$$Q = \frac{\pi R^4}{8\mu}\,\frac{\Delta p}{L} \tag{36.7}$$

with no adjustable constant beyond the viscosity μ of the liquid, the agreement holding over more than an order of magnitude in R [104, 105]. Because the coefficient in Equation (36.7) is fixed by the condition that the liquid be at rest against the wall, the accuracy of the fit is a quantitative measurement of that condition, and a liquid retaining any appreciable tangential speed at the wall is excluded.

Rests on Equation (36.2).

Derivation. *Derives Phenomenon 36.4.*

Chapter 31 derives Equation (36.7) from the Navier–Stokes equations with the no-slip condition $v(R) = 0$. What is needed here is the sensitivity of that result to the boundary condition itself, since that is the quantity the experiment actually bounds. Replace no-slip by the general linear slip condition, in which the tangential speed at the wall is proportional

to the local shear rate with a coefficient λ of the dimensions of a length, the *slip length*:

$$v(R) = \lambda \left(-\frac{\mathrm{d}v}{\mathrm{d}r} \right)_{r=R} .$$

The interior solution is unchanged, because the differential equation is untouched; only the constant of integration moves. Writing $v(r) = (\Delta p/4\mu L)\,(R^2 - r^2) + v_s$ and evaluating the shear rate of that profile at the wall, $(-\mathrm{d}v/\mathrm{d}r)_R = \Delta p\, R/2\mu L$, the slip condition fixes

$$v_s = \frac{\lambda\, \Delta p\, R}{2\mu L} ,$$

a plug velocity added uniformly across the section. Integrating,

$$Q = \frac{\pi R^4}{8\mu}\,\frac{\Delta p}{L} + v_s \pi R^2 = \frac{\pi R^4}{8\mu}\,\frac{\Delta p}{L}\left(1 + \frac{4\lambda}{R}\right) . \tag{36.8}$$

Three consequences follow, and they are the experimental content of this section. The correction is a pure enhancement, so slip can only make a tube deliver *more* than Equation (36.7), never less — the observed shortfall in short tubes cannot be slip and must be an entry effect. The correction scales as $1/R$, so it is the finest capillaries that carry the information: a family of tubes obeying the same fourth-power law across a wide range of R is direct evidence that λ/R is negligible throughout, which no single tube could establish. And the bound is quantitative: agreement with Equation (36.7) to a fractional accuracy ϵ in a tube of radius R requires $\lambda \le \epsilon R/4$, so agreement at the percent level in a capillary of radius 10 µm bounds the slip length at a few tens of nanometres — a molecular distance. The liquid is at rest against the wall, and Equation (36.7) is how we know it. □

36.2.4 Interpretation

Two separate things are established. The first is the Navier–Stokes equations themselves in their simplest nontrivial exact solution: the inertial term vanishes identically for this geometry, so Equation (36.7) is a consequence of the viscous stress model alone, and its confirmation to viscometric accuracy is a direct confirmation of Newton's linear relation between stress and rate of strain for these liquids. The second is the boundary condition, which is logically independent of the equations and had to be settled by measurement: Navier's own formulation admitted slip, and it is the capillary data, through Equation (36.8), that reduced the slip length to a molecular scale for ordinary liquids on ordinary walls.

The molecular origin of the coefficient μ is not touched here; it belongs to Chapter 55, whose sharpest prediction — that the viscosity of a gas is independent of its density — was confirmed by Maxwell in a separate measurement [167].

[104, 105].

36.3 Reynolds: the dye filament and the critical number (1883)

Tests Equation (36.9).

Assuming Equation (36.7).

This is the experiment that gave the subject its organizing parameter and its central unsolved problem in the same afternoon. Its apparatus is a glass tube and a thread of coloured water; its result is that the laminar solution of Section 36.2 ceases to describe the flow above a definite value of one dimensionless combination, and that the value of that threshold is not a property of the equations alone.

36.3.1 Apparatus

A horizontal glass tube leading out of a large glass-walled tank of water, entering the tank through a smoothly rounded bell mouth so that the fluid is not disturbed on the way in. Three such tubes were used, their diameters spanning a factor of several, so that the same transition could be sought at different sizes. A fine nozzle on the axis of the bell mouth introduces a filament of dyed water drawn from a separate reservoir, at a rate adjusted to match the local flow so that the filament neither spreads nor is drawn out. A valve at the far end of the tube sets the discharge, which is measured by collection and timing; a thermometer in the tank gives the temperature, and hence the viscosity. For the study of the broken filament the room is darkened and the tube illuminated by an electric spark, whose brief flash resolves the structure that continuous light averages into a haze [226].

The tank water is left standing for hours before a run, because the result depends on how quiet it is — a fact discovered in the course of the experiment and not anticipated by it.

36.3.2 Procedure

The valve is opened progressively and the filament watched down the length of the tube. At each setting the discharge is measured, the temperature read, and the dimensionless group

$$\mathrm{Re} = \frac{\rho\, \bar{v}\, D}{\mu} \tag{36.9}$$

formed from the mean speed $\bar{v}$, the tube diameter D, and the density and viscosity of the water at that temperature. The procedure is then repeated with a different tube and, since the viscosity is a strong function of temperature, at a different bath temperature, so that the same value of Equation (36.9) is reached by three independent routes: by changing the speed, by changing the size, and by changing the fluid property.

A second, independent series measures the pressure difference required to drive a given flux along a fixed length of pipe, over a range straddling the transition observed optically.

36.3.3 Observations and data

At low speed the dye filament runs the whole length of the tube as a sharp unbroken thread, and the water around it stays clear: the fluid moves in layers that do not interchange. As the speed is raised the thread persists until, at a definite discharge, it breaks up abruptly at some point down the tube and the colour spreads across the whole section beyond that point. Raising the speed further moves the point of breakdown upstream towards the inlet. Under the spark the region past the breakdown is not a uniform mixture but a mass of distinct eddies, which the continuous-light view had smeared into a haze — the flow is not disordered at the molecular level but structured at scales comparable to the tube.

The transition occurs at a value of Equation (36.9) of order 2000 for ordinary conditions of entry and supply, and at substantially the same value in all three tubes and at all bath temperatures — which is the essential observation, since the speed, the diameter and the viscosity individually differ by large factors between those runs. But the threshold is not sharp and not a constant of nature: with the tank water left undisturbed for long enough and the bell mouth kept clean, the unbroken filament survives to values several times larger, and no upper limit was established.

In the pressure series the two regimes obey different laws. Below the transition the pressure gradient required is proportional to the flux, as Equation (36.7) demands. Above it the gradient rises much faster, as a power of the flux near 1.7 — close to, but measurably below, the square. The change of law occurs at the same place as the optical breakdown, so the two observations are of one event [226].

Modern work has replaced the vague "of order 2000" with a sharp number, and in doing so changed what the number *means*. Below a critical Reynolds number a patch of turbulence deposited in the pipe decays; above it, patches split faster than they decay and the turbulence is sustained indefinitely. That critical point — a statistical threshold between two competing rates, not the value at which a filament happens to break — is $\mathrm{Re}_c = 2040 \pm 10$ [2169].

Table 36.1: The pipe transition as it is currently known. The first entry is what Reynolds's filament shows under ordinary conditions of supply and is not a constant of nature; the second is a sharply defined critical point, being the Reynolds number at which the decay rate of a turbulent patch equals its splitting rate. All three quantities are dimensionless.

Quantity	Value	Source
Re at which the dye filament breaks, ordinary inlet	$\sim 2 \times 10^3$	[226]
Re above which turbulence is sustained rather than transient	2040 ± 10	[2169]
Exponent of the flux in the turbulent resistance law	≈ 1.7	[226]

Phenomenon 36.5 (One parameter controls the transition)**.** Whether flow along a straight circular pipe remains laminar is determined, for a given standard of inlet quality, by the single dimensionless combination Equation (36.9) and not by the speed, the diameter, the density or the viscosity separately. Flows agreeing in Re break down at the same place and carry the same dimensionless resistance, however far apart their dimensional parameters lie [226].

Rests on Equations (36.7) *and* (36.9).

Derivation. *Derives Phenomenon 36.5.*

Measure lengths in units of the diameter D, speeds in units of the mean speed $\bar{v}$, times in $D/\bar{v}$ and pressures in $\rho\bar{v}^2$. The incompressible Navier–Stokes system then contains no dimensional quantity whatever, its viscous term carrying the single coefficient $1/\mathrm{Re}$ with Re as in Equation (36.9), and the boundary conditions on a geometrically similar pipe are identical in those units. Two experiments agreeing in Re therefore pose the identical mathematical problem, and every dimensionless property of their solutions — including whether the laminar solution is realized and including the dimensionless resistance — must agree. The observed collapse of three tubes and several temperatures onto one threshold is that statement measured, and it is the licence for all model-scale hydraulic and aerodynamic testing.

Note precisely what the argument does and does not deliver. It shows that *if* there is a threshold it must lie at a fixed value of Re, and it therefore explains the collapse completely. It says nothing about where that value is. And it does not survive the observation that the threshold moves when the inlet is made quieter: the disturbance amplitude entering the pipe is a further dimensionless datum of the experiment which the nondimensionalization of the interior equations does not see, so a flow specified only by Re is not fully specified at all. The similarity argument is exactly as strong as the control of the boundary data. □

The similarity argument explains the collapse and stops there. One further thing can be settled exactly, and it is negative: the breakdown is not the laminar solution losing stability to an infinitesimal disturbance in the way a heated layer does.

Proposition 36.6 (Rayleigh's inflexion criterion)**.** *Let $U(y)$ be a steady parallel flow of an inviscid fluid between rigid walls at y_1 and y_2. A two-dimensional normal-mode disturbance $\propto \mathrm{e}^{\mathrm{i}k(x-ct)}$ can have $\operatorname{Im} c \neq 0$ — that is, can grow — only if U'' vanishes somewhere in (y_1, y_2) [210]. The Poiseuille profile has U'' constant and non-zero, so no inviscid mode of it grows.*

Rests on Equation (36.7).

Proof. *Derives Proposition 36.6.*

Write the disturbance through a streamfunction ψ, with $u' = \partial_y \psi$ and $v' = -\partial_x \psi$, so that continuity is automatic. Linearizing the Euler equations about $U(y)$ and taking the curl removes the pressure, leaving the transport of perturbation vorticity by the base flow against the gradient of the base vorticity $-U'$:

$$(\partial_t + U\partial_x)\,\nabla^2\psi - U''\,\partial_x\psi = 0\,. \tag{36.10}$$

Putting $\psi = \varphi(y)\mathrm{e}^{\mathrm{i}k(x-ct)}$ and cancelling $\mathrm{i}k$ gives Rayleigh's equation,

$$(U-c)\left(\varphi'' - k^2\varphi\right) - U''\varphi = 0\,, \qquad \varphi(y_1) = \varphi(y_2) = 0\,, \tag{36.11}$$

From Equation (36.10) (substituting the normal mode and dividing by the common factor $\mathrm{i}k$).

the boundary conditions expressing that no fluid crosses either wall.

Suppose $c_i := \operatorname{Im} c \neq 0$. Then $U - c$ never vanishes on the real interval, so Equation (36.11) may be divided by it. Multiplying by the complex conjugate $\bar\varphi$, integrating across the channel and integrating $\int \bar\varphi\varphi''$ by parts — the boundary term dies on the wall conditions —

$$\int_{y_1}^{y_2} \left(|\varphi'|^2 + k^2\,|\varphi|^2\right) \mathrm{d}y + \int_{y_1}^{y_2} \frac{U''\,|\varphi|^2}{U-c}\,\mathrm{d}y = 0\,. \tag{36.12}$$

The first integral is real. In the second, $(U-c)^{-1} = (U-\bar c)\,/\,|U-c|^2$, whose imaginary part is $c_i/\,|U-c|^2$, so the imaginary part of Equation (36.12) reads

$$c_i \int_{y_1}^{y_2} \frac{U''\,|\varphi|^2}{|U-c|^2}\,\mathrm{d}y = 0\,. \tag{36.13}$$

From Equation (36.12) (taking the imaginary part, the first integral being real).

If $c_i \neq 0$ the remaining integral must vanish. Its weight $|\varphi|^2\,/\,|U-c|^2$ is non-negative and not identically zero, so U'' cannot keep one sign: it must vanish somewhere. For the parabolic profile of Equation (36.7), U'' is a non-zero constant, and the condition fails. □

Remark 36.7 (What that does and does not prove). Three limits must be stated, or the proposition will be read as more than it is. It is a criterion for the *inviscid* problem, and viscosity does not merely damp — for some profiles it destabilizes, so an inviscidly stable flow may still have a growing viscous mode. It is proved here for a plane channel and for two-dimensional disturbances. And the corresponding statement for the pipe, that the Hagen–Poiseuille solution has no growing eigenmode at *any* Reynolds number, is a computational result which this treatise cites no primary source for; it is recorded here as uncited, and nothing below rests on more than the plane case proved above. What survives is the conclusion that matters: the observed breakdown of Section 36.3 is of a different kind from the onset of Section 36.4, where an infinitesimal disturbance really does grow at a computable threshold.

Rests on Proposition 36.6.

If no disturbance grows, how does a disturbance ever get large? The question sounds rhetorical and is not: decay of every eigenmode forbids growth only in the long run, and the linearized operator here is not normal — its eigenfunctions are not orthogonal — so a superposition of decaying modes may become very large before it becomes small. The mechanism has a name and a simple physical form.

Proposition 36.8 (Algebraic amplification by the lift-up mechanism)**.** *A streamwise-invariant disturbance of a shear flow $U(y)$ — a pair of vortices whose axes lie along the flow — decays in its own cross-stream components while forcing the streamwise component linearly in time. Before viscosity stops it, the streamwise velocity perturbation exceeds the cross-stream one that created it by a factor of order* Re*:*

$$\frac{u_{\max}}{v} \sim \frac{U_0 R}{\nu} \sim \mathrm{Re}\,, \tag{36.14}$$

with R the pipe radius and U_0 the centreline speed. The growth is algebraic and transient, and occurs although every eigenvalue of the problem has negative real part.

Rests on Equation (36.9) *and Proposition 36.6.*

Proof. *Derives Proposition 36.8.*

Linearize about $U(y)\hat{\boldsymbol{x}}$ and take a disturbance independent of x. The cross-stream components (v, w) then satisfy a problem in the cross-stream plane alone: the base flow does not appear in it, because U has no component in that plane and no gradient along x to be advected. That sub-problem is purely viscous and simply decays, on the time

$$\tau_\nu \sim \frac{1}{\nu k_\perp^2} \sim \frac{R^2}{\nu}\,, \tag{36.15}$$

for a vortex filling the pipe, so $k_\perp \sim 1/R$. The streamwise component does not decouple. Its equation retains one coupling term, the advection of the base profile across its own gradient:

$$\left(\partial_t - \nu\nabla^2\right) u = -v\,U'(y)\,. \tag{36.16}$$

This is a *forced* equation, and that asymmetry — u driven by v, with no reaction of u back on v — is the non-normality, written out. Over times short compared with τ_ν the forcing is essentially steady and

$$u \approx -U'(y)\,v\,t\,,$$

growing linearly, not exponentially. Viscosity ends it at $t \sim \tau_\nu$, so with $U' \sim U_0/R$ and Equation (36.15),

$$u_{\max} \sim \frac{U_0}{R}\,v\,\frac{R^2}{\nu} = v\,\frac{U_0 R}{\nu}\,,$$

which is Equation (36.14). The physical content is plain: a streamwise vortex carries slow fluid from the wall towards the axis and fast fluid the other way, and because the profile it is stirring is steep, a small transverse motion redistributes a large streamwise velocity. What it leaves behind are alternating fast and slow *streaks*, elongated along the pipe.

The consequence for the experiment is a matter of arithmetic. At $\mathrm{Re} = 2\times10^3$ the factor in Equation (36.14) is of order a thousand, so a disturbance entering the bell mouth at a thousandth of the mean speed — far below anything the dye filament would reveal — can produce streaks comparable to the mean flow itself, at which point the nonlinear terms that the linear analysis discarded are no longer small. That is why the threshold moves when the tank is left to settle: what the experimenter controls by waiting is not Re but the amplitude the amplifier is fed, and Equation (36.14) says the amplifier's gain rises with Re. A transition governed jointly by a Reynolds number and a disturbance level is exactly what Equation (36.14) predicts and exactly what Table 36.1 reports. □

Remark 36.9 (Where the derivation stops, and why nothing further is owed)*.* Proposition 36.8 carries the account exactly as far as a linear argument can go, and it is worth stating plainly what lies beyond it, so that the boundary is not mistaken for an omission. What follows the algebraic amplification is the finite-amplitude stage: the streaks left by the lift-up develop a secondary instability of their own, and the breakdown of the streaks regenerates the

streamwise vortices that made them, closing a cycle that sustains itself without any growing eigenmode anywhere in it. That picture is a description of solutions found numerically and observed experimentally, not a derivation from the Navier–Stokes equations; the scaling of the critical disturbance amplitude with a negative power of Re is measured, and the near-1.75 power by which the turbulent resistance grows with the flux is an empirical correlation.

No derivation of the threshold from the equations of motion exists. That is a statement about the subject and not about this book, and it is why nothing in this chapter asserts one: the phenomenon stated here is Phenomenon 36.5, the collapse onto a single parameter, which is derived in full above, and the honest account of the threshold itself is given in the interpretation of this experiment below, as two available states whose boundary no theory predicts [2169]. An unwritten derivation would be owed only if a claim rested on it, and none does.

36.3.4 Interpretation

Three distinct claims must be separated, because they are of very different strength.

The collapse onto one parameter is explained, completely, by the derivation above; it is a consequence of the equations and needs nothing else. The existence of a transition is an observation the equations are believed to contain but from which it has never been extracted: by Proposition 36.6 the profile supports no growing inviscid mode, and the laminar solution is not found to be unstable to infinitesimal disturbances at any Reynolds number, so the observed breakdown cannot be the linear instability that the analogous calculation supplies for the convecting layer of Section 36.4. And the value of the threshold is not a property of the equations at all in the form usually quoted, since it depends on the disturbances present — Reynolds's own runs establish this by moving the threshold with nothing but patience.

That last point deserves emphasis because the number 2000 is so often quoted as though it were a constant. What the experiment establishes is a *lower* bound on the laminar range under realistic conditions, and an upper bound that has never been reached. The honest statement of the result is that the pipe has two available states, that which of them is realized depends jointly on Re and on the level of disturbance admitted [2169], and that no theory currently predicts the boundary between them.

What *is* understood is why the two must enter together. Proposition 36.8 supplies an amplifier whose gain grows with Re and which needs no instability to run, so the product of gain and input — not either alone — decides whether the disturbance reaches the amplitude at which the neglected nonlinear terms take over. A threshold in that product is a curve in the (Re, amplitude) plane, not a number; quoting $\mathrm{Re} \approx 2000$ is quoting one point of it, at whatever inlet quality the quoter had. The sharply defined 2040 ± 10 of Table 36.1 escapes that objection only because it is defined by a different question — whether turbulence, once present, persists — which does not refer to the disturbance that started it [2169].

Reynolds returned to the problem a decade later with the decomposition of the velocity field into mean and fluctuating parts, which produces the averaged equations and the Reynolds stresses [268]; that route reorganizes the problem without closing it, and is taken up in Section 36.6.

36.4 Bénard: cellular convection (1900)

Tests Equations (36.21) *and* (36.22).
Assuming Equation (36.17).

Where the pipe gives a transition no calculation predicts, the layer heated from below gives one that a calculation predicts exactly. The two sit in this chapter side by side deliberately: they show that the difficulty in the pipe is specific and not a general failure of hydrodynamic stability theory.

36.4.1 Apparatus

A shallow horizontal layer of liquid spread on a levelled metal plate that is heated from below and held at a uniform temperature, the upper surface left free and open to the air. Bénard used molten spermaceti and paraffin, liquids whose viscosity is high enough to keep the motion slow and orderly and which solidify on cooling, so that the pattern can be fixed and examined at leisure. Layer depths are of the order of a millimetre. The layer is observed from above, photographically and by the optical distortion of a reflected grid, which registers the deformation of the free surface accompanying the flow [288].

36.4.2 Procedure

The plate temperature is raised slowly and the layer watched for the onset of motion. Once cells appear, the temperature difference across the layer is increased further and the pattern followed; the layer depth is then changed and the whole sequence repeated, so that the cell size can be plotted against the depth — the measurement that distinguishes a pattern imposed by the apparatus from one selected by the fluid.

36.4.3 Observations and data

Below a threshold temperature difference nothing moves: the liquid transports heat by conduction alone, and the layer is optically featureless. Above the threshold a steady circulation appears, and it is not disordered but cellular, the layer dividing into a tessellation of nearly regular hexagons with liquid rising in the interior of each cell and descending along the shared boundaries. The cells are stable, persist indefinitely while the heating is maintained, and vanish when the temperature difference is lowered back through the threshold.

The horizontal size of a cell is proportional to the depth of the layer and independent of the lateral extent of the apparatus, which is far larger. This is the decisive quantitative observation, because it identifies the depth as the only length the fluid uses: the pattern is selected by the physics of the layer and not by its container [288].

Phenomenon 36.10 (Convective onset at a threshold, with a selected horizontal scale)**.** A horizontal fluid layer heated from below remains at rest, carrying heat by conduction, until the imposed temperature difference exceeds a threshold; above it a steady cellular circulation sets in whose horizontal periodicity is a fixed multiple of the layer depth and independent of the size of the vessel [288]. The threshold is controlled by the single dimensionless combination

$$\mathrm{Ra} = \frac{g\alpha\,\Delta T\,d^3}{\nu\kappa}\,, \tag{36.17}$$

in which α is the thermal expansion coefficient, ν the kinematic viscosity, κ the thermal diffusivity and d the depth, and it occurs at a critical value of order a thousand [438].

Rests on Equation (36.17)*.*

Derivation. *Derives Phenomenon 36.10.*

Work in the Boussinesq approximation, in which the density variation is kept only where it multiplies g and the fluid is otherwise treated as incompressible with constant ν and κ. The base state is motionless conduction, with the temperature falling linearly at the rate $\beta = \Delta T/d$ from the hot lower plate to the cold upper one. Write the perturbation velocity

$\boldsymbol{u}$, its vertical component w, and the temperature perturbation θ. Linearizing about that state and taking the double curl of the momentum equation — which removes the pressure and, using $\nabla \cdot \boldsymbol{u} = 0$, leaves an equation for w alone — gives the pair

$$\partial_t \nabla^2 w = g\alpha \nabla_h^2 \theta + \nu \nabla^4 w \,, \qquad \partial_t \theta = \beta w + \kappa \nabla^2 \theta \,, \tag{36.18}$$

with $\nabla_h^2 = \partial_x^2 + \partial_y^2$ the horizontal Laplacian. The first equation says that buoyancy, acting only where the temperature varies horizontally, drives vertical motion against viscosity; the second says that a rising parcel carries the conduction gradient with it and loses the excess by diffusion. The two effects compete, and Ra of Equation (36.17) is the ratio in which they stand.

At marginal stability the disturbance neither grows nor decays, so the time derivatives vanish. Eliminating θ between the two steady equations — solve the second for θ and substitute —

$$\nu\kappa \, \nabla^6 w = g\alpha\beta \, \nabla_h^2 w \,. \tag{36.19}$$

From Equation (36.18) (setting the time derivatives to zero, applying $\kappa\nabla^2$ to the first equation and using $\kappa\nabla^2\theta = -\beta w$ from the second).

Now separate. Horizontally, take any planform $f(x, y)$ with $\nabla_h^2 f = -a^2 f / d^2$, so that a is the horizontal wavenumber measured in units of $1/d$; a roll, a square and a hexagon all satisfy this, which is already the statement that the linear problem fixes the periodicity and not the plan form. Vertically, take the boundaries stress-free and perfectly conducting, so that $w = \partial_z^2 w = \theta = 0$ at $z = 0$ and $z = d$. The single half-wave $w = W_0 \sin(\pi z/d) \, f(x, y)$ meets every one of those conditions, together with the further conditions $\partial_z^4 w = 0$ that Equation (36.19) inherits, and it is the gravest such mode. For it,

$$\nabla^2 w = -\frac{\pi^2 + a^2}{d^2} \, w \,, \qquad \nabla_h^2 w = -\frac{a^2}{d^2} \, w \,,$$

so that Equation (36.19) becomes an identity between numbers,

$$\nu\kappa \, \frac{\left(\pi^2 + a^2\right)^3}{d^6} = g\alpha\beta \, \frac{a^2}{d^2} \,.$$

Multiplying by $d^6/\nu\kappa$ and using $\beta d = \Delta T$ to recognize $g\alpha\Delta T d^3/\nu\kappa$ as the Rayleigh number of Equation (36.17),

$$\mathrm{Ra}(a) = \frac{\left(\pi^2 + a^2\right)^3}{a^2} \,, \tag{36.20}$$

From Equations (36.17) and (36.19) (substituting the half-wave mode and collecting the dimensionless group).

which is the marginal-stability relation [438]. Note that no property of the fluid survives in it: the whole of the material physics has gone into the single number Ra.

The layer becomes unstable as soon as the imposed Rayleigh number exceeds Equation (36.20) for *some* wavenumber, so the threshold is the minimum of that curve. Writing $u = a^2$,

$$\frac{\mathrm{dRa}}{\mathrm{d}u} = \frac{3\left(\pi^2 + u\right)^2 u - \left(\pi^2 + u\right)^3}{u^2} = \frac{\left(\pi^2 + u\right)^2 \left(2u - \pi^2\right)}{u^2} \,,$$

which vanishes only at $u = \pi^2/2$ and changes sign from negative to positive there, so the minimum is unique. Substituting,

$$a_\mathrm{c} = \frac{\pi}{\sqrt{2}} \approx 2.221 \,, \qquad \mathrm{Ra}_\mathrm{c} = \frac{27\pi^4}{4} \approx 657.5 \,. \tag{36.21}$$

The critical wavenumber fixes the horizontal periodicity of the pattern that appears at onset:

$$\lambda_\mathrm{c} = \frac{2\pi d}{a_\mathrm{c}} = 2\sqrt{2}\, d \approx 2.83\, d \,, \tag{36.22}$$

so that one rising and one descending region together span a little under three depths, and a single cell is roughly one and a half depths across. This is the measured proportionality of cell size to depth, with the constant predicted and no parameter free. Note that the container never entered the calculation: the only length available to the linearized problem is d, which is why the selected scale cannot depend on the lateral extent. The numerical threshold does depend on the boundary conditions assumed — for the physically commoner case of two rigid boundaries the same calculation gives a critical Rayleigh number near 1708, with a correspondingly larger critical wavenumber [1199] — so the value quoted must always be paired with the boundary conditions it belongs to. □

Remark 36.11 (Why the rigid case is not done the same way). The half-wave $\sin(\pi z/d)$ is what makes the calculation above three lines long, and it works only because a stress-free boundary imposes $\partial_z^2 w = 0$. A rigid boundary imposes $\partial_z w = 0$ instead — no slip — which the half-wave violates, and the vertical problem no longer separates into a single trigonometric mode: the sixth-order operator must be solved with six boundary conditions, the solution is a combination of one trigonometric and two hyperbolic vertical structures, and the eigenvalue condition is a transcendental equation whose lowest root gives the $\mathrm{Ra}_c \approx 1708$ quoted above [1199]. The physics is unchanged and the architecture of the argument is unchanged; only the vertical eigenfunction is no longer elementary. That is why the stress-free value is the one derived in full here and the rigid value is cited.

Rests on Equation (36.20).

36.4.4 Interpretation

The onset of convection is the case in which hydrodynamic stability theory works completely: a threshold and a length scale are computed from the linearized equations with no adjustable parameter, and both are observed. Set beside Section 36.3, this is the useful comparison — the failure to predict the pipe threshold is a failure of a particular flow to lose stability in the linear way, not a failure of the method.

Two honest qualifications are owed. The first concerns Bénard's own configuration. His layers were thin, with a free upper surface, and in that geometry the temperature dependence of the surface tension drives a competing instability with its own threshold and its own preferred scale; later analysis — not among the primary sources verified for this treatise — attributes the cells Bénard actually photographed largely to that mechanism rather than to buoyancy [1082, 1158]. The buoyancy instability that Equation (36.21) describes is properly tested in a layer confined between two plates, where the free surface is absent. The name attached to the phenomenon is therefore, strictly, attached to the wrong experiment, and it is recorded here so that a reader comparing the 1900 photographs with the 1916 calculation is not misled into thinking they are the same system.

The second qualification is that the calculation predicts only the onset. It gives the threshold and the initial pattern; it does not give the amplitude of the motion above threshold, the hexagonal rather than striped plan form, or anything about the sequence of further instabilities that follows as the heating is increased. That sequence — steady cells, then oscillations, then a cascade of period doublings into aperiodic motion — was measured in convecting liquid metal [1693] and in the closely analogous rotating-cylinder flow [505, 1545], and it is the experimental material of Chapter 32. Taylor's rotating cylinders deserve a separate mention as the first case in which a hydrodynamic stability calculation and an experiment agreed quantitatively [505].

36.5 Prandtl: the boundary layer made visible (1904)

Tests Equations (36.23) *and* (36.24).

Assuming Equation (36.9).

The sharpest wrong answer in classical physics is d'Alembert's: steady potential flow of an inviscid fluid past a finite body exerts no drag whatever [27], and the limit of vanishing viscosity therefore contradicts every observation of a real fluid however thin. Prandtl's resolution was not a calculation but a photograph, followed by a calculation. What he showed was that the limit is singular: the viscous term never becomes negligible near a wall, however small the viscosity, because the gradients there grow as fast as the coefficient shrinks.

36.5.1 Apparatus

A small hand-cranked water channel, of the order of a metre long, with a glass side wall for observation and a paddle arrangement returning the water so that a steady stream can be maintained by hand for as long as a run requires. The water is seeded with suspended particles and illuminated from the side, so that in a photograph of finite exposure each particle draws a streak along its path and the streamline pattern is recorded directly. Models are placed in the working section: a flat plate aligned with the stream, a circular cylinder, and a channel with diverging walls. One cylinder is pierced with a narrow slit connected to a suction line [315].

36.5.2 Procedure

The flow past each model is photographed at increasing stream speed, and the streak pattern examined for the line at which the streamlines cease to follow the surface. The diverging channel is used because the same effect occurs there without a curved body, in a geometry where the pressure is known to rise along the flow direction. The decisive run is the last: with the cylinder in place and the flow separated, suction is applied through the slit on one side only, removing the fluid nearest the wall along a single line, and the photograph is repeated.

36.5.3 Observations and data

Outside a thin region adjacent to the surface, the streamline pattern over the forward part of a body agrees with the ideal-flow solution; the fluid there behaves as the inviscid theory says it should. The region in which it does not is thin, and thins further as the speed is raised.

At a definite line on the surface — always in the part of the body where the external pressure is rising along the flow — the streamlines leave the wall. Downstream of that line the photograph shows fluid moving backwards near the surface, and beyond the body a broad wake in place of the smooth closing streamlines that potential theory requires. The same departure appears in the diverging channel, where no curvature is involved, showing that the rising pressure and not the geometry of the body is the operative condition.

With suction applied through the slit, the flow on that side remains attached past the point where it had separated, and the wake becomes strongly asymmetric. Removing a thin sheet of fluid — a small fraction of the discharge, taken from immediately against the wall — changes the entire flow around the body. Nothing else was altered.

Phenomenon 36.12 (The thin viscous layer and its separation)**.** At large Reynolds number the effect of viscosity in the flow past a body is confined to a layer against the surface whose thickness decreases as the Reynolds number rises, the flow outside it being described by

the inviscid equations. The layer detaches from the surface where the external pressure rises along the flow, leaving a wake of reversed flow behind the body; the detachment can be suppressed by removing the fluid within the layer, which demonstrates that the whole downstream flow is controlled by a sheet of fluid of negligible volume [315]. Drag is therefore not zero in the limit of vanishing viscosity, and the d'Alembert paradox is a statement about a limit that is not attained uniformly [27].

Rests on Equation (36.9).

Derivation. *Derives Phenomenon 36.12.*

Consider steady flow of speed U past a body of streamwise extent L, and suppose the viscous effects confined to a layer of thickness $\delta \ll L$. Within it the streamwise velocity must rise from zero at the wall to the external value over the distance δ, so transverse gradients exceed streamwise ones by the factor L/δ and the dominant viscous term is $\nu\,\partial_y^2 u$, of order $\nu U/\delta^2$. The streamwise inertia is $u\,\partial_x u$, of order U^2/L. A layer in which viscosity acts at all exists precisely where these balance:

$$\frac{\nu U}{\delta^2} \sim \frac{U^2}{L} \quad\Longrightarrow\quad \frac{\delta}{L} \sim \left(\frac{\nu}{UL}\right)^{1/2} = \mathrm{Re}^{-1/2}\,. \tag{36.23}$$

This settles the paradox as a matter of principle. The layer thins as $\mathrm{Re}^{-1/2}$ and so disappears in the inviscid limit, which is why the potential solution describes the outer flow ever better; but the velocity gradient across it grows as $U/\delta \sim \mathrm{Re}^{1/2}$, so the viscous stress $\mu\,U/\delta$ on the surface falls only as $\mathrm{Re}^{-1/2}$ while the area over which it acts is fixed. The dissipation does not vanish with the viscosity, because the region in which it occurs sharpens at exactly the compensating rate. A limit of that kind cannot be taken by setting the small parameter to zero in the equation, which is what d'Alembert's argument does.

The scaling is confirmed in detail by the one case that solves completely, the flat plate aligned with a uniform stream, for which the boundary-layer equations reduce to a single ordinary differential equation in the similarity variable $y\sqrt{U/\nu x}$ [341]. Its solution gives the thickness at which the velocity has reached 99 % of the free stream as $\delta_{99} \approx 5.0\,x\,\mathrm{Re}_x^{-1/2}$ and the local wall stress coefficient as $0.664\,\mathrm{Re}_x^{-1/2}$, whence a friction drag coefficient $1.328\,\mathrm{Re}_L^{-1/2}$ for one side of a plate of length L. The numbers are worth making concrete: a plate 1 m long in water of kinematic viscosity $1.0\times10^{-6}\,\mathrm{m^2/s}$ at 1 m/s has $\mathrm{Re}_L = 10^6$ and a layer 5 mm thick at the trailing edge — half a percent of the plate. That is the region which, when removed by suction, changes the flow everywhere. □

The scaling settles the paradox; the two further observations — where the layer leaves the wall, and how much drag it leaves behind — are settled by two arguments that need nothing from the layer equations beyond the thinness just established.

Proposition 36.13 (Separation requires a rising pressure)**.** *In steady flow along a solid wall the curvature of the velocity profile* at *the wall is fixed by the streamwise pressure gradient alone,*

$$\mu\left(\partial_y^2 u\right)_{y=0} = \frac{\mathrm{d}p}{\mathrm{d}x}\,, \tag{36.24}$$

and consequently the wall shear can vanish — which is what separation is — only at a station where $\mathrm{d}p/\mathrm{d}x > 0$*. Wherever the external pressure falls along the flow, the boundary layer stays attached.*

Rests on Equation (36.23).

Proof. *Derives Proposition 36.13.*

Evaluate the streamwise component of the steady incompressible Navier–Stokes equation on the wall itself. There $u = v = 0$, so both convective terms $u\,\partial_x u$ and $v\,\partial_y u$ vanish identically and what remains is

$$0 = -\frac{1}{\rho}\partial_x p + \nu\left(\partial_x^2 u + \partial_y^2 u\right)_{y=0}\,.$$

By Equation (36.23) the profile varies across the layer over the distance δ and along it over the distance L, so $\partial_y^2 u$ exceeds $\partial_x^2 u$ by the factor $(L/\delta)^2 \sim \mathrm{Re}$ and the streamwise derivative may be dropped; the same thinness makes the pressure variation across the layer negligible, so p is the external pressure and depends on x alone. That is Equation (36.24), and note that it is exact at the wall — no approximation has been made to the *form* of the equation, only to the relative size of two of its terms.

Now suppose the flow separates at some station, meaning $(\partial_y u)_{y=0} = 0$ there. Expanding the profile about the wall, where u and its first derivative both vanish,

$$u(y) = \tfrac{1}{2}\left(\partial_y^2 u\right)_{y=0} y^2 + O\left(y^3\right) ,$$

so the sign of the curvature at the wall is the sign of u just above it. The fluid a little way out from the wall is still moving forward, towards the external stream $U > 0$, so $\left(\partial_y^2 u\right)_{y=0} > 0$, and by Equation (36.24) $\mathrm{d}p/\mathrm{d}x > 0$ at that station. Contrapositively, no station at which the external pressure is falling can be a separation point. That is exactly what the photographs report: the streamlines leave the wall only over the rear of the body, and they do so in the diverging channel as well, where there is no curvature at all and the rising pressure is the only thing the two geometries share. □

Proposition 36.14 (The drag is the momentum deficit of the wake)**.** *For a body of unit span held in a uniform stream U of an incompressible fluid at constant pressure far from it, the streamwise force exerted on the body equals the momentum flux missing from the wake,*

$$F = \rho \int u\,(U-u)\,\mathrm{d}y = \rho U^2 \vartheta\,, \qquad \vartheta := \int \frac{u}{U}\left(1-\frac{u}{U}\right)\mathrm{d}y\,, \tag{36.25}$$

the integrals taken across a plane downstream of the body and ϑ being the momentum thickness*. A single traverse of the velocity profile behind a body therefore measures its drag, with no access to the stress at its surface.*

Rests on Equation (36.23)*.*

Proof. *Derives Proposition 36.14.*

Take a control volume of unit span bounded below by the surface, above by a plane $y = Y$ lying wholly outside the wake, upstream by a plane where the flow is still uniform at U, and downstream by the traverse plane. Steady mass conservation fixes what crosses the top: the volume entering upstream is UY per unit span and that leaving downstream is $\int_0^Y u\,\mathrm{d}y$, so the flux through the upper plane is $\rho\left(UY - \int_0^Y u\,\mathrm{d}y\right)$, outward. That fluid crosses the top with streamwise velocity U, because $y = Y$ is outside the wake.

Balance streamwise momentum. The pressure is uniform on every face by hypothesis and contributes nothing, so the only force is the reaction $-F$ of the body on the fluid, and

$$-F = \rho\int_0^Y u^2\,\mathrm{d}y + U\rho\left(UY - \int_0^Y u\,\mathrm{d}y\right) - \rho U^2 Y\,,$$

the three terms being the momentum leaving downstream, that leaving through the top, and that entering upstream. The terms in Y cancel identically — which is what makes the answer independent of where the upper plane was drawn — and

$$-F = \rho\int_0^Y u^2\,\mathrm{d}y - \rho U\int_0^Y u\,\mathrm{d}y = -\rho\int_0^Y u\,(U-u)\,\mathrm{d}y\,,$$

which is Equation (36.25), the integrand vanishing above the wake so that the upper limit may be sent to infinity. Two things are worth noting. The result is exact: it uses conservation of mass and momentum and the uniformity of the pressure, and nothing about viscosity, the layer or the shape of the body. And it makes the content of Phenomenon 36.12 quantitative — a drag that does not vanish with the viscosity is a wake that does not close, and Equation (36.25) is the identity between the two. □

The scaling argument of Equation (36.23) and the two exact identities just proved are as far as order-of-magnitude reasoning and control volumes can take the layer. The constants quoted with them — the 5.0, the 0.664 and the 1.328 — come from somewhere else, and it is worth stating as a proposition what that is.

Proposition 36.15 (Prandtl's layer equations and the Blasius similarity solution)**.** *At large Reynolds number the Navier–Stokes system for steady two-dimensional flow past a body reduces, in the layer, to Prandtl's equations*

$$u\,\partial_x u + v\,\partial_y u = -\frac{1}{\rho}\frac{\mathrm{d}p}{\mathrm{d}x} + \nu\,\partial_y^2 u\,, \qquad \partial_x u + \partial_y v = 0\,, \qquad \partial_y p = 0\,, \tag{36.26}$$

with u the streamwise and v the wall-normal velocity component, in which the pressure is not an unknown of the layer but is handed to it by the external potential flow. For a flat plate aligned with a uniform stream U the pressure gradient vanishes and Equation (36.26) admits the similarity solution $u = U f'(\eta)$ with $\eta = y\sqrt{U/\nu x}$, where f solves the Blasius equation

$$2f''' + f f'' = 0\,, \qquad f(0) = f'(0) = 0\,, \qquad f'(\infty) = 1\,, \tag{36.27}$$

whose numerical solution has $f''(0) = 0.3321$ and $f' = 0.99$ at $\eta = 5.0$ [341]. Those two numbers are what produce the thickness $\delta_{99} \approx 5.0\,x\,\mathrm{Re}_x^{-1/2}$, the local friction coefficient $2f''(0)\,\mathrm{Re}_x^{-1/2} = 0.664\,\mathrm{Re}_x^{-1/2}$ and, on integrating the latter along the plate, the coefficient $1.328\,\mathrm{Re}_L^{-1/2}$ quoted in Phenomenon 36.12.

Rests on Equations (36.9) *and* (36.23).

Full derivation: Appendix A.68 (p. 3167).

Derives Proposition 36.15.

The reduction is a matched asymptotic expansion, and the appendix does it as one: an outer expansion in which the viscous term is dropped and which cannot satisfy the no-slip condition, an inner expansion on the stretched variable $y\,\mathrm{Re}^{1/2}$ in which it cannot be dropped, and a matching condition in the overlap which is what transfers the outer pressure to the inner problem. Two things are worth knowing before reading it. The method of matched asymptotic expansions is not built anywhere in this treatise — Chapter 9 carries the WKB approximation, which is a different singular perturbation with the same flavour, and nothing more general — so the appendix states the matching principle it uses explicitly rather than appealing to a theorem of Part II. And Equation (36.27) has no solution in closed form: the two constants above are quadratures of a numerical integration, quoted from [341] and not computed here.

36.5.4 Interpretation

The experiment does three things at once, and they are usually run together to the detriment of all three.

It rescues the inviscid theory, by showing where it is valid: outside the layer, over the forward part of a body, the potential solution is what the streaks record. It falsifies the inviscid theory's global conclusion, by exhibiting the mechanism — separation — through which a vanishingly thin region imposes a finite drag on the whole flow. And it demonstrates control: the suction run is not an illustration but an intervention, and its success is the strongest evidence that the causal chain runs from the layer outwards and not the other way about.

The practical consequences run through the rest of fluid mechanics. The layer itself undergoes the same laminar-to-turbulent transition as the pipe of Section 36.3, and a turbulent layer, carrying more momentum near the wall, separates later than a laminar one; that is why the measured drag coefficient of a sphere *falls* abruptly as the Reynolds number

rises through the transition of its own boundary layer, and why a roughened sphere can be measurably less resistant than a smooth one [384]. The drag crisis is an experimental consequence of Phenomenon 36.12, and its explanation was Prandtl's.

36.6 What the record establishes, and what it does not

Table 36.2 collects the five results. Read as a whole, they divide sharply into those the equations of Chapter 31 explain and those they do not, and the division does not follow the historical order.

Table 36.2: The five experiments of this chapter, with the status of each result relative to the equations of Chapter 31. The last column is the point of the chapter: three of the five are derivations, two are constraints on a theory that does not yet exist.

Experiment	Regime	Status of the result
Efflux, to 1738	ideal flow	speed derived exactly; discharge derived exactly for the re-entrant mouthpiece by a momentum balance, and undetermined for the flush orifice, where it needs the shape of the free streamline
Poiseuille 1840	Re small	derived exactly; its accuracy measures the no-slip condition and bounds the slip length at a molecular scale
Reynolds 1883	$\mathrm{Re} \sim 10^3$	the collapse onto one parameter is derived; so is the negative result that no infinitesimal disturbance of the profile grows, and the algebraic amplification by Re that takes its place; the threshold value is not derived, and depends on the disturbance level
Bénard 1900	Ra near critical	threshold and cell scale derived in full from linear stability with no free parameter; the plan form and everything above onset are not
Prandtl 1904	Re large	the layer thickness scaling is derived and resolves the d'Alembert paradox; separation is shown to require a rising pressure, and the drag is identified with the wake's momentum deficit; the layer equations themselves are not derived

The honest summary of the turbulent state is that there is no theory of it. What exists is a set of measured regularities, an averaging procedure that reorganizes the equations

without closing them, and a similarity argument whose hypotheses are assumed rather than derived.

The averaging is Reynolds's own [268]: split each field into a mean and a fluctuation and average the equations, and the nonlinear term leaves behind the correlations of the fluctuations acting as additional stresses on the mean flow. Those correlations are new unknowns. Writing an equation for them produces triple correlations, and so on without end: the hierarchy of moment equations never closes, and every practical calculation of a turbulent flow closes it by an assumption that is fitted to data rather than derived. This is a structural feature of the nonlinearity, not a temporary gap.

The similarity argument is Kolmogorov's [857], with the spectral form due to Obukhov [861], resting on Richardson's picture of energy passed down a cascade of scales [494]. Granted that the small scales forget how the turbulence was made and, in an intermediate range, do not feel the viscosity either, dimensional analysis fixes the energy spectrum as a power law of exponent $-5/3$ with a single constant — a result derived in Chapter 31 and confirmed across a wide range of scales by the measurements of Grant, Stewart and Moilliet in a tidal channel, at a Reynolds number no laboratory of the time could reach [1227]. The confirmation is real and the hypotheses remain hypotheses; measured departures at high order — the intermittency corrections — show that they are not exactly true.

Underneath all of it sits an unresolved mathematical question. It is not known whether smooth solutions of the three-dimensional Navier–Stokes equations exist for all time from smooth initial data; what is proved is the existence of weak solutions [745], which are not known to be unique or smooth, and the gap is the substance of the Millennium problem statement [2094]. Every statement in this chapter about the turbulent regime therefore rests on equations whose well-posedness is open — a situation with no parallel elsewhere in this treatise, and one that Chapter 133 records as such.

The five results above are set down in that spirit. A future theory of turbulence, if there is one, will not be asked to predict something new before it has reproduced these: that the transition in a pipe is governed by one dimensionless number, that its threshold moves with the disturbance level and has no established upper bound, that the resistance law changes exponent there, that the flow past the transition is composed of eddies at scales comparable to the geometry rather than being structureless, and that its intermediate-scale energy spectrum follows the five-thirds law. The standard reference for the phenomenology as a whole is Batchelor's monograph [1340].

Part IV

Special Relativity

Chapter 37

Experiments: Light, the Aether, and Time

The kinematics of special relativity is not a philosophical preference; it is forced by measurement. This chapter sets out the experimental base: the aether the nineteenth century postulated as the medium of light, the conflict between that hypothesis and the principle of relativity, and the experiments whose outcomes single out the Lorentz transformations of Chapter 38 over Galilean kinematics.

37.1 Foundations

37.1.1 The vacuum and the aether

The aether hypothesis

Every wave known before the nineteenth century was a disturbance of something: sound of air, ripples of water, elastic waves of a solid. Each has a speed fixed with respect to its medium, and each obeys Galilean velocity addition — sound travels downwind faster than upwind, by exactly the wind speed. When Maxwell's equations (Chapter 60) yielded wave solutions travelling at a speed $c = 1/\sqrt{\varepsilon_0 \mu_0}$ fixed by two laboratory constants, the analogy seemed to settle the matter: light too must be a disturbance of a medium, the *luminiferous aether*, and c must be its speed relative to that medium.

The hypothesis was not idle. It made the aether's mechanical properties calculable and alarming: to carry a transverse wave at c it had to be more rigid than steel, yet offer no measurable resistance to the planets. That tension was tolerated because the alternative — a wave in nothing — seemed worse.

The conflict with the principle of relativity

The aether hypothesis contradicts Postulate 38.1. If light travels at c relative to the aether, then in a laboratory moving at velocity $\boldsymbol{v}$ through it the speed of light must be $c - \boldsymbol{v}$ in the direction of motion and $c + \boldsymbol{v}$ against it. Measuring that anisotropy would determine $\boldsymbol{v}$ by an experiment performed entirely inside the laboratory, and the aether's rest frame would be a physically preferred inertial frame — absolute space, restored by the back door.

So the aether is testable, and the test is quantitative. The Earth's orbital speed is $v_\oplus \approx 29.8\,\mathrm{km/s}$, so $\beta_\oplus \approx 10^{-4}$; even if the Solar System happened to be at rest in the aether at one moment, six months later the Earth's velocity would have reversed and the anisotropy would be $2\beta_\oplus$. A first-order effect is out of reach of an ordinary optical measurement, but a round-trip interference measurement is sensitive at order $\beta_\oplus^2 \approx 10^{-8}$ — and interferometry can resolve that. This is the experiment Michelson and Morley performed.

37.2 The finite speed of light

That light travels at all — rather than arriving instantaneously — is itself an experimental result, and the first quantitative one. Timing the eclipses of Jupiter's moon Io, Rømer found in 1676 that they run late when the Earth is receding from Jupiter and early when it approaches, by an amount consistent with a finite propagation speed [12]. He gave the light-crossing time of the Earth's orbit rather than a speed; with the modern orbital diameter it corresponds to a c within about 25 % of the value now fixed by definition. The relevant point for this part is that c is finite, so that the question of what it is finite *with respect to* can be asked at all.

37.3 Michelson and Morley: the search for the aether wind (1887)

Tests Equation (37.1).

37.3.1 Apparatus

A Michelson interferometer (Figure 37.1) mounted on a sandstone slab about 1.5 m square, floated on a bath of mercury so that the whole instrument could be rotated continuously without flexure or interruption. Multiple reflections folded each arm to an optical path of about 11 m, which the authors quote as 2×10^7 wavelengths of yellow light. A sodium lamp supplied the source; the fringes were viewed through a telescope carried around with the slab.

37.3.2 Procedure

Monochromatic light is divided at a half-silvered plate into two beams travelling along perpendicular arms, retroreflected, and recombined to interfere. If the apparatus moves at speed v through an aether, the round-trip times along the two arms differ, and rotating the instrument by 90° exchanges the arms and reverses the difference. The observable is therefore not a fringe position — which nothing calibrates — but the *shift* of the fringes as the instrument turns, repeated at different times of day and at different seasons so that the Earth's rotation and orbital motion sweep the laboratory velocity through the sky.

37.3.3 Observations and data

For arms of equal length L, expansion of the two round-trip times to second order in $\beta = v/c$ gives a time difference $\Delta t \simeq L\beta^2/c$, hence an expected fringe shift on rotation of

$$\Delta N \simeq \frac{2L}{\lambda}\beta^2 \,, \tag{37.1}$$

which for $L = 11\,\mathrm{m}$, $\lambda = 590\,\mathrm{nm}$ and $\beta = \beta_\oplus$ is about 0.4 of a fringe — some forty times the resolution of the instrument.

The observed displacement was, in the authors' words, "certainly less than the twentieth part of this, and probably less than the fortieth part":

$$\Delta N_{\mathrm{obs}} < 0.02 \text{ fringe (certainly)}\,, \qquad < 0.01 \text{ fringe (probably)}\,. \tag{37.2}$$

Translated into a velocity through Equation (37.1), they concluded that "the relative velocity of the earth and the ether is probably less than one sixth the earth's orbital velocity, and certainly less than one-fourth." The paper states the bound only as that fraction and prints no figure in kilometres per second; with $v_\oplus = 29.8\,\mathrm{km/s}$ the two limits correspond to

about 5 km/s and 7.5 km/s, but those numbers are derived here and are not Michelson and Morley's.

37.3.4 Interpretation

The predicted effect was absent. Contraction hypotheses of the FitzGerald–Lorentz type could be arranged to cancel it, at the cost of a new postulate whose only function was to hide the aether; Kennedy and Thorndike later closed that escape with an unequal-arm version of the experiment, whose null result constrains the velocity dependence that length contraction alone cannot explain away [700]. The economical reading is the one Einstein took: there is no aether wind because there is no aether frame, and the speed of light is the same in every inertial frame — Postulate 38.2.

37.3.5 Primary references

[236]; the unequal-arm follow-up [700].

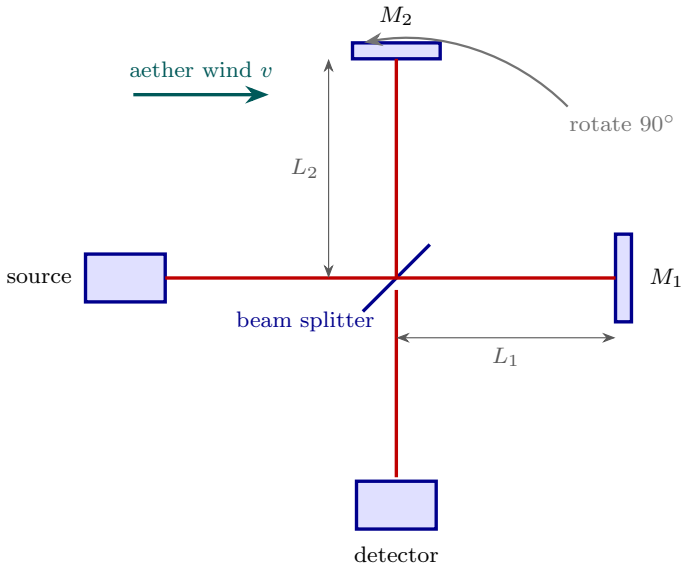

Figure 37.1: The Michelson interferometer of Section 37.3. Light is divided at the beam splitter, travels the two perpendicular arms of lengths L_1 and L_2, is retroreflected at M_1 and M_2, and recombines at the detector. An aether wind of speed v would make the two round-trip times differ at order $(v/c)^2$; rotating the whole instrument through 90° exchanges the arms and doubles the predicted fringe shift.

37.4 Fizeau: light dragged by moving water (1851)

Tests Phenomenon 38.18.

37.4.1 Apparatus

Two parallel tubes, each 1.487 m long with an interior bore of 5.3 mm, through which water was driven at 7.069 m/s. A beam of light was split so that one part traversed both tubes with the current and the other against it, the two being recombined to interfere.

37.4.2 Procedure

The water flow is started and stopped and the fringe displacement recorded. Sending each beam through both tubes — once with the flow and once against — doubles the effect and cancels systematic differences between the two optical paths.

37.4.3 Observations and data

Fizeau reports fringe displacements only. From nineteen sufficiently concurring observations the average was

$$\Delta N_{\text{simple}} = 0.23\,, \qquad \Delta N_{\text{double}} = 0.46\,, \tag{37.3}$$

against the 0.40 predicted by Fresnel's partial-drag hypothesis. No uncertainty is quoted anywhere in the note, and no numerical drag coefficient is printed; the values often attributed to Fizeau are back-derivations by later authors.

37.4.4 Interpretation

Complete dragging of the aether by the water would give a displacement proportional to the full water speed; no dragging at all would give none. The measurement sits between the two, near Fresnel's coefficient $1 - 1/n^2$, which is 0.434 for water at $n = 1.333$. As an aether result this is incoherent — the medium must be dragged partially, by an amount depending on the colour of the light. As a relativistic result it is immediate: the composition law Equation (38.29) applied to $u' = c/n$ gives exactly $c/n + v\,(1 - 1/n^2)$ to first order, with no free parameter and no medium to drag. The derivation is Example 38.20.

37.4.5 Primary references

[133]; the relativistic reading is Einstein's [321].

37.5 Cavity resonators: the modern Michelson–Morley (1979–2015)

Tests Equation (37.1).
Assuming Postulate 38.2.

37.5.1 Apparatus

Two orthogonal electromagnetic resonators — laser-stabilized optical cavities [1635, 2147], or cryogenic sapphire microwave oscillators [2258] — mounted on a turntable and rotated continuously, with their beat frequency recorded.

37.5.2 Procedure

A cavity's resonant frequency depends on its optical length; an anisotropy in the speed of light would make the beat frequency of two perpendicular cavities vary as the pair rotates, at twice the rotation frequency and with sidereal modulation as the Earth turns. The measurement is the amplitude of that modulation, integrated over months.

37.5.3 Observations and data

The searched-for fractional anisotropy is bounded at

$$\frac{\Delta c}{c} \lesssim 10^{-18}\,, \tag{37.4}$$

with the rotating optical cavities of [2147] reaching the 10^{-17} level and the rotating cryogenic microwave experiment of [2258] the 10^{-18} level in the corresponding Lorentz-violating coefficients.

37.5.4 Interpretation

Michelson and Morley bounded the anisotropy near 10^{-8} in β^2; a century of refinement has improved that by ten orders of magnitude and found nothing. Postulate 38.2 is, on present evidence, one of the most stringently tested statements in physics. The modern experiments are usually reported not as bounds on an aether velocity — nobody expects one — but as bounds on the coefficients of a general Lorentz-violating extension of the Standard Model, which is the form in which a null result remains informative (Chapter 133).

37.5.5 Primary references

[1635, 2147, 2258].

37.6 The muon lifetime

The experiments above concern the propagation of light. That the *time* of a moving system is affected as well is shown most directly by unstable particles, whose decay is a clock carried along with them. Muons created by cosmic-ray primaries at an altitude of some 15 km have a proper lifetime near 2.2 µs, so even at the speed of light they should travel only about 660 m before decaying, and essentially none should reach the ground. Very many do.

This is the subject of Chapter 41, where the measurements of Rossi and Hall [863], Frisch and Smith [1253] and the CERN storage ring [1592] are reported in full, once the time-dilation formula Equation (38.27) they test has been derived.

37.7 What the experiments establish

Taken together the results above fix the kinematics uniquely. The Michelson–Morley null result and its modern descendants say the two-way speed of light is isotropic to 10^{-18}, so no preferred frame is detectable optically. Fizeau's measurement says velocities do not add in the Galilean way, and fixes the first-order correction. Kennedy and Thorndike say the effect cannot be removed by contraction alone. The muon experiments say that moving clocks run slow by the factor γ, not by some other function of speed.

What survives is a kinematics in which c is invariant and the transformation between inertial frames is not Galilean. Chapter 38 shows that these two requirements have essentially one solution.

Chapter 38

Lorentz Transformations

A Lorentz transformation relates the space-time coordinates that two inertial frames assign to one and the same event. This chapter derives them from the two postulates of Chapter 37, reads their consequences off the geometry of Minkowski space, and characterizes the most general such transformation as a boost composed with a spatial rotation. The founding paper is Einstein's [321]; the geometric reading followed from Minkowski [357], and the group structure was identified by Poincaré [329]. Standard modern treatments are [1585, 1976].

38.1 The postulates

Everything in this part follows from two statements, both of them experimental claims rather than mathematical ones.

Postulate 38.1 (Principle of relativity)**.** The laws of physics take the same form in every inertial frame. No experiment performed within a freely moving laboratory can determine its velocity.

Postulate 38.2 (Invariance of the speed of light)**.** Light propagates in vacuum with the same speed c in every inertial frame, independently of the motion of its source.

Postulate 38.1 is old — it is Galileo's, and Newtonian mechanics obeys it. Postulate 38.2 is the new one, and it is what the aether experiments of Chapter 37 force upon us: the Michelson–Morley null result (Section 37.3) says that the speed of light does not depend on the motion of the apparatus, and the Fizeau measurement (Section 37.4) says that it does not add to the speed of its medium in the Galilean way. The two postulates are incompatible with Galilean kinematics, in which speeds simply add, and the whole of this chapter is the working out of what must replace it.

Since 1983 the second postulate has been built into the system of units: c is a defined constant, exactly $299\,792\,458\,\mathrm{m/s}$, and the metre is the distance light travels in $1/c$ seconds (Chapter 2). Measuring c is therefore no longer possible; what the experiments now test is the *isotropy* and *source-independence* asserted above, and those are still measured, to the precision reported in Section 37.5.

Notation 38.3 (Standard configuration). Throughout, K and $\bar{K}$ are inertial frames whose origins coincide at $t = \bar{t} = 0$, whose axes are parallel, and whose relative velocity is v along the common x-axis. We write

$$\beta := \frac{v}{c}\,, \qquad \gamma := \frac{1}{\sqrt{1-\beta^2}}\,, \tag{38.1}$$

so that $\gamma \geq 1$, with $\gamma = 1$ only for $\beta = 0$, and $\gamma \to \infty$ as $\beta \to 1$. Coordinates are collected as $x^\mu = (x^0, x^i) = (ct, \boldsymbol{x})$, with Greek indices running over $0, 1, 2, 3$ and Latin over $1, 2, 3$.

38.2 Lorentz boosts

38.2.1 The one-dimensional boost

Theorem 38.4 (Lorentz boost)**.** *In the standard configuration of Notation 38.3, the two postulates force the coordinate transformation*

$$\bar{x} = \gamma\,(x - vt)\ , \tag{38.2}$$

$$\bar{t} = \gamma\left(t - \frac{v}{c^2}x\right)\ , \tag{38.3}$$

$$\bar{y} = y\,, \qquad \bar{z} = z\,. \tag{38.4}$$

Rests on Postulates 38.1 and 38.2 and Notation 38.3.

Proof. *Derives Theorem 38.4.*

Step 1: the transformation is linear. Space and time are homogeneous — no event and no place is privileged — so a uniform velocity in K must appear as a uniform velocity in $\bar{K}$: straight worldlines go to straight worldlines. A map carrying straight lines to straight lines and fixing the coincident origins is linear. Write, for the x and t pair,

$$\bar{x} = Ax + Bt\,, \qquad \bar{t} = Dx + Et\,, \tag{38.5}$$

with coefficients depending on v alone.

Step 2: the origin of $\bar{K}$. The point $\bar{x} = 0$ is by construction the origin of $\bar{K}$, which moves in K along $x = vt$. Substituting into Equation (38.5) gives $Avt + Bt = 0$ for all t, whence $B = -Av$ and

$$\bar{x} = A\,(x - vt)\ . \tag{38.6}$$

From Equation (38.5) (imposing that $\bar{x} = 0$ be the worldline $x = vt$).

Step 3: the invariance of c. Emit a light pulse from the common origin at $t = \bar{t} = 0$ in the $+x$ direction. In K it obeys $x = ct$, in $\bar{K}$ it must obey $\bar{x} = c\bar{t}$ by Postulate 38.2. From Equations (38.5) and (38.6),

$$\bar{x} = A\,(c - v)\,t\,, \qquad \bar{t} = (Dc + E)\,t\,,$$

so $\bar{x} = c\bar{t}$ requires

$$A\,(c - v) = c\,(Dc + E)\ . \tag{38.7}$$

A pulse sent in the $-x$ direction obeys $x = -ct$ and $\bar{x} = -c\bar{t}$, and the same substitution gives

$$A\,(c + v) = c\,(E - Dc)\ . \tag{38.8}$$

Adding Equations (38.7) and (38.8) yields $2Ac = 2cE$, hence $E = A$; subtracting them yields $2Av = -2Dc^2$, hence $D = -Av/c^2$. So far

$$\bar{x} = A\,(x - vt)\ , \qquad \bar{t} = A\left(t - \frac{v}{c^2}x\right)\ . \tag{38.9}$$

From Equations (38.7) and (38.8) (by addition and subtraction).

Step 4: the principle of relativity fixes A. By Postulate 38.1 neither frame is privileged, so expressing (x, t) in terms of $(\bar{x}, \bar{t})$ must reproduce Equation (38.9) with v replaced by $-v$ — from $\bar{K}$, the frame K recedes at $-v$. Moreover A can depend only on $|v|$: space is isotropic, so reflecting the x-axis, which sends $v \to -v$, cannot change a scale factor. Hence $A(-v) = A(v)$, and

$$x = A\,(\bar{x} + v\bar{t})\ , \qquad t = A\left(\bar{t} + \frac{v}{c^2}\bar{x}\right)\ .$$

Substituting Equation (38.9) into the first of these,

$$\begin{aligned} x &= A\left[A\left(x-vt\right)+vA\left(t-\frac{v}{c^2}x\right)\right] \\ &= A^2\left[x-vt+vt-\frac{v^2}{c^2}x\right] = A^2\left(1-\beta^2\right)x\,, \end{aligned}$$

so $A^2(1-\beta^2)=1$. The root is fixed by requiring the transformation to reduce to the identity at $v=0$ rather than to a reflection, so $A=+\left(1-\beta^2\right)^{-1/2}=\gamma$. This is Equations (38.2) and (38.3).

Step 5: the transverse coordinates. Consider a rod of proper length ℓ lying along the y-axis, at rest in $\bar{K}$, and suppose $\bar{y}=\kappa(v)y$ with $\kappa\neq 1$. By isotropy κ depends only on $|v|$, and by the principle of relativity the inverse relation is $y=\kappa(v)\bar{y}$; composing gives $\kappa^2=1$, so $\kappa=1$ (again excluding the reflection). Lengths perpendicular to the motion are unchanged, which is Equation (38.4). □

Setting $c\to\infty$ in Equations (38.2) and (38.3) returns $\bar{x}=x-vt$ and $\bar{t}=t$: the Galilean transformation is the limit in which light is infinitely fast. Every departure from Newtonian kinematics in this part is controlled by the single dimensionless number β, and at $\beta=10^{-6}$ — a satellite in low orbit — $\gamma-1$ is about 5×10^{-13}, which is why the Galilean form survived two centuries of testing.

In matrix form, with $x^\mu=(ct,x,y,z)$,

$$\bar{x}^\mu=\Lambda^\mu{}_\nu x^\nu\,,\qquad [\Lambda]=\begin{pmatrix}\gamma & -\gamma\beta & 0 & 0\\ -\gamma\beta & \gamma & 0 & 0\\ 0 & 0 & 1 & 0\\ 0 & 0 & 0 & 1\end{pmatrix}. \tag{38.10}$$

From Equations (38.2) to (38.4) (collecting the three coordinate relations into one matrix).

38.2.2 Minkowski space

In a Euclidean space, rotations — linear homogeneous transformations — leave the norm invariant, and with it the Euclidean metric. A boost is also linear and homogeneous and resembles a rotation formally, though not physically.[1] It is natural to ask which metric a boost preserves — equivalently, since the metric defines the space, in which space a boost is a rigid motion.

Proposition 38.5 (The invariant interval)**.** *Under the boost Equations (38.2) to (38.4),*

$$c^2\bar{t}^2-\bar{x}^2-\bar{y}^2-\bar{z}^2=c^2t^2-x^2-y^2-z^2\,. \tag{38.11}$$

Rests on Theorem 38.4 and Equation (38.1).

Proof. *Derives Proposition 38.5.*

The transverse terms are unchanged. For the other two,

$$\begin{aligned} c^2\bar{t}^2-\bar{x}^2 &= \gamma^2\left(ct-\beta x\right)^2-\gamma^2\left(x-\beta ct\right)^2 \\ &= \gamma^2\left[c^2t^2-2\beta ctx+\beta^2x^2-x^2+2\beta ctx-\beta^2c^2t^2\right] \\ &= \gamma^2\left(1-\beta^2\right)\left(c^2t^2-x^2\right)=c^2t^2-x^2\,, \end{aligned}$$

the last step by Equation (38.1). □

[1] As Section 39.2.4 shows, a Euclidean rotation and a Lorentz boost are even topologically distinct: the rotation group is compact and the Lorentz group is not.

Definition 38.6 (Minkowski metric and interval)**.** *Minkowski space* is $\mathbb{R}^4$ equipped with the symmetric bilinear form of signature $(1,3)$

$$[\eta_{\mu\nu}] = \operatorname{diag}(1,-1,-1,-1)\ , \tag{38.12}$$

and the *invariant interval* between two events separated by Δx^μ is

$$\Delta s^2 := \eta_{\mu\nu}\Delta x^\mu \Delta x^\nu = c^2\Delta t^2 - |\Delta \boldsymbol{x}|^2\ . \tag{38.13}$$

Rests on Proposition 38.5.

Proposition 38.5 says precisely that a boost preserves Equation (38.13). Written with Λ, the condition that a linear transformation preserve η is

$$\eta_{\mu\nu}\Lambda^\mu{}_\lambda \Lambda^\nu{}_\rho = \eta_{\lambda\rho}\,, \qquad \text{that is} \qquad \Lambda^{\mathsf{T}}\eta\,\Lambda = \eta\,, \tag{38.14}$$

the exact analogue of the orthogonality condition $O^{\mathsf{T}}O = \mathbb{1}$ that defines a Euclidean rotation, with $\mathbb{1}$ replaced by η. Equation (38.14) is taken as the *definition* of a Lorentz transformation in Section 39.2.1, and the whole of Chapter 39 is the study of the group it defines.

Remark 38.7 (Signature conventions). This treatise uses $(+,-,-,-)$, so that $\Delta s^2 > 0$ for timelike separations and proper time is real. The opposite convention $(-,+,+,+)$ is equally common — Appendix A.1 uses it, following the gravitational-wave literature — and flips the sign of every interval. Nothing physical depends on the choice; every observable is a ratio or a sign comparison in which the convention cancels.

The light cone

The sign of Δs^2 is invariant, so all observers agree on it. It partitions the events of Minkowski space, relative to any chosen event O, into the regions of Figure 38.1.

Definition 38.8 (Causal classification)**.** A separation Δx^μ between two events is *timelike* if $\Delta s^2 > 0$, *null* or *lightlike* if $\Delta s^2 = 0$, and *spacelike* if $\Delta s^2 < 0$.

Rests on Definition 38.6.

Proposition 38.9 (Causal order is absolute)**.** *If two events are timelike or null separated, every inertial observer agrees which came first. If they are spacelike separated, their time order depends on the frame, and there are frames in which they are simultaneous.*

Rests on Equation (38.3) *and Definition 38.8.*

Proof. *Derives Proposition 38.9.*

Take the events at $\Delta x^\mu = (c\Delta t, \Delta x, 0, 0)$ with $\Delta t > 0$. By Equation (38.3), $c\Delta\bar{t} = \gamma\,(c\Delta t - \beta\Delta x)$, which changes sign when β passes through $c\Delta t/\Delta x$. This value is an admissible velocity, $|\beta| < 1$, exactly when $|\Delta x| > c\,|\Delta t|$, that is when $\Delta s^2 < 0$. For timelike and null separations no admissible boost reverses the order; for spacelike separations the boost with $\beta = c\Delta t/\Delta x$ makes $\Delta\bar{t} = 0$ and any larger β reverses the order. □

This is the reason the invariant speed also bounds causal influence. If a signal could travel faster than c, it would connect spacelike-separated events; by Proposition 38.9 some observer would see it arrive before it was sent, and the notion of cause would not survive a change of frame. Nothing in the postulates forbids superluminal *coordinate* speeds that carry no signal — the intersection point of a pair of closing scissor blades is a standard example — and nothing in them permits superluminal signalling.

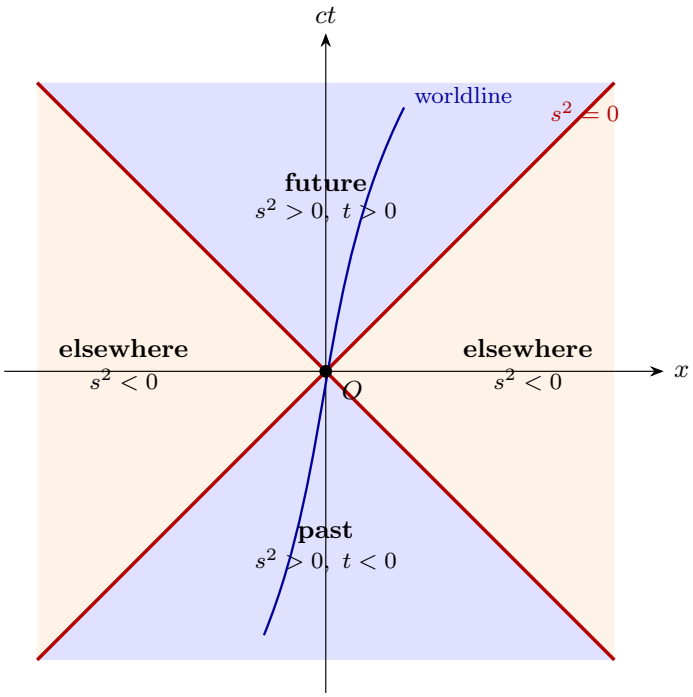

Figure 38.1: The causal structure of Minkowski space, drawn with one spatial dimension suppressed. Light through the event O travels on the 45° lines $x = \pm ct$, where $\Delta s^2 = 0$. Events with $\Delta s^2 > 0$ are timelike separated from O and lie inside the cone, divided into a future and a past that every observer agrees upon; events with $\Delta s^2 < 0$ are spacelike separated and lie outside it. A massive particle's worldline stays everywhere inside the cone, since its speed never reaches c.

38.2.3 The general boost

For a relative velocity $\boldsymbol{v} = c\boldsymbol{\beta}$ in an arbitrary direction, resolve the position into components along and across the motion,

$$\boldsymbol{x}_{\parallel} = \frac{(\boldsymbol{x}\cdot\boldsymbol{\beta})}{|\boldsymbol{\beta}|^2}\boldsymbol{\beta}\,, \qquad \boldsymbol{x}_{\perp} = \boldsymbol{x} - \boldsymbol{x}_{\parallel}\,. \tag{38.15}$$

Theorem 38.4 applies to the longitudinal pair and leaves the transverse part alone, so

$$c\bar{t} = \gamma\,(ct - \boldsymbol{\beta}\cdot\boldsymbol{x})\ , \tag{38.16}$$

$$\bar{\boldsymbol{x}}_{\parallel} = \gamma\left(\boldsymbol{x}_{\parallel} - \boldsymbol{\beta}\,ct\right)\ , \tag{38.17}$$

$$\bar{\boldsymbol{x}}_{\perp} = \boldsymbol{x}_{\perp}\,. \tag{38.18}$$

Recombining $\bar{\boldsymbol{x}} = \bar{\boldsymbol{x}}_{\parallel} + \bar{\boldsymbol{x}}_{\perp}$ and using Equation (38.15),

$$\bar{\boldsymbol{x}} = \boldsymbol{x} + \frac{\gamma-1}{|\boldsymbol{\beta}|^2}\,(\boldsymbol{\beta}\cdot\boldsymbol{x})\,\boldsymbol{\beta} - \gamma\boldsymbol{\beta}\,ct\,. \tag{38.19}$$

From Equations (38.15), (38.17) and (38.18) (recombining the longitudinal and transverse parts).

Reading off the components of $\bar{x}^{\mu} = \Lambda^{\mu}{}_{\nu}(\beta)x^{\nu}$ gives

$$\Lambda^{0}{}_{0}(\beta) = \gamma\,, \tag{38.20}$$

$$\Lambda^{0}{}_{i}(\beta) = -\gamma\beta_i\,, \tag{38.21}$$

$$\Lambda^{i}{}_{0}(\beta) = -\gamma\beta^i\,, \tag{38.22}$$

$$\Lambda^{i}{}_{j}(\beta) = \delta^{i}{}_{j} + \frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^i\beta_j\,, \tag{38.23}$$

or, in matrix form,

$$[\Lambda(\beta)] = \begin{pmatrix} \gamma & -\gamma\beta_1 & -\gamma\beta_2 & -\gamma\beta_3 \\ -\gamma\beta^1 & 1+\frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^1\beta_1 & \frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^1\beta_2 & \frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^1\beta_3 \\ -\gamma\beta^2 & \frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^2\beta_1 & 1+\frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^2\beta_2 & \frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^2\beta_3 \\ -\gamma\beta^3 & \frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^3\beta_1 & \frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^3\beta_2 & 1+\frac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^3\beta_3 \end{pmatrix}. \tag{38.24}$$

From Equations (38.20) to (38.23) (assembling the components into a matrix).

Taking $\boldsymbol{\beta} = (\beta, 0, 0)$ recovers Equation (38.10), since then $\gamma - 1$ multiplies only the 11 entry and $1 + (\gamma - 1) = \gamma$.

38.3 Spacetime diagrams

The consequences of Theorem 38.4 are algebraically trivial and conceptually treacherous; they become obvious when drawn. A *spacetime diagram* plots ct upward against x rightward, so that light travels on the 45° lines and a particle's history is a curve — its *worldline* — everywhere steeper than 45°.

The boosted frame is drawn in the same picture rather than on a separate sheet. Its time axis is the set $\bar{x} = 0$, which by Equation (38.2) is the line $x = vt$; its space axis is the set $\bar{t} = 0$, which by Equation (38.3) is the line $ct = \beta x$. Both therefore make the same angle $\alpha = \arctan\beta$ with the corresponding unprimed axis, but on opposite sides, as in Figure 38.2: the axes close like a pair of scissors on the light line, and reach it together only as $\beta \to 1$.

One warning must be issued before the diagram is used to read off numbers. The page is Euclidean and the geometry it depicts is not, so distances measured with a ruler on the paper are meaningless. What is meaningful is the invariant Equation (38.13), whose level sets are the hyperbolae of Figure 38.3. Those hyperbolae are the orbits of the boost — a boost slides events along them exactly as a Euclidean rotation slides points along circles — and they, not the ruler, calibrate the axes.

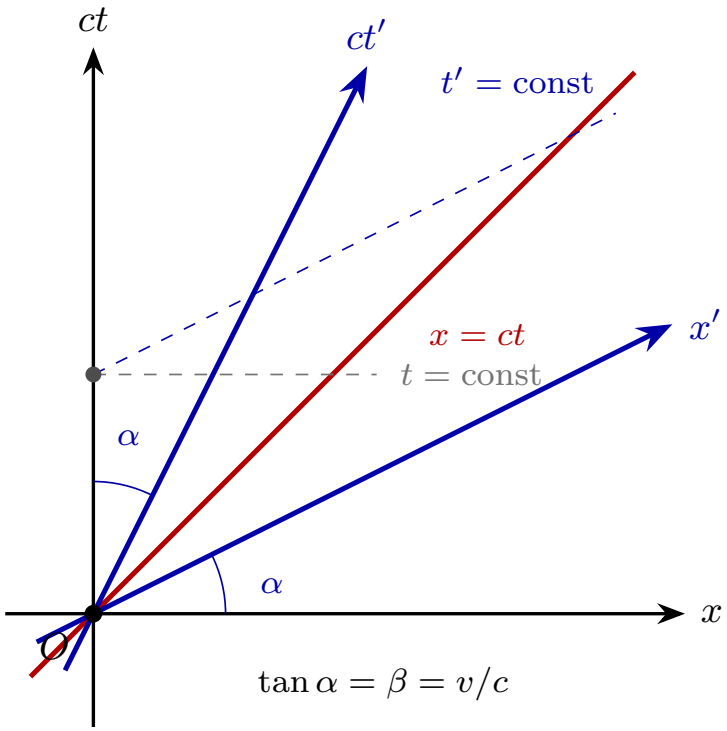

Figure 38.2: The axes of a boosted frame drawn inside the diagram of the unboosted one, for $\beta = 0.5$. The $c\bar{t}$-axis is the worldline of the moving origin and the $\bar{x}$-axis is the locus of events the moving observer calls simultaneous; both make the angle $\alpha = \arctan\beta$ with their unprimed counterparts, on opposite sides of the light line $x = ct$. Because the two axes tilt *towards* the light line rather than rotating rigidly, the surfaces of constant time in the two frames are genuinely different families.

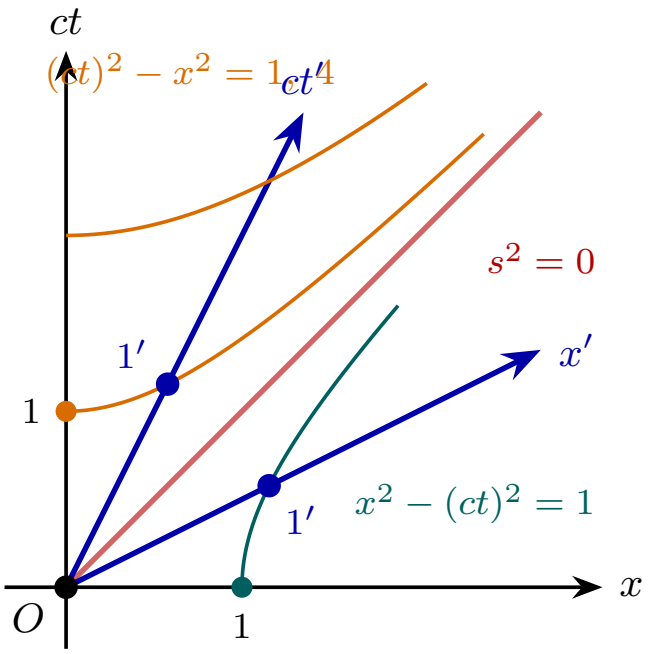

Figure 38.3: Calibration. The hyperbolae $(ct)^2 - x^2 = \pm 1$ are invariant under boosts, so a boost slides events along them, and the unit tick on any frame's time axis is where that axis cuts the timelike hyperbola. The primed ticks are farther from the origin *on the page* than the unprimed ones, and represent the same invariant interval: this is why tick spacings in the two frames may never be compared by eye.

38.4 Consequences of the postulates

38.4.1 Relativity of simultaneity

Phenomenon 38.10 (Relativity of simultaneity)**.** Two spatially separated events that are simultaneous in one inertial frame are not simultaneous in another moving relative to it. For events separated by Δx and simultaneous in K,

$$\Delta \bar{t} = -\gamma \frac{v}{c^2} \Delta x \,. \tag{38.25}$$

Rests on Theorem 38.4 and Equation (38.3).

Derivation. Derives Phenomenon 38.10.

Apply Equation (38.3) to the separation of the two events. With $\Delta t = 0$,

$$\Delta \bar{t} = \gamma \left(\Delta t - \frac{v}{c^2} \Delta x \right) = -\gamma \frac{v}{c^2} \Delta x \,,$$

which vanishes for all Δx only if $v = 0$. □

Figure 38.4 shows why this is not a paradox. "The set of events happening now" is a slice through spacetime, and the two frames slice at different angles. Neither slice is correct; simultaneity is simply not a property of a pair of events, but of a pair of events *and* a frame. Note that Equation (38.25) grows with the separation Δx: disagreement about simultaneity is unmeasurable in a laboratory and enormous over astronomical distances.

Remark 38.11 (Simultaneity is a convention, within limits). That distant simultaneity must be *defined* rather than discovered was Einstein's opening move [321]: he stipulated that light

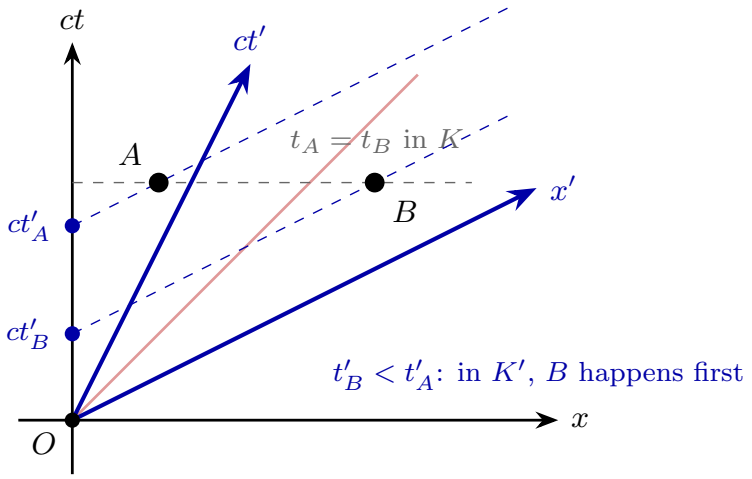

Figure 38.4: Relativity of simultaneity. The events A and B lie on one horizontal line, so K assigns them the same t. The surfaces of constant $\bar{t}$ are tilted, so A and B lie on different ones and $\bar{K}$ assigns them different times — here B happens first. Nothing has moved between the two readings; only the family of slices called "the same instant" has been re-chosen.

takes equal times on the outward and return legs of a round trip, which is what synchronizes separated clocks. The one-way speed of light is not independently measurable — measuring it presupposes synchronized clocks at the two ends — so this is a coordinative definition in the sense of Section 1.3.2, not an experimental result. What *is* measured, and what Chapter 37 reports, is the two-way speed and the isotropy of the round trip.

38.4.2 Time dilation

Definition 38.12 (Proper time)**.** The *proper time* τ along a worldline is the time read by a clock carried along it, defined through the invariant interval by

$$c^2 \mathrm{d}\tau^2 := \mathrm{d}s^2 = c^2 \mathrm{d}t^2 - |\mathrm{d}\boldsymbol{x}|^2 \,, \qquad \text{so} \qquad \mathrm{d}\tau = \frac{\mathrm{d}t}{\gamma} \,. \tag{38.26}$$

Being built from $\mathrm{d}s^2$, proper time is invariant: every frame agrees on what a given clock reads.

Rests on Definition 38.6 and Proposition 38.5.

Phenomenon 38.13 (Time dilation)**.** A clock moving uniformly with speed v relative to a frame K runs slow as judged in K: an interval $\Delta\tau$ of its proper time corresponds to

$$\Delta t = \gamma \Delta\tau > \Delta\tau \tag{38.27}$$

of K-coordinate time [816, 863].

Rests on Theorem 38.4, Equation (38.3), and Definition 38.12.

Derivation. *Derives Phenomenon 38.13.*

The clock is at rest in $\bar{K}$, so the two ticks occur at the same $\bar{x}$ and are separated by $\Delta\bar{t} = \Delta\tau$. Inverting Equation (38.3) — equivalently, applying the boost with $-v$ —

$$\Delta t = \gamma \left(\Delta\bar{t} + \frac{v}{c^2} \Delta\bar{x} \right) = \gamma \Delta\bar{t} = \gamma \Delta\tau \,,$$

since $\Delta\bar{x} = 0$. The same result follows from Equation (38.26) directly. □

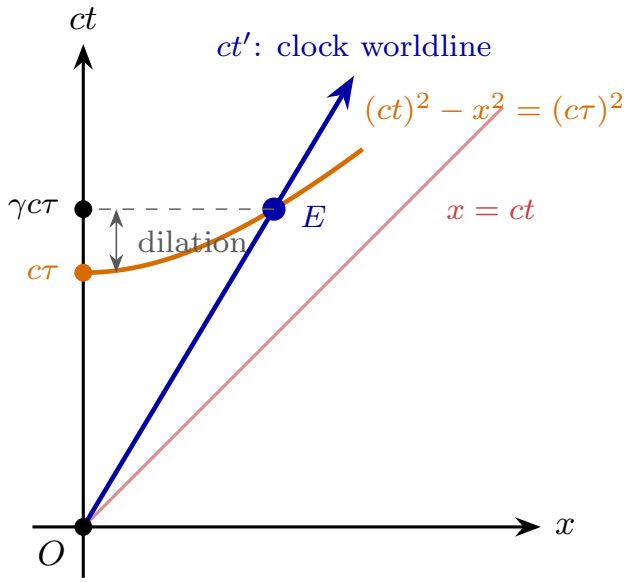

Figure 38.5: Time dilation. The moving clock sits at $\bar{x} = 0$, so its worldline is the $c\bar{t}$-axis; at the event E it has ticked off a proper time τ. The calibration hyperbola through E marks every event lying a proper time τ from O, in any frame, and it is what makes the comparison meaningful. The height of E on the ct-axis is $\gamma c\tau$, larger than $c\tau$.

Remark 38.14 (The effect is reciprocal, and that is consistent). $\bar{K}$ judges K's clocks to run slow by the same factor. The two statements do not contradict each other because each concerns a *different* pair of events: comparing a single moving clock with two stationary ones requires those two to be synchronized, and Phenomenon 38.10 says the frames disagree about that synchronization by exactly the amount needed. An asymmetry appears only when one clock changes frames, which is not a boost; that is the twin paradox, resolved in Section 40.6.

Rests on Phenomena 38.10 and 38.13.

38.4.3 Length contraction

Definition 38.15 (Proper length)**.** The *proper length* L_0 of a body is its length in the frame in which it is at rest. Its length in any other frame is defined as the distance between its two ends *taken at the same time in that frame*; the qualification is essential, because by Phenomenon 38.10 the frames disagree about what it means.

Rests on Phenomenon 38.10.

Phenomenon 38.16 (Length contraction)**.** A body of proper length L_0 moving with speed v along its own length has, in the frame through which it moves, the length

$$L = \frac{L_0}{\gamma} < L_0 \,. \tag{38.28}$$

Dimensions perpendicular to the motion are unaffected.

Rests on Definition 38.15 and Equations (38.2) and (38.4).

Derivation. *Derives Phenomenon 38.16.*

Let the body be at rest in $\bar{K}$ with its ends at $\bar{x}_1$ and $\bar{x}_2$, so $L_0 = \bar{x}_2 - \bar{x}_1$. In K the ends are located simultaneously, at some common t. Applying Equation (38.2) to each end and subtracting,

$$L_0 = \bar{x}_2 - \bar{x}_1 = \gamma\,[(x_2 - x_1) - v\,(t - t)] = \gamma L \,,$$

which is Equation (38.28). The transverse statement is Equation (38.4). □

Figure 38.6 makes the asymmetry with time dilation plain. The body sweeps out a strip in spacetime; the two frames measure its width along different directions, and the strip is what it is. The factor appears in the numerator for lengths and the denominator for times because one measurement is taken along a line of constant t and the other along a worldline.

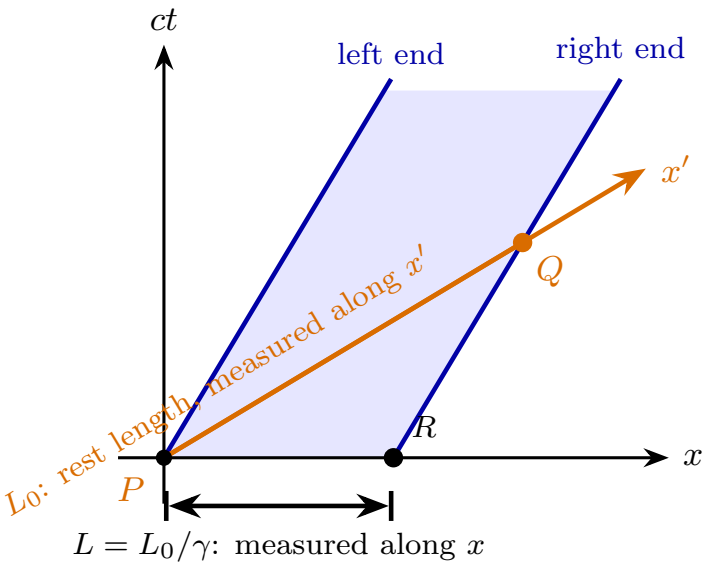

Figure 38.6: Length contraction. A rod at rest in $\bar{K}$ sweeps out the shaded strip between the worldlines of its ends. Its rest length L_0 is the interval PQ measured along the $\bar{x}$-axis, between events $\bar{K}$ calls simultaneous. K instead measures PR along its own line of constant t and obtains L_0/γ. The rod did not shrink; the two observers measured the width of the same strip in different directions.

Remark 38.17 (Contraction is not what a camera records). Phenomenon 38.16 concerns simultaneous positions, not appearances. Light reaching an eye or a plate at one instant left different parts of the body at different times, and when that is accounted for a rapidly moving object looks *rotated* rather than flattened — the Terrell–Penrose effect. Nothing in Equation (38.28) changes; the difference lies in which set of events the measurement collects.

38.5 Composition of velocities

Phenomenon 38.18 (Relativistic composition of velocities)**.** Let a particle have velocity components $u^i = \mathrm{d}x^i/\mathrm{d}t$ in K, and let $\bar{K}$ move with speed v along x. Then in $\bar{K}$ [133]

$$\bar{u}^x = \frac{u^x - v}{1 - u^x v/c^2}\,, \tag{38.29}$$

$$\bar{u}^y = \frac{u^y}{\gamma\,(1 - u^x v/c^2)}\,, \qquad \bar{u}^z = \frac{u^z}{\gamma\,(1 - u^x v/c^2)}\,. \tag{38.30}$$

Rests on Theorem 38.4 and Equations (38.2) to (38.4).

Derivation. *Derives Phenomenon 38.18.*

Differentiate Equations (38.2) to (38.4):

$$\mathrm{d}\bar{x} = \gamma\,(\mathrm{d}x - v\mathrm{d}t)\,, \qquad \mathrm{d}\bar{t} = \gamma\left(\mathrm{d}t - \frac{v}{c^2}\mathrm{d}x\right), \qquad \mathrm{d}\bar{y} = \mathrm{d}y\,.$$

Dividing the first by the second, and cancelling γ and $\mathrm{d}t$,

$$\bar{u}^x = \frac{\mathrm{d}\bar{x}}{\mathrm{d}\bar{t}} = \frac{\mathrm{d}x - v\mathrm{d}t}{\mathrm{d}t - (v/c^2)\,\mathrm{d}x} = \frac{u^x - v}{1 - u^x v/c^2}\,,$$

which is Equation (38.29). Dividing the third by the second keeps one factor of γ and gives Equation (38.30); note that a transverse velocity changes even though a transverse *length* does not, because the time interval is transformed. □

Corollary 38.19 (The speed of light is a fixed point)**.** *If $u^x = c$ then $\bar{u}^x = c$ for every $|v| < c$; and if $|u^x| < c$ and $|v| < c$ then $|\bar{u}^x| < c$.*

Rests on Equation (38.29).

Proof. *Derives Corollary 38.19.*

For the first, substitute $u^x = c$ into Equation (38.29):

$$\bar{u}^x = \frac{c - v}{1 - v/c} = \frac{c\,(1 - v/c)}{1 - v/c} = c\,.$$

For the second, put $u^x = c\beta_1$ and $v = c\beta_2$ with $|\beta_i| < 1$. Then

$$1 - \frac{\bar{u}^x}{c} = 1 - \frac{\beta_1 - \beta_2}{1 - \beta_1\beta_2} = \frac{(1 - \beta_1)\,(1 + \beta_2)}{1 - \beta_1\beta_2} > 0\,,$$

and symmetrically $1 + \bar{u}^x/c > 0$, so $|\bar{u}^x| < c$. □

Corollary 38.19 is the resolution of the puzzle that motivated the whole construction: no matter how fast a source or an observer moves, light still passes them at c, and no composition of subluminal velocities ever reaches c. In the Galilean limit $c \to \infty$ the denominators become 1 and Equation (38.29) returns $\bar{u}^x = u^x - v$.

Example 38.20 (Fizeau's experiment as a first-order effect)**.** Light travelling through water of refractive index n moving at speed v has, in the water's rest frame, the speed $u' = c/n$. In the laboratory, Equation (38.29) gives

$$u = \frac{c/n + v}{1 + v/(nc)} \simeq \frac{c}{n} + v\left(1 - \frac{1}{n^2}\right) + O\!\left(\frac{v^2}{c}\right),$$

expanding to first order in v/c. The coefficient $1 - 1/n^2$ is precisely Fresnel's drag coefficient, which Fizeau measured in 1851 (Section 37.4) and which had stood for half a century as an unexplained empirical rule. It is a first-order consequence of Equation (38.29), requiring no aether and no partial dragging of one.

Rests on Equation (38.29).

38.5.1 Rapidity

The composition law Equation (38.29) is not addition, which makes repeated boosts awkward. One change of variable repairs this.

Definition 38.21 (Rapidity)**.** The *rapidity* φ of a boost is defined by

$$\beta = \tanh\varphi\,, \qquad \text{whence} \qquad \gamma = \cosh\varphi\,, \qquad \gamma\beta = \sinh\varphi\,. \tag{38.31}$$

Rests on Equation (38.1).

The identity $\cosh^2\varphi - \sinh^2\varphi = 1$ is exactly $\gamma^2 - \gamma^2\beta^2 = 1$, so the parametrization is consistent, and φ runs over all of $\mathbb{R}$ as β runs over $(-1, 1)$. Substituting into Equation (38.10), the boost becomes

$$[\Lambda] = \begin{pmatrix} \cosh\varphi & -\sinh\varphi \\ -\sinh\varphi & \cosh\varphi \end{pmatrix} \tag{38.32}$$

in the (ct, x) block — a *hyperbolic rotation*. It is the exact analogue of the circular rotation

$$[R(\theta)] = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix},$$

with the trigonometric functions replaced by hyperbolic ones. This is the precise sense in which a boost is a rotation in Minkowski space, and it is why the orbits in Figure 38.3 are hyperbolae rather than circles.

Proposition 38.22 (Rapidities add)**.** *Two collinear boosts of rapidities φ_1 and φ_2 compose into a single boost of rapidity $\varphi_1 + \varphi_2$.*

Rests on Definition 38.21 and Equation (38.32).

Proof. *Derives Proposition 38.22.*

Multiplying two matrices of the form Equation (38.32) and using the hyperbolic addition formulas,

$$\begin{pmatrix} \cosh\varphi_1 & -\sinh\varphi_1 \\ -\sinh\varphi_1 & \cosh\varphi_1 \end{pmatrix} \begin{pmatrix} \cosh\varphi_2 & -\sinh\varphi_2 \\ -\sinh\varphi_2 & \cosh\varphi_2 \end{pmatrix} = \begin{pmatrix} \cosh(\varphi_1+\varphi_2) & -\sinh(\varphi_1+\varphi_2) \\ -\sinh(\varphi_1+\varphi_2) & \cosh(\varphi_1+\varphi_2) \end{pmatrix}.$$

Applying tanh to the sum reproduces Equation (38.29), since

$$\tanh(\varphi_1+\varphi_2) = \frac{\tanh\varphi_1 + \tanh\varphi_2}{1 + \tanh\varphi_1\tanh\varphi_2}.$$

□

Rapidity is therefore the natural parameter: it is additive, unbounded, and identifies the collinear boosts as a one-parameter group isomorphic to $(\mathbb{R}, +)$. That φ ranges over an unbounded set while β is confined to $(-1, 1)$ is the analytic face of the non-compactness proved in Section 39.2.1.

38.6 General Lorentz transformations

38.6.1 Boosts composed with rotations

In the most general case two coordinate systems have a constant relative velocity *and* axes that are not parallel. The coordinates with respect to K and $\bar{K}$ are then related by a transformation Λ containing not only the boosts $\bar{x}^\mu = \Lambda^\mu{}_\nu(\beta)x^\nu$ but also three-dimensional rotations.

For a spatial rotation the coordinate transformation is linear and homogeneous, $\bar{x}^i = R^i{}_j(\theta)x^j$ with $R(\theta) \in \mathrm{SO}(3)$. In the general case we must therefore consider

$$\bar{x}^\mu = \Lambda^\mu{}_\nu(\beta, \theta)x^\nu, \tag{38.33}$$

where $\Lambda(0, \theta)$ is a spatial rotation and $\Lambda(\beta, 0)$ is the boost Equation (38.24).

From Equation (38.33),

$$\bar{x}^0 = \Lambda^0{}_0(0,\theta)x^0 + \Lambda^0{}_i(0,\theta)x^i, \tag{38.34}$$

$$\bar{x}^i = \Lambda^i{}_0(0,\theta)x^0 + \Lambda^i{}_j(0,\theta)x^j, \tag{38.35}$$

and in a spatial rotation the time coordinate is left invariant, $\bar{x}^0 = x^0$. Hence $\Lambda^0{}_0(0,\theta) = 1$ and $\Lambda^0{}_i(0,\theta) = 0$; and for the spatial part to be a rotation, $\Lambda^i{}_0(0,\theta) = 0$ and $\Lambda^i{}_j(0,\theta) = R^i{}_j(\theta)$. In summary the general case is characterized by

$$\begin{aligned} &\Lambda^0{}_0(\beta,0) = \gamma && \Lambda^0{}_0(0,\theta) = 1 \\ &\Lambda^0{}_i(\beta,0) = -\gamma\beta_i && \Lambda^0{}_i(0,\theta) = 0 \\ &\Lambda^i{}_0(\beta,0) = -\gamma\beta^i && \Lambda^i{}_0(0,\theta) = 0 \\ &\Lambda^i{}_j(\beta,0) = \delta^i{}_j + \tfrac{\gamma-1}{|\boldsymbol{\beta}|^2}\beta^i\beta_j && \Lambda^i{}_j(0,\theta) = R^i{}_j(\theta)\,. \end{aligned}$$

Theorem 38.23 (Polar decomposition of a Lorentz transformation)**.** *Every proper orthochronous Lorentz transformation (Definition 39.5) factors uniquely as*

$$\Lambda = \Lambda\,(\boldsymbol{\beta},0)\,R\,(\theta)\ , \tag{38.36}$$

a pure boost followed by a spatial rotation.

Rests on Definition 39.5, Equations (38.14), (38.20) and (38.22), and Proposition 39.6.

Proof. *Derives Theorem 38.23.*

Existence. The first column $\Lambda^\mu{}_0$ is the image of the time direction. Taking $\mu = \nu = 0$ in Equation (38.14) gives $(\Lambda^0{}_0)^2 - \sum_i (\Lambda^i{}_0)^2 = 1$, so that column is a unit timelike vector, and it is future-directed because $\Lambda^0{}_0 \geq 1$ for an orthochronous transformation.

Let $B := \Lambda(\boldsymbol{\beta},0)$ be the pure boost with

$$\gamma := \Lambda^0{}_0\,, \qquad \beta^i := -\frac{\Lambda^i{}_0}{\Lambda^0{}_0}\,, \tag{38.37}$$

which is admissible since $|\boldsymbol{\beta}| < 1$ follows from the unit condition, and which by Equations (38.20) and (38.22) has exactly the same first column as Λ.

Put $R := B^{-1}\Lambda$, a product of Lorentz transformations and hence Lorentz. Its first column is $R^\mu{}_0 = (B^{-1})^\mu{}_\nu B^\nu{}_0 = \delta^\mu{}_0$, so $R^0{}_0 = 1$ and $R^i{}_0 = 0$. Applying the row identity of Proposition 39.6, $(R^0{}_0)^2 = 1 + \sum_i (R^0{}_i)^2$, gives $\sum_i (R^0{}_i)^2 = 0$ and hence $R^0{}_i = 0$. So $R = \operatorname{diag}\left(1, \tilde{R}\right)$ with $\tilde{R}\tilde{R}^{\mathsf{T}} = \mathbb{1}$, that is $\tilde{R} \in \mathrm{O}(3)$; and since $\det B = 1$ — directly from Equation (38.10), $\gamma^2 - \gamma^2\beta^2 = 1$ — while $\det\Lambda = 1$, also $\det\tilde{R} = 1$ and $\tilde{R} \in \mathrm{SO}(3)$. Then $\Lambda = BR$ is the required factorization.

Uniqueness. Suppose $\Lambda = B'R'$ with B' a pure boost and R' a rotation. A rotation fixes the time direction, $R'^\nu{}_0 = \delta^\nu{}_0$, so $\Lambda^\mu{}_0 = B'^\mu{}_\nu R'^\nu{}_0 = B'^\mu{}_0$: the boost B' has the same first column as Λ, and a pure boost is determined by that column through Equation (38.37). Hence $B' = B$ and therefore $R' = B^{-1}\Lambda = R$. □

The counting is $6 = 3 + 3$: three parameters for the boost velocity and three for the rotation, matching the dimension of the Lorentz group computed in Section 39.2.7.

Remark 38.24 (Boosts alone do not form a group)*.* The decomposition Equation (38.36) is not a formality. The product of two boosts in *different* directions is not a boost: it is a boost composed with a nontrivial rotation, the *Thomas rotation*. Boosts are therefore not closed under composition and do not form a subgroup, whereas rotations do. The physical consequence — the Thomas precession of a spin carried around a closed path — is measured in atomic fine structure, where it supplies the factor of $\frac{1}{2}$ in the spin–orbit coupling (Chapter 81).

Rests on Theorem 38.23.

38.6.2 Directions normal to the relative velocity

Equation (38.4) states that lengths perpendicular to the boost are unchanged, but it does not follow that *directions* are unchanged: an angle mixes a transverse with a longitudinal component, and only one of them transforms.

Proposition 38.25 (Aberration of light)**.** *Let a light ray travel in K at an angle ϑ to the x-axis. In $\bar{K}$ its angle $\bar{\vartheta}$ satisfies*

$$\cos\bar{\vartheta} = \frac{\cos\vartheta - \beta}{1 - \beta\cos\vartheta}\,. \tag{38.38}$$

Rests on Equation (38.29) and Corollary 38.19.

Proof. *Derives Proposition 38.25.*

The ray has $u^x = c\cos\vartheta$ and $u^y = c\sin\vartheta$. Substituting into Equation (38.29) and dividing by c,

$$\cos\bar{\vartheta} = \frac{\bar{u}^x}{c} = \frac{c\cos\vartheta - v}{c\,(1 - \beta\cos\vartheta)} = \frac{\cos\vartheta - \beta}{1 - \beta\cos\vartheta}\,,$$

where the speed in $\bar{K}$ is again c by Corollary 38.19. □

Aberration is why the apparent positions of the fixed stars trace small ellipses over a year as the Earth's velocity swings through $\pm 29.8\,\mathrm{km/s}$: the effect was discovered by Bradley in 1728, long before its explanation, and its first-order part $\Delta\vartheta \simeq \beta\sin\vartheta$ is Galilean. The relativistic content of Equation (38.38) lies in the denominator, at second order. At $\beta \to 1$ the formula concentrates almost all directions into a narrow forward cone of half-angle $\sim 1/\gamma$ — the relativistic beaming that makes synchrotron radiation a forward searchlight (Chapter 65).

Chapter 39

Minkowski Space and Its Symmetries

The Lorentz transformations of Chapter 38 are the symmetries of Minkowski space, and this chapter assembles them into groups: the Lorentz group of linear transformations preserving the Minkowski metric, its distinguished subsets, and the Poincaré group obtained by adjoining space-time translations, together with the Lie algebras of both. Standard accounts are found in [1746, 2132]. The source also reserves a chapter for the conserved quantities associated with these symmetries; that heading is retained below as pending.

39.1 Conserved quantities

The reason to assemble the Lorentz transformations into a group is that symmetries and conservation laws are the same thing seen twice. Noether's theorem (Chapter 16) attaches to every one-parameter group of symmetries of an action a quantity conserved along the solutions, and the ten parameters of the Poincaré group of Section 39.3 deliver the ten conservation laws that organize all of mechanics:

1. the four **translations** of spacetime give conservation of the four-momentum p^μ of Definition 40.4 — energy from the time translation, the three momenta from the spatial ones;
2. the three **rotations** give conservation of angular momentum;
3. the three **boosts** give conservation of $\boldsymbol{K} = t\boldsymbol{p} - E\boldsymbol{x}/c^2$, which is the statement that the centre of energy moves uniformly.

The last is unfamiliar only because it is rarely named; it is the relativistic form of the elementary fact that the centre of mass of an isolated system does not accelerate. All ten are components of two tensors, p^μ and the antisymmetric $J^{\mu\nu}$, whose conservation is the content of Equations (39.18) to (39.20). Which quantities are conserved is therefore fixed by the symmetry group of spacetime, and that is the subject of this chapter.

39.2 The Lorentz group

39.2.1 Foundations

Definition 39.1 (Lorentz group)**.** The set of all Lorentz transformations (those that leave the Minkowski metric invariant) is given by

$$L = \left\{ \Lambda \in \mathrm{GL}(4,\mathbb{R}) \mid \Lambda\eta\Lambda^{\mathsf{T}} = \eta \right\} . \tag{39.1}$$

Rests on Definition 38.6.

Since η is a symmetric bilinear form of signature $(1,3)$, the set Equation (39.1) is by definition the orthogonal group of that form, $L = \mathrm{O}(3,1)$.

Proposition 39.2 (L is a Lie group)**.** *L is a group under matrix multiplication and an embedded submanifold of $\mathrm{GL}(4,\mathbb{R})$ of dimension six.*

Rests on Definition 39.1 and Equation (39.2).

Proof. *Derives Proposition 39.2.*

Group. If $\Lambda_1, \Lambda_2 \in L$ then $(\Lambda_1\Lambda_2)^{\mathsf{T}}\eta\Lambda_1\Lambda_2 = \Lambda_2^{\mathsf{T}}\left(\Lambda_1^{\mathsf{T}}\eta\Lambda_1\right)\Lambda_2 = \Lambda_2^{\mathsf{T}}\eta\Lambda_2 = \eta$, so L is closed; $\mathbb{1} \in L$; and taking determinants in Equation (39.2) gives $(\det\Lambda)^2 = 1$, so every $\Lambda \in L$ is invertible, and inverting the defining relation shows $\Lambda^{-1} \in L$.

Manifold. Consider $F : \mathrm{GL}(4,\mathbb{R}) \longrightarrow \mathrm{Sym}(4)$ defined by $F(\Lambda) = \Lambda^{\mathsf{T}}\eta\Lambda - \eta$, whose target is the ten-dimensional space of symmetric matrices. Then $L = F^{-1}(0)$, and the derivative of F at $\Lambda \in L$ sends X to $X^{\mathsf{T}}\eta\Lambda + \Lambda^{\mathsf{T}}\eta X$, which is surjective onto the symmetric matrices — given symmetric S, take $X = \frac{1}{2}\eta^{-1}\left(\Lambda^{\mathsf{T}}\right)^{-1}S$. Since 0 is a regular value, the preimage theorem makes L an embedded submanifold of dimension $16 - 10 = 6$, matching Proposition 39.9. Multiplication and inversion are rational in the entries, hence smooth, so L is a Lie group (Chapter 14). □

Non-compactness of the Lorentz group

The condition satisfied by the elements of the Lorentz group is

$$\Lambda\eta\Lambda^{\mathsf{T}} = \eta \iff \eta_{\lambda\rho}\Lambda^{\lambda}{}_{\mu}\Lambda^{\rho}{}_{\nu} = \eta_{\mu\nu}\,, \tag{39.2}$$

whence, taking the $\mu = \nu = 0$ component and using $\eta_{00} = 1$ and $\eta_{ij} = -\delta_{ij}$,

$$\begin{aligned}
\eta_{\lambda\rho}\Lambda^{\lambda}{}_{0}\Lambda^{\rho}{}_{0} &= \eta_{00}\,,\\
\eta_{00}\Lambda^{0}{}_{0}\Lambda^{0}{}_{0} + \eta_{ij}\Lambda^{i}{}_{0}\Lambda^{j}{}_{0} &= 1\,,\\
\left(\Lambda^{0}{}_{0}\right)^2 - \delta_{ij}\Lambda^{i}{}_{0}\Lambda^{j}{}_{0} &= 1\,,\\
\left(\Lambda^{0}{}_{0}\right)^2 &= 1 + \Lambda^{i}{}_{0}\Lambda^{i}{}_{0}\,,
\end{aligned}$$

from which we see that $\left(\Lambda^{0}{}_{0}\right)^2 \geq 1$ and therefore

$$\left|\Lambda^{0}{}_{0}(\beta,\theta)\right| \geq 1\,. \tag{39.3}$$

From Equation (39.2) (the $\mu = \nu = 0$ component of the defining relation).

The result obtained in Equation (39.3) tells us that, as a manifold, the Lorentz group is not compact.

Derivation. A compact subset of $\mathbb{R}^{16}$ is bounded. The boosts Equation (38.32) form a curve in L parametrized by the rapidity $\varphi \in \mathbb{R}$, along which $\Lambda^{0}{}_{0} = \cosh\varphi \to \infty$ as $\varphi \to \infty$. The entries of Λ are therefore unbounded on L, so L is not compact — and neither is $L^{\uparrow}_{+}$, which contains that whole curve.

The contrast with the rotation group is the point. $\mathrm{SO}(3)$ is compact: its entries are sines and cosines, bounded by 1. Replacing the angle by a rapidity replaces the bounded circular functions by unbounded hyperbolic ones, which is the same statement as the sign difference in the last bracket of Equation (39.15). The consequence matters in Chapter 94: a non-compact group has no finite-dimensional unitary representations except the trivial one, which is why the unitary representations describing particles are infinite dimensional, and why the finite-dimensional representations that classify fields — scalars, spinors, vectors — are not unitary. □

39.2.2 The proper Lorentz group

Definition 39.3 (Proper Lorentz group)**.** The *proper Lorentz group* is

$$L_+ = \{\Lambda \in L \mid \det[\Lambda] = 1\} \,. \tag{39.4}$$

Rests on Definition 39.1.

Evidently we have $L_+ = \mathrm{SO}(3,1)$.

39.2.3 The improper Lorentz group

Taking the determinant of Equation (39.2) gives $(\det\Lambda)^2 \det\eta = \det\eta$, so $\det\Lambda = \pm 1$ and the transformations with $\det\Lambda = -1$ form the complement of L_+ in L.

Definition 39.4 (Improper Lorentz transformations)**.** $L_- := \{\Lambda \in L \mid \det[\Lambda] = -1\}$.
Rests on Definition 39.1 and Equation (39.2).

L_- is not a subgroup — it does not contain the identity, and the product of two of its elements has determinant $+1$ — but it is a coset of L_+, and every element of it is a proper transformation composed with one fixed reflection. The canonical choice is *parity*, the spatial reflection

$$[P] = \mathrm{diag}\,(1,-1,-1,-1) \,, \qquad \det P = -1 \,, \qquad P \in L_-^{\uparrow} \,, \tag{39.5}$$

which reverses the three spatial axes and leaves time alone. That P satisfies Equation (39.2) is immediate, since $[P] = [\eta]$ and $\eta\eta\eta = \eta$.

Parity is a symmetry of gravitation, electromagnetism and the strong interaction, and is *not* a symmetry of the weak interaction: that discovery (Chapter 110) is the reason $L_+^{\uparrow}$ rather than L is the group of physical relevance in particle physics.

39.2.4 The orthochronous Lorentz group

By Equation (39.3) every Lorentz transformation has $|\Lambda^0{}_0| \geq 1$, so the sign of $\Lambda^0{}_0$ splits L in two.

Definition 39.5 (Orthochronous Lorentz group)**.**

$$L^{\uparrow} = \left\{\Lambda \in L \mid \Lambda^0{}_0 \geq 1\right\} \,, \qquad L_+^{\uparrow} = L^{\uparrow} \cap L_+ \,. \tag{39.6}$$

$L_+^{\uparrow}$ is the *proper orthochronous* (or *restricted*) Lorentz group.
Rests on Definition 39.1 and Equation (39.3).

Proposition 39.6 ($L^{\uparrow}$ and $L_+^{\uparrow}$ are subgroups)**.** *$L^{\uparrow}$ is closed under products and inverses, hence so is $L_+^{\uparrow}$. Moreover the two defining conditions, $\det\Lambda = 1$ and $\Lambda^0{}_0 \geq 1$, are open and closed on L, so $L_+^{\uparrow}$ contains every connected subset of L through the identity.*
Rests on Definition 39.5 and Equations (39.2) and (39.3).

Proof. *Derives Proposition 39.6.*
The $\mu = \nu = 0$ component of Equation (39.2) is the column identity $(\Lambda^0{}_0)^2 = 1 + \sum_i \Lambda^i{}_0 \Lambda^i{}_0$ (the computation leading to Equation (39.3)); applied to $\Lambda^{-1} = \eta\Lambda^{\mathsf{T}}\eta \in L$ it becomes the row identity $(\Lambda^0{}_0)^2 = 1 + \sum_i \Lambda^0{}_i \Lambda^0{}_i$. For $\Lambda, \Lambda' \in L^{\uparrow}$,

$$(\Lambda\Lambda')^0{}_0 = \Lambda^0{}_0\, \Lambda'^0{}_0 + \sum_i \Lambda^0{}_i\, \Lambda'^i{}_0 \,,$$

and the Cauchy–Schwarz inequality together with the two identities bounds the cross term strictly:

$$|\textstyle\sum_i \Lambda^0{}_i\, \Lambda'^i{}_0| \le \sqrt{(\Lambda^0{}_0)^2 - 1}\,\sqrt{(\Lambda'^0{}_0)^2 - 1} < \Lambda^0{}_0\, \Lambda'^0{}_0\,,$$

so $(\Lambda\Lambda')^0{}_0 > 0$, hence ≥ 1 by Equation (39.3). For the inverse, $(\Lambda^{-1})^0{}_0 = (\eta\Lambda^{\mathsf{T}}\eta)^0{}_0 = \Lambda^0{}_0 \ge 1$. Clopenness: det and $\Lambda \mapsto \Lambda^0{}_0$ are continuous, $\det = \pm 1$ on L and $|\Lambda^0{}_0| \ge 1$, so each condition singles out a union of connected components; a connected set containing the identity (which satisfies both) therefore stays in $L^{\uparrow}_{+}$. □

That $L^{\uparrow}_{+}$ is itself connected — and is therefore precisely the identity component of L — is proved in Chapter 94, as the continuous image of the connected covering group $\mathrm{SL}(2,\mathbb{C})$.

39.2.5 The antichronous Lorentz group

Definition 39.7 (Antichronous transformations)**.**

$$L^{\downarrow} := \left\{ \Lambda \in L \mid \Lambda^0{}_0 \le -1 \right\}, \tag{39.7}$$

the complement of $L^{\uparrow}$ in L by Equation (39.3).

Rests on Definition 39.5 and Equation (39.3).

An antichronous transformation reverses the direction of time: it maps the future light cone of Figure 38.1 onto the past one. Like L_- it is a coset rather than a subgroup, and its canonical representative is *time reversal*

$$[T] = \mathrm{diag}\,(-1,1,1,1)\,, \qquad \det T = -1\,, \qquad T \in L^{\downarrow}_{-}\,. \tag{39.8}$$

39.2.6 The four components

The two independent signs — $\det\Lambda = \pm 1$ from Definition 39.4 and $\operatorname{sgn}\Lambda^0{}_0 = \pm 1$ from Equation (39.3) — are continuous functions taking discrete values, so neither can change along a path inside L. They therefore partition the group into four pieces that no continuous motion connects.

Proposition 39.8 (Component structure)**.** *L has exactly four connected components,*

$$L^{\uparrow}_{+}\,, \qquad L^{\uparrow}_{-} = P\,L^{\uparrow}_{+}\,, \qquad L^{\downarrow}_{-} = T\,L^{\uparrow}_{+}\,, \qquad L^{\downarrow}_{+} = PT\,L^{\uparrow}_{+}\,, \tag{39.9}$$

and the quotient of L by the identity component is the discrete group

$$\frac{L}{L^{\uparrow}_{+}} \cong \{\mathbb{1}, P, T, PT\} \cong \mathbb{Z}_2 \times \mathbb{Z}_2\,, \tag{39.10}$$

the Klein four-group.

Rests on Definitions 39.4 and 39.5, Equations (39.5) and (39.8), and Proposition 94.10.

Proof. *Derives Proposition 39.8.*

That the four sets are disjoint and exhaust L is the case analysis on the two signs. That each is a coset of $L^{\uparrow}_{+}$ follows because P, T and $PT = -\mathbb{1}$ realize every combination of the two signs, and multiplying by a fixed element is a homeomorphism of L onto itself, so each coset is connected if $L^{\uparrow}_{+}$ is. Connectedness of $L^{\uparrow}_{+}$ is proved in Chapter 94 as the continuous image of $\mathrm{SL}(2,\mathbb{C})$, which is connected. Finally $P^2 = T^2 = \mathbb{1}$ and $PT = TP$, which is the multiplication table of $\mathbb{Z}_2 \times \mathbb{Z}_2$. □

Only $L_+^\uparrow$ can be reached from the identity by a continuous sequence of physical motions, which is why it alone is generated by the Lie algebra of Section 39.2.7. The other three components are reached only by adjoining a discrete operation, and whether Nature respects those operations is an experimental question with a surprising answer: P is violated by the weak interaction (Chapter 110), the combination CP is violated in neutral-meson decays (Chapter 111), and only CPT — with C the charge conjugation of Chapter 105 — is protected by a theorem.

39.2.7 The algebra of the proper Lorentz group

In the context of Minkowski space we must find the generators of the rotations $\Lambda(0,\theta)$ and of the boosts $\Lambda(\beta,0)$, and then the algebra they satisfy.

Proposition 39.9 (The generators)**.** *Write an infinitesimal Lorentz transformation as $\Lambda^\mu{}_\nu = \delta^\mu{}_\nu + \omega^\mu{}_\nu$ with $|\omega| \ll 1$. Then Equation (39.2) holds to first order if and only if $\omega_{\mu\nu} := \eta_{\mu\lambda}\omega^\lambda{}_\nu$ is antisymmetric,*

$$\omega_{\mu\nu} = -\omega_{\nu\mu}\,, \tag{39.11}$$

so the algebra has $\binom{4}{2} = 6$ parameters: three rotations and three boosts.
Rests on Definition 39.1 and Equation (39.2).

Proof. *Derives Proposition 39.9.*
Substituting into $\Lambda^{\mathsf T}\eta\Lambda = \eta$ and keeping first-order terms,

$$\eta_{\mu\nu} = \left(\delta^\lambda{}_\mu + \omega^\lambda{}_\mu\right)\eta_{\lambda\rho}\left(\delta^\rho{}_\nu + \omega^\rho{}_\nu\right) = \eta_{\mu\nu} + \omega_{\nu\mu} + \omega_{\mu\nu} + O\!\left(\omega^2\right)\,,$$

so $\omega_{\mu\nu}+\omega_{\nu\mu}=0$. An antisymmetric 4×4 matrix has six independent entries; the three with both indices spatial generate rotations, and the three with one index equal to 0 generate boosts, as Equation (38.32) shows for a single boost. □

The six parameters are collected into an antisymmetric $\omega^{\mu\nu}$ and the six generators into an antisymmetric $J_{\mu\nu} = -J_{\nu\mu}$, so that a finite transformation is

$$\Lambda = \exp\left(\tfrac{1}{2}\omega^{\mu\nu}J_{\mu\nu}\right)\,. \tag{39.12}$$

Realizing the generators as the differential operators that implement these transformations on functions of x,

$$J_{\mu\nu} = x_\mu\partial_\nu - x_\nu\partial_\mu\,, \tag{39.13}$$

one obtains by direct computation the algebra $\mathfrak{so}(3,1)$:

$$[J_{\mu\nu}, J_{\lambda\rho}] = \eta_{\nu\lambda}J_{\mu\rho} + \eta_{\mu\rho}J_{\nu\lambda} - \eta_{\mu\lambda}J_{\nu\rho} - \eta_{\nu\rho}J_{\mu\lambda}\,, \tag{39.14}$$

in agreement with the general $\mathfrak{so}(p,q)$ relations derived in Section 14.3.2 (Equation (14.90)).

Derivation. *Derives Equation (39.14).*
Insert Equation (39.13) into the commutator and expand, using $\partial_\nu x_\lambda = \eta_{\nu\lambda}$ and the fact that the second-derivative terms cancel in pairs:

$$\begin{aligned}[J_{\mu\nu}, J_{\lambda\rho}] &= [x_\mu\partial_\nu - x_\nu\partial_\mu, x_\lambda\partial_\rho - x_\rho\partial_\lambda] \\ &= x_\mu\,[\partial_\nu, x_\lambda]\,\partial_\rho - x_\mu\,[\partial_\nu, x_\rho]\,\partial_\lambda - x_\nu\,[\partial_\mu, x_\lambda]\,\partial_\rho + x_\nu\,[\partial_\mu, x_\rho]\,\partial_\lambda \\ &\quad + x_\lambda\,[x_\mu\partial_\nu - x_\nu\partial_\mu, \partial_\rho] - x_\rho\,[x_\mu\partial_\nu - x_\nu\partial_\mu, \partial_\lambda]\,.\end{aligned}$$

Each commutator of a derivative with a coordinate is a metric component, $[\partial_\nu, x_\lambda] = \eta_{\nu\lambda}$, and collecting the eight resulting terms in pairs gives

$$[J_{\mu\nu}, J_{\lambda\rho}] = \eta_{\nu\lambda}\,(x_\mu\partial_\rho - x_\rho\partial_\mu) + \eta_{\mu\rho}\,(x_\nu\partial_\lambda - x_\lambda\partial_\nu) - \eta_{\mu\lambda}\,(x_\nu\partial_\rho - x_\rho\partial_\nu) - \eta_{\nu\rho}\,(x_\mu\partial_\lambda - x_\lambda\partial_\mu)\,,$$

each bracket being again a generator Equation (39.13). This is Equation (39.14). The computation nowhere used the signature, only the symmetry of η, which is why the same relations hold for $\mathfrak{so}(p,q)$ generally. □

Splitting the six generators into rotations $J_i = \frac{1}{2}\epsilon_{ijk}J^{jk}$ and boosts $K_i = J^{0i}$ makes the structure familiar: the J_i close among themselves — rotations form a subgroup — while

$$[J_i, J_j] = \epsilon_{ijk}J_k\,, \qquad [J_i, K_j] = \epsilon_{ijk}K_k\,, \qquad [K_i, K_j] = -\epsilon_{ijk}J_k\,. \tag{39.15}$$

From Equation (39.14) (the rotation–boost split just made).

The last bracket is the algebraic statement of Remark 38.24: two boosts do not commute, and their commutator is a rotation — the Thomas rotation. The minus sign distinguishes $\mathfrak{so}(3,1)$ from $\mathfrak{so}(4)$ and is the source of the non-compactness of Equation (39.3).

39.3 The Poincaré group

39.3.1 Foundations

The Lorentz group holds one event fixed: every Λ maps the origin to itself. But no event in Minkowski space is distinguished, so the full symmetry group must include the translations that move the origin.

Definition 39.10 (Poincaré group)**.** The *Poincaré group*, or inhomogeneous Lorentz group $\mathrm{ISO}(3,1)$, is the set of transformations

$$x^\mu \longmapsto \bar{x}^\mu = \Lambda^\mu{}_\nu x^\nu + a^\mu\,, \qquad \Lambda \in L\,, \quad a^\mu \in \mathbb{R}^4\,, \tag{39.16}$$

with the composition law

$$(\Lambda_2, a_2)\,(\Lambda_1, a_1) = (\Lambda_2\Lambda_1,\ \Lambda_2 a_1 + a_2)\ . \tag{39.17}$$

Rests on Definition 39.1.

Equation (39.17) is read off by applying the two transformations in succession, and it shows that the group is not a direct product: the translation part of the composite depends on the Lorentz part of the second factor. It is a *semidirect* product $\mathbb{R}^4 \rtimes L$, with the translations forming a normal subgroup and the Lorentz group acting on them.

Proposition 39.11 (Invariance of the interval)**.** *The Poincaré transformations are exactly the maps of Minkowski space preserving the interval Equation (38.13) between every pair of events.*

Rests on Definition 39.10 and Equations (38.13) and (39.2).

Proof. *Derives Proposition 39.11.*

The separation of two events transforms as $\Delta\bar{x}^\mu = \Lambda^\mu{}_\nu \Delta x^\nu$ — the constant a^μ cancels in the difference — so Equation (39.2) gives invariance of $\eta_{\mu\nu}\Delta x^\mu \Delta x^\nu$. Conversely, a map preserving all intervals preserves in particular those from a fixed event, and the polarization identity then forces it to be affine with linear part satisfying Equation (39.2). □

The group has ten parameters: six of Λ from Proposition 39.9 and four of a^μ. These are the ten symmetries whose conserved charges were listed in Section 39.1, and the classification of the irreducible unitary representations of this group is the classification of the possible kinds of elementary particle — Wigner's theorem, carried out in Chapter 94.

39.3.2 The algebra of the Poincaré group

The commutation relations of the Poincaré algebra are

$$[J_{\mu\nu}, J_{\lambda\rho}] = \eta_{\nu\lambda} J_{\mu\rho} + \eta_{\mu\rho} J_{\nu\lambda} - \eta_{\mu\lambda} J_{\nu\rho} - \eta_{\nu\rho} J_{\mu\lambda} \,, \tag{39.18}$$

$$[J_{\mu\nu}, P_{\lambda}] = \eta_{\nu\lambda} P_{\mu} - \eta_{\mu\lambda} P_{\nu} \,, \tag{39.19}$$

$$[P_{\mu}, P_{\nu}] = 0 \,. \tag{39.20}$$

Derivation. *Derives Equation* (39.19).

The Lorentz generators are Equation (39.13) and the translation generators are

$$P_{\mu} = \partial_{\mu} \,, \tag{39.21}$$

since $\exp(a^{\mu}\partial_{\mu})$ shifts the argument of a function by a^{μ}. Equation (39.18) was derived in Section 39.2.7. For Equation (39.19),

$$\begin{aligned} [J_{\mu\nu}, P_{\lambda}] &= [x_{\mu}\partial_{\nu} - x_{\nu}\partial_{\mu}, \partial_{\lambda}] \\ &= -(\partial_{\lambda} x_{\mu})\,\partial_{\nu} + (\partial_{\lambda} x_{\nu})\,\partial_{\mu} = -\eta_{\lambda\mu}\partial_{\nu} + \eta_{\lambda\nu}\partial_{\mu} = \eta_{\nu\lambda} P_{\mu} - \eta_{\mu\lambda} P_{\nu} \,, \end{aligned}$$

the derivative acting only on the explicit coordinate because the second-derivative terms cancel. Equation (39.20) is the commutativity of partial derivatives, $[\partial_{\mu}, \partial_{\nu}] = 0$: translations in different directions commute, so the translation subgroup is abelian.

The three relations say exactly what Definition 39.10 already said in words: Equation (39.20) that the translations are abelian, Equation (39.19) that they form a normal subgroup transforming as a four-vector under Lorentz transformations, and Equation (39.18) that the Lorentz generators close among themselves. The semidirect structure is visible in the fact that Equation (39.19) does not vanish, while it would for a direct product. □

Remark 39.12 (The Casimir invariants). Two combinations commute with every generator of the algebra:

$$P^2 = \eta^{\mu\nu} P_{\mu} P_{\nu} \,, \qquad W^2 = \eta^{\mu\nu} W_{\mu} W_{\nu} \,, \qquad W^{\mu} := -\tfrac{1}{2} \epsilon^{\mu\nu\lambda\rho} J_{\nu\lambda} P_{\rho} \,, \tag{39.22}$$

the second built from the Pauli–Lubański vector. On an irreducible representation each takes a fixed value, $P^2 = m^2 c^2$ and $W^2 = -m^2 c^2 s\,(s+1)\,\hbar^2$ for $m > 0$. Those two numbers are the mass and the spin: a particle *is* an irreducible representation of the Poincaré group, labelled by the two invariants of its algebra. This is the point at which the kinematics of this part becomes the particle classification of Chapter 94.

Rests on Equations (39.18) *to* (39.20).

Chapter 40

Relativistic Dynamics

Chapter 38 settled how coordinates transform. Dynamics must now be rebuilt on that kinematics, because Newton's second law in the form $\boldsymbol{F} = m\ddot{\boldsymbol{x}}$ is not Lorentz covariant: it singles out a frame's time as the parameter of the motion. The repair is to express everything in objects that transform under Λ in a definite way — four-vectors — and to differentiate with respect to the invariant proper time of Definition 38.12 rather than a coordinate time.

40.1 Four-vectors

Definition 40.1 (Four-vector)**.** A *four-vector* is a quadruple A^μ transforming under a change of inertial frame as the coordinates do,

$$\bar{A}^\mu = \Lambda^\mu{}_\nu A^\nu \,. \tag{40.1}$$

Its *square* $A^2 := \eta_{\mu\nu}A^\mu A^\nu$ is then invariant, by Equation (38.14), and so is the scalar product $A \cdot B = \eta_{\mu\nu}A^\mu B^\nu$ of any two four-vectors.
Rests on Definition 38.6 and Equation (38.14).

Invariants are the currency of the subject: a quantity built as the square of a four-vector has the same value in every frame, so it may be computed in whichever frame makes it easiest and quoted in any other.

Definition 40.2 (Four-velocity)**.** For a particle with worldline $x^\mu(\tau)$ parametrized by its proper time, the *four-velocity* is

$$u^\mu := \frac{\mathrm{d}x^\mu}{\mathrm{d}\tau} = \gamma_u \left(c, \boldsymbol{u}\right) , \tag{40.2}$$

where $\boldsymbol{u} = \mathrm{d}\boldsymbol{x}/\mathrm{d}t$ is the ordinary velocity and $\gamma_u = \left(1 - |\boldsymbol{u}|^2/c^2\right)^{-1/2}$.
Rests on Definitions 38.12 and 40.1.

The factor γ_u appears because $\mathrm{d}t = \gamma_u \mathrm{d}\tau$ by Equation (38.26). Since τ is invariant and x^μ is a four-vector, u^μ is one too — which $\mathrm{d}\boldsymbol{x}/\mathrm{d}t$ is not, and that is precisely why the ordinary velocity is the wrong object.

Proposition 40.3 (Normalization of the four-velocity)**.** *$u^2 = c^2$ for every massive particle, in every frame.*
Rests on Equation (40.2) *and Definition 38.6.*

Proof. *Derives Proposition 40.3.*
Directly from Equation (40.2) and $\eta = \mathrm{diag}(1,-1,-1,-1)$,

$$u^2 = \gamma_u^2\left(c^2 - |\boldsymbol{u}|^2\right) = \frac{c^2 - |\boldsymbol{u}|^2}{1 - |\boldsymbol{u}|^2/c^2} = c^2 \,.$$

Alternatively, divide $\mathrm{d}s^2 = c^2\mathrm{d}\tau^2$ by $\mathrm{d}\tau^2$. □

A four-velocity is therefore never zero and always timelike: a particle cannot stand still in spacetime, only redistribute its motion between the time and space directions. At rest it moves through time at rate c; as it speeds up, part of that is traded for spatial motion, and the trade is constrained by Proposition 40.3.

40.2 Four-momentum and mass–energy

Definition 40.4 (Four-momentum)**.** For a particle of *rest mass* m — an invariant, the same in every frame — the *four-momentum* is

$$p^\mu := mu^\mu = (\gamma_u mc,\ \gamma_u m\boldsymbol{u}) =: \left(\frac{E}{c},\ \boldsymbol{p}\right), \tag{40.3}$$

which defines the relativistic energy E and three-momentum $\boldsymbol{p}$:

$$E = \gamma_u mc^2\,, \qquad \boldsymbol{p} = \gamma_u m\boldsymbol{u}\,. \tag{40.4}$$

Rests on Definition 40.2.

Theorem 40.5 (Energy–momentum relation)**.**

$$E^2 = |\boldsymbol{p}|^2 c^2 + m^2c^4\,, \tag{40.5}$$

and equivalently $p^2 = m^2c^2$.

Rests on Definition 40.4 and Proposition 40.3.

Proof. *Derives Theorem 40.5.*

By Definition 40.4 and Proposition 40.3, $p^2 = m^2u^2 = m^2c^2$. Writing the same square in components, $p^2 = E^2/c^2 - |\boldsymbol{p}|^2$, and equating the two gives Equation (40.5). □

Phenomenon 40.6 (Mass–energy equivalence)**.** A body at rest possesses an energy

$$E_0 = mc^2\,, \tag{40.6}$$

and any change in its internal energy changes its rest mass by $\Delta m = \Delta E/c^2$.

Rests on Equation (40.4).

Derivation. *Derives Phenomenon 40.6.*

Set $\boldsymbol{u} = 0$ in Equation (40.4): $\gamma_u = 1$ and $E = mc^2$, which is Equation (40.6). That this is a real energy and not an additive constant follows from expanding Equation (40.4) for $|\boldsymbol{u}| \ll c$,

$$E = mc^2\left(1 - \frac{u^2}{c^2}\right)^{-1/2} = mc^2 + \frac{1}{2}mu^2 + \frac{3}{8}\frac{mu^4}{c^2} + O\left(\frac{u^6}{c^4}\right), \tag{40.7}$$

whose second term is the Newtonian kinetic energy. The relativistic kinetic energy is therefore $T = E - mc^2 = (\gamma_u - 1)\,mc^2$, and E_0 is what remains when all motion is removed.

For the second statement, consider a body at rest emitting two equal light pulses in opposite directions with total energy L, so that it stays at rest. Evaluating the energy balance in a frame moving at $-v$ and expanding to second order in β, the kinetic energies before and after differ by $(L/c^2)\,v^2/2$, which is the kinetic energy of a body whose mass has fallen by L/c^2. This is Einstein's argument [320]; he states the conclusion as a mass change L/V^2 and quotes it numerically as $L/(9\times10^{20})$ with the energy in erg and the mass in gram — that is, $c^2 = 9\times10^{16}\,\mathrm{J/kg}$ to one significant figure. □

Remark 40.7 (There is no "relativistic mass" in this treatise). Some older treatments absorb γ_u into the mass, writing $m_{\text{rel}} = \gamma_u m$ so that $\boldsymbol{p} = m_{\text{rel}}\boldsymbol{u}$ looks Newtonian. The device is consistent but costs more than it saves: the same m_{rel} does not make $\boldsymbol{F} = m_{\text{rel}}\boldsymbol{a}$ true (Section 40.3), and it obscures that m is a Lorentz invariant while $\gamma_u m$ is one component of a four-vector. Throughout this book *mass* means rest mass, and it never depends on speed.
Rests on Equation (40.9).

Example 40.8 (Nuclear binding as a mass deficit)**.** Phenomenon 40.6 is not an exotic effect: it is how nuclear masses are read. The mass of a bound nucleus is less than the sum of its constituents' masses by B/c^2, with B the binding energy; for ^{4}He the deficit is about $28.3\,\text{MeV}/c^2$, close to 0.8 % of the total. The systematics of that deficit across the nuclide chart is what makes both fission and fusion energetically possible (Chapter 107).
Rests on Phenomenon 40.6.

40.3 The relativistic force law

Definition 40.9 (Four-force)**.**

$$f^\mu := \frac{\mathrm{d}p^\mu}{\mathrm{d}\tau}\,, \tag{40.8}$$

whose spatial part is related to the ordinary force $\boldsymbol{F} = \mathrm{d}\boldsymbol{p}/\mathrm{d}t$ by $f^i = \gamma_u F^i$, and whose time component is $f^0 = \gamma_u\,(\boldsymbol{F}\cdot\boldsymbol{u})\,/c$, the rate at which the force does work.
Rests on Definitions 38.12 and 40.4.

Newton's second law is recovered in the covariant form $f^\mu = m\,\mathrm{d}u^\mu/\mathrm{d}\tau$, which reduces to $\boldsymbol{F} = m\boldsymbol{a}$ when $|\boldsymbol{u}| \ll c$. It does *not* reduce to $\boldsymbol{F} = \gamma_u m\boldsymbol{a}$ in general, because γ_u depends on time through $\boldsymbol{u}$:

$$\boldsymbol{F} = \frac{\mathrm{d}}{\mathrm{d}t}\,(\gamma_u m\boldsymbol{u}) = \gamma_u m\boldsymbol{a} + \gamma_u^3\frac{m}{c^2}\,(\boldsymbol{u}\cdot\boldsymbol{a})\,\boldsymbol{u}\,. \tag{40.9}$$

From Equation (40.4) (differentiating $\boldsymbol{p} = \gamma_u m\boldsymbol{u}$ with respect to coordinate time, with γ_u carried along).
Force and acceleration are therefore not parallel unless $\boldsymbol{a}$ is parallel or perpendicular to $\boldsymbol{u}$, in which cases Equation (40.9) collapses to $F_\parallel = \gamma_u^3 m a_\parallel$ and $F_\perp = \gamma_u m a_\perp$ respectively. The two different coefficients were once called the longitudinal and transverse masses; they are a symptom of forcing a Newtonian form onto a non-Newtonian law, and Remark 40.7 applies.

Corollary 40.10 (Nothing massive reaches c)**.** *A body of nonzero rest mass cannot be accelerated to the speed of light by any finite energy.*
Rests on Equation (40.4).

Proof. *Derives Corollary 40.10.*
By Equation (40.4), $E = \gamma_u mc^2 \to \infty$ as $|\boldsymbol{u}| \to c$, since $\gamma_u \to \infty$. The kinetic energy required is $(\gamma_u - 1)\,mc^2$, which diverges. □

This is measured directly, and simply: Bertozzi accelerated electrons through known potentials up to 15 MeV and timed their flight over a measured baseline, finding the speed saturating just below c while the kinetic energy continued to rise in proportion to the applied potential [1272]. Galilean kinematics predicts $v^2 \propto T$ without limit; the data follow $(\gamma - 1)\,mc^2 = T$ instead.

40.4 Massless particles

Setting $m = 0$ in Equation (40.5) gives

$$E = |\boldsymbol{p}|\,c\,, \tag{40.10}$$

a consistent possibility, describing a particle whose four-momentum is null, $p^2 = 0$. Such a particle has no rest frame — there is no boost carrying a null vector to a purely timelike one — and by Equation (40.4) it must travel at exactly c in every frame, since $\boldsymbol{u} = \boldsymbol{p}c^2/E$. The photon is the instance (Chapter 69); the four-momentum $p^\mu = \hbar k^\mu$ ties Equation (40.10) to the wave description, and the Doppler and aberration formulas of Section 38.5 are then statements about how k^μ transforms.

40.5 Collisions

Postulate 40.11 (Conservation of four-momentum)**.** In any isolated process the total four-momentum is conserved:

$$\sum_{\text{in}} p^\mu = \sum_{\text{out}} p^\mu \,. \tag{40.11}$$

Rests on Definition 40.4.

Because Equation (40.11) is an equation between four-vectors, it holds in every frame if it holds in one — which is exactly what a conservation law must do, and what separate conservation of energy and of momentum could not guarantee on its own. Its time component is conservation of energy and its spatial components conservation of momentum; the two are no longer independent statements but components of a single one.

Definition 40.12 (Invariant mass)**.** For a system of particles the *invariant mass* M is defined by

$$M^2c^2 := \left(\sum_a p_a^\mu\right)^2 = \frac{1}{c^2}\left(\sum_a E_a\right)^2 - \left(\sum_a \boldsymbol{p}_a\right)^2 . \tag{40.12}$$

Rests on Definitions 40.1 and 40.4.

The invariant mass of a system is not the sum of its constituents' masses: kinetic energy and binding energy contribute, which is Example 40.8 again. It is, however, invariant and conserved, and it equals the total energy divided by c^2 in the frame where the total momentum vanishes — the centre-of-momentum frame.

Example 40.13 (Threshold energy for pair production)**.** A proton of energy E strikes a proton at rest; what is the least E at which $p + p \to p + p + p + \bar{p}$ can proceed? At threshold the four final particles are produced at rest in the centre-of-momentum frame, so the final invariant mass is $4m_p$. Evaluating Equation (40.12) for the initial state in the laboratory, where $p_1 = (E/c, \boldsymbol{p})$ and $p_2 = (m_p c, \boldsymbol{0})$,

$$M^2c^2 = (p_1 + p_2)^2 = p_1^2 + p_2^2 + 2p_1 \cdot p_2 = 2m_p^2c^2 + 2Em_p \,,$$

using $p_i^2 = m_p^2c^2$. Setting $M = 4m_p$ and solving,

$$E = 7m_pc^2 \,, \qquad T = E - m_pc^2 = 6m_pc^2 \approx 5.6\,\text{GeV} \,. \tag{40.13}$$

From Equations (40.5) and (40.12) (setting $M = 4m_p$ at threshold and solving the laboratory invariant for E).

Six rest masses of kinetic energy are needed to create two, because momentum conservation forbids the products from being at rest in the laboratory. This is why colliders beat fixed targets: with two beams of equal and opposite momentum the centre-of-momentum frame *is* the laboratory, and the whole of the energy is available (Chapter 113).

Rests on Postulate 40.11 and Definition 40.12.

Example 40.14 (Compton scattering)**.** A photon of wavelength λ scatters off an electron at rest and emerges at angle ϑ with wavelength λ'. Conservation Equation (40.11) reads $k + p = k' + p'$; isolating the unobserved electron and squaring,

$$p'^2 = (k - k' + p)^2 = -2k \cdot k' + 2p \cdot (k - k') + p^2 ,$$

and since $p'^2 = p^2 = m_e^2 c^2$ and $k^2 = k'^2 = 0$, the terms rearrange to $k \cdot k' = p \cdot (k - k')$. Evaluating in the laboratory with $p = (m_e c, \mathbf{0})$ and $k^\mu = (\hbar\omega/c)\,(1, \hat{\boldsymbol{n}})$ gives the Compton relation

$$\lambda' - \lambda = \frac{h}{m_e c}\,(1 - \cos\vartheta) , \tag{40.14}$$

whose measurement is reported in Chapter 69. The whole derivation used only Postulate 40.11 and the invariance of the squares — no dynamics of the interaction at all.

Rests on Postulate 40.11, Theorem 40.5, and Equation (40.10)*.*

40.6 The twin paradox

Phenomenon 40.15 (Differential ageing)**.** Of two clocks that separate from a common event and reunite at another, the one that travelled inertially throughout records the greater proper time [1476, 1592].

Rests on Definitions 38.6 and 38.12.

Derivation. Derives Phenomenon 40.15.

Proper time along a worldline is $\tau = \int \mathrm{d}t/\gamma_u$ by Equation (38.26). For the inertial twin, who may be taken at rest, $\gamma_u = 1$ throughout and $\tau_{\text{stay}} = T$, the coordinate time between departure and reunion. For the travelling twin $\gamma_u > 1$ wherever $\boldsymbol{u} \neq 0$, so

$$\tau_{\text{trip}} = \int_0^T \frac{\mathrm{d}t}{\gamma_u} < T = \tau_{\text{stay}} ,$$

strictly, since the traveller must move to return. For a trip out and back at constant speed v, $\tau_{\text{trip}} = T/\gamma$. □

The result is often called a paradox on the grounds that Remark 38.14 makes time dilation reciprocal, so each twin should find the other younger. The objection fails because the situation is not symmetric: the stay-at-home twin occupies one inertial frame, while the traveller occupies two different ones joined by a turnaround. Only the traveller feels an acceleration, and only the traveller's surfaces of simultaneity swing round at the turn, skipping over a long stretch of the stay-at-home's worldline.

No appeal to general relativity is needed. The proper times are path lengths in Minkowski space, and Phenomenon 40.15 is the statement that the straight path between two timelike-separated events is the *longest* in proper time — the reversal, forced by the minus signs in η, of the Euclidean fact that a straight line is the shortest path. The effect has been measured directly on flown atomic clocks [1476, 1477] and, far more precisely, on circulating muons [1592]; both are reported in Chapter 41.

40.7 Covariant electrodynamics in one line

Relativistic dynamics was not invented to repair mechanics; it was extracted from electrodynamics, which had been Lorentz covariant all along without anyone noticing. The Lorentz force law $\boldsymbol{F} = q\,(\boldsymbol{E} + \boldsymbol{u} \times \boldsymbol{B})$ becomes, in the covariant notation of this chapter,

$$\frac{\mathrm{d}p^\mu}{\mathrm{d}\tau} = qF^\mu{}_\nu u^\nu , \tag{40.15}$$

with $F^{\mu\nu}$ the electromagnetic field tensor assembled from $\boldsymbol{E}$ and $\boldsymbol{B}$. That single equation contains both the electric and magnetic force, and the transformation properties of $F^{\mu\nu}$ explain why the split between them is frame-dependent: what one observer calls a magnetic force on a moving charge, another calls an electric force on a charge at rest. The construction belongs with Maxwell's equations and is carried out in Chapters 60 and 64.

Chapter 41

Experiment: Time Dilation and Relativistic Kinematics

Chapter 38 derived time dilation (Phenomenon 38.13) and Chapter 40 the energy–momentum relation. This chapter reports the measurements. They span five orders of magnitude in $\gamma - 1$, from canal-ray ions at $\beta \approx 4 \times 10^{-3}$ to storage-ring muons at $\gamma = 29.33$, and they agree with the same one-parameter formula throughout.

41.1 Ives and Stilwell: the moving atomic clock (1938)

Tests Phenomenon 38.13.

Assuming Definition 38.12.

The cleanest laboratory test uses light itself as the clock. A moving atom radiating at a known rest frequency is a clock whose ticking is read optically; the first-order Doppler shift is a classical effect, but the *second*-order part is pure time dilation and survives when the first-order part is cancelled.

41.1.1 Apparatus

A canal-ray tube producing fast hydrogen ions (H_2^+ and H_3^+) at accelerating potentials from about 6788 V to 18 350 V — the tube sparked above roughly 20 kV. A spectrograph viewed the beam at 7° to its axis, recording simultaneously the direct beam and its image in a mirror behind the tube, so that light emitted forward and backward reached the plate side by side. The line studied was the blue-green Hβ Balmer line at $\lambda_0 = 486.1\,\text{nm}$.

41.1.2 Procedure

Viewing the same emitters both ways gives two lines displaced by the first-order Doppler effect, one to the red and one to the blue. Their *mean* position is what matters: the first-order terms cancel in the average, leaving the second-order shift

$$\Delta\lambda = \frac{\lambda_b + \lambda_f}{2} - \lambda_0 = (\gamma - 1)\,\lambda_0 \simeq \frac{1}{2}\beta^2 \lambda_0\,, \tag{41.1}$$

From Equation (38.27) (written for a moving light source).

The experimental art is that the first-order displacement is some 2 mm on the plate while the second-order shift to be extracted is about 0.005 mm.

41.1.3 Observations and data

Ion speeds ran from $\beta = 2.184\,736 \times 10^{-3}$ to $\beta = 4.433\,244 \times 10^{-3}$, that is v from about $6.55 \times 10^5\,\text{m/s}$ to $1.33 \times 10^6\,\text{m/s}$; the beam velocities inferred from the first-order shifts

agreed with $eV = \tfrac{1}{2}Mv^2$ to within 1 %. The measured second-order shifts for the eight tabulated cases, against the values predicted by Equation (41.1), were

Table 41.1: Measured and predicted second-order Doppler shift in Section 41.1, in picometres (the paper tabulates ångström; 1 Å=100 pm). The ratio scatters between 0.911 and 1.035 about the relativistic value.

$\Delta\lambda$ measured	$\Delta\lambda$ predicted	ratio
1.10	1.16	0.948
1.85	2.03	0.911
2.25	2.38	0.945
2.70	2.75	0.982
2.05	1.98	1.035
3.45	3.52	0.980
2.15	2.33	0.923
4.70	4.78	0.983

41.1.4 Interpretation

The mean displacement is nonzero, of the predicted sign, and of the predicted size — a classical clock would show none at all, since the first-order effects cancel exactly. Ives and Stilwell quote no single headline ratio with an uncertainty, presenting instead graphs of $\Delta\lambda$ against $\tfrac{1}{2}\beta^2\lambda_0$ and concluding that the results are a satisfactory confirmation. A later assessment by Mandelberg and Witten puts the experimental uncertainty of this generation of measurements nearer 10–15 %, and their own repeat found the exponent n in $(1-\beta^2)^n$ to be 0.498 ± 0.025 where special relativity requires exactly $\tfrac{1}{2}$.

41.1.5 Primary references

[816]. The 10–15 % uncertainty estimate and the exponent 0.498 ± 0.025 are from Mandelberg and Witten, *J. Opt. Soc. Am.* **52**, 529 (1962), and are quoted here at second hand.

A muon is a clock with a single tick: it decays, and the distribution of decay times is exponential with a mean proper lifetime $\tau_0 \approx 2.2\,\mu\text{s}$. Muons are created by cosmic-ray primaries in the upper atmosphere and arrive at the ground in numbers that Galilean kinematics cannot account for.

41.2 Rossi and Hall: muon survival with altitude (1941)

Tests Phenomena 38.13 and 115.55.
Assuming Definition 38.12.

41.2.1 Apparatus

A telescope of self-quenching Geiger–Müller tubes of 4 cm internal diameter, in coincidence and anticoincidence, with a permanent absorber equivalent to $186\,\text{g/cm}^2$ of lead above and between the counters and 11.5 cm lead side walls. The assembly, except the variable absorber, sat in a thermostatic box and was carried by truck between stations.

41.2.2 Procedure

Coincidences with anticoincidence in the lower counters select particles that stop in the absorber; inserting $115\,\text{g/cm}^2$ of lead and differencing isolates muons in a chosen residual-range interval, and hence a chosen momentum band. Comparing rates at two altitudes measures the fraction surviving the flight between them. A $200\,\text{g/cm}^2$ iron compensator at

the higher station equalizes the total material traversed, so that the difference in counts reflects decay rather than absorption.

41.2.3 Observations and data

Stations: Echo Lake, Colorado, at 3240 m altitude and 709 g/cm^2 atmospheric depth, and Denver at 1616 m and 856 g/cm^2 — a difference of 1624 m, equivalent to 147 g/cm^2 of air, at practically the same geomagnetic latitude. Survival ratios between the two stations:

$$w_{12} = 0.698 \pm 0.031 \quad \text{(residual range 196–311 g/cm}^2\text{ of Pb)}\,, \tag{41.2}$$

$$W_{12} = 0.883 \pm 0.007 \quad \text{(residual range above 311 g/cm}^2\text{ of Pb)}\,. \tag{41.3}$$

The softer group, of effective momentum 5.0×10^8 eV/c, disintegrates about three times faster than the penetrating group, of effective momentum 1.5×10^9 eV/c. Converting the survival fractions to a mean range before decay, $L = (4.5 \pm 0.6) \times 10^5$ cm, and using a muon mass of 8×10^7 eV/c^2, the authors obtain the proper lifetime

$$\tau_0 = (2.4 \pm 0.3) \times 10^{-6}\,\text{s}\,. \tag{41.4}$$

From Equations (41.2) and (41.3) (the two survival fractions converted to a mean range before decay).

41.2.4 Interpretation

The two momentum groups traverse the same distance, so under Galilean kinematics they would decay in the same proportion; they do not. The faster group survives better, by the amount Equation (38.27) requires for its larger γ. The abstract states the conclusion plainly: the rates are "in agreement with the theoretical predictions based on the relativity change in rate of a moving clock".

41.2.5 Primary references

[863]. "Mesotron" in the original is the modern muon.

41.3 Frisch and Smith: Mount Washington to sea level (1963)

Tests Phenomena 38.13 and 115.55.
Assuming Definition 38.12.

41.3.1 Apparatus

A doped-polystyrene scintillator cylinder 28 cm high and 28 cm in diameter (about 30 g/cm^2), viewed by a 13 cm photomultiplier, with the pulse train displayed on a Tektronix 581 oscilloscope at 8.5 µs sweep and photographed. Iron absorber above the scintillator: 600 g/cm^2 on the mountain and 359 g/cm^2 at sea level (the paper reports the apparatus in inches and feet; SI equivalents are given here per the unit axiom of Chapter 2), the difference compensating the 218 g/cm^2 of air between the stations.

41.3.2 Procedure

The absorber and geometry select muons in a narrow speed band, between 0.9950c and 0.9954c. A muon that stops in the scintillator gives a first pulse; its decay electron gives a second. Counting stopped muons per hour at the two altitudes measures the survival fraction over the descent, and the distribution of intervals between the pulse pairs measures the lifetime in the same apparatus.

41.3.3 Observations and data

Six one-hour runs on the summit of Mount Washington at 1909 m gave 568, 554, 582, 527, 588 and 559 counts; five at Cambridge, Massachusetts, 3 m above sea level, gave 412, 403, 436, 395 and 393. The averages are

$$N_{\text{summit}} = 563 \pm 10 \text{ h}^{-1}, \qquad N_{\text{sea}} = 408 \pm 9 \text{ h}^{-1}. \tag{41.5}$$

The vertical descent is 1907 m, covered in 6.4 µs of earth-frame time at $0.9952c$. With backgrounds of 13 ± 2 and 11 ± 2 subtracted, the survival ratio is

$$\frac{397 \pm 9}{550 \pm 10} = 0.722 \pm 0.021, \tag{41.6}$$

and equating this to $\exp[-1907/(\gamma c \tau_0)]$ with $\tau_0 = (2.211 \pm 0.003) \times 10^{-6}$ s gives the observed dilation factor

$$\gamma_{\text{obs}} = 8.8 \pm 0.8, \tag{41.7}$$

against the predicted effective value 8.4 ± 2.0 for this geometry.

41.3.4 Interpretation

Without dilation the expected sea-level rate would be about 27 per hour rather than 408: the muons survive some fifteen times better than Galilean kinematics permits. The measured factor Equation (41.7) agrees with the prediction within the uncertainties, which the authors are careful to describe as statistical only, the quoted ± 2 on the prediction being "essentially only guessed at". The experiment is included here because it is the most direct possible reading of Phenomenon 38.13: two numbers of counts, one distance, one lifetime.

[1253].

41.4 The CERN muon storage ring (1977)

Tests Equations (38.26) *and* (38.27).

41.4.1 Apparatus

The CERN Muon Storage Ring, holding polarized positive and negative muons in a circular orbit at Lorentz factor $\gamma = 29.33$, with detectors counting the decay electrons as a function of time.

41.4.2 Procedure

Muons circulate and decay; the decay-electron rate falls exponentially with a time constant that is the *dilated* lifetime. Measuring it for μ^+ and μ^- separately tests the dilation factor and, by comparison with the at-rest lifetime, also tests CPT.

41.4.3 Observations and data

$$\tau_+ = (64.419 \pm 0.058)\,\mu\text{s}, \qquad \tau_- = (64.368 \pm 0.029)\,\mu\text{s}. \tag{41.8}$$

The dilation factor agrees with the special-relativistic prediction with a fractional error of 2×10^{-3} at 95 % confidence. Dividing, $\tau_-/\gamma = 2.1948\,\mu\text{s}$, consistent with the free-muon lifetime.

41.4.4 Interpretation

This is the most precise direct test of Equation (38.27), and it is performed at a γ thirteen times larger than Frisch and Smith's. Note also what it does *not* disturb: the muons are in circular orbit and therefore permanently accelerated, at some 10^{18} times the acceleration of gravity, and the dilation depends only on their speed. That is the experimental content of the *clock hypothesis* — proper time along a worldline depends on the instantaneous velocity and not on the acceleration — which Equation (38.26) assumes and which the twin-paradox analysis of Section 40.6 needs.

41.4.5 Primary references

[1592]. The derived rest lifetime $\tau_0 = (2.1948 \pm 0.0010)\,\mu s$ is quoted from the abstract record rather than from the article body, which was not consulted; the storage-ring beam momentum and radius are deliberately not quoted here for the same reason. The 1979 final report of the same collaboration states the special-relativistic time transformation valid to $(8 \pm 7) \times 10^{-4}$.

41.5 Hafele and Keating: caesium clocks flown around the world (1972)

Tests Phenomenon 38.13.
Assuming Phenomenon 42.5.

41.5.1 Apparatus

Four caesium-beam atomic clocks, flown as ordinary airline passengers eastward and then westward around the world, and compared before and after with the reference ensemble of the United States Naval Observatory.

41.5.2 Procedure

Both flights circumnavigate the globe; the eastward one moves with the Earth's rotation and the westward against it, so the two have different speeds relative to the non-rotating frame in which the analysis is done. The prediction [1477] was published before the observation [1476].

41.5.3 Observations and data

Predicted and observed time differences relative to the ground clocks, in nanoseconds, are reported for each direction, with the eastward clocks losing time and the westward clocks gaining it — opposite signs, which is the striking part.

41.5.4 Interpretation

This experiment is included with a caveat that matters for the architecture of this treatise: it is *not* a clean test of special relativity. The total effect is the sum of the kinematic dilation of this part, which always slows the flying clock, and the gravitational blueshift of Chapter 42, which speeds it up at altitude. The two are comparable in size at airline altitudes and have opposite signs, which is why the eastward and westward results differ in sign. The experiment therefore tests the *sum* of two predictions from two different theories; it is quoted here because it is the most familiar demonstration that dilation applies to ordinary macroscopic clocks, and its gravitational half is properly treated in Part V.

41.5.5 Primary references

[1477], the advance prediction; [1476], the observation.

41.6 Bertozzi: the speed limit (1964)

Tests Equations (40.4) *and* (40.5).

41.6.1 Apparatus

A Van de Graaff accelerator and a linear accelerator delivering electrons of kinetic energy from about 0.5 MeV to 15 MeV, with a time-of-flight baseline of several metres and a calorimeter to measure the beam energy independently of the applied potential.

41.6.2 Procedure

Electron bunches are timed over the baseline, giving the speed directly; the kinetic energy is known from the accelerating potential and confirmed calorimetrically. Plotting v^2 against T separates the two predictions.

41.6.3 Observations and data

As T rises through the megavolt range, v approaches c and saturates: the measured v^2 flattens while T continues to climb in proportion to the applied potential. The calorimetric energies confirm that the energy really is being delivered to the beam and not lost.

41.6.4 Interpretation

Newtonian mechanics predicts $T = \tfrac{1}{2}mv^2$, hence v^2 linear in T without bound and $v > c$ above 0.25 MeV. The data instead follow $T = (\gamma - 1)\,mc^2$ from Equation (40.7), with $v \to c$ asymptotically. This is Corollary 40.10 measured directly, and it is the most economical demonstration that the relativistic energy–momentum relation Equation (40.5) and not the Newtonian one governs fast particles.

41.6.5 Primary references

[1272].

41.7 Summary of the evidence

No result in Table 41.2 is compatible with Galilean kinematics, and all of them are described by the single factor γ with no adjustable parameter. Together with the isotropy tests of Chapter 37, they close the experimental case for the transformations of Chapter 38.

Table 41.2: Direct tests of relativistic kinematics reported in this chapter. The regime column gives the Lorentz factor or velocity parameter reached.

Experiment	Regime	Result
Ives–Stilwell 1938	$\beta \sim 4 \times 10^{-3}$	second-order Doppler shift present, of predicted size to a few percent
Rossi–Hall 1941	$p \sim 1\,\mathrm{GeV}/c$	momentum-dependent decay rate; $\tau_0 = (2.4 \pm 0.3)\,\mu\mathrm{s}$
Frisch–Smith 1963	$\gamma \approx 8$	$\gamma_{\mathrm{obs}} = 8.8 \pm 0.8$ against 8.4 ± 2.0 predicted
Bailey *et al.* 1977	$\gamma = 29.33$	dilation factor confirmed to 2×10^{-3} at 95 % confidence
Bertozzi 1964	$T \leq 15\,\mathrm{MeV}$	speed saturates at c; $T = (\gamma - 1)\,mc^2$
Hafele–Keating 1972	$\beta \sim 10^{-6}$	flown clocks disagree with ground clocks, kinematic plus gravitational

Part V

General Relativity and Cosmology

Chapter 42

The Equivalence Principle and Classical Tests

General relativity is admitted to this treatise on the same terms as every other theory in it: by its evidence, and evidence first. This chapter collects that evidence in its historical and logical order — the strict proportionality of inertial and gravitational mass, which is what makes gravity universal and first suggests that it is geometry rather than force; the anomalous perihelion advance of Mercury, measured half a century before the theory that explained it; the deflection of starlight and the gravitational redshift; the fourth test found by Shapiro in the radar age; and the engineering test performed daily by every satellite-navigation receiver. The geometric formulation these facts support is constructed in Chapter 43, and the field equations they constrain in Chapter 44.

The organizing principle is the equivalence principle in its three strengths — weak, Einstein, strong — each tested by a different class of experiments and each licensing a different part of the geometric description [2240]. The chapter states the principles precisely, reports the experiments with their numbers and uncertainties, and keeps prediction and postdiction carefully apart. The measurements themselves — apparatus, procedure, observations, error budgets — are set out in Chapter 53, which tests the phenomena stated here and the field equations of Chapter 44.

42.1 The universality of free fall

42.1.1 From Galileo to Newton

That all bodies fall alike is not obvious — everyday experience, where air resistance discriminates between a stone and a feather, argues against it — and it was established as an idealized law before it could be tested cleanly. Galileo's route, set out in the *Discorsi*, was to dilute free fall on an inclined plane until its acceleration could be timed, and to argue away the residual disagreement between bodies as the work of the medium; his logical argument is still the sharpest short statement of the law. Suppose the heavy body fell faster. Tying a light body to it should then retard it, as the light partner drags; but the two tied together are a heavier body still, and should fall faster than either. The supposition contradicts itself, and composition-dependent fall with it [4]. The kinematics of uniformly accelerated fall that this law makes universal is developed in Chapter 18, and its direct measurement — Galileo's plane among the rest — in Chapter 20.

Newton made the statement quantitative, and he could, because his own dynamics is the first in which it is a statement at all: the *inertial* mass in the second law and the *gravitational* mass coupling a body to attraction are logically independent quantities (Chapter 19), and nothing in the theory forces them to be proportional. His instrument was the pendulum

of Chapter 34, with the two masses now kept carefully distinct: a bob of inertial mass m_{I} and gravitational mass m_{G} on a cord of length ℓ obeys $\ell\,\ddot{\vartheta} = -\,(m_{\mathrm{G}}/m_{\mathrm{I}})\,g\sin\vartheta$, so that for small swings

$$T = 2\pi\sqrt{\frac{m_{\mathrm{I}}}{m_{\mathrm{G}}}\cdot\frac{\ell}{g}}\,. \tag{42.1}$$

Two pendulums of equal length therefore beat together if and only if the ratio $m_{\mathrm{G}}/m_{\mathrm{I}}$ is common to their bobs, a fractional difference in the ratio appearing as half of itself in the period. Newton hung identical wooden boxes filled in turn with gold, silver, lead, glass, sand, salt, water, wood and wheat, swung them in pairs beside one another, and observed no difference in their beats; he concluded that the ratio is common to all these materials to about one part in a thousand [14]. In the modern figure of merit — the Eötvös parameter η of Equation (42.2) below — Galileo's argument bounds nothing numerically, and Newton's pendulums give $|\eta| \lesssim 10^{-3}$.

42.1.2 The Eötvös torsion balance

The next six orders of magnitude came not from refining the pendulum but from abandoning it for a null instrument. A pendulum comparison must difference two separately measured periods, each carrying the full value of g with all its local disturbances; a torsion balance measures the *difference* directly, as a torque that vanishes identically when universality holds. The instrument descends from the Cavendish balance of Chapter 33: a horizontal beam hung from a fine wire, with test bodies of different composition at its ends.

The signal is geometrically subtle, and worth stating because it explains the design. On the rotating Earth a suspended body is acted on by the gravitational attraction, proportional to m_{G}, and by the centrifugal acceleration, proportional to m_{I}; the horizontal component of the latter, about $1.7\times10^{-2}\,\mathrm{m/s^2}$ at 45° of latitude, is what a composition dependence would fail to cancel. Two bodies with different ratios then pull the beam ends toward the equator with different horizontal forces, and the beam turns. The full geometry — the torque, its maximum near 45° of latitude, its reversal under a 180° turn of the beam in azimuth — is derived in Section 53.5, as Equation (53.8). The reversal is the crucial operation: Eötvös performed it by hand, differencing the two orientations so that instrumental torques cancel while a genuine composition dependence changes sign.

The campaign of Eötvös, Pekár and Fekete ran from 1906 to 1909 and was published, posthumously for Eötvös, only in 1922. It compared platinum against copper, water, asbestos and several other materials, and bounded $|\eta|$ at the level of a few parts in 10^9 [486] — six orders of magnitude past Newton, with an instrument whose essential parts are a beam, a wire and a mirror.

42.1.3 Modern limits

Every later improvement has been an improvement in modulation — in making the sought signal vary in a known way while the instrument stays still. The Princeton experiment of Roll, Krotkov and Dicke took the Sun as attractor: a violation would then produce a torque that rotates with the Earth, modulated at the diurnal period with no hand ever touching the balance, and the bound reached $|\eta| \lesssim 10^{-11}$ for aluminium against gold [1294]. The Moscow experiment of Braginsky and Panov refined the same scheme to 10^{-12} [1469]. The Eöt-Wash balance in Seattle rotates continuously on a turntable, so the signal appears at the turntable frequency, far above the drift of the fibre, and bounds $|\eta|$ for beryllium against titanium at 10^{-13} [2135].

The current limit belongs to orbit. The MICROSCOPE satellite compared the free fall of concentric titanium and platinum-alloy test masses around the Earth, drag-free and spin-modulated, where the driving acceleration is the full orbital g rather than a small

horizontal residue of it; the first results bounded $|\eta|$ at 10^{-14} [2289] and the final analysis at parts in 10^{15} [2409]. The instruments, procedures and the full table of bounds are reported in Section 53.5 (Table 53.3).

Phenomenon 42.1 (Universality of free fall)**.** Two bodies of different composition, released at the same place in the same external gravitational field, fall with accelerations that agree to within the precision of every experiment yet performed. Writing the fractional differential acceleration of a pair (A, B) as the Eötvös parameter

$$\eta_{AB} := \frac{2\,(a_A - a_B)}{a_A + a_B}\,, \tag{42.2}$$

every measurement is consistent with $\eta_{AB} = 0$: at the 10^{-9} level in the terrestrial torsion balance of Eötvös, Pekár and Fekete [486]; at 10^{-11} with the Sun as attractor [1294]; at 10^{-12} [1469] and 10^{-13} [2135] in later torsion balances; and at the level of parts in 10^{15} for titanium and platinum test masses compared in orbital free fall [2289, 2409].

Rests on Postulate 19.8.

Derivation. *Derives Phenomenon 42.1.*

Newtonian dynamics carries two logically independent masses: the inertial mass m_{I} multiplying the acceleration in the second law, and the gravitational mass m_{G} that couples the body to the field $\boldsymbol{g}$. The equation of motion $m_{\mathrm{I}}\boldsymbol{a} = m_{\mathrm{G}}\boldsymbol{g}$ gives

$$\boldsymbol{a} = \frac{m_{\mathrm{G}}}{m_{\mathrm{I}}}\,\boldsymbol{g}\,,$$

and both bodies sample the same $\boldsymbol{g}$, so on substituting into Equation (42.2) the field cancels and

$$\eta_{AB} = 2\,\frac{(m_{\mathrm{G}}/m_{\mathrm{I}})_A - (m_{\mathrm{G}}/m_{\mathrm{I}})_B}{(m_{\mathrm{G}}/m_{\mathrm{I}})_A + (m_{\mathrm{G}}/m_{\mathrm{I}})_B}\,.$$

Hence η_{AB} vanishes for every pair of bodies if and only if the ratio $m_{\mathrm{G}}/m_{\mathrm{I}}$ is one and the same number for all matter — in which case a choice of units sets it to unity and the two masses may be identified. Nothing in Newtonian mechanics requires this identification; it is precisely the experimental content of the null results above. Its consequence is that the trajectory of a freely falling body depends on nothing but its initial position and velocity, which is what permits gravitation to be described as a property of spacetime rather than as a force with a body-dependent coupling. □

42.2 The equivalence principle in three strengths

42.2.1 Weak, Einstein and strong forms

Einstein's 1907 review took the null result of the pendulum and torsion experiments and elevated it to a principle: for an observer in free fall the gravitational field is locally absent, so a laboratory falling freely in a uniform field is indistinguishable, by any experiment performed within it, from a laboratory floating in empty space — and, equally, a laboratory at rest in the field is indistinguishable from one uniformly accelerated in the absence of gravity [334]. The principle comes in three strengths, distinguished by *which* experiments are admitted to the comparison, and the distinction is not pedantry: each strength is tested by a different class of measurements and licenses a different part of the geometric description [2240].

Definition 42.2 (The equivalence principle in three strengths)**.** (i) *Weak equivalence principle* (universality of free fall): the trajectory of a freely falling test body — one small enough that tidal gradients and its own gravity are negligible — depends only on its initial

position and velocity, not on its composition or internal structure. (ii) *Einstein equivalence principle*: the weak principle holds, and in addition the outcome of any local *non-gravitational* experiment performed in a freely falling laboratory is independent of the laboratory's velocity (local Lorentz invariance) and of where and when in the universe it is performed (local position invariance). (iii) *Strong equivalence principle*: the Einstein principle extended to bodies with non-negligible gravitational self-energy and to local *gravitational* experiments — self-gravitating bodies fall like test bodies, and the locally measured gravitational coupling is the same everywhere and everywhen [2240].

Each strength buys a definite piece of the theory. The weak principle makes the family of free-fall trajectories a property of spacetime alone, which is what allows them to be declared the geodesics of a connection — the content of Postulate 43.1 in Chapter 43. The Einstein principle forces all non-gravitational physics to couple to one and the same metric, which is what makes the theory a *metric* theory and puts the special relativity of Chapter 38 in every freely falling laboratory. The strong principle is the most restrictive: among the metric theories surviving the first two, it is satisfied by general relativity and violated by nearly every proposed alternative, scalar–tensor theories included, which is why its test — lunar laser ranging, below — discriminates where the others cannot [2240].

Remark 42.3 (Schiff's conjecture). The three strengths may not be as independent as their statements suggest. Schiff observed that the gravitational redshift, nominally a test of the Einstein principle, already follows from the weak principle together with energy conservation, and conjectured that any complete, self-consistent theory of gravity satisfying the weak principle necessarily satisfies the Einstein principle in full [1190]. The conjecture remains unproved in generality, but every concrete framework in which it can be checked supports it; on this argument the composition tests of Phenomenon 42.1, at parts in 10^{15}, are also the sharpest available probes of the Einstein form, since a violation of local position invariance would feed back into composition-dependent binding energies and show as a nonzero η [2240].

In the language of this chapter, then: the torsion balances and MICROSCOPE test the weak form; the redshift and clock comparisons of Section 42.3 test the Einstein form directly, and specifically its position invariance; and lunar laser ranging tests the strong form, through the Nordtvedt effect stated next [1377]. The quantitative bookkeeping in which all these tests are compared — the parametrized post-Newtonian expansion and its parameters γ and β — is taken up in Section 42.8.

42.2.2 Lunar laser ranging

Laboratory masses have no usable self-gravity: the gravitational binding energy of a metre-scale test body is a fraction of order 10^{-27} of its rest energy, hopelessly below any balance. The strong form of the principle therefore needs astronomical test bodies, and the Earth–Moon pair falling toward the Sun is the cleanest available: the Earth stores about 4.6×10^{-10} of its rest energy as gravitational binding, the Moon about 1.9×10^{-11}, so the two differ in the relevant quantity by half a part in 10^{9} while being tracked with millimetre-level precision [2067, 2198].

The tracking is lunar laser ranging: timing pulses against the retroreflector arrays left on the Moon by the Apollo 11, 14 and 15 crews and the two Lunokhod rovers, a programme running continuously since 1969, with the APOLLO instrument now returning normal points at the millimetre level [2198]. The apparatus and procedure are reported in Section 53.6. Two relativistic quantities are extracted from the decades-long range series. The first is the Nordtvedt signal of Phenomenon 42.4 below, whose null result is the strong principle's test. The second is a bound on any secular variation of the gravitational constant: $\dot G/G$ comes out consistent with zero to within about 1×10^{-12}/yr [2067]. That number answers a

question older than the data: Dirac's large-numbers hypothesis, which read the coincidence of the great dimensionless ratios of physics as a law and required G to fall with cosmic age at about that rate [812], is excluded by it — a connection developed with the constants of nature in Chapter 2.

Phenomenon 42.4 (The lunar orbit is not polarized toward the Sun)**.** The Earth and the Moon store different fractions of their mass-energy as gravitational binding energy, so if the gravitational mass of a body depended on that fraction the two would fall toward the Sun at different rates and the lunar orbit would be displaced along the Earth–Sun line, with a signature periodic at the synodic month [1377]. Lunar laser ranging to the retroreflectors left on the surface, with residuals at the centimetre level, sees no such displacement: the Nordtvedt parameter is consistent with zero at the level of parts in 10^4 [2067]. Self-gravitating bodies therefore fall like test bodies, which is the observational content of the strong form of the equivalence principle [2240].

Rests on Phenomenon 42.1 and Theorem 29.51.

Derivation. *Derives Phenomenon 42.4.*

Let the gravitational-to-inertial mass ratio of a body depend on its fractional gravitational self-energy,

$$\frac{m_{\mathrm{G}}}{m_{\mathrm{I}}} = 1 + \eta_{\mathrm{N}} \frac{U}{mc^2}\,, \tag{42.3}$$

where $U < 0$ is the body's Newtonian self-energy and the *Nordtvedt parameter* η_{N} vanishes exactly when self-gravitating bodies obey Phenomenon 42.1 [1377]. For a uniform sphere $|U| = 3GM^2/(5R)$ (Equation (49.23)), which gives $|U|/(Mc^2) = 4.2 \times 10^{-10}$ for the Earth and 1.9×10^{-11} for the Moon, both computed here; interior models concentrate the Earth's mass and raise its value to 4.6×10^{-10} [2067]. The two ratios Equation (42.3) therefore differ by about $4.4 \times 10^{-10}\,\eta_{\mathrm{N}}$, and in the Sun's field at the Earth's orbit, $GM_\odot/r_{\mathrm{ES}}^2 = 5.93 \times 10^{-3}\,\mathrm{m/s^2}$, the Moon falls sunward relative to the Earth with the differential acceleration

$$\delta a = 4.4 \times 10^{-10} \times 5.93 \times 10^{-3}\,\mathrm{m/s^2} \times \eta_{\mathrm{N}} = \eta_{\mathrm{N}}\, 2.6 \times 10^{-12}\,\mathrm{m/s^2}\,,$$

directed along the Earth–Sun line (toward the Sun for $\eta_{\mathrm{N}} > 0$, since the Earth, with the larger binding fraction, then couples the more weakly).

What matters is how the lunar orbit responds. Work in the frame rotating about the Earth with the Moon's mean motion $n = 2.662 \times 10^{-6}/\mathrm{s}$, in which the unperturbed Moon rests on a circular orbit of radius r_0 with $n^2 = \mu/r_0^3$, μ the gravitational parameter of the pair. Linearizing the rotating-frame equation of motion Equation (29.66) about this orbit — gravity contributing $+2n^2\xi$ radially and $-n^2\zeta$ along track, the centrifugal term $+n^2\xi$ and $+n^2\zeta$, the Coriolis term coupling the two — gives, for a radial displacement ξ and an along-track displacement ζ,

$$\ddot{\xi} - 2n\dot{\zeta} - 3n^2\xi = \delta a \cos Dt\,, \qquad \ddot{\zeta} + 2n\dot{\xi} = -\delta a \sin Dt\,. \tag{42.4}$$

The forcing rotates at the synodic frequency $D = n - n_\odot = 2.463 \times 10^{-6}/\mathrm{s}$ (synodic month 29.53 days), because the frame rotates at n while the Earth–Sun direction advances at the annual rate $n_\odot = 1.991 \times 10^{-7}/\mathrm{s}$. The ordinary solar tidal terms are omitted: they are independent of η_{N} and already carried by the Newtonian lunar ephemeris.

Substituting the forced solution $\xi = X\cos Dt$, $\zeta = Z\sin Dt$ into Equation (42.4), the along-track equation gives $Z = (\delta a - 2nDX)/D^2$, and eliminating Z from the radial equation leaves $X(n^2 - D^2) = \delta a\,(1 + 2n/D)$, that is

$$X = \frac{\delta a\,(1 + 2n/D)}{(n - D)\,(n + D)}\,. \tag{42.5}$$

The denominator is the physics: $n - D = n_\odot$, so the forcing lies close to the orbit's own frequency — they differ only by the annual rate — and the response is amplified by more than an order of magnitude over the naive estimate $\delta a/n^2$. Numerically the response coefficient $(1 + 2n/D)\,/\,(n^2 - D^2)$ is $3.1 \times 10^{12}\,\mathrm{s}^2$, so

$$X \simeq \eta_{\mathrm{N}} \times 8.2\,\mathrm{m}\,,$$

computed here from the linear response alone. The full lunar theory does better: the classical solar perturbations of the orbit feed the displacement back at the same frequency and amplify it by roughly a further 1.6, to about 13 m per unit η_{N} — a figure quoted from the detailed computations rather than derived here [1377, 2067]. The signature is a range oscillation $X \cos Dt$, largest along the Earth–Sun line and periodic at the synodic month, which is what separates it from the Newtonian terms in the fit.

Ranging residuals at the level of millimetres to centimetres against a 13 m coefficient then bound the parameter at parts in 10^4: the joint fit of the ranging data gives $\eta_{\mathrm{N}} = (4.4 \pm 4.5) \times 10^{-4}$ [2067]. In the parametrized post-Newtonian bookkeeping of Section 42.8 the parameter is, for a metric theory with no preferred-frame or preferred-location effects, the combination

$$\eta_{\mathrm{N}} = 4\beta - \gamma - 3\,, \tag{42.6}$$

a result imported from the post-Newtonian analysis of massive bodies [1377, 2240]. General relativity has $\beta = \gamma = 1$ and predicts $\eta_{\mathrm{N}} = 0$ identically — the null result above — while any theory in which the effective coupling depends on the local gravitational potential predicts $\eta_{\mathrm{N}} \neq 0$ at some level. □

42.3 Gravitational redshift

42.3.1 The prediction

The redshift was the first new phenomenon Einstein extracted from the equivalence principle, in the 1907 review, and it is the one prediction of this chapter that needs no field equation whatever: it follows from the principle together with kinematics, as the derivation below shows, and Einstein reworked it in 1911 with the optics made explicit — a periodic signal climbing a potential difference $\Delta\Phi$ arrives with its frequency shifted by $-\Delta\Phi/c^2$ [334, 371]. Over a laboratory height H in a uniform field the fraction is gH/c^2; from the surface of the Sun to the Earth it is $GM_\odot/\,(c^2 R_\odot) = 2.12 \times 10^{-6}$, computed here from the solar mass parameter and radius.

Because no field equation enters, a redshift measurement tests the equivalence principle itself — in the classification of Definition 42.2, the local position invariance of the Einstein form — and not the dynamics of gravity. A theory that failed it would not need different field equations but a different foundation; conversely, *any* metric theory passes it, which is why the classical redshift experiments, for all their beauty, do not discriminate between general relativity and its metric rivals [1190, 2240].

The obvious place to look first was the Fraunhofer spectrum of the Sun, and the search there stayed inconclusive for half a century: the solar lines are shifted by pressure and by the Doppler effect of convective granulation by amounts comparable to the sought 2.12×10^{-6}, and the early claims scattered on both sides of the prediction [2240]. The clean confirmation came indoors, from an effect discovered in 1958 that turned a nucleus into a frequency standard of quality 10^{13}.

42.3.2 Pound–Rebka and Pound–Snider

Recoil-free gamma emission — the Mössbauer effect — pins the emitting nucleus to its crystal lattice, so that the recoil momentum is taken up by the crystal as a whole and the

emitted line keeps its natural width, a fractional width of about 3×10^{-13} for the 14.4 keV transition of ^{57}Fe [1154]. That is what made a shift of order 10^{-15} measurable at all. Pound and Rebka sent these gamma rays up and down the 22.5 m tower of the Jefferson Physical Laboratory at Harvard, detected the shift as an asymmetry in resonant absorption, and confirmed the prediction to about ten per cent in 1960 [1189]; the 1965 repetition with Snider reached one per cent [1321].

The decisive systematic is thermal: the second-order Doppler shift of nuclei vibrating in their lattices amounts to -2.4×10^{-15}/K of temperature difference between source and absorber — comparable to the entire gravitational effect per kelvin — and controlling it is the limiting art of the experiment. The apparatus, the reversal procedure that cancels almost everything else, and the derivation of that temperature coefficient (Equation (53.4)) are set out in Section 53.3.

Phenomenon 42.5 (Gravitational redshift)**.** A signal emitted by a source at rest low in a static gravitational field and received by an observer at rest higher up arrives with its frequency lowered. Over a height difference H small enough that the field strength g may be treated as uniform,

$$\frac{\Delta\nu}{\nu} = -\frac{gH}{c^2}\,. \tag{42.7}$$

For the 22.5 m tower of the Harvard experiment this is a fractional shift of 2.5×10^{-15}, resolvable only because the recoil-free emission and absorption of gamma rays by nuclei bound in a lattice [1154] supplies a line of comparable relative width. The measurement confirmed Equation (42.7) to about ten per cent [1189] and, in the 1965 repetition, to about one per cent [1321]. A hydrogen maser carried on a suborbital rocket verified it at the 7×10^{-5} level [1660], and optical clocks now resolve it across a height difference of less than one metre [2154].

Rests on Definition 42.2.

Derivation. *Derives Phenomenon 42.5.*

By the Einstein equivalence principle a laboratory held static in a uniform field g is locally indistinguishable from a laboratory in flat spacetime accelerating with proper acceleration g, and the second is the easier to analyse [334, 371]. Work in the momentarily comoving inertial frame in which the emitter is at rest at the instant of emission. Light leaves the floor and reaches the ceiling a height H above it after a time $t = H/c$, up to corrections of higher order in gH/c^2. During that time the receiver, which is accelerating, has acquired the velocity

$$v = gt = \frac{gH}{c}$$

directed away from the source. The receiver is therefore receding, and to first order in v/c the Doppler formula of Chapter 38 gives

$$\frac{\Delta\nu}{\nu} = -\frac{v}{c} = -\frac{gH}{c^2}\,,$$

which is Equation (42.7). Two features of the argument deserve notice. It uses only the equivalence principle, kinematics and the conservation of energy — no field equation enters — so a redshift measurement tests the equivalence principle rather than the dynamics of the gravitational field; and the sign is fixed by the geometry, an upward-travelling signal always being received redshifted. □

42.3.3 Clocks on rockets and in orbit

Everything since Pound and Snider has been a better clock at a bigger height difference. Gravity Probe A flew a hydrogen maser on a suborbital trajectory to 1×10^7 m altitude in

1976, comparing it continuously against a ground maser through a Doppler-cancelling radio link, and verified the combined gravitational and kinematic frequency shift to 7×10^{-5} [1660] — still the sharpest dedicated test of Equation (42.7) on a terrestrial potential difference. At the opposite extreme of scale, optical clocks of fractional instability below 10^{-17} resolve the shift across laboratory height differences: first 0.33 m between two aluminium-ion clocks [2154], and by 2022 across a single millimetre-scale sample of strontium atoms, mapping Equation (42.7) within one atomic cloud [2401].

Two further measurements belong to this family though they are reported elsewhere. The caesium clocks Hafele and Keating flew around the world in 1972 measured the redshift summed with the kinematic time dilation of Phenomenon 38.13, eastward and westward [1476, 1477]; the flights are treated in full in Section 41.5. And the same shift has now been seen in an astronomical spectrum under a potential four orders of magnitude deeper than the Sun's: the star S2, at its 2018 closest approach to the Galactic-centre black hole, showed the predicted combined redshift [2295], a measurement belonging to Chapter 50. The engineering counterpart of all of these — the satellite-navigation clock budget — closes this chapter in Section 42.7.

42.4 The perihelion of Mercury

42.4.1 Le Verrier's anomaly

The oldest evidence in this chapter predates the theory by fifty-six years, and it was found by accounting. Le Verrier, having predicted Neptune from the misbehaviour of Uranus, applied the same perturbation theory — the secular expansion of Chapter 27 — to Mercury, using the accumulated record of transits across the solar disc. The observed advance of Mercury's perihelion, referred to the moving equinox, is about 5600 seconds of arc per century; the precession of the equinoxes accounts for some 5025 of them, and the Newtonian perturbations of Venus, the Earth, Mars, Jupiter and Saturn for another 531. In 1859 Le Verrier announced that the books do not balance: a residual advance remained, near 38 seconds of arc per century in his reduction [151], moved to the modern 43 by Newcomb's re-reduction with improved planetary masses [267]. The full budget, with the numbers above, stands as Table 53.1 in Section 53.1.

Every Newtonian repair was tried and failed. An intramercurial planet — Vulcan, hunted for decades — would have been seen in transit; a sufficient solar oblateness contradicts the observed figure of the Sun; a modified force-law exponent tuned to Mercury disturbs the Moon [2240]. In the terms of Chapter 1 this is the textbook case of an anomaly held open: a small, stubborn, well-measured discrepancy, resistant to parametric patching, waiting half a century for a theory with no free parameter to claim it.

Phenomenon 42.6 (Anomalous perihelion advance of Mercury)**.** After every Newtonian perturbation by the other planets has been computed and subtracted, the perihelion of Mercury is observed to advance in the direction of the orbital motion at a residual rate of about 43 seconds of arc per century — a discrepancy isolated by Le Verrier in 1859 and left unexplained for half a century [151]. General relativity accounts for it with no adjustable parameter: a bound orbit of semi-major axis a and eccentricity e about a mass M has its perihelion advanced by

$$\Delta\varphi = \frac{6\pi GM}{c^2 a\,(1-e^2)} \tag{42.8}$$

per revolution, to lowest order in $GM/(c^2a)$ [428]. Inserting Mercury's orbital elements and the Sun's mass parameter, and multiplying by the 415 revolutions Mercury completes in a century, reproduces the observed residual.

Rests on Postulate 43.1 and Equation (53.2)*.*

Derivation. *Derives Phenomenon 42.6.*

This is carried out in Section 53.1, in the derivation following Phenomenon 53.1. In outline: the timelike geodesics of the Schwarzschild geometry (Chapter 45) give, for the inverse radius $u = 1/r$ in the orbital plane, the orbit equation Equation (53.2), which is the Newtonian equation of Chapter 27 plus the single correction term $3GMu^2/c^2$, smaller than the Newtonian terms by a factor of order $v^2/c^2 \sim 10^{-7}$ for Mercury. Treating it as a perturbation of the Keplerian ellipse, only its $\cos\varphi$ harmonic is resonant with the orbit and accumulates; the ellipse's apsis line turns by $\Delta\varphi = 6\pi G^2M^2/(c^2h^2)$ per revolution, and eliminating the angular momentum h through $h^2 = GMa\,(1-e^2)$ gives Equation (42.8). Numerically, Mercury's elements yield 5.02×10^{-7} radian per revolution, or 42.98 seconds of arc per century — the residual of Table 53.1. □

42.4.2 Einstein's 1915 computation

Einstein computed the advance in the 18 November 1915 communication to the Prussian Academy, from the vacuum field equations in the approximation that was all he had — the exact Schwarzschild solution was still two months away — and obtained the observed 43 seconds of arc per century with nothing to adjust [428]. The same paper carries the doubled light deflection of Section 42.5, so the one communication contains both the postdiction that validated the field equations and the prediction that would test them four years later.

It must be said plainly, as Section 53.1 says it, that this is a postdiction: the number was known, and Einstein knew what he had to match. It is equally important that this costs the result almost nothing. Equation (42.8) contains no parameter that could have been tuned — the field equations were fixed by general covariance and the Newtonian limit, and the orbit followed — whereas every rival explanation on offer was parametric, and each, tuned to Mercury, then contradicted some other observation. A parameter-free postdiction carries the evidential weight of a prediction; the epistemology is Chapter 1's. The same formula has since been confirmed as a genuine prediction far outside the solar system, in the Schwarzschild precession of the star S2 about the Galactic-centre mass [2347], reported with its instrument in Chapter 50.

42.5 The deflection of light

42.5.1 Half and full values

If the equivalence principle holds, light must fall: a horizontal beam crossing a laboratory that accelerates upward arrives lower on the far wall, so the same must happen in the laboratory held static in a gravitational field. The principle alone even fixes the rate, because whatever falls, falls universally. Treat the ray as a trajectory traversed at speed c in the Newtonian field of a mass M, passing at impact parameter b, and integrate the transverse acceleration $GMb/\left(b^2+x^2\right)^{3/2}$ along the undeflected straight line $x = ct$:

$$\Delta\vartheta_{\mathrm{EP}} = \frac{\Delta v_\perp}{c} = \frac{1}{c^2}\int_{-\infty}^{\infty} \frac{GM\,b\,\mathrm{d}x}{\left(b^2+x^2\right)^{3/2}} = \frac{2GM}{c^2 b}\,. \tag{42.9}$$

For a ray grazing the Sun, $b = R_\odot$, this is 4.24×10^{-6} in radian measure, or 0.87 seconds of arc, computed here. Einstein published exactly this value in 1911, from the equivalence principle dressed as optics — the potential-dependent clock rate of Equation (42.7) makes the coordinate speed of light vary with height, and Huygens' principle turns the gradient into a bending of the wavefront — which is the same physics as the falling corpuscle and gives the same number [371].

The completed theory of November 1915 doubled it, to $4GM/\left(c^2 b\right) = 1.75$ seconds of arc at the limb [428]. The second half has a precise pedigree: the equivalence principle

constrains only the time–time part of the metric, but in the full theory the mass curves space as well, and the two contributions to the bending of a null ray are equal. In the parametrized post-Newtonian bookkeeping the deflection is $(1+\gamma)/2$ times the full value, with γ the space-curvature parameter: $\gamma = 0$ reproduces Equation (42.9), and general relativity's $\gamma = 1$ doubles it [2240]. The factor of two is therefore exactly what separates a metric theory from Newtonian gravity dressed in geometry, and it is what the eclipse expeditions were designed to resolve.

42.5.2 The 1919 eclipse expeditions

The measurement asked for stars photographed close to the eclipsed Sun, compared with the same field photographed months away from it. The Greenwich expeditions of 29 May 1919 — Sobral, in northern Brazil, and Príncipe, in the Gulf of Guinea — were placed under an eclipse of unusual length with the Sun standing in the Hyades, and their announced result favoured the full deflection: 1.98 ± 0.12 seconds of arc at the limb from the Sobral 10 cm lens and 1.61 ± 0.30 from Príncipe, bracketing the predicted 1.75 and both far above 0.87 [465]. The apparatus, the plate reduction, and the celebrated difficulty — the Sobral astrographic plates, set aside for a coelostat mirror that had changed figure in the heat — are reported in Section 53.2 (Table 53.2), together with the modern re-measurement of those same plates, which returned values consistent with the full deflection and showed that the rejection had not biased the conclusion [1640].

The announcement of November 1919 made general relativity a public fact, and the treatise's assessment of its evidential weight is the experiment chapter's: the two accepted determinations were designed to separate hypotheses differing by a factor of two, and they did; the precision claimed was modest, and what settles the matter today is not photography at all.

Phenomenon 42.7 (Deflection of light by the Sun)**.** Starlight passing close to the Sun is deflected toward it, so that the apparent positions of stars seen near the eclipsed limb are displaced radially outward. For a ray of impact parameter b passing a mass M with $b \gg GM/c^2$, the total deflection is

$$\Delta\vartheta = \frac{4GM}{c^2 b}\,, \tag{42.10}$$

which for a ray grazing the solar limb amounts to 8.49×10^{-6} in radian measure, or 1.75 seconds of arc. This is exactly twice the value that the equivalence principle alone yields [371], the second half coming from the curvature of space [428]. The eclipse expeditions of 1919 measured a deflection favouring the full value [465]; radio interferometry on very long baselines now confirms it at the 10^{-4} level [2240]. The same bending, exerted by galaxies and clusters, produces the multiple images of gravitational lenses, of which the twin quasar 0957+561 was the first identified [1645].

Rests on Postulate 43.1 and Equation (53.2)*.*

Derivation. *Derives Phenomenon 42.7.*

The full computation is carried out in Section 53.2, in the derivation following Phenomenon 53.2. In outline: for a null geodesic of the Schwarzschild geometry the orbit equation Equation (53.2) loses its Newtonian constant term — that term came from the rest mass — leaving $\mathrm{d}^2u/\mathrm{d}\varphi^2 + u = 3GMu^2/c^2$; perturbing the straight line $u_0 = \sin\varphi/b$ and following the asymptotes where $u = 0$ shows the ray's two asymptotic directions closing by $4GM/\left(c^2 b\right)$, which is Equation (42.10), and numerically 1.751 seconds of arc at the solar limb.

The origin of the factor of two over Equation (42.9) is cleanest in the isotropic form of the weak-field metric used for the Shapiro derivation in Section 53.4: the potential enters

twice, once in the time–time coefficient and once in the spatial one, and the two retard the coordinate speed of light equally. The equivalence principle fixes only the first — it is the clock-rate effect of Equation (42.7) — and by itself reproduces the half value Equation (42.9); the spatial curvature, absent from any account of gravity as a mere universal acceleration, contributes the equal second half. The parametrized statement is that the deflection carries the factor $(1+\gamma)/2$, and the 1919 result is the measurement that first required $\gamma \neq 0$ [2240]. □

42.5.3 Radio interferometry and gravitational lensing

The modern measurement is radio astrometry. Very-long-baseline interferometry locates compact quasars to fractions of a milliarcsecond, and the Sun's deflection field is not a limb-grazing curiosity but a whole-sky distortion: even a source at right angles to the Sun is displaced by about four milliarcseconds, so global astrometry must carry Equation (42.10) everywhere it points [2240]. Dedicated campaigns following quasars as the Sun passes them measure the space-curvature parameter directly: $\gamma - 1$ consistent with zero at the level of a few parts in 10^4 [1903, 2145], four orders of magnitude past the eclipse plates.

The same bending, scaled up to galaxy and cluster masses, is gravitational lensing. The twin quasar 0957+561 — two images, identical spectra, one source — was identified in 1979 as the first gravitational lens [1645], and lensing has since become an astrophysical instrument in its own right: it weighs the dark matter of Chapter 134, and it magnifies and multiplies the strong-field sources of Chapter 50. In this chapter it stands as the demonstration that Equation (42.10) operates identically from $b \sim R_\odot$ to megaparsec impact parameters.

42.6 The Shapiro time delay

42.6.1 Radar ranging to the inner planets

The fourth classical test was proposed, not by Einstein, but by radar. Shapiro observed in 1964 that a pulse whose path passes close to the Sun takes measurably longer to return than the flat-space geometry predicts — an excess of some 200 µs for an Earth–Venus round trip at superior conjunction, growing logarithmically as the ray approaches the limb [1296]. The logarithmic conjunction profile is the effect's signature: it is not degenerate with an ephemeris error, which varies on the orbital timescale rather than with the impact parameter. The first measurement followed within four years, radar echoes from Mercury and Venus timed at Haystack and Arecibo agreeing with the prediction at the level of tens of per cent [1382]; the transmitters, the coded pulse trains and the conjunction-by-conjunction procedure are reported in Section 53.4.

42.6.2 Viking and Cassini

Replacing the passive planetary echo with a spacecraft transponder sharpened the test by orders of magnitude. Ranging to the Viking landers on Mars through several superior conjunctions confirmed the delay to about one part in 10^3 [1644]. The Cassini spacecraft, tracked on its cruise to Saturn in 2002, ran its radio link simultaneously at multiple widely separated frequencies, using the known dispersion of the solar-corona plasma to solve the corona away — the systematic that had limited every predecessor — and delivered $\gamma - 1 = (2.1 \pm 2.3) \times 10^{-5}$ [2046], the tightest solar-system constraint on any metric theory of gravity. The same delay, imposed by a companion star on the timing of a pulsar, is now a standard tool for weighing neutron stars [2155]; that use belongs to Chapter 49.

Phenomenon 42.8 (Shapiro time delay)**.** A radar pulse sent from Earth to an inner planet and reflected back takes measurably longer when its path passes close to the Sun than when the same geometric distance is traversed far from it. For a round trip between points at radii r_1 and r_2 from a mass M past a closest approach b, with $b \ll r_1, r_2$, the excess is

$$\Delta t = \frac{4GM}{c^3} \ln\!\left(\frac{4r_1 r_2}{b^2}\right) , \tag{42.11}$$

of order 200 µs for an Earth–Venus circuit at superior conjunction. Proposed as a fourth test in 1964 [1296] and first measured against Mercury and Venus [1382], the delay was confirmed to one part in 10^3 by ranging to the Viking landers [1644]. The Cassini radio link measured the post-Newtonian parameter γ, which enters Equation (42.11) through an overall factor $(1+\gamma)/2$, as $\gamma - 1 = (2.1 \pm 2.3) \times 10^{-5}$ [2046].

Rests on Postulate 43.1 and Proposition 45.14.

Derivation. *Derives Phenomenon 42.8.*

Carried out in Section 53.4, in the derivation following Phenomenon 53.4. In outline: write the weak-field Schwarzschild metric in isotropic coordinates, whose spatial part is conformally flat, so that the unperturbed ray is a coordinate straight line and the whole effect sits in the coordinate speed of light, $c\,\mathrm{d}t \simeq \mathrm{d}l\,(1 + 2GM/c^2 r)$ — one factor of $GM/c^2 r$ from time dilation and one from spatial curvature, the same equal split as in the deflection. Integrating the excess along the straight path with $r = \sqrt{b^2 + l^2}$ and doubling for the return trip gives Equation (42.11); for an Earth–Venus circuit grazing the limb the logarithm is 11.8 and $\Delta t = 2.3 \times 10^{-4}$ s. The characteristic weakness of the dependence on b — halving the impact parameter adds only 2.7×10^{-5} s — is why the measurement needs a well-sampled conjunction rather than a single well-placed shot. □

42.7 Relativity in the Global Positioning System

Satellite navigation is a clock experiment run as infrastructure. A receiver fixes its position by differencing the arrival times of signals from satellites whose clocks are synchronized to a common timescale; light covers 30 cm per nanosecond, so metre-level positioning demands nanosecond-level timekeeping, held continuously, by caesium and rubidium standards in orbit [2043]. At that precision both relativistic clock effects of this chapter are not corrections but the largest terms in the error budget: the orbiting clocks sit higher in the Earth's potential than the geoid — the redshift of Phenomenon 42.5 makes them run fast — and they move at orbital speed — the time dilation of Phenomenon 38.13 makes them run slow. The budget below is computed here, and the design of the system confirms it daily.

Phenomenon 42.9 (The relativistic clock budget of satellite navigation)**.** The atomic clocks carried by the satellites of the Global Positioning System, in nearly circular orbits of radius $r = 2.656 \times 10^7$ m, run fast with respect to clocks on the geoid by about 38.5 µs per day. The offset is not a small correction: it is designed into the hardware, the flight oscillators being deliberately set low in frequency before launch, with the residual terms modelled in every receiver. Left unaccounted for it would introduce a ranging error $c\,\Delta t$ growing by about 11 km per day, so that positions would become useless within minutes [2043].

Rests on Phenomena 38.13 and 42.5.

Derivation. *Derives Phenomenon 42.9.*

To first order in Φ/c^2 and v^2/c^2, a clock at Newtonian potential Φ moving with speed v in a static weak field accumulates proper time at the rate

$$\frac{\mathrm{d}\tau}{\mathrm{d}t} = 1 + \frac{\Phi}{c^2} - \frac{v^2}{2c^2} , \tag{42.12}$$

the second term being the gravitational redshift of Phenomenon 42.5 written with $\Phi = gH$, and the third the time dilation of Chapter 38. The two have opposite signs: height makes a clock run fast, motion makes it run slow.

For a circular orbit of radius r about a mass M the Newtonian relations $\Phi = -GM/r$ and $v^2 = GM/r$ hold simultaneously, so the two effects combine into one term,

$$\left.\frac{\mathrm{d}\tau}{\mathrm{d}t}\right|_{\text{orbit}} = 1 - \frac{GM}{rc^2} - \frac{GM}{2rc^2} = 1 - \frac{3GM}{2rc^2}\,,$$

while a clock at rest on the ground at radius R has $\mathrm{d}\tau/\mathrm{d}t = 1 - GM/(Rc^2)$, the Earth's rotation and its equatorial bulge being absorbed into the definition of the geoid. The fractional rate at which the orbiting clock gains is therefore

$$\delta = \frac{GM}{c^2}\left(\frac{1}{R} - \frac{3}{2r}\right). \tag{42.13}$$

With $GM = 3.986 \times 10^{14}\,\mathrm{m^3/s^2}$ for the Earth, $R = 6.371 \times 10^{6}\,\mathrm{m}$ and $r = 2.656 \times 10^{7}\,\mathrm{m}$, the bracket is $1.005 \times 10^{-7}\,\mathrm{m^{-1}}$ and $GM/c^2 = 4.435 \times 10^{-3}\,\mathrm{m}$, so $\delta = 4.46 \times 10^{-10}$. Over one day of 86 400 s the accumulated gain is $3.85 \times 10^{-5}\,\mathrm{s}$. Separating the two contributions, $GM/(Rc^2) - GM/(rc^2)$ gives 45.7 µs per day of gravitational blueshift and $GM/(2rc^2)$ gives 7.2 µs per day of velocity dilation, whose difference is the quoted 38.5 µs. Multiplying by c turns the daily offset into 11.5 km of range. □

The system absorbs the constant rate δ in the factory: the fundamental frequency of 10.23 MHz is set before launch to 10.229 999 995 43 MHz, a fractional offset of -4.4647×10^{-10} [2043], agreeing with the δ computed here to a fraction of a per cent — the residue reflecting the rounded orbital radius used above. Two smaller terms remain for the receiver. An orbit of eccentricity e trades height against speed around each revolution, producing a periodic residual of amplitude $2e\sqrt{GMa}/c^2$ [2043] — about 23 ns at $e = 0.01$, computed here — which every receiver applies from the broadcast elements. And a receiver fixed to the rotating Earth is not in an inertial frame: consistent synchronization requires the Sagnac correction of Section 67.6.4,

$$\Delta t_{\text{Sagnac}} = \frac{2\Omega_{\oplus}}{c^2} A_z\,, \tag{42.14}$$

with A_z the equatorial-plane projection of the area swept by the position vector of the signal, counted positive eastward [2043]. For a receiver on the equator watching a satellite near the horizon this reaches about 133 ns, computed here — 40 m of pseudorange, far above the system's accuracy goals.

What the system tests, in the classification of Definition 42.2, is the Einstein principle's position dependence of clock rates summed with special-relativistic time dilation, continuously and publicly; the field equations proper it does not touch, the next order in $GM/\left(rc^2\right)$ entering at 10^{-19} and accumulating femtoseconds per day, far below the flight clocks' stability. Nor is it a precision test — its residuals answer to engineering tolerances, orders of magnitude short of Gravity Probe A [1660] — but it is the test that never stops running: every position fix is a check that Equation (42.12), with both signs, is physics [2043].

42.8 Beyond the classical tests

The tests of this chapter are compared, across theories, in one common language: the parametrized post-Newtonian (PPN) expansion, which writes the metric of any metric theory, to first order beyond Newton, in terms of a small set of dimensionless parameters

and lets each experiment bound a combination of them [2240]. Two parameters carry nearly everything measured here: γ, the space curvature per unit mass, and β, the nonlinearity of superposition. General relativity has $\gamma = \beta = 1$. The deflection and the Shapiro delay each measure $(1+\gamma)/2$, and Cassini's $\gamma - 1 = (2.1 \pm 2.3) \times 10^{-5}$ is the sharpest entry [2046]; the perihelion advance measures $(2 + 2\gamma - \beta)/3$; and the Nordtvedt combination Equation (42.6) closes the system, lunar laser ranging bounding it at parts in 10^4 [2067]. Taken together the solar-system tests pin γ and β to unity at the level of parts in 10^4 or better [2240].

One sector of the weak field is not touched by any test above: the gravitational effect of *rotation*. A spinning mass drags inertial frames around with it, precessing an orbiting gyroscope about the spin axis [455, 458], on top of the larger geodetic precession that any orbiting gyroscope suffers from the curvature of the static field [1191]. Gravity Probe B measured both against a guide star — the geodetic rate to about 0.3 %, the frame-dragging rate to about twenty per cent [2173] — and lunar laser ranging sees the geodetic precession of the lunar orbit independently [2067]. The rates, the apparatus and the honest accounting of Gravity Probe B's error budget are given in Section 53.6.

Everything above is weak-field: the dimensionless potential $GM/(c^2 r)$ never exceeds a few parts in 10^6 in any solar-system test. The evidence beyond that regime opens with the binary pulsar PSR B1913+16, discovered in 1974 [1550]: a clock in an eight-hour relativistic orbit, whose periastron advances four degrees per year where Mercury manages 43 seconds of arc per century, and whose orbit shrinks by energy lost to gravitational radiation at the rate the quadrupole formula of Chapter 46 predicts — confirmed within a few per cent by 1982 [1703] and to a fraction of a per cent over four decades of timing [2275]. The radiation itself was detected directly in 2015, two black holes of thirty-odd solar masses observed in their final orbits by laser interferometry [2264]; that story is Chapter 47's. The strongest fields of all — orbits, spectra and images at a few gravitational radii — are the subject of Chapter 50.

The order of this part follows the logic these tests establish. The universality of free fall licenses geometry (Chapter 43); the classical tests constrain the field equations that the geometry must obey (Chapter 44); and the chapters after them follow the equations into the strong field, confident at the level of parts in 10^5 where the confidence was earned.

Chapter 43

Geometric Formulation of Gravity

The equivalence principle (Chapter 42) motivates, but does not by itself prove, a specific mathematical statement: that gravity is the geometry of the spacetime manifold itself. This chapter states that geometric formulation precisely, reusing throughout the machinery already built, in full generality, in Chapters 13 and 14. Physical spacetime instantiates that general framework at $p+q=3+1$, torsion set to zero: no experiment to date requires $T^a \neq 0$ (Section 13.13.2), and this treatise's scope rule (Chapter 1) accordingly restricts the physical theory to the Levi-Civita connection.

43.1 Geodesics as the trajectories of free fall

Postulate 43.1 (Geodesic motion)**.** A test particle subject to no force other than gravity follows a timelike geodesic of (M,g): an autoparallel curve of the Levi-Civita connection (Definition 13.146), parametrized by its own proper time τ,

$$\frac{\mathrm{d}^2 x^\lambda}{\mathrm{d}\tau^2} + \mathring{\Gamma}^\lambda{}_{\mu\nu}\,\frac{\mathrm{d}x^\mu}{\mathrm{d}\tau}\,\frac{\mathrm{d}x^\nu}{\mathrm{d}\tau} = 0\,, \tag{43.1}$$

the specialization of Equation (13.297) to the torsion-free connection of Theorem 13.150.

This is the direct generalization of Newton's first law (Chapter 19): in the absence of gravity, $g_{\mu\nu}=\eta_{\mu\nu}$, $\mathring{\Gamma}=0$, and Equation (43.1) reduces to $\mathrm{d}^2x^\lambda/\mathrm{d}\tau^2=0$, uniform motion. Equation (43.1) also follows from extremizing the proper-time functional $\int \mathrm{d}\tau = \int \sqrt{-g_{\mu\nu}\dot{x}^\mu\dot{x}^\nu}/c\,\mathrm{d}\lambda$ (Remark 13.151), the relativistic analogue of Hamilton's principle (Chapter 21).

Derivation. *Derives Equation* (43.1).

Take the action of a free massive particle proportional to its proper time,

$$S[x] = -mc^2\int \mathrm{d}\tau = -mc\int \mathrm{d}\lambda\,\sqrt{-g_{\mu\nu}(x)\,\dot{x}^\mu\dot{x}^\nu}\,, \tag{43.2}$$

with $\dot{x}^\mu = \mathrm{d}x^\mu/\mathrm{d}\lambda$ and λ an arbitrary parameter. The Euler–Lagrange equations of Chapter 16 applied to $L=\sqrt{-g_{\mu\nu}\dot{x}^\mu\dot{x}^\nu}$ simplify upon choosing $\lambda=\tau$ after the variation, so that $L=c$ is constant along the curve:

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\left(g_{\lambda\nu}\dot{x}^\nu\right) - \frac{1}{2}\,\partial_\lambda g_{\mu\nu}\,\dot{x}^\mu\dot{x}^\nu = 0\,,$$

i.e. $g_{\lambda\nu}\ddot{x}^\nu + (\partial_\mu g_{\lambda\nu} - \tfrac{1}{2}\partial_\lambda g_{\mu\nu})\dot{x}^\mu\dot{x}^\nu = 0$. Symmetrizing $\partial_\mu g_{\lambda\nu} \to \tfrac{1}{2}(\partial_\mu g_{\lambda\nu} + \partial_\nu g_{\lambda\mu})$ (legitimate under the symmetric contraction with $\dot{x}^\mu\dot{x}^\nu$) and raising with $g^{\sigma\lambda}$ produces exactly the Levi-Civita coefficients of Equation (13.301) with $T=0$, which is Equation (43.1).

For the Newtonian limit take a static weak field, $g_{00} = -(1 + 2\Phi/c^2)$ with $|\Phi|/c^2 \ll 1$, and slow motion, $|\mathrm{d}x^i/\mathrm{d}t| \ll c$, so that with $x^0 = ct$ the four-velocity is dominated by $\mathrm{d}x^0/\mathrm{d}\tau \approx c$. The only Christoffel symbol surviving at leading order in Equation (43.1) is $\mathring{\Gamma}^i{}_{00} = -\frac{1}{2}\,\delta^{ij}\partial_j g_{00} = \partial_i\Phi/c^2$, and the spatial components collapse to

$$\frac{\mathrm{d}[}{\mathrm{d}2}]x^i t = -c^2\,\mathring{\Gamma}^i{}_{00} = -\partial_i\Phi\,,$$

which is Newton's law of gravitation $\ddot{\boldsymbol{x}} = -\nabla\Phi$ (Chapter 19): the geodesic postulate contains Newtonian free fall as its slow-motion, weak-field limit. □

43.2 Curvature and tidal forces

Two neighbouring free-falling geodesics, separated by a small connecting vector ξ^μ, obey the geodesic deviation equation

$$\frac{\mathrm{D}^2\xi^\lambda}{\mathrm{d}\tau^2} = -R^\lambda{}_{\mu\nu\rho}\,\frac{\mathrm{d}x^\mu}{\mathrm{d}\tau}\,\xi^\nu\,\frac{\mathrm{d}x^\rho}{\mathrm{d}\tau}\,, \tag{43.3}$$

with $\mathrm{D}/\mathrm{d}\tau$ the covariant derivative along the geodesic and $R^\lambda{}_{\mu\nu\rho}$ the Riemann tensor of Theorem 13.152 (torsion-free). Curvature, not the connection, is therefore the geometric object with direct physical content: it is observed as the relative (tidal) acceleration of nearby free-falling bodies, exactly as Newtonian tidal forces are governed by the second derivatives of the potential, $-\partial_i\partial_j\Phi$.

Derivation. *Derives Equation (43.3).*

This is the Jacobi equation Equation (13.309) (Proposition 13.155), instantiated on spacetime with the Levi-Civita connection: in the index order of Equation (13.309), $\mathrm{D}^2\xi^\lambda/\mathrm{d}\tau^2 = R^\lambda{}_{\rho\mu\nu}u^\rho u^\mu\xi^\nu$, and the antisymmetry of the Riemann tensor in its last index pair (Proposition 13.154) rewrites this as $-R^\lambda{}_{\mu\nu\rho}\,u^\mu\xi^\nu u^\rho$, the form quoted in Equation (43.3).

For the Newtonian identification take the static weak field of the previous derivation, $u^\mu \approx (c, \mathbf{0})$, and compute from Equation (13.306): at linear order in Φ/c^2 and for time-independent fields,

$$R^i{}_{0j0} = \partial_j\mathring{\Gamma}^i{}_{00} - \partial_0\mathring{\Gamma}^i{}_{j0} = \frac{\partial_i\partial_j\Phi}{c^2}\,,$$

so Equation (43.3) reduces to

$$\frac{\mathrm{d}[}{\mathrm{d}2}]\xi^i t = -c^2 R^i{}_{0j0}\,\xi^j = -\partial_i\partial_j\Phi\;\xi^j\,,$$

the Newtonian tidal equation: the Riemann component $R^i{}_{0j0}$ *is* the tidal tensor $\partial_i\partial_j\Phi/c^2$, which is the sense of the correspondence asserted above. □

43.3 The Einstein–Hilbert action

The field equations governing $g_{\mu\nu}$ itself (Chapter 44) follow from an action principle, stated here in both the variables of this treatise's double geometric language (Section 13.1): the metric $g_{\mu\nu}$, and the vielbein e^a together with the curvature two-form $R^a{}_b$ of Section 13.12.

Definition 43.2 (Einstein–Hilbert action)**.** In $D = p + q$ dimensions,

$$S_{\mathrm{EH}}[g] = \frac{1}{2\kappa}\int_M \mathrm{d}^D x\,\sqrt{|g|}\;R\,, \tag{43.4}$$

with κ a gravitational coupling constant, fixed in $D = 4$ by the Newtonian limit to $\kappa = 8\pi G/c^4$ (Chapter 44). Equivalently, in vielbein-form variables,

$$S_{\mathrm{EH}}[e,\omega] = \frac{1}{2\kappa\,(D-2)!}\int_M \epsilon_{a_1\ldots a_D}\, R^{a_1 a_2}\wedge e^{a_3}\wedge\cdots\wedge e^{a_D}\,, \tag{43.5}$$

with $\omega^a{}_b = \omega^a{}_b(e)$ the torsion-free connection determined by e (Proposition 13.158).

Theorem 43.3 (Equivalence of the two variable sets)**.** *$S_{\mathrm{EH}}[g] = S_{\mathrm{EH}}[e,\omega]$ for $g_{\mu\nu} = \eta_{ab}e^a{}_\mu e^b{}_\nu$ (Equation (13.264)).*

Proof. This is Equation (A.150), proven in Appendix A.8. □

Remark 43.4 (Why the vielbein form matters). The equivalence of Theorem 43.3 shows that Equation (43.5) is not a mere notational variant: it is the *same* physical action, written in the language in which gravity appears as an $\mathrm{SO}(p,q)$ gauge theory (Remark 13.159) — the language required the moment matter includes spinor fields (Chapter 93), which possess no tensorial transformation law under diffeomorphisms and must instead be coupled through the frame and the spin connection [2259]. Varying Equation (43.5) independently with respect to e^a (with ω eliminated via Proposition 13.158, first-order/Palatini formalism) reproduces the same field equations obtained from varying Equation (43.4) with respect to $g_{\mu\nu}$; that variation, and the resulting field equations, are carried out in full in Section 44.1.3: the metric route is Theorem 44.9, and the independent first-order (vielbein–connection) route is Proposition 44.13.

Chapter 44

The Einstein Field Equations

The field equations relate the curvature of spacetime, constructed in Chapter 43 on the mathematical foundation of Chapter 13, to the energy and momentum of matter. This chapter presents them along Einstein's route of November 1915 [427], derives them in full from the Hilbert action [431], establishes energy–momentum conservation as a consequence of the Bianchi identities rather than a separate postulate, fixes the coupling constant by Newtonian correspondence, and states, with Lovelock, that in four dimensions the equations are essentially unique [1451].

The remaining sections supply what every later chapter of this part draws on: the cosmological constant [445], the energy conditions that power the singularity theorems, the initial-value formulation that makes the theory predictive [999], and an overview of the exact solutions — Schwarzschild, Kerr, Friedmann–Lemaître–Robertson–Walker — whose detailed study is Chapter 45 and Chapter 48.

Conventions, fixed once for the whole chapter: the signature is $(-,+,+,+)$ with coordinates $x^\mu = (x^0, x^i) = (ct, \boldsymbol{x})$, as in Chapter 46 and Appendix A.1; the connection is the torsion-free Levi-Civita connection of Theorem 13.150, written $\Gamma^\lambda{}_{\mu\nu}$ without the ring accent of Chapter 43 since no other connection appears; and the curvature conventions are Equation (13.306) and Equation (13.307), for which the round sphere has $R > 0$. The mostly-minus convention of Chapter 39 differs by $g_{\mu\nu} \to -g_{\mu\nu}$; wherever this chapter leans on a result stated in that convention, the statement used is one whose signature bookkeeping is tracked explicitly (the ϵ discipline of Appendix A.52), and the substitution made is said in place.

44.1 The route to the field equations

44.1.1 Requirements on a relativistic theory of gravity

Newtonian gravity fails relativity twice: the Poisson equation propagates influence instantaneously, and the force law singles out a preferred family of frames. What replaces it cannot be guessed freely; by 1915 the constraints on any candidate were sharp, and it is worth stating them as the specification the field equations must meet, because the rest of this chapter checks them off one by one [435].

1. *The equivalence principle.* Free fall is universal to the accuracy of the Eötvös-class experiments (Phenomenon 42.1), so gravity is not a force field on spacetime but a property of spacetime itself: test bodies follow geodesics of a metric $g_{\mu\nu}$ (Postulate 43.1), and the field variable of the theory is the metric.

2. *General covariance.* The equations must be tensor equations, well formed in every coordinate system, since the equivalence principle deprives any coordinate system of

intrinsic meaning (but see the caveat of Remark 44.1).

3. *Newtonian correspondence.* For weak, static fields and slow motion the theory must reduce to the inverse-square dynamics of Chapters 19 and 27, in the field form of the Poisson equation; this is Section 44.4.

4. *Second-order field equations.* The equations should contain no derivatives of $g_{\mu\nu}$ beyond the second, so that the initial-value problem has the shape of every other field theory in this treatise; higher-derivative dynamics generically suffers the Ostrogradsky instability (Proposition 16.39 and Remark 16.40).

5. *A conserved source.* The source must be the energy–momentum content of matter, described by a symmetric tensor $T_{\mu\nu}$ (Section 44.2), and the equations must be compatible with its local conservation — not impose it as an extra axiom.

These five requirements do not merely motivate the Einstein equations; by Lovelock's theorem (Section 44.7) they very nearly *force* them, up to the two constants κ and Λ fixed in Sections 44.4.2 and 44.6.

Remark 44.1 (The Kretschmann objection). General covariance by itself is physically empty: as Kretschmann observed — the argument circulated in 1917, the printed issue is dated 1918 — *any* theory, Newtonian gravity included, can be rewritten in generally covariant form by carrying enough auxiliary structure along [454]. What distinguishes general relativity is not covariance but the absence of prior geometry: the metric is the *only* spacetime structure, and it is dynamical. The modern assessment of the dispute, and of what Einstein's covariance arguments do and do not establish, is reviewed in [1869]. Requirement (ii) above is therefore to be read together with this stronger condition: no non-dynamical background fields.

44.1.2 The November 1915 papers

The final theory arrived in four communications to the Prussian Academy, one week apart. On 4 November Einstein abandoned the restricted covariance of the 1913 Entwurf theory — whose troubled trajectory, including the hole argument against general covariance that he first accepted and then dismantled, is traced in [1869] — and proposed equations covariant under unimodular coordinate transformations [429]. On 11 November an addendum sharpened the hypothesis on the trace of the source [430]. On 18 November he applied the vacuum equations — which the later correction would not touch — to the perihelion of Mercury and obtained the observed 43 seconds of arc per century with no adjustable parameter [428], the computation whose experimental content is Chapter 53. On 25 November the trace term fell into place and the equations took their final, generally covariant form [427]. The episode is a working example of the methodology of Chapter 1: two years of false steps constrained by one hard number.

Definition 44.2 (Einstein tensor)**.** The *Einstein tensor* of (M, g) is

$$G_{\mu\nu} = R_{\mu\nu} - \tfrac{1}{2}\, g_{\mu\nu} R\,, \tag{44.1}$$

with $R_{\mu\nu}$ and R the Ricci contractions of Definition 13.153. It is symmetric, carries SI dimension $1/\mathrm{m}^2$, and is divergence-free as an identity (Theorem 44.23).

Rests on Definition 13.153.

Postulate 44.3 (Einstein field equations)**.** The metric of spacetime is determined by the energy–momentum content of matter through

$$G_{\mu\nu} = \frac{8\pi G}{c^4}\, T_{\mu\nu}\,, \tag{44.2}$$

with $T_{\mu\nu}$ the stress–energy tensor of Section 44.2 [427]. The coupling constant $\kappa = 8\pi G/c^4$ is fixed by Newtonian correspondence in Section 44.4.2.

Rests on Definition 44.2.

Equation (44.2) is ten coupled, quasilinear, second-order partial differential equations for the ten components of $g_{\mu\nu}$ — of which only six are independent, by the four contracted Bianchi identities (Remark 44.25). The same physical postulate can be packaged as an action principle, which is the subject of Section 44.1.3; the postulate proper is then the choice of action.

Proposition 44.4 (Trace-reversed form)**.** *Equation* (44.2) *is equivalent to*

$$R_{\mu\nu} = \kappa \left(T_{\mu\nu} - \tfrac{1}{2}\, g_{\mu\nu} T \right) , \qquad T = g^{\alpha\beta} T_{\alpha\beta} \, . \tag{44.3}$$

In particular the vacuum equations are $R_{\mu\nu} = 0$: vacuum solutions are Ricci-flat, not flat.

Rests on Postulate 44.3.

Proof. *Derives Proposition 44.4.*

Tracing Equation (44.2) with $g^{\mu\nu}$ in $D = 4$ gives $R - 2R = \kappa T$, so $R = -\kappa T$. Substituting back, $R_{\mu\nu} = \kappa T_{\mu\nu} + \frac{1}{2} g_{\mu\nu} R = \kappa (T_{\mu\nu} - \frac{1}{2} g_{\mu\nu} T)$, and the two forms determine each other. With $T_{\mu\nu} = 0$ both give $R_{\mu\nu} = 0$, while the Riemann tensor need not vanish — the Schwarzschild exterior (Section 44.10) is the standing example. This trace-reversed form is the one Einstein printed on 25 November [427], and it is the form the Newtonian limit reads most easily (Section 44.4.2). □

44.1.3 The Hilbert action

Five days before the final field equations, Hilbert presented an action from which they follow by variation [431]: the Einstein–Hilbert action of Definition 43.2, here instantiated at $D = 4$,

$$S_{\mathrm{EH}}[g] = \frac{1}{2\kappa} \int_{\Omega} \mathrm{d}^4 x \, \sqrt{|g|} \, R \, , \tag{44.4}$$

together with a matter action $S_{\mathrm{m}}[\psi; g]$ for the matter fields ψ. This subsection carries out the variation in full — it is the derivation deferred to this chapter by Remark 43.4 — including the boundary term that the usual compact-support argument hides, and the first-order variation in vielbein-form variables.

Remark 44.5 (SI bookkeeping for the action). With $x^0 = ct$ the measure $\mathrm{d}^4 x$ carries m^4, R carries $1/\mathrm{m}^2$ and $\kappa = 8\pi G/c^4$ carries $\mathrm{s}^2/(\mathrm{kg\,m})$, so Equation (44.4) carries J m: it is c times a conventional action in J s, because the time coordinate is measured in metres. Extremals are unaffected by the constant factor. The same convention is applied to S_{m}, so that the tensor defined next comes out in $\mathrm{J/m}^3$, the SI unit of energy density.

Definition 44.6 (Stress–energy tensor)**.** Let $S_{\mathrm{m}}[\psi; g]$ be the action of the matter fields, covariantly coupled to the metric and carrying no other spacetime structure. The *stress–energy tensor* of the matter is its metric variational derivative,

$$T_{\mu\nu} := -\frac{2}{\sqrt{|g|}} \frac{\delta S_{\mathrm{m}}}{\delta g^{\mu\nu}} \, , \qquad \text{equivalently} \qquad \delta S_{\mathrm{m}} = -\frac{1}{2} \int \mathrm{d}^4 x \, \sqrt{|g|} \, T_{\mu\nu} \, \delta g^{\mu\nu} \, , \tag{44.5}$$

the functional derivative being the field-theoretic first variation of Theorem 16.36. $T_{\mu\nu}$ is symmetric by construction, and $T_{\mu\nu}$ carries $\mathrm{J/m}^3$: T_{00} is an energy density, cT_{0i} an energy flux, T_{ij} a stress.

Rests on Theorem 16.36.

Two variational lemmas do all the work. Both are pure algebra plus one classical determinant identity.

Lemma 44.7 (Variation of inverse and determinant)**.** *Under a variation $\delta g_{\mu\nu}$ of the metric,*

$$\delta g^{\mu\nu} = -\, g^{\mu\alpha} g^{\nu\beta}\, \delta g_{\alpha\beta}\,, \tag{44.6}$$

$$\delta\sqrt{|g|} = \tfrac{1}{2}\sqrt{|g|}\; g^{\mu\nu}\, \delta g_{\mu\nu} = -\tfrac{1}{2}\sqrt{|g|}\; g_{\mu\nu}\, \delta g^{\mu\nu}\,. \tag{44.7}$$

Rests on Proposition 5.1.

Proof. *Derives Lemma 44.7.*

Varying $g^{\mu\alpha} g_{\alpha\nu} = \delta^\mu_\nu$ gives $\delta g^{\mu\alpha}\, g_{\alpha\nu} = -g^{\mu\alpha}\, \delta g_{\alpha\nu}$; contracting with $g^{\nu\beta}$ yields Equation (44.6). For the determinant, Jacobi's formula Equation (5.21) applied to the matrix $g_{\mu\nu}$ along any one-parameter family gives $\delta(\det g) = (\det g)\, g^{\mu\nu}\delta g_{\mu\nu}$, and since $|g| = -\det g$ here, $\delta\sqrt{|g|} = \tfrac{1}{2}\,|g|^{-1/2}\;\delta\,|g| = \tfrac{1}{2}\sqrt{|g|}\, g^{\mu\nu}\delta g_{\mu\nu}$. The second equality in Equation (44.7) follows from Equation (44.6). □

Lemma 44.8 (Palatini identity)**.** *The variation of the Levi-Civita connection is the tensor*

$$\delta\Gamma^\lambda{}_{\mu\nu} = \tfrac{1}{2} g^{\lambda\rho}\left(\nabla_\mu \delta g_{\rho\nu} + \nabla_\nu \delta g_{\rho\mu} - \nabla_\rho \delta g_{\mu\nu}\right)\,, \tag{44.8}$$

and the variation of the Ricci tensor is its covariant curl,

$$\delta R_{\mu\nu} = \nabla_\lambda\, \delta\Gamma^\lambda{}_{\nu\mu} - \nabla_\nu\, \delta\Gamma^\lambda{}_{\lambda\mu}\,. \tag{44.9}$$

Consequently the trace is a pure divergence,

$$g^{\mu\nu}\, \delta R_{\mu\nu} = \nabla_\mu v^\mu\,, \qquad v^\mu = g^{\alpha\beta}\, \delta\Gamma^\mu{}_{\alpha\beta} - g^{\mu\beta}\, \delta\Gamma^\lambda{}_{\lambda\beta}\,, \tag{44.10}$$

with, explicitly in terms of the metric variation,

$$v^\mu = g^{\mu\rho} g^{\alpha\beta}\left(\nabla_\alpha \delta g_{\rho\beta} - \nabla_\rho \delta g_{\alpha\beta}\right)\,. \tag{44.11}$$

Rests on Theorems 13.150 and 13.152 and Definition 13.149.

Proof. *Derives Lemma 44.8.*

Step 1: Equation (44.8). Vary the Christoffel formula of Theorem 13.150, $\Gamma^\lambda{}_{\mu\nu} = \tfrac{1}{2} g^{\lambda\rho}(\partial_\mu g_{\rho\nu} + \partial_\nu g_{\rho\mu} - \partial_\rho g_{\mu\nu})$. The $\delta g^{\lambda\rho}$ term contributes, by Equation (44.6) and the same formula read backwards, $-g^{\lambda\alpha}\,\Gamma^\sigma{}_{\mu\nu}\,\delta g_{\alpha\sigma}$. In the $\delta(\partial g)$ terms replace each $\partial\,\delta g$ by $\nabla\,\delta g$ plus its two connection terms; summing the three combinations, four of the six connection terms cancel in pairs by the symmetry of Γ, and the surviving two give $+g^{\lambda\rho}\,\Gamma^\sigma{}_{\mu\nu}\,\delta g_{\rho\sigma}$, which cancels the $\delta g^{\lambda\rho}$ contribution exactly. What remains is Equation (44.8); being built covariantly from the tensor $\delta g_{\mu\nu}$, it is a tensor — as the difference of two connections must be.

Step 2: Equation (44.9). Vary Equation (13.306):

$$\delta R^\lambda{}_{\rho\mu\nu} = \partial_\mu \delta\Gamma^\lambda{}_{\nu\rho} - \partial_\nu \delta\Gamma^\lambda{}_{\mu\rho} + \delta\Gamma^\lambda{}_{\mu\sigma}\Gamma^\sigma{}_{\nu\rho} + \Gamma^\lambda{}_{\mu\sigma}\delta\Gamma^\sigma{}_{\nu\rho} - \delta\Gamma^\lambda{}_{\nu\sigma}\Gamma^\sigma{}_{\mu\rho} - \Gamma^\lambda{}_{\nu\sigma}\delta\Gamma^\sigma{}_{\mu\rho}\,.$$

On the other hand, treating $\delta\Gamma$ as the $(1,2)$ tensor it is,

$$\nabla_\mu \delta\Gamma^\lambda{}_{\nu\rho} - \nabla_\nu \delta\Gamma^\lambda{}_{\mu\rho} = \partial_\mu \delta\Gamma^\lambda{}_{\nu\rho} - \partial_\nu \delta\Gamma^\lambda{}_{\mu\rho} + \Gamma^\lambda{}_{\mu\sigma}\delta\Gamma^\sigma{}_{\nu\rho} - \Gamma^\lambda{}_{\nu\sigma}\delta\Gamma^\sigma{}_{\mu\rho} + \Gamma^\sigma{}_{\nu\rho}\delta\Gamma^\lambda{}_{\mu\sigma} - \Gamma^\sigma{}_{\mu\rho}\delta\Gamma^\lambda{}_{\nu\sigma}\,,$$

the terms in $\Gamma^\sigma{}_{\mu\nu}\delta\Gamma^\lambda{}_{\sigma\rho}$ cancelling between the two covariant derivatives because $\Gamma^\sigma{}_{\mu\nu}$ is symmetric. The right-hand sides agree term by term, so $\delta R^\lambda{}_{\rho\mu\nu} = \nabla_\mu \delta\Gamma^\lambda{}_{\nu\rho} - \nabla_\nu \delta\Gamma^\lambda{}_{\mu\rho}$; contracting λ with μ gives Equation (44.9).

Step 3: Equation (44.10). Contract Equation (44.9) with $g^{\mu\nu}$ and pull the metric through ∇ by metricity (Definition 13.149); the first expression for v^μ results. Substituting Equation (44.8): in the first slot, $g^{\alpha\beta}\delta\Gamma^\mu{}_{\alpha\beta} = g^{\mu\rho}g^{\alpha\beta}(\nabla_\alpha \delta g_{\rho\beta} - \tfrac{1}{2}\nabla_\rho \delta g_{\alpha\beta})$; in the second, $\delta\Gamma^\lambda{}_{\lambda\beta} = \tfrac{1}{2} g^{\lambda\rho}\nabla_\beta \delta g_{\rho\lambda}$ because the first and third terms of Equation (44.8) cancel under the $\lambda\rho$ contraction. Combining the two, the half-terms add up and give Equation (44.11). □

Theorem 44.9 (Variation of the Einstein–Hilbert action)**.** *For any variation $\delta g_{\mu\nu}$,*

$$\delta S_{\mathrm{EH}} = \frac{1}{2\kappa}\int_\Omega \mathrm{d}^4x\,\sqrt{|g|}\,G_{\mu\nu}\,\delta g^{\mu\nu} + \frac{1}{2\kappa}\int_\Omega \mathrm{d}^4x\,\sqrt{|g|}\,\nabla_\mu v^\mu\,, \tag{44.12}$$

with v^μ as in Equation (44.10). For variations supported in a compact subset of the interior of Ω the second integral vanishes, and stationarity of $S_{\mathrm{EH}} + S_{\mathrm{m}}$ for all such variations is equivalent to the field equations Equation (44.2),

$$G_{\mu\nu} = \kappa\, T_{\mu\nu}\,. \tag{44.13}$$

In vacuum (S_{m} absent) the equations are $G_{\mu\nu} = 0$, equivalently $R_{\mu\nu} = 0$ [427, 431].
Rests on Lemmas 44.7 and 44.8 and Definition 44.6.

Proof. *Derives Theorem 44.9.*

Write $\sqrt{|g|}\,R = \sqrt{|g|}\,g^{\mu\nu}R_{\mu\nu}$ and vary the three factors:

$$\delta\Big(\sqrt{|g|}\,R\Big) = \delta\sqrt{|g|}\;R + \sqrt{|g|}\;\delta g^{\mu\nu}\,R_{\mu\nu} + \sqrt{|g|}\;g^{\mu\nu}\,\delta R_{\mu\nu}\,.$$

By Equation (44.7) the first term is $-\frac{1}{2}\sqrt{|g|}\,g_{\mu\nu}R\,\delta g^{\mu\nu}$, which combines with the second into $\sqrt{|g|}\,G_{\mu\nu}\,\delta g^{\mu\nu}$; by Equation (44.10) the third is $\sqrt{|g|}\,\nabla_\mu v^\mu$. That is Equation (44.12).

For the divergence term, note the identity $\Gamma^\lambda{}_{\lambda\mu} = \frac{1}{2}g^{\lambda\rho}\partial_\mu g_{\lambda\rho} = \partial_\mu \ln\sqrt{|g|}$ — Jacobi's formula Equation (5.21) again — whence $\sqrt{|g|}\,\nabla_\mu v^\mu = \partial_\mu(\sqrt{|g|}\,v^\mu)$: a coordinate divergence. If $\delta g_{\mu\nu}$, and with it v^μ, vanishes outside a compact subset of the interior, the integral of $\partial_\mu(\sqrt{|g|}\,v^\mu)$ vanishes by the fundamental theorem of calculus applied coordinate by coordinate (Theorem 7.101 is its three-dimensional integral form). Adding δS_{m} from Equation (44.5),

$$\delta\left(S_{\mathrm{EH}} + S_{\mathrm{m}}\right) = \int_\Omega \mathrm{d}^4x\,\sqrt{|g|}\left[\frac{1}{2\kappa}G_{\mu\nu} - \frac{1}{2}T_{\mu\nu}\right]\delta g^{\mu\nu}\,,$$

and since $\delta g^{\mu\nu}$ is an arbitrary symmetric compactly supported tensor, the fundamental lemma of the calculus of variations in its several-variable form (Lemma 16.18, as used in Theorem 16.36) gives Equation (44.13). The vacuum case and the equivalence $G_{\mu\nu} = 0 \Leftrightarrow R_{\mu\nu} = 0$ are Proposition 44.4. □

The compact-support restriction is not a technicality to be waved away: on a region with boundary the discarded divergence is a genuine obstruction, and its repair is a boundary action in its own right.

Lemma 44.10 (Divergence theorem on (M, g))**.** *Let Ω be a compact coordinate region whose boundary $\partial\Omega$ is piecewise smooth and nowhere null, with outward unit conormal n_μ ($n^\mu n_\mu = \epsilon = \pm 1$), induced metric $h_{\alpha\beta}$ and area element $\sqrt{|h|}\,\mathrm{d}^3y$. Then for any C^1 vector field v^μ,*

$$\int_\Omega \mathrm{d}^4x\,\sqrt{|g|}\,\nabla_\mu v^\mu = \oint_{\partial\Omega} \mathrm{d}^3y\,\sqrt{|h|}\;n_\mu v^\mu\,. \tag{44.14}$$

Rests on Theorem 7.101 and Proposition 5.1.

Proof. *Derives Lemma 44.10.*

As in Theorem 44.9, $\sqrt{|g|}\,\nabla_\mu v^\mu = \partial_\mu(\sqrt{|g|}\,v^\mu)$, and the flat divergence theorem (Theorem 7.101, in its four-dimensional form, which is proved by the identical slicing argument) turns the left side into the flux of $\sqrt{|g|}\,v^\mu$ through $\partial\Omega$. It remains to identify the flux element. On a boundary face given by $x^1 = \text{const}$ (outward direction of increasing x^1, the other faces being identical), the flux is $\int \mathrm{d}^3y\,\sqrt{|g|}\,v^1$. By the adjugate formula for the inverse matrix (Proposition 5.47), g^{11} equals the $(1,1)$ cofactor of $g_{\mu\nu}$ divided by $\det g$; the cofactor is the determinant of the 3×3 block of g on the coordinates (x^0, x^2, x^3) of the face, which is exactly $\det h$. Hence $|g|\;|g^{11}| = |h|$, so $\sqrt{|g|} = \sqrt{|h|}/\sqrt{|g^{11}|}$ — finite precisely because the face is not null, $g^{11} \neq 0$. The outward unit conormal is $n_\mu = \partial_\mu x^1/\sqrt{|g^{11}|}$, with $n^\mu n_\mu = g^{11}/\,|g^{11}| = \epsilon$, and $n_\mu v^\mu = v^1/\sqrt{|g^{11}|}$. Therefore $\sqrt{|g|}\,v^1 = \sqrt{|h|}\;n_\mu v^\mu$, which is Equation (44.14). □

Proposition 44.11 (The boundary term, and the Gibbons–Hawking–York action)**.** *Let $\partial\Omega$ be nowhere null, and consider variations with $\delta g_{\mu\nu} = 0$ on $\partial\Omega$ but with unconstrained normal derivatives there — the boundary data of a second-order variational problem. Then the divergence term of Equation (44.12) does* not *vanish:*

$$n_\mu v^\mu\big|_{\partial\Omega} = -\,h^{\alpha\beta}\,n^\rho\,\partial_\rho \delta g_{\alpha\beta} = -\,2\,\delta K\,, \tag{44.15}$$

with $K = h^{\alpha\beta}\nabla_\alpha n_\beta$ the trace of the extrinsic curvature of $\partial\Omega$. Consequently the action with a well-defined variational principle on Ω is not S_{EH} but

$$S_{\mathrm{EH}} + S_{\mathrm{GHY}}\,, \qquad S_{\mathrm{GHY}} = \frac{1}{\kappa}\oint_{\partial\Omega} \mathrm{d}^3y\,\sqrt{|h|}\;K\,, \tag{44.16}$$

whose total variation under these boundary conditions is $(2\kappa)^{-1}\int\sqrt{|g|}\,G_{\mu\nu}\,\delta g^{\mu\nu}$ [1490, 1596].
Rests on Theorem 44.9 and Lemma 44.10.

Proof. *Derives Proposition 44.11.*

On $\partial\Omega$ every term of v^μ in Equation (44.11) may be written with partial derivatives, since $\nabla\delta g = \partial\,\delta g - \Gamma\,\delta g$ and $\delta g = 0$ there. Decompose $g^{\alpha\beta} = h^{\alpha\beta} + \epsilon^{-1} n^\alpha n^\beta$ along the boundary. In $n_\mu v^\mu = g^{\alpha\beta} n^\rho(\partial_\alpha \delta g_{\rho\beta} - \partial_\rho \delta g_{\alpha\beta})$ the two $n^\alpha n^\beta$ contributions are equal and cancel between the two terms; in the $h^{\alpha\beta}$ part, the first term is a tangential derivative of δg, which vanishes because δg vanishes identically along $\partial\Omega$. That is the first equality of Equation (44.15).

For the second, vary $K = h^{\alpha\beta}\nabla_\alpha n_\beta$ at fixed boundary metric. Since $\delta g_{\mu\nu} = 0$ on $\partial\Omega$, the unit conormal $n_\mu \propto \partial_\mu(\text{boundary function})$ and its normalization are unvaried there, and so is $h^{\alpha\beta}$; moreover δn_β vanishes identically *along* $\partial\Omega$, so its h-projected (tangential) derivatives vanish too, and the only surviving variation is through the connection, $\delta(\nabla_\alpha n_\beta) = -\delta\Gamma^\sigma{}_{\alpha\beta}\,n_\sigma$. With Equation (44.8), again dropping tangential derivatives of δg,

$$\delta K = -\tfrac{1}{2}\,h^{\alpha\beta}n^\rho\,(\partial_\alpha\delta g_{\rho\beta} + \partial_\beta\delta g_{\rho\alpha} - \partial_\rho\delta g_{\alpha\beta}) = +\tfrac{1}{2}\,h^{\alpha\beta}n^\rho\,\partial_\rho\delta g_{\alpha\beta} = -\tfrac{1}{2}\,n_\mu v^\mu\,.$$

By Lemma 44.10 the offending term of Equation (44.12) is $(2\kappa)^{-1}\oint\sqrt{|h|}\,n_\mu v^\mu = -\kappa^{-1}\oint\sqrt{|h|}\,\delta K = -\,\delta S_{\mathrm{GHY}}$, using once more that $\sqrt{|h|}$ is unvaried on the boundary. Adding S_{GHY} therefore cancels it identically. □

Remark 44.12 (Reading the boundary term). The obstruction arises because R contains second derivatives of the metric, so Equation (44.4) is a second-order Lagrangian whose boundary variation involves $\partial_n\,\delta g$; the Gibbons–Hawking–York term subtracts exactly the offending total derivative. The same divergence appears, from the opposite direction, in the $3+1$ split: one of the two total derivatives discarded in the ADM decomposition Equation (26.80) of Proposition 26.41 is this boundary term, as identified in Appendix A.52. Three honest caveats. The construction above assumes a nowhere-null boundary; null segments and the corners where segments meet require refinements that this treatise does not need. On non-compact regions the subtraction of a reference term is needed to make Equation (44.16) finite — that subtraction is where the ADM energy of Remark 26.45 enters. And the conventions here use the outward unit *conormal* throughout; the literature's explicit factors of ϵ [1596] appear when the future-directed normal vector is used on spacelike segments instead, and the two bookkeepings agree.

Proposition 44.13 (First-order variation in vielbein-form variables)**.** *Treat, in the vielbein form Equation (43.5) of the action at $D = 4$,*

$$S[e,\omega] = \frac{1}{4\kappa}\int_M \epsilon_{abcd}\,R^{ab}\wedge e^c\wedge e^d\,, \tag{44.17}$$

the vielbein e^a and the connection ω^{ab} as independent *fields (first-order or Palatini formalism), with compactly supported variations. Stationarity with respect to ω is equivalent to*

the vanishing of the torsion, $T^a = 0$ — so that $\omega = \omega(e)$ by Proposition 13.158 — and stationarity with respect to e then reproduces the vacuum Einstein equations $G_{\mu\nu} = 0$ of Theorem 44.9.

Rests on Theorems 13.156 and 43.3 and Proposition 13.158.

Proof. *Derives Proposition 44.13.*

The ω equation. From the second structure equation Equation (13.312), $\delta R^{ab} = \mathrm{d}\,\delta\omega^{ab} + \delta\omega^a{}_c \wedge \omega^{cb} + \omega^a{}_c \wedge \delta\omega^{cb} = \mathrm{D}\,\delta\omega^{ab}$. The frame Levi-Civita symbol is D-constant: $\mathrm{D}\epsilon_{abcd}$ is totally antisymmetric in $abcd$, hence proportional to ϵ_{abcd}, with coefficient the trace $\omega^e{}_e = \eta_{ef}\,\omega^{ef} = 0$ by the antisymmetry Equation (13.310). The graded Leibniz rule for D, applied to the one-form $\delta\omega^{ab}$, therefore gives

$$\epsilon_{abcd}\,\mathrm{D}\delta\omega^{ab} \wedge e^c \wedge e^d = \mathrm{d}\left(\epsilon_{abcd}\,\delta\omega^{ab} \wedge e^c \wedge e^d\right) + \epsilon_{abcd}\,\delta\omega^{ab} \wedge \mathrm{D}\left(e^c \wedge e^d\right) ,$$

where d replaces D on the full contraction because it is a Lorentz scalar. The exact term integrates to zero, so $\delta_\omega S = (4\kappa)^{-1}\int \epsilon_{abcd}\,\delta\omega^{ab} \wedge \mathrm{D}(e^c \wedge e^d)$. With $\mathrm{D}(e^c \wedge e^d) = T^c \wedge e^d - e^c \wedge T^d$ (first structure equation, Equation (13.311)) and the relabelling symmetry of ϵ_{abcd}, the integrand equals $2\,\epsilon_{abcd}\,\delta\omega^{ab} \wedge T^c \wedge e^d$, so the field equation is $\epsilon_{abcd}\,T^c \wedge e^d = 0$ for every pair ab.

To see that this forces $T^a = 0$, expand $T^c = \frac{1}{2}T^c{}_{ef}\,e^e \wedge e^f$ and wedge the equation with e^g; using $e^e \wedge e^f \wedge e^d \wedge e^g = \epsilon^{efdg}\,e^0 \wedge e^1 \wedge e^2 \wedge e^3$ with the numerical symbol, the content is $\epsilon_{abcd}\,\epsilon^{defg}\,T^c{}_{ef} = 0$. The numerical contraction identity $\epsilon^{defg}\epsilon_{dabc} = \delta^{efg}_{abc}$ (the 3×3 determinant of Kronecker deltas; Lemma A.50 is its twice-contracted consequence) reduces this, after the six contractions, to

$$T^g{}_{ab} = \delta^g{}_b\,T^c{}_{ac} - \delta^g{}_a\,T^c{}_{bc} .$$

Tracing g with b gives $T^c{}_{ac} = 4T^c{}_{ac} - T^c{}_{ac}$, so the trace vanishes, and with it the whole tensor: $T^a = 0$.

The e equation. On the surface $T^a = 0$ the connection is the unique torsion-free $\omega(e)$ of Proposition 13.158, and substituting it back gives the second-order functional $S[e, \omega(e)]$, which by Theorem 43.3 equals $S_{\mathrm{EH}}[g]$ with $g_{\mu\nu} = \eta_{ab}e^a{}_\mu e^b{}_\nu$. Now vary e in the first-order action at $\omega = \omega(e)$: the chain rule splits the variation into the explicit δ_e at fixed ω and the induced δ_ω evaluated on $\delta\omega(e)$ — and the latter vanishes, because $\omega(e)$ is precisely the point where $\delta_\omega S = 0$. So the first-order e equation coincides with the total variation of $S_{\mathrm{EH}}[g(e)]$, which by Theorem 44.9 and $\delta g_{\mu\nu} = \eta_{ab}(e^a{}_\mu\,\delta e^b{}_\nu + e^a{}_\nu\,\delta e^b{}_\mu)$ is $\kappa^{-1}\int \sqrt{|g|}\,G^{\mu\nu}\,\eta_{ab}e^b{}_\nu\,\delta e^a{}_\mu\,\mathrm{d}^4x$. Since the vielbein is invertible, stationarity for all $\delta e^a{}_\mu$ is equivalent to $G^{\mu\nu} = 0$. □

Remark 44.14 (The priority question). Hilbert's Göttingen communication is dated 20 November 1915, five days before Einstein's [427, 431], and for eighty years the field equations were sometimes said to have been found first by Hilbert. The printer's proofs of Hilbert's paper, recovered in 1997, show that the explicit field equations were not present in the version submitted on 20 November and entered only in revision, after Einstein's paper had appeared; the published version also carries a December revision date [1937]. What is securely Hilbert's is the action route itself — the recognition that Equation (44.4) is the scalar whose variation does the work, which this section has followed.

44.2 The stress–energy tensor

44.2.1 Matter models

Definition 44.6 assigns every covariantly coupled matter action a symmetric stress–energy tensor. Three models carry all the matter physics this part needs [1509, 1552]; their special-relativistic particle content — four-momentum and its conservation — is Chapter 40.

Definition 44.15 (Dust)**.** A pressureless fluid — *dust* — with proper mass density ρ (in $\mathrm{kg/m^3}$) and four-velocity field u^μ ($u^\mu u_\mu = -c^2$, Definition 40.2) has

$$T^{\mu\nu} = \rho\, u^\mu u^\nu \,. \tag{44.18}$$

In the local rest frame $T^{00} = \rho c^2$ — the rest energy density of Phenomenon 40.6 — and all other components vanish.

Rests on Definition 40.2 and Phenomenon 40.6.

Definition 44.16 (Perfect fluid)**.** A fluid with proper energy density ρc^2 (internal energy included), proper pressure p (in Pa), and four-velocity u^μ, but no viscosity and no heat flux, has

$$T^{\mu\nu} = \left(\rho + \frac{p}{c^2}\right) u^\mu u^\nu + p\, g^{\mu\nu} \,. \tag{44.19}$$

In the local rest frame $T^{\mu\nu} = \mathrm{diag}(\rho c^2, p, p, p)$: isotropic pressure, no energy flux. Dust is the case $p = 0$; radiation the case $p = \rho c^2/3$, for which the trace $T = -\rho c^2 + 3p$ vanishes.

Rests on Definition 44.15.

Proposition 44.17 (Stress–energy of the electromagnetic field)**.** *The Maxwell action in curved spacetime,*

$$S_{\mathrm{EM}} = -\frac{1}{4\mu_0}\int \mathrm{d}^4x\, \sqrt{|g|}\; F_{\alpha\beta}F^{\alpha\beta} \,, \tag{44.20}$$

with $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ the field tensor of Chapter 60, yields

$$T_{\mu\nu} = \frac{1}{\mu_0}\left(F_\mu{}^\alpha F_{\nu\alpha} - \tfrac{1}{4}\, g_{\mu\nu}\, F_{\alpha\beta}F^{\alpha\beta}\right) . \tag{44.21}$$

It is traceless, $g^{\mu\nu}T_{\mu\nu} = 0$, and its time–time component in any local orthonormal frame is the familiar energy density $\epsilon_0 E^2/2 + B^2/2\mu_0$.

Rests on Definition 44.6 and Lemma 44.7.

Proof. *Derives Proposition 44.17.*

$F_{\mu\nu}$, defined from the potential with lower indices, does not involve the metric; all metric dependence of Equation (44.20) sits in the two raised indices and the volume factor. Varying,

$$\delta S_{\mathrm{EM}} = -\frac{1}{4\mu_0}\int \mathrm{d}^4x \left[\delta\sqrt{|g|}\; F_{\alpha\beta}F^{\alpha\beta} + \sqrt{|g|}\; 2F_{\mu\alpha}F_{\nu\beta}\, g^{\alpha\beta}\, \delta g^{\mu\nu}\right] ,$$

and inserting Equation (44.7) for the first term,

$$\delta S_{\mathrm{EM}} = -\frac{1}{2}\int \mathrm{d}^4x\, \sqrt{|g|}\; \frac{1}{\mu_0}\left(F_\mu{}^\alpha F_{\nu\alpha} - \tfrac{1}{4} g_{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}\right)\delta g^{\mu\nu} \,,$$

which by Equation (44.5) is Equation (44.21). The trace is $\mu_0^{-1}(F^{\nu\alpha}F_{\nu\alpha} - \tfrac{1}{4}\cdot 4\, F_{\alpha\beta}F^{\alpha\beta}) = 0$, a special feature of $D = 4$. For the energy density, work in a local orthonormal frame: $F_0{}^\alpha F_{0\alpha} = g^{ij}F_{0i}F_{0j} = E^2/c^2$ and $F_{\alpha\beta}F^{\alpha\beta} = 2(B^2 - E^2/c^2)$, so

$$T_{00} = \frac{1}{\mu_0}\left[\frac{E^2}{c^2} + \frac{1}{2}\left(B^2 - \frac{E^2}{c^2}\right)\right] = \frac{\epsilon_0 E^2}{2} + \frac{B^2}{2\mu_0} \,,$$

using $\epsilon_0\mu_0 = 1/c^2$; both intermediate quantities are squares, so the identification is independent of the sign convention relating F_{0i} to E_i. □

Remark 44.18 (Hilbert versus canonical tensor). Translation invariance already gives every flat-spacetime field theory a conserved energy–momentum tensor by Noether's first theorem — the canonical tensor Equation (16.83) of Corollary 16.91 — but that tensor is in general not symmetric, and only becomes so after adding an identically conserved improvement term.

The metric definition Equation (44.5) is symmetric from the start, and for the Maxwell field it reproduces exactly the improved (symmetrized) canonical tensor; the systematic statement of that equivalence, the Belinfante construction, belongs to Chapter 64 (Sections 64.4.2 and 64.4.3). It is the metric tensor, not the canonical one, that gravity couples to: the right-hand side of Equation (44.2) is defined by the same variation that produces the left-hand side.

44.2.2 Conservation and Noether's theorem

Theorem 44.19 (Covariant conservation of stress–energy)**.** *Let $S_{\mathrm{m}}[\psi; g]$ be diffeomorphism invariant, and let the matter fields satisfy their own Euler–Lagrange equations. Then*

$$\nabla_\mu T^{\mu\nu} = 0\,. \tag{44.22}$$

Rests on Theorem 16.93, Definition 44.6, and Proposition 13.127.

Proof. *Derives Theorem 44.19.*

Let ξ^μ be an arbitrary compactly supported vector field and drag all fields along its flow. Diffeomorphism invariance says the action does not change: $0 = \delta_\xi S_{\mathrm{m}} = \int (\delta S_{\mathrm{m}}/\delta\psi)\,\delta_\xi\psi + \int (\delta S_{\mathrm{m}}/\delta g^{\mu\nu})\,\delta_\xi g^{\mu\nu}$. On shell the first integral vanishes. For the second, the Lie derivative of the metric is $\delta_\xi g_{\mu\nu} = \nabla_\mu\xi_\nu + \nabla_\nu\xi_\mu$ (Equation (13.275) with $\partial \to \nabla$ by metricity, as in the proof of Killing's equation Equation (13.290)), so by Equations (44.5) and (44.6)

$$0 = +\frac{1}{2}\int \mathrm{d}^4x\,\sqrt{|g|}\;T^{\mu\nu}\,(\nabla_\mu\xi_\nu + \nabla_\nu\xi_\mu) = \int \mathrm{d}^4x\,\sqrt{|g|}\;T^{\mu\nu}\nabla_\mu\xi_\nu\,,$$

using the symmetry of $T^{\mu\nu}$. Integrate by parts with Lemma 44.10 (no boundary term, compact support): $0 = -\int \sqrt{|g|}\,(\nabla_\mu T^{\mu\nu})\,\xi_\nu$, and since ξ_ν is arbitrary, Equation (44.22) follows. This is Noether's second theorem (Theorem 16.93) in action: the symmetry group depends on four arbitrary functions ξ^μ, and what it yields is not four conserved charges but four differential identities [456]. □

Proposition 44.20 (Perfect-fluid equations of motion)**.** *For the perfect fluid Equation (44.19), Equation (44.22) splits along u^μ and orthogonally to it into*

$$\nabla_\mu\,(\rho u^\mu) = -\frac{p}{c^2}\,\nabla_\mu u^\mu\,, \tag{44.23}$$

$$\left(\rho + \frac{p}{c^2}\right) u^\mu \nabla_\mu u^\lambda = -\left(g^{\lambda\nu} + \frac{u^\lambda u^\nu}{c^2}\right)\partial_\nu p\,, \tag{44.24}$$

the relativistic continuity and Euler equations. In the limit $|\boldsymbol{v}| \ll c$, $p \ll \rho c^2$ they reduce to the continuity and Euler equations of Chapter 31.

Rests on Theorem 44.19 and Definition 44.16.

Proof. *Derives Proposition 44.20.*

Insert Equation (44.19) into $\nabla_\mu T^{\mu\lambda} = 0$:

$$\nabla_\mu\Big[\Big(\rho + \tfrac{p}{c^2}\Big)\,u^\mu\Big]\,u^\lambda + \Big(\rho + \tfrac{p}{c^2}\Big)\,u^\mu\nabla_\mu u^\lambda + g^{\lambda\nu}\partial_\nu p = 0\,.$$

Contract with u_λ: since $u_\lambda u^\lambda = -c^2$ is constant, $u_\lambda\nabla_\mu u^\lambda = 0$, so the middle term dies, the first gives $-c^2\nabla_\mu[(\rho + p/c^2)u^\mu]$, and the last gives $u^\mu\partial_\mu p$. Expanding $\nabla_\mu[(p/c^2)u^\mu] = (p/c^2)\nabla_\mu u^\mu + (u^\mu/c^2)\partial_\mu p$, the two pressure-gradient terms cancel and what remains, divided by $-c^2$, is exactly Equation (44.23). Projecting instead with $h^\lambda{}_\sigma = \delta^\lambda{}_\sigma + u^\lambda u_\sigma/c^2$, which annihilates u^λ, kills the first term and produces Equation (44.24). In the nonrelativistic limit $u^\mu \to (c, \boldsymbol{v})$, $\nabla \to \partial$, $\rho + p/c^2 \to \rho$ and the projector becomes spatial; Equation (44.23) becomes $\partial_t\rho + \nabla\cdot(\rho\boldsymbol{v}) = 0$ and Equation (44.24) becomes $\rho(\partial_t + \boldsymbol{v}\cdot\nabla)\boldsymbol{v} = -\nabla p$, the equations of Chapter 31. □

Corollary 44.21 (Dust flows on geodesics)**.** *For dust ($p = 0$), Equation (44.24) reduces to $u^\mu \nabla_\mu u^\lambda = 0$: the integral curves of u^μ are timelike geodesics. The geodesic postulate Postulate 43.1 is therefore not independent of the field equations for this matter model: conservation of the source, itself enforced by the field equations (Corollary 44.24), already moves the matter on geodesics.*

Rests on Proposition 44.20 and Postulate 43.1.

Proof. *Derives Corollary 44.21.*

Set $p = 0$ in Equation (44.24); the right side vanishes and the left is ρ times the geodesic equation Equation (43.1) in its velocity-field form. □

Remark 44.22 (What covariant conservation does and does not conserve)*.* In flat spacetime $\partial_\mu T^{\mu\nu} = 0$ integrates to four conserved charges. The covariant law Equation (44.22) does not: the connection terms act as sources, describing the exchange of energy and momentum between matter and the gravitational field, and no coordinate-independent gravitational energy *density* exists to book the exchange against — by the equivalence principle, the connection can be made to vanish at any one event, taking any candidate density with it. What survives is either of two honest substitutes. With a symmetry: a Killing vector ξ makes $T^{\mu\nu}\xi_\nu$ a genuinely conserved current, by Equation (44.22) and Killing's equation Equation (13.290). With asymptotic flatness: the total energy, momentum and angular momentum of an isolated system are boundary integrals at spatial infinity — the ADM integrals, whose constrained-dynamics origin is Remark 26.45 [1221]. Between the two sits the Landau–Lifshitz pseudotensor [1552], coordinate-dependent by construction, useful because its integrals reproduce the ADM quantities in asymptotically Cartesian coordinates; the energy carried by gravitational waves, computed via the closely related Isaacson average in Appendix A.1, is the one place this part meets the issue quantitatively.

44.3 The Bianchi identities

The differential identities of the curvature tensor are established, in both index and Cartan form, in Chapter 13: the first and second Bianchi identities are Equation (13.308) and, as two lines of form algebra, Proposition 13.157. The customary attribution to Bianchi [302] is loose — the identities were known to Voss in 1880 and within Ricci's school — and this treatise keeps the customary name while recording the fact. What Part II deliberately does not do is contract them (Remark 16.95 notes the omission); the contraction is where the physics lives, and it is performed here.

Theorem 44.23 (Contracted Bianchi identity)**.** *For the Levi-Civita connection,*

$$\nabla^\mu G_{\mu\nu} = 0\,, \qquad \textit{equivalently} \qquad \nabla^\mu R_{\mu\nu} = \tfrac{1}{2}\,\partial_\nu R\,. \tag{44.25}$$

Rests on Proposition 13.154 and Definitions 13.149 and 44.2.

Proof. *Derives Theorem 44.23.*

Write the second Bianchi identity of Equation (13.308) with its cycle explicit,

$$\nabla_\sigma R^\lambda{}_{\rho\mu\nu} + \nabla_\mu R^\lambda{}_{\rho\nu\sigma} + \nabla_\nu R^\lambda{}_{\rho\sigma\mu} = 0\,.$$

Contract λ with μ (legitimate under ∇ by metricity): the first term gives $\nabla_\sigma R_{\rho\nu}$; the third, by antisymmetry in the last index pair, $-\nabla_\nu R_{\rho\sigma}$; the second stays $\nabla_\lambda R^\lambda{}_{\rho\nu\sigma}$:

$$\nabla_\sigma R_{\rho\nu} - \nabla_\nu R_{\rho\sigma} + \nabla_\lambda R^\lambda{}_{\rho\nu\sigma} = 0\,. \tag{44.26}$$

Now contract with $g^{\rho\sigma}$. The first term gives $\nabla^\rho R_{\rho\nu}$ and the second $-\partial_\nu R$. In the third, lower the index, $g^{\rho\sigma} R^\lambda{}_{\rho\nu\sigma} = g^{\rho\sigma} g^{\lambda\alpha} R_{\alpha\rho\nu\sigma}$, and use the pair-exchange symmetry of Equation (13.308) followed by antisymmetry in each pair:

$$g^{\rho\sigma} R_{\alpha\rho\nu\sigma} = g^{\rho\sigma} R_{\nu\sigma\alpha\rho} = g^{\rho\sigma}\,(-1)\,(-1)\,R_{\sigma\nu\rho\alpha} = R^\rho{}_{\nu\rho\alpha} = R_{\nu\alpha}\,,$$

the last step being the Ricci contraction Equation (13.307) of the first and third slots. So the third term is $\nabla_\lambda(g^{\lambda\alpha}R_{\nu\alpha}) = \nabla^\rho R_{\rho\nu}$. Altogether $2\nabla^\rho R_{\rho\nu} = \partial_\nu R$, and

$$\nabla^\mu G_{\mu\nu} = \nabla^\mu R_{\mu\nu} - \tfrac{1}{2}\, g_{\mu\nu}\nabla^\mu R = \tfrac{1}{2}\,\partial_\nu R - \tfrac{1}{2}\,\partial_\nu R = 0\,.$$

□

Corollary 44.24 (Conservation is an integrability condition)**.** *Any metric satisfying Equation (44.2) has $\nabla_\mu T^{\mu\nu} = 0$ automatically. Local energy–momentum conservation is therefore not an extra postulate of general relativity: it is the integrability condition of the field equations, exactly as charge conservation is the integrability condition of the Maxwell equations (Remark 16.95). Conversely, a candidate left-hand side that is* not *identically divergence-free could not consistently couple to conserved matter — the flaw that doomed Einstein's 1913–1915 intermediate theories (Section 44.1.2).*

Rests on Theorem 44.23 and Postulate 44.3.

Proof. *Derives Corollary 44.24.*

Apply ∇^μ to both sides of Equation (44.2) and use Equation (44.25). □

Remark 44.25 (Ten equations, four identities). Equation (44.25) is four differential identities among the ten field equations, so at most six are independent — the situation anticipated in general form by Corollary 16.94: the identities are the Noether identities of the four-parameter diffeomorphism freedom. The count is exactly right, not a defect: four of the ten $g_{\mu\nu}$ are gauge (coordinate choice), and the four equations "lost" to the identities resurface as constraints on initial data rather than evolution equations. That story is Section 44.9.

44.4 The Newtonian correspondence

44.4.1 Geodesics and the potential

Proposition 44.26 (Newtonian limit of geodesic motion)**.** *Let the metric be static and weakly curved,*

$$g_{00} = -\left(1 + \frac{2\Phi}{c^2}\right), \qquad g_{0i} = 0\,, \qquad g_{ij} = \delta_{ij} + O\!\left(\Phi/c^2\right), \tag{44.27}$$

with $|\Phi| \ll c^2$ time-independent, and let a test body move slowly, $|\mathrm{d}x^i/\mathrm{d}t| \ll c$. Then the geodesic equation Equation (43.1) reduces to Newton's second law in the potential Φ,

$$\frac{\mathrm{d}^2 x^i}{\mathrm{d}t^2} = -\,\partial_i\Phi\,, \tag{44.28}$$

identifying Φ (in $\mathrm{m}^2/\mathrm{s}^2$) with the Newtonian gravitational potential of Chapters 19 and 27.

Rests on Postulate 43.1.

Proof. *Derives Proposition 44.26.*

For slow motion $\mathrm{d}x^i/\mathrm{d}\tau \ll \mathrm{d}x^0/\mathrm{d}\tau$ and $\mathrm{d}x^0/\mathrm{d}\tau = c\,\mathrm{d}t/\mathrm{d}\tau \approx c$, so among the $\Gamma^i{}_{\mu\nu}\,\dot{x}^\mu\dot{x}^\nu$ terms of Equation (43.1) only $\Gamma^i{}_{00}(\dot{x}^0)^2$ survives at leading order. For a static metric,

$$\Gamma^i{}_{00} = \tfrac{1}{2}g^{i\rho}\left(2\partial_0 g_{\rho 0} - \partial_\rho g_{00}\right) = -\tfrac{1}{2}\,g^{ij}\partial_j g_{00} = -\tfrac{1}{2}\,\delta^{ij}\partial_j\left(-\frac{2\Phi}{c^2}\right) + O(\Phi^2/c^4) = \frac{\partial_i\Phi}{c^2}\,,$$

where the spatial perturbation in g^{ij} multiplies a quantity already $O(\Phi)$ and drops. Hence $\mathrm{d}^2x^i/\mathrm{d}\tau^2 = -c^2\,\Gamma^i{}_{00} = -\partial_i\Phi$ and, since $\mathrm{d}\tau \approx \mathrm{d}t$ at this order, Equation (44.28). Note that only g_{00} enters: the identification of the potential is insensitive to the spatial part of Equation (44.27). The same g_{00} is what the gravitational-redshift measurements read directly (Phenomenon 42.5). □

44.4.2 Fixing the coupling constant

Theorem 44.27 (Newtonian correspondence of the field equations)**.** *For the static weak field Equation (44.27) sourced by static dust of density ρ, the time–time component of the field equations Equation (44.2) reduces to the Poisson equation*

$$\nabla^2\Phi = \frac{\kappa c^4}{2}\,\rho\,, \tag{44.29}$$

and correspondence with Newtonian gravity, $\nabla^2\Phi = 4\pi G\rho$, fixes

$$\kappa = \frac{8\pi G}{c^4} \approx 2.0766\times 10^{-43}\,\mathrm{s}^2/(\mathrm{kg\,m})\,, \tag{44.30}$$

with G the constant measured in Chapter 33 [427].

Rests on Propositions 44.4 and 44.26 and Definition 44.15.

Proof. *Derives Theorem 44.27.*

Work in the trace-reversed form Equation (44.3). For static dust at rest, Equation (44.18) gives $T_{00} = \rho c^2$, the other components vanishing, and $T = g^{\mu\nu}T_{\mu\nu} = -\rho c^2$ to leading order. Hence

$$R_{00} = \kappa\left(T_{00} - \tfrac{1}{2}g_{00}T\right) = \kappa\left(\rho c^2 - \tfrac{1}{2}(-1)(-\rho c^2)\right) = \tfrac{1}{2}\,\kappa\rho c^2\,.$$

On the geometric side, the Ricci contraction of Equation (13.306) is $R_{00} = \partial_\lambda\Gamma^\lambda{}_{00} - \partial_0\Gamma^\lambda{}_{\lambda 0} + O(\Gamma^2)$; the Γ^2 terms are $O(\Phi^2/c^4)$ and every time derivative vanishes, so with $\Gamma^i{}_{00} = \partial_i\Phi/c^2$ from Proposition 44.26,

$$R_{00} = \partial_i\Gamma^i{}_{00} = \frac{\nabla^2\Phi}{c^2}\,.$$

Equating the two expressions gives Equation (44.29). The Newtonian side is the field form of the inverse-square law: for a point mass, $\Phi = -Gm/|\boldsymbol{x}|$ (Chapter 27), and superposing over a continuous density, $\Phi(\boldsymbol{x}) = -G\int \rho(\boldsymbol{x}')\,|\boldsymbol{x}-\boldsymbol{x}'|^{-1}\,\mathrm{d}^3x'$, the fundamental-solution property of $-1/4\pi\,|\boldsymbol{x}|$ (Proposition 10.67) gives $\nabla^2\Phi = 4\pi G\rho$. Matching coefficients, $\kappa c^4/2 = 4\pi G$, which is Equation (44.30); the numerical value uses the CODATA G of Appendix B, whose laboratory determination is Chapter 33. □

Remark 44.28 (What the Newtonian limit does and does not fix). The correspondence reads only g_{00} and only the trace-reversed time–time equation; it fixes the single constant κ and nothing else. It does not test the spatial part of the weak-field metric — that is done by light deflection and the Shapiro delay, which measure exactly the spatial curvature the Newtonian limit is blind to, and which decided against Einstein's own 1911 half-value (Section 42.5, Chapter 53); in the parametrized post-Newtonian language the limit fixes no PPN parameter at all, while the classical tests fix γ and β [2240]. Nor does the limit exclude a cosmological term: Λ adds to Equation (44.29) a contribution $-\Lambda c^2$ — a constant outward acceleration $\Lambda c^2 r/3$ — utterly negligible at solar-system scales for the measured value of Remark 44.32, which is why Section 44.6 must be settled by cosmology rather than by laboratory gravity.

44.5 The linearized theory

Far from strong sources spacetime is nearly flat, and the field equations linearize. The full derivation — linearized curvature, gauge fixing, wave solutions, energy flux and the quadrupole formula — is carried out once, in Appendix A.1; this section states the equations, since both Chapter 46 and the cosmological perturbation theory of Chapter 48 start from them.

Proposition 44.29 (Linearized field equations)**.** *Write $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$ with $|h_{\mu\nu}| \ll 1$, raise and lower indices with η, and set $h = \eta^{\mu\nu} h_{\mu\nu}$. To first order in h:*

1. *The Einstein tensor is*

$$G_{\mu\nu} = \tfrac{1}{2}\left(\partial_\rho\partial_\mu h^\rho{}_\nu + \partial_\rho\partial_\nu h^\rho{}_\mu - \Box h_{\mu\nu} - \partial_\mu\partial_\nu h - \eta_{\mu\nu}\partial_\rho\partial_\sigma h^{\rho\sigma} + \eta_{\mu\nu}\Box h\right), \tag{44.31}$$

   with $\Box = \eta^{\alpha\beta}\partial_\alpha\partial_\beta$.

2. *Under an infinitesimal coordinate change $x^\mu \to x^\mu + \xi^\mu$ (with $\partial\xi$ of order h),*

$$h_{\mu\nu} \;\longrightarrow\; h_{\mu\nu} - \partial_\mu\xi_\nu - \partial_\nu\xi_\mu\,, \tag{44.32}$$

   and Equation (44.31) is invariant, as is the linearized Riemann tensor.

3. *The Lorenz gauge $\partial^\mu \bar{h}_{\mu\nu} = 0$, with $\bar{h}_{\mu\nu} = h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}h$ the trace-reversed perturbation, is always attainable, and in it the field equations Equation (44.2) collapse to the inhomogeneous wave equation*

$$\Box\,\bar{h}_{\mu\nu} = -\,2\kappa\,T_{\mu\nu} = -\,\frac{16\pi G}{c^4}\,T_{\mu\nu}\,, \tag{44.33}$$

   which is Equation (46.2) [436, 1509, 1746].

Rests on Postulate 44.3 and Theorem 44.27.

Full derivation: Appendix A.1 (p. 2759).

Derives Proposition 44.29.

The proof is the opening of Appendix A.1: Equation (44.31) is Equation (A.9), assembled from the linearized Christoffel symbols and Riemann tensor Equations (A.4) and (A.6); the gauge transformation Equation (44.32) is Equation (A.16); the attainability of the Lorenz gauge and the reduction to Equation (44.33) are Equations (A.20) and (A.21).

Three comments place the result. First, Equation (44.33) is the whole causal structure of the theory in miniature: disturbances of the metric propagate at speed c, sourced by stress–energy — the qualitative break with the instantaneous Poisson equation that requirement (iii) of Section 44.1.1 preserved only as a limit. Second, the residual gauge freedom inside the Lorenz class reduces the ten $h_{\mu\nu}$ to two physical polarizations; the transverse-traceless construction is Section 46.2, and the same count falls out of the exact Hamiltonian analysis, with no linearization, in Theorem 26.42. Third, the history: Einstein integrated Equation (44.33) approximately in 1916 [436] and corrected the radiation formula in 1918 [453]; the theory of the waves is Chapter 46 and their observation — indirect through the binary pulsar, direct with the LIGO interferometers — is Chapter 47.

44.6 The cosmological constant

Proposition 44.30 (The cosmological term)**.** *For any constant Λ (SI dimension $1/\mathrm{m}^2$), the equations*

$$G_{\mu\nu} + \Lambda\, g_{\mu\nu} = \kappa\, T_{\mu\nu} \tag{44.34}$$

retain every structural property of Equation (44.2): the left side is symmetric, built from g and its first two derivatives, and identically divergence-free, since $\nabla_\lambda g_{\mu\nu} = 0$ by metricity. They follow from the action Equation (44.4) with R replaced by $R - 2\Lambda$. By Theorem 44.33 below, this one-parameter enlargement is the only *one available in four dimensions.*

Rests on Theorems 44.9 and 44.23 and Definition 13.149.

Proof. *Derives Proposition 44.30.*

Divergence-freedom is $\nabla^\mu(\Lambda g_{\mu\nu}) = \Lambda\nabla^\mu g_{\mu\nu} = 0$ together with Equation (44.25). For the action route, the extra term is $-(\Lambda/\kappa)\int \mathrm{d}^4x\sqrt{|g|}$, whose variation by Equation (44.7) is $+(\Lambda/2\kappa)\int \sqrt{|g|}\, g_{\mu\nu}\delta g^{\mu\nu}$; added to Equation (44.12) it shifts $G_{\mu\nu} \to G_{\mu\nu} + \Lambda g_{\mu\nu}$ in Equation (44.13). □

Einstein introduced the term in 1917, to permit a static, spatially closed universe of uniform dust — the balance requires $\Lambda = 4\pi G\rho/c^2$, with the curvature radius $1/\sqrt{\Lambda}$ [445]. The motive did not survive: the balance is unstable, a slight expansion diluting the dust and unbalancing the repulsion further, as Eddington showed in 1930 [649], and the observed expansion of the universe removed the desire for a static solution altogether; the dynamical (Friedmann) analysis in which both statements live belongs to Section 48.2.2. What survived is the term itself.

Proposition 44.31 (de Sitter geometry)**.** *With $T_{\mu\nu} = 0$ and $\Lambda > 0$, the maximally symmetric solution of Equation (44.34) has*

$$R_{\mu\nu} = \Lambda\, g_{\mu\nu}\,, \qquad R = 4\Lambda\,, \qquad R_{\lambda\rho\mu\nu} = \frac{\Lambda}{3}\left(g_{\lambda\mu}g_{\rho\nu} - g_{\lambda\nu}g_{\rho\mu}\right)\,, \tag{44.35}$$

the constant-curvature spacetime of curvature radius $\ell = \sqrt{3/\Lambda}$: de Sitter space, realized as a quadric in five flat dimensions in Section 13.13 [450]. Λ alone, with no matter whatever, curves spacetime.

Rests on Theorem 13.160 and Proposition 44.30.

Proof. *Derives Proposition 44.31.*

By Theorem 13.160 a maximally symmetric metric has $R_{\lambda\rho\mu\nu} = \frac{R}{12}(g_{\lambda\mu}g_{\rho\nu} - g_{\lambda\nu}g_{\rho\mu})$ with R constant, whence $R_{\mu\nu} = \frac{R}{4}g_{\mu\nu}$. Insert into Equation (44.34) with $T = 0$: $\frac{R}{4}g_{\mu\nu} - \frac{R}{2}g_{\mu\nu} + \Lambda g_{\mu\nu} = 0$, so $R = 4\Lambda$, and back-substitution gives Equation (44.35). The curvature constant of Equation (13.318) is $R/12 = \Lambda/3$, giving $\ell = (3/\Lambda)^{1/2}$; existence is the explicit quadric construction of Section 13.13. The case $\Lambda < 0$ gives anti-de Sitter space the same way. □

Remark 44.32 (The measured cosmological constant). Λ is today a measured cosmological parameter, not an option. The accelerating expansion discovered in the type-Ia supernova surveys [1962, 1981] (Phenomenon 48.17) and the CMB-anchored fits of [2348] concordantly give, through $\Lambda = 3\Omega_\Lambda H_0^2/c^2$ with $\Omega_\Lambda \approx 0.685$ and $H_0 \approx 67.4\,\mathrm{km/(s\,Mpc)}$,

$$\Lambda \approx 1.1 \times 10^{-52}/\mathrm{m}^2\,, \tag{44.36}$$

equivalently a vacuum energy density $\rho_\Lambda c^2 = \Lambda c^4/8\pi G \approx 5.3 \times 10^{-10}\,\mathrm{J/m^3}$ — about half a nanojoule per cubic metre. Moved to the right-hand side of Equation (44.34), the term is a perfect fluid with $p = -\rho c^2$, which is what makes it gravitationally repulsive (Remark 44.40). Why it is so small is not known: naive quantum-field-theoretic estimates of vacuum energy exceed the measured value by up to some 120 orders of magnitude, depending on the cutoff assumed — the cosmological-constant problem, stated sharply in [1828]. The observational treatment of Λ, and of the broader dark-energy question, is Chapter 48 (Section 48.6.2).

44.7 Lovelock's uniqueness theorem

The requirements of Section 44.1.1 were presented as motivation; remarkably, they are a characterization. The following theorem is imported: its proof is a classification of tensor concomitants that belongs to the mathematical literature, and this treatise uses only its statement.

Theorem 44.33 (Lovelock's uniqueness theorem; imported)**.** *In four dimensions, let $A^{\mu\nu}$ be a tensor concomitant of the metric and its first and second partial derivatives, $A^{\mu\nu} = A^{\mu\nu}(g_{\alpha\beta}, \partial_\gamma g_{\alpha\beta}, \partial_\gamma\partial_\delta g_{\alpha\beta})$, satisfying $\nabla_\mu A^{\mu\nu} = 0$ identically. Then there exist constants α and λ with*

$$A^{\mu\nu} = \alpha\, G^{\mu\nu} + \lambda\, g^{\mu\nu}\,. \tag{44.37}$$

Neither symmetry of $A^{\mu\nu}$ nor linearity in the second derivatives needs to be assumed: in $D = 4$ both follow [1451, 1479].

Remark 44.34 (Status and scope of the import). The proof is in Lovelock's two papers: the 1971 paper [1451] classifies the divergence-free symmetric concomitants in arbitrary dimension, and the 1972 paper [1479] shows that in four dimensions the symmetry and linearity hypotheses are redundant. The statement is naturally dimension-general in the sense of the Part II conventions: in $D > 4$ the classification admits further terms, one for each even dimension below D — the Lovelock tensors, obtained by varying dimensionally continued Euler densities, of which the first beyond Einstein is the quadratic Gauss–Bonnet combination $R^2 - 4R_{\mu\nu}R^{\mu\nu} + R_{\lambda\rho\mu\nu}R^{\lambda\rho\mu\nu}$. In $D = 4$ that combination is the Euler density itself: a topological term whose variation vanishes identically, contributing nothing to the field equations — which is precisely why the four-dimensional answer Equation (44.37) is so short. Physical spacetime instantiates $D = 4$, and only Equation (44.37) is used in this treatise.

Corollary 44.35 (The field equations are essentially unique)**.** *Any four-dimensional theory meeting the requirements of Section 44.1.1 — metric field variable, tensorial second-order field equations, identically conserved left-hand side coupled to the stress–energy tensor — has field equations of the form $\alpha G_{\mu\nu} + \lambda g_{\mu\nu} = T_{\mu\nu}$; absorbing the normalization into $\kappa = 1/\alpha$ and writing $\Lambda = \lambda/\alpha$, these are Equation (44.34). The Newtonian limit then fixes κ (Theorem 44.27), and observation fixes Λ (Remark 44.32). Nothing else was available.*
Rests on Theorems 44.27 and 44.33.

Proof. *Derives Corollary 44.35.*
Immediate from Theorem 44.33 applied to the left-hand side, plus the two calibrations cited. □

44.8 Energy conditions

The field equations place no restriction whatever on $T_{\mu\nu}$: any metric solves them for *some* source. Physical conclusions therefore need model-independent positivity assumptions about matter, and four standard ones do nearly all the work in this part — above all as hypotheses of the singularity theorems of Section 45.4.2 [1319, 1504].

Definition 44.36 (Energy conditions)**.** Let w^μ range over future-directed timelike vectors with $w^\mu w_\mu = -c^2$, and k^μ over future-directed null vectors. The stress–energy tensor satisfies the

- *null energy condition* (NEC) if $T_{\mu\nu}k^\mu k^\nu \geq 0$ for all k;
- *weak energy condition* (WEC) if $T_{\mu\nu}w^\mu w^\nu \geq 0$ for all w — every observer measures nonnegative energy density;
- *strong energy condition* (SEC) if $(T_{\mu\nu} - \tfrac{1}{2}T g_{\mu\nu})\, w^\mu w^\nu \geq 0$ for all w;
- *dominant energy condition* (DEC) if WEC holds and, for every w, the flux vector $-T^\mu{}_\nu w^\nu$ is causal (non-spacelike) and future-directed — energy does not flow faster than light.

WEC implies NEC by continuity as w tilts to the light cone; SEC also implies NEC the same way, but SEC does *not* imply WEC.

Rests on Definition 44.6.

Proposition 44.37 (Energy conditions for the perfect fluid)**.** *For the perfect fluid Equation (44.19):*

Condition	*Equivalent inequalities*
NEC	$\rho c^2 + p \geq 0$
WEC	$\rho \geq 0$ *and* $\rho c^2 + p \geq 0$
SEC	$\rho c^2 + 3p \geq 0$ *and* $\rho c^2 + p \geq 0$
DEC	$\rho \geq 0$ *and* $\lvert p\rvert \leq \rho c^2$

Rests on Definitions 44.16 and 44.36.

Proof. *Derives Proposition 44.37.*

Write the observer as $w^\mu = \gamma(u^\mu + v^\mu)$ with $u_\mu v^\mu = 0$, v^μ spacelike of norm $v^2 < c^2$; normalization forces $\gamma^2(c^2 - v^2) = c^2$, the Lorentz factor of the relative motion, and $u_\mu w^\mu = -\gamma c^2$. Then from Equation (44.19),

$$T_{\mu\nu} w^\mu w^\nu = \left(\rho + \tfrac{p}{c^2}\right)\gamma^2 c^4 - p\,c^2 = c^2\left[\gamma^2 c^2 \rho + \left(\gamma^2 - 1\right) p\right] .$$

Nonnegativity for all $\gamma \geq 1$ is equivalent to the two endpoint conditions $\gamma = 1$ ($\rho \geq 0$) and $\gamma \to \infty$ ($\rho c^2 + p \geq 0$), since the expression is affine in γ^2: that is WEC. For a null k, $T_{\mu\nu} k^\mu k^\nu = (\rho + p/c^2)(u_\mu k^\mu)^2$ with $u_\mu k^\mu \neq 0$, giving NEC. For SEC, the trace is $T = -\rho c^2 + 3p$, and

$$\left(T_{\mu\nu} - \tfrac{1}{2} T g_{\mu\nu}\right) w^\mu w^\nu = c^2\left[\gamma^2\left(\rho c^2 + p\right) + \tfrac{1}{2}\left(p - \rho c^2\right)\right] ,$$

again affine in γ^2: nonnegative for all γ iff the slope $\rho c^2 + p \geq 0$ and the value at $\gamma = 1$, $\frac{1}{2}(\rho c^2 + 3p)$, is nonnegative. For DEC, compute the flux:

$$f^\mu = -T^\mu{}_\nu w^\nu = \gamma\left(\rho c^2\, u^\mu - p\, v^\mu\right) , \qquad f^\mu f_\mu = \gamma^2\left(-\rho^2 c^6 + p^2 v^2\right) .$$

Causality of f for every $v^2 < c^2$ is equivalent to $p^2 c^2 \leq \rho^2 c^6$, i.e. $\lvert p\rvert \leq \rho c^2$, and future-direction follows from $f^\mu u_\mu = -\gamma \rho c^4 \leq 0$ when $\rho \geq 0$. □

Proposition 44.38 (The electromagnetic field satisfies NEC, WEC, SEC and DEC)**.** *The stress–energy tensor Equation (44.21) satisfies all four conditions of Definition 44.36.*

Rests on Proposition 44.17 and Definition 44.36.

Proof. *Derives Proposition 44.38.*

WEC: for any observer, evaluate in that observer's local orthonormal frame; by Proposition 44.17, $T_{\mu\nu} w^\mu w^\nu / c^2 = T_{\hat{0}\hat{0}} = \epsilon_0 E^2/2 + B^2/2\mu_0 \geq 0$, with E, B the fields that observer measures. NEC follows by continuity. SEC: the tensor is traceless, so the SEC quadratic form equals the WEC form. DEC: in the observer's frame the flux components are $f^{\hat{0}} = c\,T^{\hat{0}\hat{0}} = cu$ and $f^{\hat{\imath}} = c\,T^{\hat{\imath}\hat{0}} = S^{\hat{\imath}}$, where u is the energy density above and $\boldsymbol{S} = \boldsymbol{E} \times \boldsymbol{B}/\mu_0$ is the Poynting flux (Chapter 60); causality of f is $c^2 u^2 \geq \lvert\boldsymbol{S}\rvert^2$. With $a = \epsilon_0 E^2$, $b = B^2/\mu_0$,

$$u^2 - \frac{\lvert\boldsymbol{S}\rvert^2}{c^2} = \frac{(a+b)^2}{4} - \frac{\epsilon_0}{\mu_0}\lvert\boldsymbol{E} \times \boldsymbol{B}\rvert^2 \geq \frac{(a+b)^2}{4} - ab = \frac{(a-b)^2}{4} \;\geq\; 0 ,$$

using $\lvert\boldsymbol{E} \times \boldsymbol{B}\rvert \leq \lvert\boldsymbol{E}\rvert\,\lvert\boldsymbol{B}\rvert$ and $\epsilon_0/\mu_0 \cdot E^2 B^2 = ab$. Future-direction is $f^{\hat{0}} = cu \geq 0$. □

Proposition 44.39 (SEC is the attraction condition)**.** *Assume the field equations Equation* (44.34)*. Then for every timelike w,*

$$R_{\mu\nu}w^\mu w^\nu = \kappa\left(T_{\mu\nu} - \tfrac{1}{2}Tg_{\mu\nu}\right)w^\mu w^\nu - \Lambda c^2\,, \tag{44.38}$$

so with $\Lambda = 0$ the SEC is exactly the timelike convergence condition $R_{\mu\nu}w^\mu w^\nu \geq 0$: through the geodesic deviation equation Equation (43.3)*, matter satisfying the SEC focuses congruences of free-falling worldlines — gravity attracts. This is the geometric hypothesis under which the singularity theorems of Penrose and of Hawking–Penrose operate [1319, 1425, 1504] (Section 45.4.2); the null convergence condition used in Penrose's theorem follows the same way from the NEC, with the Λ term dropping out on null vectors.*

Rests on Proposition 44.4 and Definition 44.36.

Proof. *Derives Proposition 44.39.*

Trace-reverse Equation (44.34) as in Proposition 44.4: tracing gives $-R + 4\Lambda = \kappa T$, so $R_{\mu\nu} = \kappa(T_{\mu\nu} - \frac{1}{2}g_{\mu\nu}T) + \Lambda g_{\mu\nu}$, and contracting twice with w (using $g_{\mu\nu}w^\mu w^\nu = -c^2$) gives Equation (44.38). For a null vector the $g_{\mu\nu}$ terms contract to zero, leaving $R_{\mu\nu}k^\mu k^\nu = \kappa T_{\mu\nu}k^\mu k^\nu$. □

Remark 44.40 (The measured universe violates the SEC). A positive cosmological constant, read as vacuum matter with $p = -\rho_\Lambda c^2$ (Remark 44.32), has $\rho c^2 + 3p = -2\rho_\Lambda c^2 < 0$: it violates the SEC while satisfying NEC, WEC and DEC (marginally, at the $|p| = \rho c^2$ boundary). The observed accelerating expansion [1962, 1981] is precisely the statement that the SEC fails for the universe's present energy budget (Phenomenon 48.17, Section 48.6): cosmic repulsion is measured, not hypothesized. The SEC therefore has the status of a classical-matter hypothesis, valid for the fluids and fields of Section 44.2.1, appropriate to the collapse and black-hole settings of Chapter 45 — not a law of nature. The NEC, by contrast, holds for every matter model in this book, and the modern singularity and area theorems lean on it wherever possible.

44.9 The initial-value problem

General covariance hides the causal structure of the field equations: ten equations for ten $g_{\mu\nu}$, but four identities (Remark 44.25) and four coordinate freedoms. The honest count — what data on a spacelike surface determine the future, and through what evolution equations — is the subject of this section. It is also what makes the theory *predictive*, numerical relativity possible, and the waveform science of Chapter 47 more than curve fitting.

44.9.1 Constraints and evolution

Proposition 44.41 (Four of the ten equations are constraints)**.** *In any coordinates in which x^0 is a time function, the four components $G^{0\nu}$ of the Einstein tensor contain no second x^0-derivative of the metric. The four field equations $G^{0\nu} = \kappa T^{0\nu}$ are therefore not evolution equations but* constraints *on the data induced on each surface $x^0 = \text{const}$.*

Rests on Theorem 44.23.

Proof. *Derives Proposition 44.41.*

The contracted Bianchi identity Equation (44.25), written out,

$$\partial_0 G^{0\nu} = -\,\partial_i G^{i\nu} - \Gamma^\mu{}_{\mu\lambda}G^{\lambda\nu} - \Gamma^\nu{}_{\mu\lambda}G^{\mu\lambda}\,,$$

holds identically in the metric. Every term on the right contains at most second x^0-derivatives of $g_{\mu\nu}$ (G is second order and ∂_i, Γ add no time derivative). If $G^{0\nu}$ contained a second time derivative, say a term $A\,\partial_0^2 g_{\alpha\beta}$ with A built from lower-order quantities, the left side would contain the third derivative $A\,\partial_0^3 g_{\alpha\beta}$, which nothing on the right can supply; since the identity holds for *every* metric, the coefficient A vanishes identically. □

Theorem 44.42 (The constraint equations)**.** *Let Σ be a spacelike hypersurface with future-directed unit normal n^μ ($n^\mu n_\mu = -1$), induced Riemannian metric h_{ij}, and extrinsic curvature $K_{\mu\nu} = h^\alpha{}_\mu h^\beta{}_\nu \nabla_\alpha n_\beta$, where $h^\alpha{}_\mu = \delta^\alpha{}_\mu + n^\alpha n_\mu$ projects onto Σ. Write ${}^{(3)}R$ for the Ricci scalar of h_{ij}, D_i for its Levi-Civita connection, and $K = h^{ij}K_{ij}$. Then the normal–normal and normal–tangential projections of the field equations Equation (44.2) read*

$$ {}^{(3)}R + K^2 - K_{ij}K^{ij} = 2\kappa\, T_{\mu\nu} n^\mu n^\nu \,, \tag{44.39} $$

$$ D_j \left(K^j{}_i - \delta^j{}_i\, K \right) = \kappa\, T_{\mu\nu}\, n^\mu h^\nu{}_i \,, \tag{44.40} $$

the Hamiltonian *and* momentum *constraints: equations on the data (h_{ij}, K_{ij}) alone, with $T_{\mu\nu}n^\mu n^\nu$ the energy density and $-T_{\mu\nu}n^\mu h^\nu{}_i$ the momentum density measured by the observers at rest in Σ.*

Rests on Lemmas A.628 and A.630 and Postulate 44.3.

Proof. *Derives Theorem 44.42.*

The geometric identities are the Gauss and Codazzi equations, proved for arbitrary signature in Appendix A.52 with the normalization $\epsilon = n^\mu n_\mu$ carried as a symbol; in this chapter's signature a spacelike surface has $\epsilon = -1$ and the induced metric $\gamma_{\mu\nu} = g_{\mu\nu} - \epsilon n_\mu n_\nu$ used there is our positive-definite $h_{\mu\nu}$.

Hamiltonian constraint. Contract the Gauss equation Equation (A.985) over its first and third indices, then trace with $h^{\nu\mu}$. The intrinsic side gives ${}^{(3)}R$. The quadratic terms give $-\epsilon(K_{\mu\nu}K^{\mu\nu} - K^2)$. The ambient side is the double h-trace of the projected Riemann tensor; expanding $h^{\mu\nu} = g^{\mu\nu} + n^\mu n^\nu$ in both traces and using the Riemann symmetries, the $nnnn$ term vanishes by antisymmetry, and

$$ h^{\alpha\lambda} h^{\tau\sigma} R_{\alpha\tau\lambda\sigma} = R + 2R_{\mu\nu}n^\mu n^\nu \,. $$

Hence, at $\epsilon = -1$, ${}^{(3)}R = R + 2R_{\mu\nu}n^\mu n^\nu + K_{\mu\nu}K^{\mu\nu} - K^2$. But $2G_{\mu\nu}n^\mu n^\nu = 2R_{\mu\nu}n^\mu n^\nu + R$ since $g_{\mu\nu}n^\mu n^\nu = -1$, so

$$ {}^{(3)}R + K^2 - K_{ij}K^{ij} = 2\, G_{\mu\nu} n^\mu n^\nu \,, $$

and the field equations replace G_{nn} by κT_{nn}, giving Equation (44.39).

Momentum constraint. The contracted Codazzi equation Equation (A.990) is $D_\nu(K^\nu{}_\mu - K\, h^\nu{}_\mu) = h^\alpha{}_\mu R_{\alpha\kappa} n^\kappa$, with no factor of ϵ. Since $h^\alpha{}_\mu g_{\alpha\kappa} n^\kappa = h^\alpha{}_\mu n_\alpha = 0$, the Ricci tensor may be replaced by the Einstein tensor, and the field equations by κT; restricting the free index to Σ gives Equation (44.40).

That these are the four equations of Proposition 44.41 follows because $G_{\mu\nu}n^\nu$ and $G^{0\nu}$ span the same four combinations: $n_\mu \propto \partial_\mu x^0$ on the surface. Neither Equation (44.39) nor Equation (44.40) contains a time derivative of K_{ij}, i.e. a second time derivative of h_{ij}: they restrict the initial data. □

Remark 44.43 (The constrained-Hamiltonian reading, and the count of degrees of freedom)*.* The same split is the backbone of the canonical formulation worked out, as constrained dynamics, in Section 26.6.5: there the lapse and shift appear as multipliers, the vacuum forms of Equations (44.39) and (44.40) are the secondary constraints $\mathcal{H}_\perp \approx 0$, $\mathcal{H}_i \approx 0$ of Theorem 26.42 (stated in the mostly-minus convention; the dictionary is the ϵ bookkeeping of Appendix A.52), all eight constraints are first class with the hypersurface-deformation algebra Proposition 26.43, and the count $2 \times 10 - 2 \times 8 = 4$ leaves *two* configuration degrees of freedom per point of space — the two gravitational-wave polarizations of Section 46.2, with no linearization anywhere in the argument. Given constraint-satisfying data, the remaining six field equations evolve (h_{ij}, K_{ij}) once a lapse and shift — pure gauge — are chosen. Solving the constraints themselves is a nontrivial elliptic problem; the standard method, York's conformal technique, is [1490]. And the constraints, once solved, stay solved: Theorem 44.45 below includes the propagation statement, whose engine is again the contracted Bianchi identity.

44.9.2 Well-posedness

That the remaining equations really do evolve the data — existence, uniqueness, continuous dependence, the Hadamard well-posedness of Definition 10.24 — is not visible until the coordinate freedom is fixed, and the fixing that works is the harmonic (de Donder) gauge.

Proposition 44.44 (Harmonic-gauge reduction)**.** *Define* $\Gamma^\alpha = g^{\mu\nu}\Gamma^\alpha{}_{\mu\nu}$ *and* $\Gamma_\nu = g_{\nu\alpha}\Gamma^\alpha$*. Then, identically,*

$$R_{\mu\nu} = -\tfrac{1}{2}\, g^{\lambda\rho}\, \partial_\lambda \partial_\rho\, g_{\mu\nu} + \tfrac{1}{2}\left(\partial_\mu \Gamma_\nu + \partial_\nu \Gamma_\mu\right) + Q_{\mu\nu}(g, \partial g)\ , \tag{44.41}$$

where $Q_{\mu\nu}$ *is a polynomial in* $g^{\alpha\beta}$ *and* $\partial_\gamma g_{\alpha\beta}$*, quadratic in the first derivatives, containing no second derivative. In* harmonic coordinates *— coordinates each satisfying the curved wave equation, equivalently* $\Gamma^\alpha = 0$ *— the vacuum equations* $R_{\mu\nu} = 0$ *become the* reduced equations

$$g^{\lambda\rho}\, \partial_\lambda \partial_\rho\, g_{\mu\nu} = 2\, Q_{\mu\nu}(g, \partial g)\ , \tag{44.42}$$

ten quasilinear wave equations with a common principal part, the curved d'Alembertian, acting on each component separately.

Rests on Theorems 13.150 and 13.152.

Proof. *Derives Proposition 44.44.*

Only the terms of $R_{\mu\nu}$ carrying second derivatives need tracking; everything else is by definition collected in $Q_{\mu\nu}$. From the Ricci contraction of Equation (13.306), $R_{\mu\nu} = \partial_\lambda \Gamma^\lambda{}_{\nu\mu} - \partial_\nu \Gamma^\lambda{}_{\lambda\mu} + \Gamma\Gamma$, and the Christoffel formula, the second-derivative content is

$$R_{\mu\nu} \ \simeq\ \tfrac{1}{2} g^{\lambda\sigma}\left(\partial_\lambda \partial_\mu g_{\sigma\nu} + \partial_\lambda \partial_\nu g_{\sigma\mu} - \partial_\lambda \partial_\sigma g_{\mu\nu} - \partial_\mu \partial_\nu g_{\lambda\sigma}\right)\ ,$$

$\simeq$ denoting equality modulo first-derivative terms. On the other hand $\Gamma_\nu \simeq g^{\lambda\sigma}(\partial_\lambda g_{\sigma\nu} - \tfrac{1}{2}\partial_\nu g_{\lambda\sigma})$ up to products $(\partial g)(g)$, so

$$\tfrac{1}{2}\left(\partial_\mu \Gamma_\nu + \partial_\nu \Gamma_\mu\right) \ \simeq\ \tfrac{1}{2} g^{\lambda\sigma}\left(\partial_\lambda \partial_\mu g_{\sigma\nu} + \partial_\lambda \partial_\nu g_{\sigma\mu} - \partial_\mu \partial_\nu g_{\lambda\sigma}\right)\ .$$

Subtracting reproduces exactly the missing $-\tfrac{1}{2} g^{\lambda\sigma}\partial_\lambda \partial_\sigma g_{\mu\nu}$, which is Equation (44.41). A coordinate function x^α satisfies $\Box_g x^\alpha = g^{\mu\nu}\nabla_\mu \nabla_\nu x^\alpha = -g^{\mu\nu}\Gamma^\alpha{}_{\mu\nu} = -\Gamma^\alpha$, so harmonicity of all four coordinates is $\Gamma^\alpha = 0$, and Equation (44.42) follows. □

The reduced equations are hyperbolic wherever the metric is Lorentzian, and for *analytic* data the Cauchy–Kovalevskaya theorem (Theorem 10.22) already yields local solutions. Analyticity, however, is poison for relativity — analytic continuation propagates data instantaneously, defeating the causal structure the equations exist to express — and the honest function spaces are Sobolev, where the machinery is energy estimates for quasilinear hyperbolic systems. That machinery lies beyond this treatise, and the two theorems that close the problem are imported.

Theorem 44.45 (Local existence and uniqueness; Choquet-Bruhat; imported)**.** *Let* (Σ, h_{ij}, K_{ij}) *be smooth initial data satisfying the vacuum constraints (Equations* (44.39) *and* (44.40) *with* $T_{\mu\nu} = 0$*). Then there exists a vacuum spacetime* $(M, g_{\mu\nu})$ *— a* development *of the data — containing an embedded hypersurface with induced metric* h_{ij} *and extrinsic curvature* K_{ij}*, obtained by solving the reduced equations Equation* (44.42)*; the harmonic gauge condition and the constraints, imposed at the initial surface, propagate; and any two developments agree, near* Σ*, up to a diffeomorphism fixing* Σ*. The Cauchy problem of general relativity is well posed in the sense of Definition 10.24 [999].*

Theorem 44.46 (Maximal globally hyperbolic development; Choquet-Bruhat and Geroch; imported)**.** *Among all globally hyperbolic vacuum developments of given constraint-satisfying data there is a maximal one, unique up to isometry, into which every other embeds isometrically [1399].*

Remark 44.47 (Status of the imports, and what hangs on them). Theorem 44.45 is Choquet-Bruhat's 1952 theorem, published under the name Fourès-Bruhat [999]; modern proofs, with the Sobolev thresholds and the constraint-propagation computation written out, are in [1746] (ch. 10) and [1504] (ch. 7). The propagation argument is worth stating even unproved, because it closes this chapter's circle: if the reduced equations hold, the contracted Bianchi identity Equation (44.25) forces the four quantities Γ^α to satisfy a linear homogeneous hyperbolic system; data satisfying the constraints start the Γ^α and their first time derivatives at zero; and the unique solution of a homogeneous system with zero data is zero — so the gauge condition maintains itself and the reduced solution solves the full Einstein equations. Theorem 44.46 then removes the arbitrariness of gauge and extent in one stroke: general relativity assigns to each admissible initial datum a unique maximal spacetime. Determinism holds exactly as far as global hyperbolicity does; whether it can fail beyond — Cauchy horizons, naked singularities — is the cosmic-censorship question of Section 45.4.3 [1405]. On these two theorems rests numerical relativity: well-posedness is what guarantees that discretized evolutions converge to the continuum solution, and with it the template waveforms against which the detections of Chapter 47 are read.

44.10 Exact solutions: an overview

The field equations are ten coupled quasilinear PDEs, and their generic solution is numerical. The exactly solved cases are few, each purchased with heavy symmetry, and almost every observational confrontation in this part runs through one of them. They are collected here once, with their working homes; each named solution is derived in the chapter that consumes it.

Table 44.1: The exact solutions this treatise uses. Each is derived and exploited in the chapter of the last column; the citations for the original papers are given in the text below.

Solution	Symmetry	Source	Treated in
Minkowski	maximal, flat	vacuum	Chapter 39
de Sitter / anti-de Sitter	maximal	Λ only	Section 44.6
Schwarzschild exterior	static, spherical	vacuum	Chapter 45
Interior fluid spheres	static, spherical	perfect fluid	Chapter 49
Kerr	stationary, axial	vacuum	Chapter 45
FLRW cosmologies	homogeneous, isotropic	perfect fluid	Chapter 48
Oppenheimer–Snyder	spherical, dynamical	dust	Chapter 45
Linearized waves	none (perturbative)	weak sources	Chapter 46

The Schwarzschild exterior solution — found within weeks of the field equations, from the trenches of the eastern front — describes the vacuum outside any spherical mass [440], with Droste's independent derivation arriving months later in the now-standard coordinates [444]; by Birkhoff's theorem (Section 45.1.2) it is the *unique* spherically symmetric vacuum solution, static or not. It underwrites the classical tests (Chapter 53) and, continued inside its horizon, the black hole (Chapter 45). Its interior companions — Schwarzschild's constant-density sphere and the Tolman–Oppenheimer–Volkoff hydrostatics built on Equation (44.24) — carry relativistic stellar structure [845, 848] and are the business of Chapter 49; the Oppenheimer–Snyder collapse of a dust ball [844] is the exactly solvable model of black-hole formation (Section 45.4.1). The Kerr solution, the stationary rotating vacuum found only in 1963 [1259], is by the no-hair theorems (Section 45.5.3) the endpoint of every gravitational collapse and the metric read directly by the observations of Chapter 50. The Friedmann–Lemaître–Robertson–Walker family — Friedmann's dynamical solutions [490], Lemaître's

independent expansion physics [583], and the Robertson–Walker proof that the metric form is forced by homogeneity and isotropy alone [758, 804] — instantiates the maximally symmetric *spaces* of Section 13.13 as the spatial sections of cosmology, and carries all of Chapter 48. Plane gravitational waves close the list (Chapter 46). The systematic monographs are [1509, 1746].

What the short list teaches is the shape of the subject: a handful of exact geometries, each pinned to data — planetary orbits and light bending for Schwarzschild, X-ray binaries, stellar dynamics and horizon-scale imaging for Kerr, the expansion history for FLRW, interferometer strain for the waves — with the equations themselves, checked in Section 44.4.2 against the Newtonian world and secured as a well-posed dynamical system in Section 44.9, mediating between them. The chapters that follow take up each geometry in turn.

Chapter 45

Schwarzschild Geometry and Black Holes

The first exact solution of the field equations of Chapter 44 was found within weeks of their publication [440], and it carries a remarkable fraction of the theory's observable content: the orbits behind the classical tests of Chapter 42, the innermost stable orbit and photon sphere that set the scales of accretion, and — once its coordinate singularity was understood — the event horizon and the black hole. This chapter derives the solution, studies its geodesics, extends it maximally, and follows gravitational collapse to the singularity theorems that make the outcome generic [1319].

The second half opens the black-hole family: the Kerr rotating solution [1259], its charged relatives, and the uniqueness (no-hair) theorems that reduce every stationary black hole to two observable parameters [1351, 1443]. The shadow of the horizon is derived as a prediction here; the observations — stellar orbits about the galactic centre, the Event Horizon Telescope images, ringdown spectroscopy — are deferred with their full apparatus to the black-hole experiment chapter, Chapter 50, and to Chapter 47. Standard treatments are [1509, 1746].

45.1 The Schwarzschild solution

45.1.1 Derivation and the 1916 paper

A gravitational field is *static* when spacetime admits a timelike Killing vector (Definition 13.139) whose orthogonal distribution is integrable — there is a time coordinate t that the geometry neither depends on nor mixes with space — and *spherically symmetric* when the rotation group acts by isometries with two-dimensional spacelike orbits. On each orbit sphere the metric must be a multiple of the round metric, and the multiple defines the *areal radius* r: the sphere labelled r has area $4\pi r^2$ by construction, whatever "distance to the centre" turns out to mean. Wherever $\mathrm{d}r \neq 0$ these choices reduce the metric to two unknown functions of r [1746],

$$\mathrm{d}s^2 = -\mathrm{e}^{2\alpha(r)}c^2\mathrm{d}t^2 + \mathrm{e}^{2\beta(r)}\mathrm{d}r^2 + r^2\left(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2\right). \tag{45.1}$$

Staticity is assumed here for transparency and *proved* redundant in Section 45.1.2.

Write $x^0 := ct$, so that primes denote $\mathrm{d}/\mathrm{d}r$ throughout. A mechanical application of Equation (13.299) (torsion zero, per Chapter 43) gives the nonvanishing Christoffel symbols

of Equation (45.1),

$$\begin{aligned} \Gamma^0{}_{0r} &= \alpha' , & \Gamma^r{}_{00} &= \alpha' \mathrm{e}^{2(\alpha-\beta)} , & \Gamma^r{}_{rr} &= \beta' , \\ \Gamma^r{}_{\theta\theta} &= -r\mathrm{e}^{-2\beta} , & \Gamma^r{}_{\varphi\varphi} &= -r\mathrm{e}^{-2\beta}\sin^2\theta , & \Gamma^\theta{}_{r\theta} &= \frac{1}{r} , \\ \Gamma^\theta{}_{\varphi\varphi} &= -\sin\theta\cos\theta , & \Gamma^\varphi{}_{r\varphi} &= \frac{1}{r} , & \Gamma^\varphi{}_{\theta\varphi} &= \cot\theta , \end{aligned} \tag{45.2}$$

and contracting the Riemann tensor Equation (13.306) as in Definition 13.153 yields the Ricci components

$$R_{00} = \mathrm{e}^{2(\alpha-\beta)}\left[\alpha'' + \alpha'^2 - \alpha'\beta' + \frac{2\alpha'}{r}\right] , \tag{45.3}$$

$$R_{rr} = -\alpha'' - \alpha'^2 + \alpha'\beta' + \frac{2\beta'}{r} , \tag{45.4}$$

$$R_{\theta\theta} = 1 - \mathrm{e}^{-2\beta}\left[1 + r\left(\alpha' - \beta'\right)\right] , \tag{45.5}$$

with $R_{\varphi\varphi} = \sin^2\theta\, R_{\theta\theta}$ and all off-diagonal components zero.

Theorem 45.1 (Schwarzschild solution)**.** *The unique static, spherically symmetric, asymptotically flat solution of the vacuum field equations $R_{\mu\nu} = 0$ (Chapter 44) exterior to a body of mass M is*

$$\mathrm{d}s^2 = -\left(1 - \frac{r_\mathrm{s}}{r}\right)c^2\mathrm{d}t^2 + \left(1 - \frac{r_\mathrm{s}}{r}\right)^{-1}\mathrm{d}r^2 + r^2\left(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2\right) , \tag{45.6}$$

with the Schwarzschild radius

$$r_\mathrm{s} := \frac{2GM}{c^2} . \tag{45.7}$$

Rests on Equation (13.306)*, Theorem 13.150, and Postulate 43.1.*

Derivation. *Derives Theorem 45.1.*

Vacuum demands that Equations (45.3) to (45.5) vanish. The combination

$$\mathrm{e}^{2(\beta-\alpha)}R_{00} + R_{rr} = \frac{2}{r}\left(\alpha' + \beta'\right) = 0$$

kills every second-derivative term at a stroke: $\alpha + \beta$ is constant, and asymptotic flatness ($\alpha, \beta \to 0$ as $r \to \infty$) sets the constant to zero, so $\beta = -\alpha$. Inserting this into $R_{\theta\theta} = 0$ gives

$$1 = \mathrm{e}^{2\alpha}\left(1 + 2r\alpha'\right) = \left(r\,\mathrm{e}^{2\alpha}\right)' ,$$

which integrates to $r\mathrm{e}^{2\alpha} = r - C$ with C an integration constant:

$$\mathrm{e}^{2\alpha} = 1 - \frac{C}{r} .$$

Direct substitution confirms that $R_{00} = 0$ then holds identically — as it must, since the contracted Bianchi identity (Equation (13.308)) makes the field equations degenerate.

The constant C is fixed by the Newtonian limit. A slow test particle on a geodesic (Postulate 43.1) has $\mathrm{d}t/\mathrm{d}\tau \simeq 1$ and, by Equation (45.2),

$$\frac{\mathrm{d}^2 r}{\mathrm{d}\tau^2} \simeq -c^2\,\Gamma^r{}_{00} = -c^2\alpha'\mathrm{e}^{4\alpha} \simeq -\frac{c^2 C}{2r^2}$$

at large r. Newtonian gravity requires $\ddot{r} = -GM/r^2$ for the same source, so $C = 2GM/c^2 = r_\mathrm{s}$, which is Equations (45.6) and (45.7). Uniqueness within the ansatz is manifest — every step was forced — and the ansatz itself is generic by the reduction above. □

The scale Equation (45.7) is tiny for ordinary bodies: $r_{\mathrm{s}} = 2.95\,\mathrm{km}$ for the Sun ($M_\odot = 1.989\times10^{30}\,\mathrm{kg}$) and 8.87 mm for the Earth, which is why every solar-system test of Chapter 53 probes the far field $r \gg r_{\mathrm{s}}$, where Equation (45.6) deviates from flatness at the level $r_{\mathrm{s}}/r \sim 10^{-6}$ or less.

Remark 45.2 (The 1916 papers, and whose coordinates these are). Schwarzschild found the solution in the winter of 1915–16, on the Russian front, using a radial coordinate for which his "r" was not the areal radius [440]; the form Equation (45.6), in the coordinates now universally called Schwarzschild coordinates, is due independently to Droste [444]. Neither author regarded the locus $r = r_{\mathrm{s}}$ as physical: for every known star it lies far inside the matter, where the vacuum solution does not apply. The interior problem — matching Equation (45.6) to a matter-filled region and the resulting structure equations — is developed with the compact stars that need it, in Chapter 49.

Remark 45.3 (Gravitational redshift from the static metric). Two static observers at radii $r_1 < r_2$ exchange light. Staticity means successive wave crests follow congruent paths, so the *coordinate* time between crests is the same at both ends, while each observer's proper time is $\mathrm{d}\tau = \sqrt{1 - r_{\mathrm{s}}/r}\,\mathrm{d}t$ by Equation (45.6). The received frequency is therefore shifted by

$$\frac{\nu_2}{\nu_1} = \sqrt{\frac{1 - r_{\mathrm{s}}/r_1}{1 - r_{\mathrm{s}}/r_2}} \simeq 1 - \frac{GM}{c^2}\left(\frac{1}{r_1} - \frac{1}{r_2}\right), \tag{45.8}$$

whose weak-field form is the tower redshift measured by Pound, Rebka and Snider and the clock-rate budget of satellite navigation (Chapters 42 and 53). As $r_1 \to r_{\mathrm{s}}$ the shift diverges: the horizon is an infinite-redshift surface for static sources, a fact that controls the appearance of collapse in Section 45.4.1.

45.1.2 Birkhoff's theorem

Staticity was an input above. It is in fact a consequence of spherical symmetry alone — a theorem proved by Jebsen two years before the customary source [476, 497].

Theorem 45.4 (Jebsen–Birkhoff). *Every spherically symmetric solution of the vacuum field equations is locally isometric to the Schwarzschild solution Equation (45.6). In particular the field outside any spherically symmetric body is static, however violently the body itself pulsates, collapses or explodes, so long as it does so spherically.*

Rests on Theorem 45.1 and Equation (13.306).

Proof. *Derives Theorem 45.4.*

Spherical symmetry alone reduces the metric, wherever the areal radius has spacelike gradient, to the form Equation (45.1) with t-dependent functions $\alpha(t,r)$, $\beta(t,r)$: the orbit spheres fix the angular block, the areal radius supplies r, and the residual freedom in relabelling t removes the single cross term g_{tr} [1509, 1746]. The time dependence adds exactly one new nonvanishing Ricci component,

$$R_{0r} = \frac{2}{r}\,\partial_0\beta\,,$$

with $\partial_0 = \partial/\partial x^0$, and adds to R_{00} and R_{rr} terms each of which carries at least one factor of $\partial_0\beta$ or $\partial_0^2\beta$. Vacuum makes R_{0r} vanish, so $\beta = \beta(r)$; all the new terms in R_{00} and R_{rr} then vanish identically, and the static computation of Theorem 45.1 applies verbatim at each instant. It gives $\partial_r(\alpha + \beta) = 0$, i.e. $\alpha = -\beta + f(t)$; the redefinition $\mathrm{d}\tilde{t} = \mathrm{e}^{f(t)}\mathrm{d}t$ absorbs f, and $R_{\theta\theta} = 0$ integrates as before to $\mathrm{e}^{-2\beta} = 1 - C(t)/r$ — with C in fact constant because β is t-independent. The result is Equation (45.6). □

Corollary 45.5 (No monopole gravitational radiation)**.** *A radially pulsating star cannot radiate gravitationally: its exterior field is exactly the static Equation (45.6) at all times, so no disturbance whatever propagates outward. Gravitational radiation begins at the quadrupole (Chapter 46), and Theorem 45.4 is the exact, nonlinear statement of which the absence of monopole terms in the quadrupole formula is the weak-field shadow.*

Rests on Theorem 45.4.

Theorem 45.4 is also the tool that makes collapse computable: whatever happens inside a collapsing spherical star, the exterior is Equation (45.6) with a constant M. That is the key to Section 45.4.1.

45.2 Geodesics and orbits

45.2.1 The effective potential

The metric Equation (45.6) has two obvious Killing vectors, $\boldsymbol{\xi} = \partial_t$ and $\boldsymbol{\eta} = \partial_\varphi$, and each gives a conserved quantity along geodesics (Proposition 13.141). For a timelike geodesic with four-velocity $u^\mu = \mathrm{d}x^\mu/\mathrm{d}\tau$, normalized as always to $g_{\mu\nu}u^\mu u^\nu = -c^2$ (Proposition 40.3, in this part's signature), define the conserved specific energy and specific angular momentum

$$\mathcal{E} := \left(1 - \frac{r_\mathrm{s}}{r}\right) c^2 \frac{\mathrm{d}t}{\mathrm{d}\tau}\,, \qquad L := r^2 \sin^2\theta\, \frac{\mathrm{d}\varphi}{\mathrm{d}\tau}\,. \tag{45.9}$$

Spherical symmetry confines each orbit to a plane: with initial conditions $\theta = \pi/2$, $\mathrm{d}\theta/\mathrm{d}\tau = 0$, the θ geodesic equation gives $\mathrm{d}^2\theta/\mathrm{d}\tau^2 = 0$, so the motion stays equatorial, and we take $\theta = \pi/2$, $L = r^2\mathrm{d}\varphi/\mathrm{d}\tau$ throughout.

Proposition 45.6 (Radial equation and effective potential)**.** *Along an equatorial timelike geodesic,*

$$\frac{1}{2}\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2 + V_\mathrm{eff}(r) = \mathcal{E}_\mathrm{N} := \frac{\mathcal{E}^2 - c^4}{2c^2}\,, \tag{45.10}$$

with the effective potential

$$V_\mathrm{eff}(r) = -\frac{GM}{r} + \frac{L^2}{2r^2} - \frac{GML^2}{c^2 r^3}\,. \tag{45.11}$$

Rests on Theorem 45.1 and Propositions 13.141 and 40.3.

Derivation. *Derives Proposition 45.6.*

Write out the normalization $g_{\mu\nu}u^\mu u^\nu = -c^2$ in the equatorial plane,

$$-\left(1 - \frac{r_\mathrm{s}}{r}\right) c^2 \left(\frac{\mathrm{d}t}{\mathrm{d}\tau}\right)^2 + \left(1 - \frac{r_\mathrm{s}}{r}\right)^{-1} \left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2 + r^2 \left(\frac{\mathrm{d}\varphi}{\mathrm{d}\tau}\right)^2 = -c^2\,,$$

and eliminate the cyclic velocities with Equation (45.9): $\mathrm{d}t/\mathrm{d}\tau = \mathcal{E}/(c^2(1 - r_\mathrm{s}/r))$ and $\mathrm{d}\varphi/\mathrm{d}\tau = L/r^2$. Multiplying through by $\tfrac{1}{2}(1 - r_\mathrm{s}/r)$,

$$\frac{1}{2}\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2 = \frac{\mathcal{E}^2}{2c^2} - \frac{1}{2}\left(1 - \frac{r_\mathrm{s}}{r}\right)\left(c^2 + \frac{L^2}{r^2}\right).$$

Expanding the product and using $r_\mathrm{s}c^2 = 2GM$ gives Equations (45.10) and (45.11) exactly — no weak-field approximation has been made. □

Remark 45.7 (One new term, and everything it changes). The first two terms of Equation (45.11) are precisely the Newtonian effective potential of the Kepler problem (Equation (27.32) with $U = -GM/r$), with $\mathcal{E}_{\mathrm{N}}$ reducing at $r \gg r_{\mathrm{s}}$, where $\mathcal{E} \simeq c^2 + E_{\mathrm{Newt}}$, to the Newtonian specific energy. The whole of general relativity's modification of bound motion is the single attractive term $-GML^2/(c^2 r^3)$, and it changes the phase portrait qualitatively: in Newtonian mechanics any $L \neq 0$ erects an infinite centrifugal barrier (Section 27.3.2), whereas here $V_{\mathrm{eff}} \to -\infty$ as $r \to 0$ for every L. The barrier survives only for $L > L_{\mathrm{crit}} = 2\sqrt{3}\,GM/c$: below that angular momentum a particle is captured from *any* energy — there are orbits that spiral into the centre, which Newtonian gravity forbids.

Proposition 45.8 (Orbit equation)**.** *In terms of the inverse radius $u := 1/r$, an equatorial timelike geodesic with $L \neq 0$ obeys*

$$\frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2} + u = \frac{GM}{L^2} + \frac{3GM}{c^2}\,u^2 . \tag{45.12}$$

Dropping the u^2 term gives the Binet equation of the Kepler problem (Equation (27.28) with the inverse-square force), whose solutions are the closed conics of Section 27.4.

Rests on Proposition 45.6 and Equation (27.28).

Derivation. *Derives Proposition 45.8.*

Since $\mathrm{d}\varphi/\mathrm{d}\tau = Lu^2$,

$$\frac{\mathrm{d}r}{\mathrm{d}\tau} = \frac{\mathrm{d}r}{\mathrm{d}\varphi}\,\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = -\frac{1}{u^2}\,\frac{\mathrm{d}u}{\mathrm{d}\varphi}\cdot Lu^2 = -L\,\frac{\mathrm{d}u}{\mathrm{d}\varphi},$$

so the first integral of Proposition 45.6 reads

$$L^2\left(\frac{\mathrm{d}u}{\mathrm{d}\varphi}\right)^2 = \frac{\mathcal{E}^2}{c^2} - (1 - r_{\mathrm{s}}u)\left(c^2 + L^2u^2\right).$$

Differentiating with respect to φ and dividing by $2L^2\,\mathrm{d}u/\mathrm{d}\varphi$ (legitimate except at turning points, which are isolated),

$$\frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2} = \frac{r_{\mathrm{s}}c^2}{2L^2} - u + \frac{3r_{\mathrm{s}}}{2}\,u^2 ,$$

which is Equation (45.12) on using $r_{\mathrm{s}}c^2 = 2GM$. □

Phenomenon 45.9 (Relativistic advance of the periastron)**.** A bound orbit in the field of a spherical mass M does not close: the periastron advances in the direction of the motion by

$$\Delta\varphi = \frac{6\pi GM}{c^2 a\,(1 - e^2)} \tag{45.13}$$

per revolution, to lowest order in $GM/(c^2 a)$, for an orbit of semi-major axis a and eccentricity e. Two measurements span nine orders of magnitude in central mass and confirm the same formula. For Mercury the advance is the 43 seconds of arc per century that Le Verrier isolated as a residual half a century before there was a theory to explain it [151, 428]; for the star S2 orbiting the compact mass at the Galactic centre it is about twelve minutes of arc per sixteen-year orbit, detected by near-infrared interferometry [2347].

Rests on Equation (45.12) and Proposition 45.8.

Derivation. *Derives Phenomenon 45.9.*

The orbit equation Equation (45.12) is exact; the advance is its lowest-order consequence. The relativistic term is smaller than the linear terms by $3L^2u^2/c^2 \sim v^2/c^2$, so one solves perturbatively about the Keplerian ellipse: substituting the conic $u_0 = (GM/L^2)(1 + e\cos\varphi)$ into the u^2 term produces, among bounded forced terms, one resonant term proportional to

$\cos\varphi$, and its secular growth rotates the apsidal line by Equation (45.13) per revolution. That computation is carried out in full — including the numerical budget that turns it into Mercury's 43 seconds of arc per century — in the derivation of Phenomenon 53.1 in Chapter 53, which takes Equation (45.12) from this chapter as its input; it is not repeated here. For S2 the same formula, with the mass and orbital elements measured in Chapter 50, gives the twelve-minute advance per orbit reported by the GRAVITY interferometer [2347]. □

45.2.2 Circular orbits, the ISCO and the photon sphere

Circular orbits sit at extrema of Equation (45.11), and the systematic treatment of what follows — including the rotating generalization — is [1464].

Proposition 45.10 (Circular orbits and their energy)**.** *Circular timelike geodesics of radius r exist iff $r > 3GM/c^2$, with*

$$L^2 = \frac{GMr^2}{r - 3GM/c^2}\,, \tag{45.14}$$

and carry specific energy

$$\frac{\mathcal{E}}{c^2} = \frac{1 - r_{\mathrm{s}}/r}{\sqrt{1 - 3GM/(c^2 r)}}\,. \tag{45.15}$$

They are stable iff $r \geq r_{\mathrm{ISCO}} = 6GM/c^2$; at the innermost stable circular orbit, $\mathcal{E} = \sqrt{8/9}\,c^2$ and $L = 2\sqrt{3}\,GM/c$.

Rests on Proposition 45.6.

Derivation. *Derives Proposition 45.10.*

Write $m := GM/c^2$. Setting $V'_{\mathrm{eff}}(r) = 0$ in Equation (45.11) and multiplying by r^4,

$$GMr^2 - L^2 r + 3GM\frac{L^2}{c^2} = 0 \qquad \Longrightarrow \qquad L^2\,(r - 3m) = GMr^2\,,$$

which is Equation (45.14); a positive solution requires $r > 3m$, and $L^2 \to \infty$ as $r \to 3m$. For the energy, evaluate $\mathcal{E}^2 = c^4 + 2c^2 V_{\mathrm{eff}}(r)$ on Equation (45.14): putting the terms of Equation (45.11) over the denominator $2r(r - 3m)$,

$$V_{\mathrm{eff}} = -\frac{GM\,(r - 4m)}{2r\,(r - 3m)} \qquad \Longrightarrow \qquad \frac{\mathcal{E}^2}{c^4} = \frac{r^2 - 4mr + 4m^2}{r\,(r - 3m)} = \frac{(r - 2m)^2}{r\,(r - 3m)}\,,$$

whose square root is Equation (45.15). For stability, differentiate Equation (45.11) twice and insert Equation (45.14):

$$V''_{\mathrm{eff}}(r) = \frac{GM}{r^3}\cdot\frac{r - 6m}{r - 3m}\,, \tag{45.16}$$

positive for $r > 6m$, negative for $3m < r < 6m$: the inner branch of circular orbits is unstable, and the marginal case is $r_{\mathrm{ISCO}} = 6m = 6GM/c^2$. There Equations (45.14) and (45.15) give $L^2 = GM \cdot 36m^2/(3m) = 12G^2M^2/c^2$ and $\mathcal{E}/c^2 = (1 - \tfrac{1}{3})/\sqrt{1 - \tfrac{1}{2}} = \tfrac{2}{3}\sqrt{2} = \sqrt{8/9}$. □

Remark 45.11 (The photon sphere as a limit). As $L \to \infty$ the unstable branch radius tends to $3GM/c^2$: the faster the particle, the closer its unstable circular orbit sits to the limiting value, which is the circular orbit of light itself. The same radius reappears in Section 45.7 as the top of the null effective potential, Equation (45.59), where its instability makes it the rim of the shadow rather than a place where light accumulates. Nothing in the Kepler problem corresponds to either radius: both are creatures of the r^{-3} term of Equation (45.11).

Phenomenon 45.12 (Efficiency of accretion onto compact objects)**.** Matter accreting onto a compact object radiates a fraction of order ten per cent of its rest energy, an order of magnitude above the 0.7% that hydrogen burning can release. This is what allows a quasar to outshine its entire host galaxy from a region light-days across [1265], and it is the argument that identified quasars with accreting massive black holes in the nuclei of ordinary galaxies [1403]. The scale is set by the innermost stable circular orbit: circular geodesics of the Schwarzschild geometry exist inward to $r = 3GM/c^2$ but are stable only outside

$$r_{\mathrm{ISCO}} = \frac{6GM}{c^2} = 3r_{\mathrm{s}}\,, \tag{45.17}$$

where a unit mass has specific energy $\sqrt{8/9}\,c^2$. Matter spiralling slowly inward through a thin disc therefore radiates at most

$$\varepsilon = 1 - \sqrt{\tfrac{8}{9}} = 0.057 \tag{45.18}$$

of its rest energy before it crosses the horizon [1464, 1509]. For a rapidly rotating hole the innermost stable orbit moves inward and the figure rises toward about 0.4, which is why the observed efficiencies are informative about spin.

Rests on Proposition 45.10.

Derivation. *Derives Phenomenon 45.12.*

In a geometrically thin, optically thick disc (Chapter 50 for the observational side) the gas drifts inward through a sequence of nearly circular orbits, each lasting many orbital periods, so its specific energy at radius r is Equation (45.15); the difference from c^2 has been carried away by radiation. The drift ends at r_{ISCO}: inside, no stable circular orbit exists (Equation (45.16)), and the remaining infall to the horizon is dynamical, too fast to radiate efficiently, so the energy still aboard is advected in. The radiated fraction is therefore the binding energy at the innermost stable orbit,

$$\varepsilon = 1 - \frac{\mathcal{E}\left(r_{\mathrm{ISCO}}\right)}{c^2} = 1 - \sqrt{\frac{8}{9}} = 0.0572\,,$$

which is Equation (45.18). For a rotating hole the co-rotating ISCO moves inward — to GM/c^2 in the extremal limit — and the same computation on the Kerr geometry gives binding energies up to $1 - 1/\sqrt{3} = 0.42$; those orbits are catalogued in [1464], and the spin dependence is taken up in Section 45.5.1. □

45.2.3 Null geodesics: deflection and delay

Light follows null geodesics, for which proper time is unavailable; let λ be an affine parameter with dimensions of length and define the conserved quantities

$$E := \left(1 - \frac{r_{\mathrm{s}}}{r}\right) c\,\frac{\mathrm{d}t}{\mathrm{d}\lambda}\,, \qquad L := r^2\,\frac{\mathrm{d}\varphi}{\mathrm{d}\lambda} \tag{45.19}$$

for an equatorial ray (E dimensionless, L a length; both are the constants of Proposition 13.141 in convenient normalizations). The null condition $g_{\mu\nu}\,\mathrm{d}x^\mu \mathrm{d}x^\nu = 0$, treated exactly as in the derivation of Proposition 45.6, gives the first integral

$$\left(\frac{\mathrm{d}r}{\mathrm{d}\lambda}\right)^2 = E^2 - \frac{L^2}{r^2}\left(1 - \frac{r_{\mathrm{s}}}{r}\right)\,. \tag{45.20}$$

Passing to $u = 1/r$ as in Proposition 45.8,

$$\left(\frac{\mathrm{d}u}{\mathrm{d}\varphi}\right)^2 + u^2 = \frac{E^2}{L^2} + r_{\mathrm{s}}u^3 \qquad \Longrightarrow \qquad \frac{\mathrm{d}^2u}{\mathrm{d}\varphi^2} + u = \frac{3GM}{c^2}\,u^2\,, \tag{45.21}$$

the orbit equation Equation (45.12) with the mass term absent — it came from the rest mass. As $r \to \infty$ the first form of Equation (45.21) degenerates to $(\mathrm{d}u/\mathrm{d}\varphi)^2 + u^2 = E^2/L^2$, whose straight-line solution passes the centre at perpendicular distance

$$b = \frac{L}{E}\,, \tag{45.22}$$

the *impact parameter*: the ratio of the two conserved quantities is the one geometric datum a distant observer can assign to a ray.

Remark 45.13 (Light deflection at the formula level). Solving Equation (45.21) perturbatively about the straight line $u_0 = \sin\varphi/b$ shifts the two asymptotes of the ray and bends it, for $b \gg r_\mathrm{s}$, through

$$\Delta\vartheta = \frac{4GM}{c^2 b}\,,$$

which is Equation (53.3). The computation — and the observational history from the 1919 eclipse through modern radio interferometry, where the formula is confirmed to a part in 10^4 — is carried out in full in Chapter 53 (derivation of Phenomenon 53.2), taking Equation (45.21) from this chapter as its input [465]. Half the value comes from the equivalence principle alone; the other half is the spatial curvature visible in Equation (45.23) below.

Proposition 45.14 (Isotropic coordinates)**.** *The substitution* $r = \rho\,(1 + r_\mathrm{s}/(4\rho))^2$ *brings Equation* (45.6) *to the isotropic form*

$$\mathrm{d}s^2 = -\left(\frac{1 - r_\mathrm{s}/(4\rho)}{1 + r_\mathrm{s}/(4\rho)}\right)^2 c^2\mathrm{d}t^2 + \left(1 + \frac{r_\mathrm{s}}{4\rho}\right)^4 \left(\mathrm{d}\rho^2 + \rho^2\mathrm{d}\Omega^2\right)\,, \tag{45.23}$$

whose spatial part is conformally flat. To first order in r_s/ρ *it reads* $\mathrm{d}s^2 \simeq -\,(1 - r_\mathrm{s}/\rho)\,c^2\mathrm{d}t^2 + (1 + r_\mathrm{s}/\rho)\,(\mathrm{d}\rho^2 + \rho^2\mathrm{d}\Omega^2)$.

Rests on Theorem 45.1.

Derivation. *Derives Proposition 45.14.*

Write $x := r_\mathrm{s}/(4\rho)$. Differentiating the substitution, $\mathrm{d}r = (1 + x)\,(1 - x)\,\mathrm{d}\rho$, and a two-line computation gives

$$1 - \frac{r_\mathrm{s}}{r} = \frac{(1 + x)^2 - r_\mathrm{s}/\rho}{(1 + x)^2} = \left(\frac{1 - x}{1 + x}\right)^2\,.$$

Hence $(1 - r_\mathrm{s}/r)^{-1}\,\mathrm{d}r^2 = (1 + x)^4\,\mathrm{d}\rho^2$ and $r^2\mathrm{d}\Omega^2 = (1 + x)^4\,\rho^2\mathrm{d}\Omega^2$: every spatial term acquires the same conformal factor, which is Equation (45.23). Expanding $((1 - x)/(1 + x))^2 \simeq 1 - 4x$ and $(1 + x)^4 \simeq 1 + 4x$ gives the first-order form. □

Remark 45.15 (The Shapiro delay at the formula level). In the isotropic form the coordinate speed of light is isotropic and equals $c\,(1 - r_\mathrm{s}/\rho)$ to first order — one factor from time dilation, one from spatial curvature. Integrating the deficit along a straight path between radii r_1 and r_2 passing the mass at distance b gives the round-trip excess delay

$$\Delta t = \frac{4GM}{c^3}\ln\!\left(\frac{4r_1 r_2}{b^2}\right)\,,$$

which is Equation (53.5), proposed by Shapiro as the fourth classical test [1296]. The integration, and the radar and spacecraft measurements that verify it — now at the 2×10^{-5} level via the Cassini link — are in Chapter 53 (derivation of Phenomenon 53.4), which starts from Equation (45.23).

45.3 The horizon

45.3.1 Coordinate and curvature singularities

At $r = r_{\mathrm{s}}$ the metric component g_{rr} of Equation (45.6) diverges and g_{tt} vanishes. Whether anything physical diverges there is a question the coordinates cannot answer; curvature invariants can, because they are scalars.

Proposition 45.16 (Curvature at the horizon and at the centre)**.** *In the orthonormal frame of a static observer the nonvanishing components of the Riemann tensor of Equation* (45.6) *are*

$$R_{\hat{0}\hat{r}\hat{0}\hat{r}} = -\frac{r_{\mathrm{s}}}{r^3}\,, \quad R_{\hat{0}\hat{\theta}\hat{0}\hat{\theta}} = R_{\hat{0}\hat{\varphi}\hat{0}\hat{\varphi}} = \frac{r_{\mathrm{s}}}{2r^3}\,, \quad R_{\hat{r}\hat{\theta}\hat{r}\hat{\theta}} = R_{\hat{r}\hat{\varphi}\hat{r}\hat{\varphi}} = -\frac{r_{\mathrm{s}}}{2r^3}\,, \quad R_{\hat{\theta}\hat{\varphi}\hat{\theta}\hat{\varphi}} = \frac{r_{\mathrm{s}}}{r^3}\,, \tag{45.24}$$

(up to index symmetries), so the Kretschmann scalar is

$$R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} = 4\left[1+\frac{1}{4}+\frac{1}{4}+\frac{1}{4}+\frac{1}{4}+1\right]\frac{r_{\mathrm{s}}^2}{r^6} = \frac{12\,r_{\mathrm{s}}^2}{r^6} = \frac{48\,G^2M^2}{c^4r^6}\,. \tag{45.25}$$

It is finite at $r = r_{\mathrm{s}}$ and diverges only at $r = 0$: the horizon is a coordinate singularity, the centre a curvature singularity.

Rests on Theorem 45.1 and Equation (13.306).

Derivation. *Derives Proposition 45.16.*

Mechanical evaluation of Equation (13.306) on Equation (45.2) with $\mathrm{e}^{2\alpha} = \mathrm{e}^{-2\beta} = 1 - r_{\mathrm{s}}/r$, followed by projection onto the orthonormal frame $\hat{e}_0 = (1-r_{\mathrm{s}}/r)^{-1/2}\,c^{-1}\partial_t$, $\hat{e}_r = (1-r_{\mathrm{s}}/r)^{1/2}\partial_r$, $\hat{e}_\theta = r^{-1}\partial_\theta$, $\hat{e}_\varphi = (r\sin\theta)^{-1}\partial_\varphi$, gives Equation (45.24). In the contraction each of the six independent pair components enters with multiplicity four and, in an orthonormal frame, with a positive square, which is the bracket in Equation (45.25). □

Remark 45.17 (Tides at the horizon can be gentle). By geodesic deviation (Equation (43.3)) the frame components Equation (45.24) are tidal accelerations per unit separation: radial stretching $2GM/r^3$, transverse compression GM/r^3, in exact correspondence with the Newtonian tidal tensor $\partial_i\partial_j\Phi$ — and finite at the horizon, where they equal $2GM/r_{\mathrm{s}}^3 = c^6/(4G^2M^2)$ radially. The scale *falls* with mass: for $M = M_\odot$ it is $1.0\times10^{10}/\mathrm{s}^2$ — an infalling body is shredded long before reaching the horizon — while for the $4.3\times10^6\,M_\odot$ object at the Galactic centre it is $5.6\times10^{-4}/\mathrm{s}^2$, milder than the tide in a fast elevator. Locally the horizon of a large black hole is unremarkable; what distinguishes it is global, as the next construction shows.

The diagnosis of $r = r_{\mathrm{s}}$ as an artefact is completed by exhibiting coordinates regular there. Define the *tortoise coordinate* and the *advanced time*

$$r_* := r + r_{\mathrm{s}}\ln\left|\frac{r}{r_{\mathrm{s}}} - 1\right|\,, \qquad v := ct + r_*\,, \tag{45.26}$$

so that $\mathrm{d}r_* = (1-r_{\mathrm{s}}/r)^{-1}\,\mathrm{d}r$ and ingoing radial light rays are $v = \text{const}$. Substituting $c\,\mathrm{d}t = \mathrm{d}v - \mathrm{d}r_*$ into Equation (45.6),

$$\mathrm{d}s^2 = -\left(1-\frac{r_{\mathrm{s}}}{r}\right)\mathrm{d}v^2 + 2\,\mathrm{d}v\,\mathrm{d}r + r^2\mathrm{d}\Omega^2\,, \tag{45.27}$$

the *ingoing Eddington–Finkelstein form*: every component is regular for all $r > 0$, and the determinant $g = -r^4\sin^2\theta$ never vanishes there. The coordinate v was introduced by Eddington [510], its meaning recognized by Lemaître [723] and sharpened by Finkelstein [1145].

Proposition 45.18 (The one-way membrane)**.** *In the geometry Equation (45.27), every future-directed causal curve at $r \le r_{\mathrm{s}}$ has $\mathrm{d}r \le 0$, with equality only for radial null curves on $r = r_{\mathrm{s}}$ itself. The surface $r = r_{\mathrm{s}}$ is a null hypersurface that can be crossed inward but not outward: the* event horizon*.*

Rests on Theorem 45.1.

Derivation. *Derives Proposition 45.18.*

Radial null directions of Equation (45.27) satisfy $\mathrm{d}v\,[(1 - r_{\mathrm{s}}/r)\,\mathrm{d}v - 2\,\mathrm{d}r] = 0$: either $\mathrm{d}v = 0$, the ingoing family, along which r strictly decreases toward the future; or $\mathrm{d}r/\mathrm{d}v = \frac{1}{2}(1 - r_{\mathrm{s}}/r)$, the would-be outgoing family — positive outside the horizon, zero on it, *negative* inside. A causal curve lies inside or on the local light cone spanned by the two, so inside the horizon both bounding directions, and hence every causal direction, have $\mathrm{d}r < 0$. On $r = r_{\mathrm{s}}$ the normal $n_\mu = \partial_\mu (r - r_{\mathrm{s}})$ has $n^\mu n_\mu = g^{rr} = 1 - r_{\mathrm{s}}/r = 0$: the surface is null, generated by the marginally outgoing rays that run along it forever. □

Nothing locally distinguishes the horizon — the curvature there is finite and can be arbitrarily small (Remark 45.17) — and no signal sent from inside ever reaches a distant observer. The horizon is a *globally* defined surface: the boundary of the region from which future null infinity cannot be reached [1504]. Inside it the roles of r and t interchange — $g_{rr} < 0$, $g_{tt} > 0$ in Equation (45.6) — so decreasing r is there a direction in *time*: reaching $r = 0$ is as unavoidable as reaching tomorrow.

45.3.2 The Kruskal–Szekeres extension

Eddington–Finkelstein coordinates extend the exterior across the future horizon. The *maximal* analytic extension, found independently by Kruskal and Szekeres [1185, 1194], is reached by one further exponential substitution.

Proposition 45.19 (Kruskal–Szekeres coordinates)**.** *On the exterior $r > r_{\mathrm{s}}$ define null coordinates $u := ct - r_*$, $v := ct + r_*$ and*

$$U := -\mathrm{e}^{-u/(2r_{\mathrm{s}})}\,, \qquad V := \mathrm{e}^{v/(2r_{\mathrm{s}})}\,, \qquad T := \frac{U+V}{2}\,, \qquad X := \frac{V-U}{2}\,. \tag{45.28}$$

Then

$$\mathrm{d}s^2 = \frac{4r_{\mathrm{s}}^3}{r}\,\mathrm{e}^{-r/r_{\mathrm{s}}}\left(-\mathrm{d}T^2 + \mathrm{d}X^2\right) + r^2\mathrm{d}\Omega^2\,, \tag{45.29}$$

with $r(T,X) > 0$ determined implicitly by

$$X^2 - T^2 = \left(\frac{r}{r_{\mathrm{s}}} - 1\right)\mathrm{e}^{r/r_{\mathrm{s}}}\,, \qquad \frac{T}{X} = \tanh\frac{ct}{2r_{\mathrm{s}}} \quad \textit{(region } X > |T|\,)\,. \tag{45.30}$$

The metric Equation (45.29) is regular on the whole domain $T^2 - X^2 < 1$, which is the maximal analytic extension of the Schwarzschild geometry.

Rests on Theorem 45.1.

Derivation. *Derives Proposition 45.19.*

In null coordinates the (t,r) block of Equation (45.6) is $-(1 - r_{\mathrm{s}}/r)\,\mathrm{d}u\,\mathrm{d}v$. From Equation (45.28),

$$\mathrm{d}U\,\mathrm{d}V = \frac{1}{4r_{\mathrm{s}}^2}\,\mathrm{e}^{(v-u)/(2r_{\mathrm{s}})}\,\mathrm{d}u\,\mathrm{d}v = \frac{1}{4r_{\mathrm{s}}^2}\,\mathrm{e}^{r_*/r_{\mathrm{s}}}\,\mathrm{d}u\,\mathrm{d}v\,,$$

and by Equation (45.26), $\mathrm{e}^{r_*/r_{\mathrm{s}}} = (r/r_{\mathrm{s}} - 1)\,\mathrm{e}^{r/r_{\mathrm{s}}}$ outside the horizon. Hence

$$-\left(1 - \frac{r_{\mathrm{s}}}{r}\right)\mathrm{d}u\,\mathrm{d}v = -\left(1 - \frac{r_{\mathrm{s}}}{r}\right)\frac{4r_{\mathrm{s}}^2\,\mathrm{e}^{-r/r_{\mathrm{s}}}}{r/r_{\mathrm{s}} - 1}\,\mathrm{d}U\,\mathrm{d}V = -\frac{4r_{\mathrm{s}}^3}{r}\,\mathrm{e}^{-r/r_{\mathrm{s}}}\,\mathrm{d}U\,\mathrm{d}V\,,$$

since $(1-r_{\mathrm{s}}/r)\,/\,(r/r_{\mathrm{s}}-1) = r_{\mathrm{s}}/r$. Rewriting $\mathrm{d}U\,\mathrm{d}V$ in (T,X) gives Equation (45.29); the identities $UV = T^2 - X^2$ and $UV = -\mathrm{e}^{r_*/r_{\mathrm{s}}}$ give the first of Equation (45.30), and $-V/U = \mathrm{e}^{ct/r_{\mathrm{s}}}$ the second. The right-hand side of Equation (45.30) is a monotonic function of r mapping $(0,\infty)$ onto $(-1,\infty)$, so r is well defined and positive exactly where $X^2 - T^2 > -1$, and the conformal factor in Equation (45.29) is analytic and nonzero there. The extension is maximal because every geodesic either runs to infinite affine parameter or ends on the curvature singularity $T^2 - X^2 = 1$, i.e. $r = 0$ (Proposition 45.16). □

Remark 45.20 (Anatomy of the extended geometry). The two lines $T = \pm X$ divide the domain into four wedges. Region I ($X > |T|$) is the original exterior, with static observers on hyperbolae of constant $X^2 - T^2$ and constant-t lines through the origin. Region II ($T > |X|$) is the black-hole interior: every future-directed causal curve entering it ends on the singularity $T = \sqrt{1+X^2}$, the interior statement of Proposition 45.18. Region III ($T < -|X|$) is the time-reverse — a *white hole*, out of which everything must pass — and region IV ($X < -|T|$) is a second asymptotically flat exterior, causally disconnected from region I: the two are joined only through the spacelike "throat", and no causal curve crosses from one to the other. The conformal compactification of this diagram is the prototype Penrose diagram [1509]. Regions III and IV are artefacts of exact vacuum eternity: in a black hole formed by collapse the matter's interior occupies the part of the diagram where they would lie, and only regions I and II survive (Section 45.4.1). The white hole and the second universe are not predictions about Nature; the black hole is.

45.4 Gravitational collapse

45.4.1 Oppenheimer–Snyder collapse

The simplest collapse that can be followed exactly is a uniform ball of pressureless dust [844]. Outside, spherical symmetry forces the geometry to be Schwarzschild (Theorem 45.4); the surface of the ball falls along a radial timelike geodesic, so the first computation is radial free fall.

Proposition 45.21 (Radial plunge: the cycloid)**.** *A test particle released from rest at $r = R_0$ falls along the cycloid*

$$r = \frac{R_0}{2}\,(1+\cos\eta)\,, \qquad \tau = \sqrt{\frac{R_0^3}{8GM}}\,(\eta+\sin\eta)\,, \tag{45.31}$$

reaching $r = 0$ at the finite proper time

$$\tau_{\mathrm{collapse}} = \pi\sqrt{\frac{R_0^3}{8GM}}\,, \tag{45.32}$$

identical to the Newtonian free-fall time from the same radius. The horizon is crossed strictly earlier, also at finite proper time.

Rests on Proposition 45.6.

Derivation. *Derives Proposition 45.21.*

Set $L = 0$ in Proposition 45.6; release from rest at R_0 fixes $\mathcal{E} = c^2\sqrt{1 - r_{\mathrm{s}}/R_0}$, so

$$\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2 = \frac{\mathcal{E}^2}{c^2} - c^2\left(1-\frac{r_{\mathrm{s}}}{r}\right) = c^2 r_{\mathrm{s}}\left(\frac{1}{r}-\frac{1}{R_0}\right) = 2GM\left(\frac{1}{r}-\frac{1}{R_0}\right).$$

This is *exactly* the Newtonian energy equation — the relativistic corrections have been absorbed into the meaning of r and τ — and the substitution Equation (45.31) solves it:

$$\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2 = \frac{(R_0^2/4)\sin^2\eta}{(R_0^3/8GM)\,(1+\cos\eta)^2} = \frac{2GM}{R_0}\cdot\frac{1-\cos\eta}{1+\cos\eta} = 2GM\left(\frac{1}{r}-\frac{1}{R_0}\right),$$

using $\sin^2\eta = (1-\cos\eta)(1+\cos\eta)$ and $R_0/r = 2/(1+\cos\eta)$. The collapse time is $\eta = \pi$ in Equation (45.31); since $r = r_\mathrm{s}$ is reached at some $\eta < \pi$, the horizon crossing is earlier and finite. For a ball of one solar mass released from the Sun's present radius, Equation (45.32) gives $\tau_\mathrm{collapse} = 1.8 \times 10^3\,\mathrm{s}$ — half an hour of proper time from star to singularity. □

Proposition 45.22 (The view from outside: exponential freezing)**.** *To a distant static observer the same infall never ends: the areal radius of the falling surface asymptotes to r_s, and light received from it at late observer time t is redshifted as*

$$1 + z \;\propto\; \exp\!\left(\frac{ct}{2r_\mathrm{s}}\right) = \exp\!\left(\frac{c^3 t}{4GM}\right), \tag{45.33}$$

an e-folding time $4GM/c^3 = 2.0 \times 10^{-5}\,\mathrm{s}$ per solar mass. The luminosity dies on the same timescale: within milliseconds a stellar collapse is, observationally, black.

Rests on Proposition 45.21 and Remark 45.3.

Derivation. *Derives Proposition 45.22.*

Near the horizon write $r = r_\mathrm{s}(1+\epsilon)$, $\epsilon \ll 1$. Dividing the radial equation of Proposition 45.21 by $\mathrm{d}t/\mathrm{d}\tau = \mathcal{E}/(c^2(1-r_\mathrm{s}/r))$ gives $\mathrm{d}r/\mathrm{d}t \simeq -c\,(1-r_\mathrm{s}/r) \simeq -c\,\epsilon$ as $\epsilon \to 0$ (the remaining factors tend to constants), so $r_\mathrm{s}\,\mathrm{d}\epsilon/\mathrm{d}t \simeq -c\,\epsilon$ and $\epsilon \propto \mathrm{e}^{-ct/r_\mathrm{s}}$: the surface approaches the horizon exponentially in coordinate time and never crosses it at any finite t.

For the redshift, compound two factors at emission radius r. Relative to the static observer there, the faller has Lorentz factor $\gamma = -g_{\mu\nu}u^\mu_\mathrm{fall}u^\nu_\mathrm{stat}/c^2 = \mathcal{E}/(c^2\sqrt{1-r_\mathrm{s}/r}) \propto \epsilon^{-1/2}$, so light it emits radially outward is Doppler-shifted by $\sqrt{(1-v/c)/(1+v/c)} \simeq 1/(2\gamma) \propto \sqrt{\epsilon}$; climbing out then costs the gravitational factor $\sqrt{1-r_\mathrm{s}/r} \simeq \sqrt{\epsilon}$ (Equation (45.8)). The received frequency is suppressed by the product, of order ϵ. Finally, the outgoing photon spends a coordinate time $\simeq (r_\mathrm{s}/c)\ln(1/\epsilon)$ escaping the near zone (integrating $\mathrm{d}t = \mathrm{d}r_*/c$), which at $\epsilon \propto \mathrm{e}^{-ct_\mathrm{em}/r_\mathrm{s}}$ doubles the elapsed time: $t \simeq 2t_\mathrm{em}$. Hence $1+z \propto \epsilon^{-1} \propto \mathrm{e}^{ct_\mathrm{em}/r_\mathrm{s}} = \mathrm{e}^{ct/(2r_\mathrm{s})}$, which is Equation (45.33); with $M = M_\odot$, $2r_\mathrm{s}/c = 1.97 \times 10^{-5}\,\mathrm{s}$. The luminosity, proportional to the received photon rate times the energy per photon, falls at least as fast. □

The interior completes the picture, and its computation is the matching of two exact solutions along the falling surface.

Theorem 45.23 (Oppenheimer–Snyder collapse)**.** *Let a uniform, pressureless, momentarily static ball of dust of mass M and initial areal radius $R_0 > r_\mathrm{s}$ collapse under its own gravity. Then: (i) the interior geometry is a portion $0 \le \chi \le \chi_0$ of a closed matter-dominated Friedmann–Lemaître–Robertson–Walker spacetime (Chapter 48),*

$$\mathrm{d}s^2 = -c^2\mathrm{d}\tau^2 + a^2(\tau)\left[\mathrm{d}\chi^2 + \sin^2\chi\,\mathrm{d}\Omega^2\right], \tag{45.34}$$

whose scale factor traverses the collapsing half of the dust cycloid; (ii) the exterior is the Schwarzschild geometry Equation (45.6), and the two match smoothly across the surface — induced metric and extrinsic curvature both continuous — iff

$$R_0 = a_\mathrm{m}\sin\chi_0\,, \qquad r_\mathrm{s} = a_\mathrm{m}\sin^3\chi_0\,, \tag{45.35}$$

with a_m the initial (maximal) scale factor; equivalently $M = \frac{4}{3}\pi\rho_0 R_0^3$ with ρ_0 the initial density — the Schwarzschild mass is exactly the Newtonian mass of the ball; (iii) every dust particle reaches the central singularity at the same finite proper time $\tau = \pi a_\mathrm{m}/(2c)$, the surface crossing the horizon strictly earlier, while a distant observer sees the exponential freezing of Proposition 45.22.

Rests on Theorem 45.4 and Proposition 45.21.

Full derivation: Appendix A.2 (p. 2771).
Derives Theorem 45.23.

Phenomenon 45.24 (Compact objects exist above every cold-support limit)**.** Dark objects are observed with masses far above the maximum that any cold equation of state consistent with causality can hold up. X-ray binaries yield dynamical masses between about $5\,M_\odot$ and $20\,M_\odot$ for the accreting component [2103], and the gravitational-wave merger catalogue reaches tens of solar masses [2264, 2324], against a neutron-star maximum bounded near $3\,M_\odot$ (Chapter 49). No equilibrium configuration is available to such objects, and the idealized collapse of a pressureless homogeneous ball ends at a horizon after finite proper time on the infalling matter, while a distant observer sees the surface asymptote to r_s with exponentially growing redshift and never quite arrive [844]. The observational record of these objects is Chapter 50.
Rests on Theorems 45.23 and 45.27 and Proposition 45.22.

Derivation. *Derives Phenomenon 45.24.*
The absence of equilibria above the maximum mass is the structure theory of Chapter 49. Given that, the collapse statements are Proposition 45.21 (finite proper time to horizon and singularity), Proposition 45.22 (exponential fading and freezing outside), and Theorem 45.23 (the complete interior–exterior solution, proved in Appendix A.2). The idealization — exact sphericity, zero pressure — is dispensable: once the surface is inside r_s, trapped surfaces exist (Remark 45.26), and Theorem 45.27 makes the singular outcome generic, independent of symmetry. What no theorem supplies is the horizon itself in the general case; that is the censorship conjecture of Section 45.4.3. □

45.4.2 The singularity theorems

Is the singularity an artefact of exact spherical symmetry — all the matter aimed at one point? Penrose's 1965 theorem [1319], for which the 2020 Nobel prize in physics was awarded, says no: what forces it is not symmetry but a trapped surface, and trapped surfaces are stable under perturbations.

Definition 45.25 (Trapped surface)**.** Let S be a closed spacelike 2-surface. Through each point of S run two future-directed families of null geodesics orthogonal to S — outgoing and ingoing — and let $\theta_\pm$ be their expansions: the fractional rate of change of the area element dragged along each family. S is *trapped* when both $\theta_+ < 0$ and $\theta_- < 0$: even the outgoing light front loses area. In flat spacetime every round sphere has $\theta_+ > 0$; trapping is the statement that gravity has bent the outgoing light cone back onto itself.

Remark 45.26 (Collapse produces trapped surfaces). In the Eddington–Finkelstein geometry Equation (45.27), consider the sphere $(v, r) = \text{const}$ with $r < r_\mathrm{s}$. The two orthogonal null families are those of Proposition 45.18: the ingoing rays have $\mathrm{d}r < 0$, and the "outgoing" ones have $\mathrm{d}r/\mathrm{d}v = \frac{1}{2}(1 - r_\mathrm{s}/r) < 0$ as well. Since the area is $4\pi r^2$, both expansions are negative: every sphere inside the horizon is trapped. In the Oppenheimer–Snyder spacetime the exterior is exactly this geometry once the surface has passed r_s (Theorem 45.23), so trapped surfaces form in finite proper time — and they persist under any sufficiently small perturbation of the initial data, because $\theta_\pm < 0$ are open conditions.

Theorem 45.27 (Penrose; imported)**.** *Let (M, g) satisfy the null convergence condition $R_{\mu\nu}k^\mu k^\nu \geq 0$ for every null vector k — which the field equations translate into the null energy condition on matter (Section 44.8) — and contain a noncompact Cauchy hypersurface (a spacelike hypersurface met exactly once by every inextendible causal curve). If M contains a trapped surface, then M is future null geodesically incomplete: some outgoing light ray ends at finite affine parameter [1319].*
Rests on Definition 45.25.

Theorem 45.28 (Hawking–Penrose; imported)**.** *Let (M, g) satisfy the timelike and null convergence conditions (strong energy condition via the field equations, Section 44.8), the generic condition (every causal geodesic feels some curvature), and contain no closed timelike curves. If in addition it contains a trapped surface, or a compact achronal hypersurface, or a point whose past light cone starts reconverging, then M contains at least one incomplete timelike or null geodesic [1425].*

Rests on Definition 45.25.

Remark 45.29 (Status of the proofs, and what "singularity" means). Both proofs are global variational arguments — Raychaudhuri focusing plus a topological obstruction — and belong to mathematics; the standard complete accounts are [1319, 1425] and the monograph [1504], and this treatise imports them. What the theorems deliver is deliberately weak: *geodesic incompleteness*, a freely falling history that cannot be continued, not a place of infinite curvature — though in every explicitly known collapse solution the incompleteness is accompanied by divergent curvature, as in Proposition 45.16. Their hypotheses matter: quantum fields violate the pointwise energy conditions (Chapter 109), which is one reason the theorems say nothing about what replaces the singularity, a question quarantined to Chapter 135. The cosmological instance of Theorem 45.28 — the universe's own past incompleteness — belongs to Chapter 48.

45.4.3 Cosmic censorship

The singularity theorems guarantee incompleteness; they do not guarantee a horizon around it. The *weak cosmic censorship conjecture* [1405] asserts that, for generic asymptotically flat initial data with physically reasonable matter, the singularities of gravitational collapse are hidden behind event horizons — no "naked" singularity is visible from infinity, and the exterior remains predictable. Despite half a century of effort it remains a conjecture: no proof exists, and the fine-tuned counterexamples known (critical collapse, certain non-generic dust configurations) are exactly the non-generic cases the conjecture excludes. This treatise therefore treats censorship as a working hypothesis, not a result: it underwrites the astrophysical use of the Kerr geometry below, it is what the area theorem (Theorem 45.47) assumes, and its only observational support to date is indirect — every measured compact-object spin respects the Kerr bound (Phenomenon 45.35). The honest accounting of its status sits with the other open problems in Chapter 133.

45.5 Rotating and charged black holes

45.5.1 The Kerr solution

Astrophysical bodies rotate, and their collapse remnants must carry angular momentum. The stationary axisymmetric vacuum solution that describes them was found by Kerr [1259]; no elementary route to it exists, and its derivation is imported — Kerr's own, via algebraically special metrics, and the systematic construction in [1717].

Theorem 45.30 (Kerr solution; imported)**.** *For each mass M and angular momentum J, define*

$$a := \frac{J}{Mc}\,, \qquad \Sigma := r^2 + a^2\cos^2\theta\,, \qquad \Delta := r^2 - r_{\mathrm{s}} r + a^2\,. \tag{45.36}$$

The metric, in the coordinates of Boyer and Lindquist [1342],

$$\begin{aligned} \mathrm{d}s^2 = &-\left(1 - \frac{r_{\mathrm{s}} r}{\Sigma}\right) c^2 \mathrm{d}t^2 - \frac{2 r_{\mathrm{s}} r\, a \sin^2\theta}{\Sigma}\, c\,\mathrm{d}t\,\mathrm{d}\varphi + \frac{\Sigma}{\Delta}\,\mathrm{d}r^2 + \Sigma\,\mathrm{d}\theta^2 \\ &+ \left(r^2 + a^2 + \frac{r_{\mathrm{s}} r\, a^2 \sin^2\theta}{\Sigma}\right) \sin^2\theta\,\mathrm{d}\varphi^2\,, \end{aligned} \tag{45.37}$$

is a stationary, axisymmetric, asymptotically flat solution of the vacuum field equations [1259, 1342]. At $a = 0$ it reduces to Equation (45.6); at $M = 0$ it is flat spacetime in spheroidal coordinates; at large r its $g_{t\varphi}$ identifies J as the source's angular momentum.
Rests on Theorem 45.1.

That Equation (45.37) solves $R_{\mu\nu} = 0$ is a finite mechanical verification; the discovery was finding it. Its properties, by contrast, are derivable in a few lines each, and they are the physics.

Proposition 45.31 (Horizons and the extremal bound)**.** *The surfaces $\Delta = 0$, at*

$$r_{\pm} = \frac{GM}{c^2} \pm \sqrt{\left(\frac{GM}{c^2}\right)^2 - a^2}\,, \tag{45.38}$$

are null hypersurfaces; r_+ is the event horizon. They exist iff $|a| \le GM/c^2$, i.e. iff the dimensionless spin $\chi = cJ/(GM^2) = ac^2/(GM)$ satisfies $|\chi| \le 1$; at $|\chi| = 1$ (the extremal *hole) the two coincide, and for $|\chi| > 1$ the metric has no horizon at all — its ring singularity at $\Sigma = 0$ would be naked.*
Rests on Theorem 45.30.

Derivation. *Derives Proposition 45.31.*
$\Delta = r^2 - r_{\mathrm{s}} r + a^2$ is a quadratic in r with roots Equation (45.38), real iff $(r_{\mathrm{s}}/2)^2 \ge a^2$, which is $|a| \le GM/c^2$. A surface of constant r has normal $n_\mu = \partial_\mu r$ with norm $g^{\mu\nu} n_\mu n_\nu = g^{rr} = \Delta/\Sigma$, which vanishes exactly on $\Delta = 0$: those surfaces are null, hence one-way membranes for causal curves exactly as in Proposition 45.18. Curvature invariants diverge only on $\Sigma = 0$ — the equatorial ring $r = 0$, $\theta = \pi/2$ — so $r_\pm$ are coordinate singularities removable by Eddington–Finkelstein-type coordinates. With $a = \chi GM/c^2$, the reality condition is $|\chi| \le 1$. □

Proposition 45.32 (Static limit, ergosphere and frame dragging)**.** *(i) Static observers (fixed r, θ, φ) exist only outside the* static limit

$$r_E(\theta) = \frac{GM}{c^2} + \sqrt{\left(\frac{GM}{c^2}\right)^2 - a^2 \cos^2\theta}\,, \tag{45.39}$$

which lies outside r_+ everywhere except at the poles. In the ergosphere *$r_+ < r < r_E$ every observer is dragged around the hole. (ii) An observer with zero angular momentum orbits at*

$$\Omega(r,\theta) := \frac{\mathrm{d}\varphi}{\mathrm{d}t} = \frac{r_{\mathrm{s}} r\, a\, c}{\left(r^2 + a^2\right)^2 - a^2 \Delta \sin^2\theta}\,, \tag{45.40}$$

falling off at large r as $\Omega \simeq 2GJ/(c^2 r^3)$; on the horizon the dragging rate becomes uniform,

$$\Omega_{\mathrm{H}} = \frac{a\,c}{r_+^2 + a^2} = \frac{a\,c}{r_{\mathrm{s}} r_+}\,, \tag{45.41}$$

the angular velocity of the black hole.
Rests on Theorem 45.30.

Derivation. *Derives Proposition 45.32.*
(i) A static worldline has tangent $\propto \partial_t$, timelike iff $g_{tt} < 0$, i.e. $\Sigma > r_{\mathrm{s}} r$; the boundary $r^2 - r_{\mathrm{s}} r + a^2 \cos^2\theta = 0$ gives Equation (45.39), which exceeds r_+ of Equation (45.38) wherever $\sin\theta \neq 0$. Inside it ∂_t is spacelike: remaining at rest with respect to infinity would require moving faster than light against the dragging. (ii) Zero angular momentum means $u_\varphi = g_{\varphi t}\, u^t + g_{\varphi\varphi} u^\varphi = 0$, so $\Omega = u^\varphi/u^t = -g_{t\varphi}/g_{\varphi\varphi}$. Reading the components off Equation (45.37) and using the identity $\Sigma\,(r^2 + a^2) + r_{\mathrm{s}} r\, a^2 \sin^2\theta = \left(r^2 + a^2\right)^2 - a^2 \Delta \sin^2\theta$

gives Equation (45.40); the far-field fall-off follows from $r_s a\, c = 2GJ/c^2$. On $\Delta = 0$ the denominator is $(r_+^2 + a^2)^2$ and $r_s r_+ = r_+^2 + a^2$ (from $\Delta(r_+) = 0$), whence Equation (45.41), independent of θ: the horizon rotates rigidly. The weak-field limit of Equation (45.40) is the Lense–Thirring precession rate whose measurement by Gravity Probe B and lunar laser ranging is reported in Chapter 53. □

Remark 45.33 (The Penrose process). Inside the ergosphere the Killing energy $\mathcal{E} = -\xi_\mu u^\mu$ of a particle can be *negative*, because $\boldsymbol{\xi} = \partial_t$ is there spacelike. A body that splits in the ergosphere can therefore send one fragment into the hole with negative energy and eject the other to infinity with *more* energy than went in: rotational energy is extracted [1405]. The process cannot be repeated indefinitely — each extraction spins the hole down, and the bookkeeping of what is extractable is exactly the irreducible-mass inequality Equation (45.50), quantified in Section 45.6.1: at most $1 - 1/\sqrt{2} \approx 29\%$ of the mass–energy of an extremal hole. Its astrophysical descendants (magnetically mediated extraction from accreting holes) power the relativistic jets observed in Chapter 50.

Remark 45.34 (Carter's constant and integrability). The Kerr metric has only the two Killing vectors ∂_t and ∂_φ — two constants of motion where the Schwarzschild case, with its full rotation group, had three. Geodesic motion is nevertheless integrable: Carter found a fourth invariant by separating the Hamilton–Jacobi equation (Chapter 23, whose separability machinery, Section 23.2, is exactly what is applied) in Boyer–Lindquist coordinates [1366]. The invariant is quadratic in the momenta and derives from a rank-two Killing tensor (Definition 13.142) that is not a product of Killing vectors — the physically important instance of that definition, and a hidden symmetry with no isometry behind it. All Kerr geodesics used below (accretion orbits, photon rings, the spin-dependent ISCO of [1464]) rest on this integrability.

Phenomenon 45.35 (Astrophysical black holes rotate, and stay inside the Kerr bound)**.** The compact objects in accreting binaries and the remnants of gravitational-wave mergers carry angular momentum. Writing the dimensionless spin as

$$\chi := \frac{cJ}{GM^2}\,, \tag{45.42}$$

measured values are non-zero in many systems and in no case exceed $|\chi| = 1$, the value at which the two horizons of the Kerr solution merge and beyond which the solution has no horizon at all. The broad, gravitationally redshifted iron Kα line emitted by the inner accretion disc is one measurement channel [1911]; the remnant of the first detected binary merger, for which $\chi \approx 0.67$, is another [2264]. That the bound is respected wherever it has been tested is the only observational evidence bearing on cosmic censorship (Section 45.4.3).

Rests on Proposition 45.31.

Derivation. *Derives Phenomenon 45.35.*

The bound itself is Proposition 45.31: horizons exist iff $|\chi| \le 1$, the extremal case being the merger of $r_\pm$ at $r = GM/c^2$, so a measured $|\chi| > 1$ would mean either a naked singularity or a non-Kerr object — either way a violation of the framework whose consistency is being tested. The two channels lean on different parts of this chapter: the iron-line profile is set by the spin-dependent inner edge of the disc (Remark 45.36: the co-rotating ISCO sweeps from $6GM/c^2$ at $\chi = 0$ to GM/c^2 at $\chi = 1$, and the gravitational redshift Equation (45.8) from that edge is what broadens the line [1911]); the merger-remnant spin is inferred from the ringdown frequencies, whose dependence on (M, J) is Equation (45.45) below. Both are assembled, with their apparatus, in Chapter 50 and Chapter 47. □

Remark 45.36 (The spin-dependent ISCO). Repeating the circular-orbit analysis of Section 45.2.2 on Equation (45.37) — the computation, using Carter's integrability, is carried

out in [1464] and its results are imported here — gives an ISCO that depends on spin and on orbital sense: for co-rotating equatorial orbits it descends from $6GM/c^2$ at $\chi = 0$ to GM/c^2 at $\chi = 1$, while counter-rotating orbits retreat to $9GM/c^2$. The bounding energy rises correspondingly: the extremal co-rotating ISCO has $\mathcal{E} = c^2/\sqrt{3}$, so thin-disc accretion can radiate up to $1 - 1/\sqrt{3} = 0.42$ of the rest energy — the origin of the "toward 0.4" in Phenomenon 45.12, and the lever by which disc spectroscopy measures spin.

45.5.2 Charge: Reissner–Nordström and Kerr–Newman

Charge is the one other parameter a stationary black hole can carry (Section 45.5.3). The static charged solution was found within two years of Schwarzschild's [439, 457], and unlike Kerr's it is an exercise: the Schwarzschild derivation reruns with the Coulomb field's stress–energy as source.

Proposition 45.37 (Reissner–Nordström solution)**.** *The unique spherically symmetric, asymptotically flat solution of the Einstein–Maxwell equations with charge Q and mass M is*

$$\mathrm{d}s^2 = -f(r)\,c^2\mathrm{d}t^2 + f(r)^{-1}\mathrm{d}r^2 + r^2\mathrm{d}\Omega^2\,, \qquad f(r) = 1 - \frac{r_\mathrm{s}}{r} + \frac{r_Q^2}{r^2}\,, \tag{45.43}$$

with the radial Coulomb field $E = Q/(4\pi\epsilon_0 r^2)$ and the charge length

$$r_Q^2 := \frac{GQ^2}{4\pi\epsilon_0 c^4}\,. \tag{45.44}$$

Horizons sit at $r_\pm = r_\mathrm{s}/2 \pm \sqrt{r_\mathrm{s}^2/4 - r_Q^2}$, existing iff $r_Q \le r_\mathrm{s}/2$.

Rests on Theorem 45.1.

Derivation. *Derives Proposition 45.37.*

Spherical symmetry admits only a radial electrostatic field. The curved-space source-free Maxwell equations reduce, in the ansatz Equation (45.1) with $\alpha + \beta = 0$, to $\partial_r\,(r^2 E) = 0$ — the flux integral — so $E = Q/(4\pi\epsilon_0 r^2)$ exactly as in flat space. Its stress–energy is that of an electromagnetic field with energy density $u_\mathrm{em} = \epsilon_0 E^2/2$ (Section 60.4.2), radial tension equal to the energy density and isotropic transverse pressure: $T^0{}_0 = T^r{}_r = -u_\mathrm{em}$, $T^\theta{}_\theta = T^\varphi{}_\varphi = +u_\mathrm{em}$. Because $T^0{}_0 = T^r{}_r$, the combination that gave $\alpha + \beta = \text{const}$ in the proof of Theorem 45.1 does so again, and asymptotic flatness sets $\beta = -\alpha$. The tensor is traceless, so $R = 0$ and the field equations read $R_{\mu\nu} = (8\pi G/c^4)T_{\mu\nu}$; the $\theta\theta$ component becomes

$$\left(r\mathrm{e}^{2\alpha}\right)' = 1 - \frac{8\pi G}{c^4}\,r^2 u_\mathrm{em} = 1 - \frac{GQ^2}{4\pi\epsilon_0 c^4}\cdot\frac{1}{r^2}\,,$$

which integrates to $r\mathrm{e}^{2\alpha} = r - r_\mathrm{s} + r_Q^2/r$, i.e. Equation (45.43). The horizon condition $f = 0$ is a quadratic with the stated roots. □

Remark 45.38 (Kerr–Newman, and why charge is academic). The rotating charged solution — charge Q grafted onto Equation (45.37) by $\Delta \to r^2 - r_\mathrm{s} r + a^2 + r_Q^2$, with the accompanying electromagnetic field — was found by Newman and collaborators [1318] and is imported here; it completes the stationary family of Section 45.5.3. Astrophysically, charge is negligible by two crushing margins. For charge to matter geometrically requires $r_Q \sim r_\mathrm{s}/2$, i.e. $Q \sim \sqrt{4\pi\epsilon_0 G}\,M \approx 1.7 \times 10^{20}\,\mathrm{C}$ per solar mass. But a hole charged to just $Q_\mathrm{eq} = 4\pi\epsilon_0 G M m_\mathrm{p}/e \approx 1.5 \times 10^2\,\mathrm{C}$ per solar mass already attracts protons electrostatically as strongly as it does gravitationally: surrounding plasma neutralizes any astrophysical hole to about one part in 10^{18} of the geometrically relevant charge. Charge is therefore a logical parameter of the classification, not an observable of astronomy, and (M, J) is the observable list.

45.5.3 The no-hair theorems

Collapse is messy; its endpoint is not. The stationary states available to it are classified by uniqueness theorems of remarkable strength, and they are pure mathematics: this treatise imports them with hypotheses stated.

Theorem 45.39 (Israel; imported)**.** *A static, asymptotically flat vacuum spacetime whose event horizon is a connected, regular, non-degenerate closed 2-surface is isometric to the Schwarzschild solution Equation* (45.6)*; the horizon is then a round sphere. The electrovac counterpart, with Maxwell field, is Reissner–Nordström [1351, 1374].*

Rests on Theorem 45.1 and Proposition 45.37.

Theorem 45.40 (Carter–Robinson; imported)**.** *A stationary, axisymmetric, asymptotically flat vacuum spacetime, regular on and outside a connected non-degenerate event horizon, is a member of the two-parameter Kerr family Equation* (45.37)*, labelled by* (M, J) *with* $|\chi| < 1$*: Carter reduced the problem to two-parameter families [1443], Robinson closed it [1560]. With electromagnetism the endpoint is Kerr–Newman, labelled by* (M, J, Q) *[1697].*

Rests on Theorem 45.30.

Remark 45.41 (Hypotheses, and the honest perimeter)*.* Axisymmetry is not an extra assumption in the end: Hawking's rigidity theorem shows a stationary rotating black hole must be axisymmetric [1504] — though its original proof assumes analyticity of the metric, a technical gap still not closed in full generality. "Non-degenerate" excludes the extremal case $|\chi| = 1$, which needs and has separate treatment. And "vacuum or electrovac" is essential: with other matter — Yang–Mills fields, complex scalars with harmonic time dependence — stationary "hairy" solutions exist mathematically. None is known to be both stable and producible by collapse, and no observation requires one; within the matter content actually observed (Chapter 1's scope rule), the theorems say a stationary black hole is characterized *completely* by (M, J, Q), and astrophysically (Remark 45.38) by (M, J). Wheeler's slogan for this — "a black hole has no hair" — entered the literature through [1454]: every other memory of the progenitor (baryon number, magnetic moments, mountains, history) is radiated away in the ringdown.

Phenomenon 45.42 (Stationary black holes are two-parameter objects)**.** No stationary black hole has yet been observed to carry any property beyond a mass and an angular momentum. The sharpest test available is the ringdown of a merger remnant: for a Kerr hole the frequencies and damping times of the quasi-normal oscillations are fixed functions of M and J alone, so measuring two of them over-determines the remnant and any third measurement is a consistency check. The remnant of the first observed binary black-hole merger rings at the frequency and damping time predicted for a Kerr hole of the mass and spin inferred independently from the inspiral [2264], and the growing merger catalogue has produced no counterexample [2324].

Rests on Theorems 45.39 and 45.40.

Derivation. *Derives Phenomenon 45.42.*

The two-parameter character of the *spectrum* follows from the uniqueness theorems by dimensional analysis, with no wave computation at all. A perturbed remnant settles to Kerr (Theorem 45.40); its perturbations obey linear wave equations on the Kerr background with outgoing radiation at infinity and ingoing at the horizon, and those two boundary conditions make the frequency spectrum discrete and complex — damped resonances, the *quasi-normal modes* [1174, 1438]. The background carries exactly one dimensional scale, GM/c^3 (a time), and one dimensionless parameter, χ; therefore every mode must take the form

$$\omega_{n\ell m} = \frac{c^3}{GM}\, F_{n\ell m}(\chi) \ , \tag{45.45}$$

with $F_{n\ell m}$ *universal* dimensionless functions — computed once and for all, never fit per source. Their values are imported: for Schwarzschild the fundamental quadrupole mode is $\omega = (0.374 - 0.089\,\mathrm{i})\,c^3/(GM)$ [1438, 1717]. The test is then over-determination: one complex frequency (one f, one damping time) inverts Equation (45.45) for (M, χ); any second mode, or the (M, χ) inferred independently from the inspiral, must agree — and for GW150914, ringing at about 250 Hz with the mass and spin the inspiral gave, it does [2264]. A single confirmed extra parameter in the spectrum would falsify the uniqueness theorems' applicability to Nature. □

45.6 Black-hole mechanics

45.6.1 The four laws

Black holes obey mechanical laws with the exact structure of thermodynamics [1493]. The dictionary needs two quantities: the horizon area, and the surface gravity.

Proposition 45.43 (Static acceleration and surface gravity)**.** *A static observer at radius r in Equation (45.6) requires proper acceleration*

$$\mathrm{a}(r) = \frac{GM}{r^2}\left(1 - \frac{r_\mathrm{s}}{r}\right)^{-1/2}, \tag{45.46}$$

which diverges at the horizon. The redshifted acceleration — the force per unit mass an operator at infinity *must supply, holding the observer on an ideal massless tether — stays finite, and its horizon limit defines the* surface gravity*:*

$$\kappa := \lim_{r\to r_\mathrm{s}} \sqrt{1 - \frac{r_\mathrm{s}}{r}}\,\mathrm{a}(r) = \frac{GM}{r_\mathrm{s}^2} = \frac{c^4}{4GM}. \tag{45.47}$$

For Kerr the same construction on the horizon-generating Killing field $\partial_t + \Omega_\mathrm{H}\partial_\varphi$ gives

$$\kappa = \frac{c^2\,(r_+ - r_-)}{2\,(r_+^2 + a^2)}, \tag{45.48}$$

uniform over the horizon (the zeroth law); the Kerr evaluation is imported [1493, 1746].
Rests on Theorems 45.1 and 45.30.

Derivation. *Derives Proposition 45.43.*
The static four-velocity has $u^0 = c\,(1 - r_\mathrm{s}/r)^{-1/2}$ (normalization) and acceleration $a^\mu = u^\nu \nabla_\nu u^\mu$ with single nonvanishing component $a^r = \Gamma^r{}_{00}\,(u^0)^2$. From Equation (45.2) with $\mathrm{e}^{2\alpha} = 1 - r_\mathrm{s}/r$, $\Gamma^r{}_{00} = (r_\mathrm{s}/2r^2)\,(1 - r_\mathrm{s}/r)$, so $a^r = GM/r^2$ and the invariant magnitude is $\mathrm{a} = \sqrt{g_{rr}}\,a^r$, which is Equation (45.46). The tether argument for the redshift factor is the energy bookkeeping of Equation (45.8): work done at infinity is redshifted by $\sqrt{-g_{tt}}/c$ relative to work delivered locally. The limit is elementary. For the Schwarzschild check of Equation (45.48): $r_+ = r_\mathrm{s}$, $r_- = 0$, $a = 0$ gives $c^2/(2r_\mathrm{s}) = c^4/(4GM)$, agreeing with Equation (45.47). Numerically $\kappa = 1.5\times10^{13}\,\mathrm{m/s^2}$ for $M = M_\odot$, scaling as $1/M$ — enormous, yet the temperature it will buy in Section 45.6.2 is tens of nanokelvin. □

Lemma 45.44 (Horizon area)**.** *The area of the Kerr horizon is*

$$A = 4\pi\left(r_+^2 + a^2\right) = 8\pi\,\frac{GM}{c^2}\,r_+ \qquad \left(A = 4\pi r_\mathrm{s}^2 = \frac{16\pi G^2 M^2}{c^4}\ \text{at } a = 0\right). \tag{45.49}$$

Rests on Proposition 45.31.

Derivation. *Derives Lemma 45.44.*

On $r = r_+$, $t = \text{const}$ the induced metric from Equation (45.37) is $\Sigma_+ \mathrm{d}\theta^2 + \left((r_+^2 + a^2)^2 \sin^2\theta/\Sigma_+\right)\mathrm{d}\varphi^2$, writing $\Sigma_+ := \Sigma(r_+, \theta)$ and using the identity from the proof of Proposition 45.32 at $\Delta = 0$. Its area element is $(r_+^2 + a^2)\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\varphi$ — the Σ_+ factors cancel — so $A = 4\pi\,(r_+^2 + a^2)$, and $r_+^2 + a^2 = r_{\mathrm{s}} r_+$ gives the second form. □

Proposition 45.45 (Irreducible mass and the Christodoulou–Smarr mass formula)**.** *Define the* irreducible mass *by* $A =: 16\pi G^2 M_{\mathrm{irr}}^2/c^4$. *Then*

$$M^2 = M_{\mathrm{irr}}^2 + \frac{c^2 J^2}{4G^2 M_{\mathrm{irr}}^2}\,, \tag{45.50}$$

so $M \geq M_{\mathrm{irr}}$, *with equality iff* $J = 0$ *[1417]. In particular, since the area theorem below forbids* M_{irr} *ever to decrease, at most*

$$\frac{M - M_{\mathrm{irr}}}{M} \;\leq\; 1 - \frac{1}{\sqrt{2}} \approx 0.29 \tag{45.51}$$

of a hole's mass–energy is extractable by any process — the bound saturated only from the extremal state, where $M_{\mathrm{irr}} = M/\sqrt{2}$.

Rests on Lemma 45.44 and Proposition 45.31.

Derivation. *Derives Proposition 45.45.*

By Lemma 45.44, $16\pi G^2 M_{\mathrm{irr}}^2/c^4 = 8\pi\,(GM/c^2)\,r_+$, i.e. $r_+ = 2GM_{\mathrm{irr}}^2/\,(Mc^2)$. Substitute this into $r_{\mathrm{s}} r_+ = r_+^2 + a^2$ with $a = J/(Mc)$:

$$\frac{2GM}{c^2}\cdot\frac{2GM_{\mathrm{irr}}^2}{Mc^2} = \frac{4G^2 M_{\mathrm{irr}}^4}{M^2c^4} + \frac{J^2}{M^2c^2}\,,$$

and multiplication by $M^2c^4/\,(4G^2)$ gives $M^2 M_{\mathrm{irr}}^2 = M_{\mathrm{irr}}^4 + c^2J^2/\,(4G^2)$, which is Equation (45.50). At extremality $J = GM^2/c$, and Equation (45.50) becomes $M^2 = M_{\mathrm{irr}}^2 + M^4/\,(4M_{\mathrm{irr}}^2)$, whose solution is $M_{\mathrm{irr}}^2 = M^2/2$; extracting all the angular momentum at fixed M_{irr} leaves a Schwarzschild hole of mass $M/\sqrt{2}$, which is Equation (45.51). □

Proposition 45.46 (The first law)**.** *Along the Kerr family, with* $E = Mc^2$,

$$\mathrm{d}E = \frac{\kappa c^2}{8\pi G}\,\mathrm{d}A + \Omega_{\mathrm{H}}\,\mathrm{d}J\,, \tag{45.52}$$

with κ *and* Ω_{H} *as in Equations (45.41) and (45.48). Moreover the homogeneity of the mass formula yields Smarr's integral form [1513],*

$$E = \frac{\kappa c^2}{4\pi G}\,A + 2\,\Omega_{\mathrm{H}} J\,. \tag{45.53}$$

Rests on Propositions 45.43 and 45.45.

Derivation. *Derives Proposition 45.46.*

Differentiate Equation (45.50) at fixed functional form, using $\mathrm{d}M_{\mathrm{irr}}^2 = c^4\mathrm{d}A/\,(16\pi G^2)$:

$$2M\,\mathrm{d}M = \left(1 - \frac{c^2J^2}{4G^2M_{\mathrm{irr}}^4}\right)\frac{c^4\,\mathrm{d}A}{16\pi G^2} + \frac{c^2 J}{2G^2 M_{\mathrm{irr}}^2}\,\mathrm{d}J\,.$$

Two substitutions, both via $M_{\mathrm{irr}}^2 = Mc^2 r_+/(2G)$ (from Lemma 45.44), turn the coefficients geometric. The full $\mathrm{d}J$ coefficient is

$$\frac{c^2}{2M}\cdot\frac{c^2 J}{2G^2 M_{\mathrm{irr}}^2} = \frac{c^2 J}{2GM^2 r_+} = \frac{c^3 a}{2GMr_+} = \frac{a\,c}{r_{\mathrm{s}} r_+} = \Omega_{\mathrm{H}}$$

by Equation (45.41), using $J = Mca$ and $r_{\mathrm{s}} = 2GM/c^2$. In the $\mathrm{d}A$ coefficient, $c^2J^2/\left(4G^2M_{\mathrm{irr}}^4\right) = a^2/r_+^2$ by the same substitution, and $r_+r_- = a^2$ (product of the roots of Δ) turns the bracket into $1 - r_-/r_+ = (r_+ - r_-)/r_+$; assembling,

$$\left(\frac{\partial E}{\partial A}\right)_J = \frac{c^6\,(r_+ - r_-)}{32\pi G^2 M\, r_+} = \frac{c^2}{8\pi G}\cdot\frac{c^2\,(r_+ - r_-)}{2\,(r_+^2 + a^2)} = \frac{\kappa c^2}{8\pi G}\,,$$

the middle equality by $r_+^2 + a^2 = r_{\mathrm{s}}r_+ = 2GMr_+/c^2$, matching Equation (45.48). This is Equation (45.52). For Equation (45.53): under $(A, J) \to (\lambda^2 A, \lambda^2 J)$ the mass formula gives $E \to \lambda E$; differentiating $E(\lambda^2 A, \lambda^2 J) = \lambda E(A, J)$ at $\lambda = 1$ gives $2A\,\partial E/\partial A + 2J\,\partial E/\partial J = E$, which with the coefficients just computed is Equation (45.53). The Schwarzschild case checks in one line: with Equations (45.47) and (45.49), $\mathrm{d}A = 32\pi G^2 M\,\mathrm{d}M/c^4$ and $(\kappa c^2/8\pi G)\,\mathrm{d}A = c^2\,\mathrm{d}M$ exactly. □

Theorem 45.47 (Area theorem; imported)**.** *In an asymptotically predictable spacetime (cosmic censorship, Section 45.4.3, holds) whose matter satisfies the null energy condition (Section 44.8), the total area of event horizons is non-decreasing toward the future [1447].*

Rests on Proposition 45.18.

Remark 45.48 (The four laws assembled). The parallel with thermodynamics (Chapter 54) is now structural, law by law [1493]:

Law	Black-hole mechanics	Thermodynamics
Zeroth	κ uniform over the horizon of a stationary hole	T uniform at equilibrium
First	$\mathrm{d}E = \dfrac{\kappa c^2}{8\pi G}\,\mathrm{d}A + \Omega_{\mathrm{H}}\,\mathrm{d}J$	$\mathrm{d}U = T\,\mathrm{d}S - p\,\mathrm{d}V$
Second	$\mathrm{d}A \geq 0$ (Theorem 45.47)	$\mathrm{d}S \geq 0$
Third	$\kappa = 0$ (extremality) unattainable in any finite process	$T = 0$ unattainable

The correspondence pairs E with internal energy, κ with temperature and A with entropy, up to constants; Bekenstein argued on information-theoretic grounds that the pairing is physical and the entropy real [1494]. Classically that seems absurd — a classical black hole absorbs everything and emits nothing, so its temperature ought to be exactly zero; the area theorem's own hypotheses (null energy condition) are what quantum fields refuse to satisfy, and quantum theory is exactly what turns the analogy literal (Section 45.6.2). One consequence of Theorem 45.47 is already observable bookkeeping: two merging Schwarzschild holes of mass M each have final mass at least $\sqrt{2}M$ (areas add, $A \propto M^2$), so at most $1 - 1/\sqrt{2} \approx 29\%$ of the total can be radiated — GW150914's measured $3.0\,M_\odot$ out of $65\,M_\odot$, under 5%, sits comfortably inside the bound [2264].

45.6.2 Hawking radiation: prediction without observation

Theorem 45.49 (Hawking temperature; imported)**.** *Quantum fields on the spacetime of a body collapsing to a black hole of surface gravity κ settle, at late times, into a state in which the hole emits thermal radiation to infinity at the temperature*

$$T_{\mathrm{H}} = \frac{\hbar\,\kappa}{2\pi c\,k_{\mathrm{B}}} = \frac{\hbar c^3}{8\pi G M k_{\mathrm{B}}} \qquad (\textit{second form: Schwarzschild})\,, \tag{45.54}$$

and the four laws of Section 45.6.1 become literal thermodynamics with entropy

$$S_{\mathrm{BH}} = \frac{k_{\mathrm{B}}c^3}{4G\hbar}\,A \qquad \left(\frac{S_{\mathrm{BH}}}{k_{\mathrm{B}}} \approx 1.0\times10^{77}\ \textit{for}\ M_\odot\right). \tag{45.55}$$

[1549].
Rests on Propositions 45.43 and 45.46.

Remark 45.50 (Where the prediction comes from, and how firmly). The derivation is imported [1549, 1890]: it is a computation in quantum field theory on the fixed collapse background, comparing the field's in-vacuum with the late-time out-modes. Its structural core, however, is already in this treatise: Proposition 109.74 establishes — as a theorem of axiomatic field theory, via the KMS condition — that the vacuum restricted to a wedge is thermal with respect to the boost flow, at the temperature $T = \hbar a/(2\pi c k_{\mathrm{B}})$ for the observer of proper acceleration a [1590]. Near the horizon a static observer is precisely such an accelerated observer, and Equation (45.54) is the wedge temperature evaluated at the surface gravity and redshifted to infinity (Equation (45.47)); the Euclidean route — regularity of the imaginary-time geometry forcing periodicity $\hbar/(k_{\mathrm{B}}T_{\mathrm{H}})$ — gives the same number [1596]. Consistency of three independent derivations is why the prediction is regarded as robust *given* its premise: quantum field theory remains valid on a classical black-hole background. That premise is untested, and everything that hangs on the answer — the information problem, the microscopic meaning of Equation (45.55) — is quarantined with the quantum-gravity programme in Chapter 135.

Proposition 45.51 (Evaporation: scale and timescale)**.** *A hole radiating thermally at Equation (45.54) from area Equation (45.49) loses mass as* $\mathrm{d}M/\mathrm{d}t \propto -1/M^2$ *and evaporates in*

$$t_{\mathrm{evap}} \simeq \frac{5120\,\pi\,G^2M^3}{\hbar c^4} \approx 2\times 10^{67}\,\mathrm{yr}\left(\frac{M}{M_\odot}\right)^3, \tag{45.56}$$

where the numerical prefactor is the photon-only, geometric-optics Stefan–Boltzmann estimate; emitted-species and greybody corrections change it by factors of order unity [1549].
Rests on Theorem 45.49.

Derivation. *Derives Proposition 45.51.*
Treat the hole as a black body of area $A = 16\pi G^2M^2/c^4$ at temperature Equation (45.54) and apply the Stefan–Boltzmann law (Chapter 54), $P = \sigma A T_{\mathrm{H}}^4$ with $\sigma = \pi^2 k_{\mathrm{B}}^4/(60\hbar^3c^2)$:

$$c^2\frac{\mathrm{d}M}{\mathrm{d}t} = -\sigma A T_{\mathrm{H}}^4 = -\frac{\hbar c^6}{15360\,\pi\,G^2M^2} \qquad\Longrightarrow\qquad t_{\mathrm{evap}} = \frac{5120\,\pi\,G^2M^3}{\hbar c^4},$$

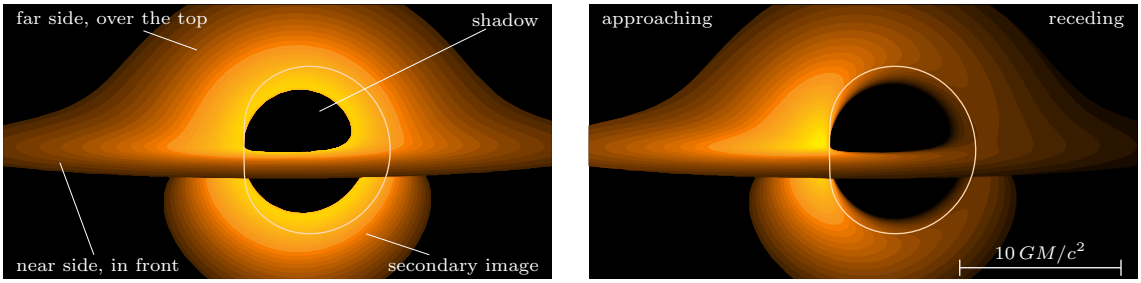
by integrating $M^2\mathrm{d}M$. Inserting $M_\odot$ gives $6.6\times10^{74}\,\mathrm{s}$, i.e. about $2\times10^{67}\,\mathrm{yr}$ — 10^{57} Hubble times. The estimate ignores the frequency-dependent horizon absorptivity and the species count, which is why only its scaling and order of magnitude are asserted. □

The honest evidence status must be stated plainly, in the terms of Chapter 1: *Hawking radiation has never been observed, and for every black hole known to exist it never can be by any foreseeable instrument.* The arithmetic is unforgiving: Equation (45.54) gives $T_{\mathrm{H}} = 6.2\times10^{-8}\,\mathrm{K}$ for one solar mass — colder than the 2.725 K microwave background by nearly eight orders of magnitude, so every astrophysical hole *absorbs* background radiation faster than it emits, and will until cosmic expansion has cooled the background below its temperature. A hole hotter than the background must be lighter than $4.5\times10^{22}\,\mathrm{kg}$ (half a lunar mass, horizon smaller than a tenth of a millimetre); one completing its evaporation today — the potentially detectable terminal γ-ray burst — must have been born primordial at about 10^{11}–$10^{12}\,\mathrm{kg}$ [1549], and searches for such bursts have found nothing attributable. The status is therefore exactly that recorded for the acceleration temperature in Remark 109.75, and for the same structural reason: the KMS mathematics is theorem-solid, the physical consequence unobserved. What *would* count as evidence: the terminal burst of a primordial hole with the predicted spectrum, or — more remotely — thermal spectra from any horizon at the predicted temperature. Analogue systems (sonic horizons in condensates) confirm

the mode-conversion mathematics, not the gravitational claim [1675]. No phenomenon environment appears in this section: the book reserves that environment for observed facts, and this is a prediction — the sharpest untested prediction general relativity and quantum theory jointly make.

45.7 The shadow

Seen from outside, a black hole's mark is what it does to light. Rays with impact parameter below a critical value b_c are captured (Section 45.2.3); an observer looking at a hole backlit or surrounded by emission therefore sees a dark disc of radius b_c — the capture cross-section, not the horizon — bounded by a bright ring where rays that nearly orbited the photon sphere pile up. The escape-cone geometry was computed by Synge [1338], and the first realistic image of a hole with a thin accretion disc — ring, asymmetry and all — by Luminet [1642]. The same construction is carried out in Figure 45.1 for a rapidly spinning hole viewed almost edge-on — the configuration rendered for the film *Interstellar*, whose images leave out the Doppler and gravitational frequency shifts deliberately, so that the disc appears left–right symmetric [2255]; the second panel restores them. The angular size is set by $b_c \approx 2.6\, r_s$: about ten gravitational radii across, only weakly dependent on spin and inclination [1988], which is what makes the measurement a test of the geometry rather than of astrophysical modelling. The imaging observations themselves — and the stellar-orbit mass that calibrates them — are deferred, with the full apparatus, to Chapter 50.



(a) frequency shifts omitted, as filmed

(b) brightness carrying the factor g^4

Figure 45.1: A thin accretion disc around a rapidly spinning black hole, computed by integrating the Kerr null geodesic equations backwards from the observer. The hole has $a = 0.999\,GM/c^2$ and is seen 5° out of the equatorial plane; the disc is opaque, geometrically thin, and reaches from the innermost stable circular orbit at $1.18\,GM/c^2$ out to $20\,GM/c^2$, radiating with the time-averaged flux of a steady thin disc [1531]. Lensing does all the work. Light from the far side is bent over and under the hole, so the far side of the disc appears as an arc *above* the dark region and its underside as a second arc below, while the near side crosses in front as a thin band: a flat disc is wrapped into the shape one sees. The dark region is the capture cross-section, flattened on the left — the side on which co-rotating photons appear — by the dragging of inertial frames, and the thin ring is the analytic boundary of that cross-section, which the disc's own images partly cover and on which the higher-order images pile up too closely to be drawn. Panel (a) omits the Doppler and gravitational frequency shifts, as the film *Interstellar* did [2255]; panel (b) restores them, multiplying the surface brightness by g^4, where g is the redshift factor of a prograde circular orbit. The approaching side is on the left, and outshines the receding one by orders of magnitude. Brightness is logarithmic over four decades and both panels share one normalisation, so they differ by exactly the factor g^4. The first image of this kind was computed by Luminet [1642].

Phenomenon 45.52 (The shadow)**.** A black hole surrounded by an optically thin emitting region appears as a bright ring enclosing a central brightness depression. The depression is bounded by the photon-capture impact parameter, so a Schwarzschild hole of mass M seen from distance D subtends an angular diameter

$$\theta_{\mathrm{sh}} = \frac{2b_{\mathrm{c}}}{D}\,, \qquad b_{\mathrm{c}} = \frac{3\sqrt{3}\,GM}{c^2} = \frac{3\sqrt{3}}{2}\,r_{\mathrm{s}}\,, \tag{45.57}$$

that is $\theta_{\mathrm{sh}} D = 3\sqrt{3}\,r_{\mathrm{s}} \simeq 5.20\,r_{\mathrm{s}}$, some ten gravitational radii and only weakly dependent on spin and on viewing angle [1338, 1988]. Rings of about this size have been imaged at millimetre wavelengths around the nucleus of M87 and around Sgr A* [2328, 2403]; the observations, with their apparatus, are assembled in Chapter 50.

Rests on Equation (45.20)*, Theorem 45.1, and Proposition 13.141.*

Derivation. *Derives Phenomenon 45.52.*

Take the first integral Equation (45.20) of the null geodesic equation, established in Section 45.2.3, which for a ray confined to the equatorial plane reads

$$\left(\frac{\mathrm{d}r}{\mathrm{d}\lambda}\right)^2 = E^2 - \frac{L^2}{r^2}\left(1 - \frac{r_{\mathrm{s}}}{r}\right)\,,$$

with E and L the constants conjugate to the two Killing vectors and $b := L/E$ the impact parameter measured at infinity (Equation (45.22)) [1509]. Radial turning points are the zeros of the right-hand side, so a ray of impact parameter b turns where

$$\frac{1}{b^2} = W(r) := \frac{1}{r^2}\left(1 - \frac{r_{\mathrm{s}}}{r}\right)\,. \tag{45.58}$$

An incoming ray escapes if it meets a turning point outside the horizon and is captured if it does not, so the critical impact parameter separating the two behaviours is fixed by the maximum of W. Differentiating,

$$W'(r) = -\frac{2}{r^3} + \frac{3r_{\mathrm{s}}}{r^4}\,,$$

which vanishes at

$$r_{\mathrm{ph}} = \frac{3}{2}r_{\mathrm{s}} = \frac{3GM}{c^2}\,, \tag{45.59}$$

the photon sphere, and $W'' < 0$ there, so this is the maximum. Its value is

$$W\left(r_{\mathrm{ph}}\right) = \frac{1}{\left(3r_{\mathrm{s}}/2\right)^2}\left(1 - \frac{2}{3}\right) = \frac{4}{9r_{\mathrm{s}}^2}\cdot\frac{1}{3} = \frac{4}{27\,r_{\mathrm{s}}^2}\,,$$

so that $b_{\mathrm{c}}^2 = 27r_{\mathrm{s}}^2/4$ and $b_{\mathrm{c}} = \frac{3}{2}\sqrt{3}\,r_{\mathrm{s}} = 3\sqrt{3}\,GM/c^2$, which is Equation (45.57). The apparent diameter of the capture cross-section is twice this, $2b_{\mathrm{c}} = 3\sqrt{3}\,r_{\mathrm{s}} = 5.196\,r_{\mathrm{s}}$.

Two remarks. The shadow is larger than the horizon by the factor $3\sqrt{3}/2 \approx 2.60$, because the impact parameter is measured at infinity while the horizon radius is a coordinate radius: what is imaged is the capture cross-section, not the horizon. And rays with b slightly above b_{c} orbit many times near r_{ph} before escaping, which piles emission up at the rim and produces the bright ring rather than a mere edge. □

Chapter 46

Gravitational-Wave Theory

The Einstein field equations are nonlinear, but far from strong sources spacetime is very nearly flat, and the equations linearize into a wave equation. The resulting radiative solutions — gravitational waves — are the subject of this short chapter. We state the results and their physical content; the complete derivation, from the linearized field equations through the quadrupole formula, is carried out in Appendix A.1. The experimental record, indirect and direct, occupies Chapter 47.

46.1 Linearized gravity and the wave equation

Consider a metric that deviates only slightly from the Minkowski metric,

$$g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}\,, \qquad |h_{\mu\nu}| \ll 1\,. \tag{46.1}$$

Keeping only terms of first order in $h_{\mu\nu}$, and introducing the trace-reversed perturbation $\bar{h}_{\mu\nu} = h_{\mu\nu} - \tfrac{1}{2}\eta_{\mu\nu}\,h$ with $h = \eta^{\alpha\beta}h_{\alpha\beta}$, one may always choose coordinates satisfying the Lorenz gauge condition $\partial^{\mu}\bar{h}_{\mu\nu} = 0$. In this gauge the linearized Einstein equations collapse to an inhomogeneous wave equation [436, 1509, 1746],

$$\Box\,\bar{h}_{\mu\nu} = -\frac{16\pi G}{c^{4}}\,T_{\mu\nu}\,, \tag{46.2}$$

where $\Box = \eta^{\alpha\beta}\partial_{\alpha}\partial_{\beta}$ is the flat-space d'Alembertian. Every statement in this equation is physical: disturbances of the metric propagate at the speed of light, they are sourced by the stress–energy tensor, and the coupling $G/c^{4} \approx 8.3\times10^{-45}\,\mathrm{s^{2}/(kg\,m)}$ is so small that only astrophysical masses moving at relativistic speeds produce perturbations of detectable size. We do not derive Equation (46.2) here; the derivation is the opening step of Appendix A.1.

46.2 Transverse-traceless gauge and the two polarizations

In vacuum ($T_{\mu\nu} = 0$) the residual gauge freedom within the Lorenz class can be used to set $h_{0\mu} = 0$, $h^{i}{}_{i} = 0$ and $\partial^{i}h_{ij} = 0$: the *transverse-traceless* (TT) gauge. For a plane wave travelling along the z-axis only two independent components survive, the polarization amplitudes h_{+} and $h_{\times}$ [1509, 2132]:

$$\mathrm{d}s^{2} = -c^{2}\mathrm{d}t^{2} + (1+h_{+})\mathrm{d}x^{2} + (1-h_{+})\mathrm{d}y^{2} + 2h_{\times}\,\mathrm{d}x\,\mathrm{d}y + \mathrm{d}z^{2}\,, \tag{46.3}$$

with $h_{+,\times} = h_{+,\times}(t - z/c)$. A gravitational wave therefore carries exactly two physical polarizations, as befits a massless spin-2 field.

The effect on matter is tidal. A circular ring of free test masses in the xy-plane is deformed by the $+$ polarization into an ellipse stretched along x while squeezed along y,

and half a period later the reverse; the $\times$ polarization produces the same pattern rotated by 45°. For two free masses separated by a distance L along a principal axis of the wave, the fractional change in proper separation is

$$\frac{\Delta L}{L} = \frac{h}{2}\,, \tag{46.4}$$

where h is the relevant polarization amplitude. This is precisely the quantity a laser interferometer measures: a differential arm-length oscillation at the wave frequency, of fractional size $h/2$ per arm.

46.3 The quadrupole formula

Phenomenon 46.1. Accelerated masses whose quadrupole moment varies in time radiate gravitational waves. The waves propagate at the speed of light c and carry energy away from the source; at leading order the radiated strain and luminosity are given by the quadrupole formula. This radiation has been observed indirectly, through the orbital decay of binary pulsars [1703], and directly, by the LIGO interferometers in 2015 [2264], exactly as predicted by the linearized theory [436, 453].

Rests on Postulate 44.3.

Full derivation: Appendix A.1 (p. 2759).

Derives Phenomenon 46.1.

We state the results proved there. Let $Q_{ij} = \int \rho\,(x_i x_j - \tfrac{1}{3}\delta_{ij} r^2)\mathrm{d}^3x$ denote the traceless mass quadrupole moment of the source. A distant observer at distance d measures the strain

$$\bar{h}_{ij}(t) = \frac{2G}{c^4 d}\,\ddot{Q}_{ij}\!\left(t - \frac{d}{c}\right)\,, \tag{46.5}$$

and the total power radiated by the source, averaged over several wave periods, is

$$P = \frac{G}{5c^5}\left\langle \dddot{Q}_{ij}\,\dddot{Q}^{ij}\right\rangle\,. \tag{46.6}$$

The prefactor $G/c^5 \approx 2.8\times10^{-53}\,1/\mathrm{W}$ explains at once why gravitational radiation is negligible in the laboratory and why only compact binaries reach detectable luminosities [2132].

For a binary of masses m_1 and m_2 on a circular orbit, the gravitational-wave frequency is twice the orbital frequency, and the entire leading-order evolution is controlled by a single mass combination, the *chirp mass*

$$\mathcal{M} = \frac{(m_1 m_2)^{3/5}}{(m_1+m_2)^{1/5}}\,. \tag{46.7}$$

Energy loss through Equation (46.6) shrinks the orbit and drives the frequency upward according to

$$\frac{\mathrm{d}f_{\mathrm{gw}}}{\mathrm{d}t} = \frac{96}{5}\,\pi^{8/3}\left(\frac{G\mathcal{M}}{c^3}\right)^{5/3} f_{\mathrm{gw}}^{11/3}\,, \tag{46.8}$$

so that a measurement of the frequency and its rate of change during the inspiral yields $\mathcal{M}$ directly, with no astrophysical modelling. This accelerating sweep — the *chirp* — is the unmistakable signature by which compact binaries announce themselves in the data of Chapter 47 [2132, 2264].

46.4 Beyond linear order

The linearized treatment above suffices for the propagation of the waves and for the leading-order emission from slowly moving sources. It does not by itself define the energy carried by the waves — a second-order quantity in $h_{\mu\nu}$ — nor does it describe the late inspiral and merger of black holes, where the full nonlinearity of the field equations takes over and only post-Newtonian expansions and numerical relativity give quantitative waveforms [1509, 1746, 2132].

The first of these gaps is closed in this book: the second-order (Isaacson) analysis — expanding the Ricci tensor to $O(h^2)$, averaging over several wavelengths, and reading the averaged quadratic terms as an effective stress–energy tensor of the radiation — is carried out in Appendix A.1.5, culminating in Equation (A.46); it is that tensor whose flux, integrated over a sphere, yields the luminosity Equation (46.6) quoted above. The second gap is imported knowledge, and honestly so: the post-Newtonian expansion of the two-body problem has been driven to the orders required by detector phase templates [2231], and the merger itself yielded only to numerical solution of the full field equations [2082]. This book states those results where the experiments need them (Chapter 47) and does not rederive them; each is a controlled approximation to, or a numerical solution of, the same field equations derived in Chapter 44, so nothing in the evidential chain rests on machinery outside the theory already stated.

The history of the subject mirrors its subtlety. Einstein's founding 1916 paper on gravitational waves [436] contained a celebrated error of a numerical factor in the radiation formula, which he himself corrected in the 1918 paper that first stated the quadrupole formula in its modern form [453]; decades of confusion about whether the waves were physical or mere coordinate ripples followed, and were settled only in the late 1950s with gauge-invariant treatments of the energy flux [1509, 2132]. That the formula so laboriously secured now agrees with binary-pulsar timing to a fraction of a percent, and with direct interferometry, is the subject of the next chapter: Chapter 47.

Chapter 47

Experiment: Gravitational Waves

The prediction of Chapter 46 — that accelerated masses radiate energy in ripples of spacetime — was confirmed twice, by two utterly different techniques separated by four decades. First indirectly: a binary pulsar, timed for years with radio telescopes, was observed to lose orbital energy at exactly the rate demanded by the quadrupole formula of Appendix A.1. Then directly: kilometre-scale laser interferometers recorded the strain of a passing wave itself. This chapter presents both records in full phenomenological detail; no derivations are performed here.

47.1 The Hulse–Taylor Binary Pulsar (PSR B1913+16) (1974–2016)

Tests Phenomenon 46.1 and Equation (46.6).

A pulsar is a rotating neutron star whose radio beam sweeps past the Earth once per rotation, providing a clock of extraordinary stability. A pulsar bound in a tight orbit around a second neutron star is therefore a moving clock in a strong gravitational field — a ready-made laboratory for relativistic orbital dynamics, including the slow decay of the orbit by gravitational radiation.

47.1.1 Apparatus

The 305 m radio telescope at Arecibo, Puerto Rico, equipped for precision pulsar timing: dispersion-corrected radio receivers and time-tagging of pulse arrival times against maser clocks, later linked to international atomic time. The pulsar PSR B1913+16 was found in a systematic survey for new pulsars conducted by Hulse and Taylor in the summer of 1974 [1550].

47.1.2 Procedure

The pulsar's spin period of about 59 ms was observed to shift periodically by up to 80 µs, revealing orbital Doppler motion: the pulsar orbits an unseen companion, with orbital period 7.75 h and orbital eccentricity $e \approx 0.617$ [1550]. Over the following four decades, pulse arrival times were accumulated and fitted to a fully relativistic timing model, whose post-Keplerian parameters — periastron advance, combined time dilation and gravitational redshift, and the secular decay of the orbital period — are measured without assuming general relativity and only then compared with its predictions [1703, 2275].

47.1.3 Observations and data

The key fitted parameters are collected below [1550, 2275].

Quantity	Value
Pulsar spin period	59 ms
Orbital period P_b	7.75 h
Orbital eccentricity e	0.617
Periastron advance $\langle\dot\omega\rangle$	4.226° per year
Orbital period decay $\dot P_b$	$\approx -2.4\times10^{-12}$ s/s
Observed/predicted decay ratio	0.9983 ± 0.0016

The periastron of the orbit advances by 4.226° per year — in a single day, roughly what Mercury's perihelion accumulates in a century. The orbital period shrinks by about -2.4×10^{-12} s/s, i.e. some 76.5 µs per year. The most vivid presentation of the timing data is the cumulative shift of periastron passage times relative to a constant-period orbit: the data points trace a downward-opening parabola, reaching a cumulative shift of about −40 s after roughly thirty years of observation, with the general-relativistic prediction drawn through them as a solid curve from which no point visibly departs [2275]. After correcting for the small relative acceleration of the solar system and the pulsar in the Galaxy, the ratio of the observed period decay to that predicted by the quadrupole formula is 0.9983 ± 0.0016 [2275].

47.1.4 Interpretation

The orbit decays because the system radiates energy in gravitational waves, at precisely the rate given by the quadrupole formula (Appendix A.1): agreement at the level of 0.16%, with no adjustable parameters. This was the first evidence — indirect but quantitative — for the existence of gravitational radiation, and it earned Hulse and Taylor the 1993 Nobel Prize in Physics. The steadily improving timing residuals of [2275] remain among the most stringent tests of the radiative sector of general relativity.

Every post-Keplerian parameter entering these fits is now derived in this book. The orbital decay $\dot P_b$ — the parameter carrying the gravitational-wave result quoted above — follows from the quadrupole formula proved in Appendix A.1, including the eccentricity enhancement factor $f(e)$ evaluated there at the measured $e = 0.617$. The remaining three rest on the classical-test machinery of Chapter 53 and are short enough to derive here.

Derivation of the remaining post-Keplerian parameters. (i) *Periastron advance.* Equation (53.1) gives the relativistic advance per orbit, $\Delta\varphi = 6\pi GM/[c^2 a(1-e^2)]$; for a binary the relative orbit obeys the same equation with $M = m_1 + m_2$ at leading order. The secular rate is $\dot\omega = \Delta\varphi/P_b$, and eliminating the semi-major axis through Kepler's third law $(2\pi/P_b)^2 a^3 = GM$ gives

$$\langle\dot\omega\rangle = 3\left(\frac{2\pi}{P_b}\right)^{5/3}\left(\frac{G(m_1+m_2)}{c^3}\right)^{2/3}\frac{1}{1-e^2}\,. \tag{47.1}$$

Evaluated at the measured P_b, e and the fitted masses $m_1 = 1.4398\,M_\odot$, $m_2 = 1.3886\,M_\odot$ [2275], this gives 4.23° per year (computed here), against the fitted 4.2266°.

(ii) *Einstein delay.* The pulsar's proper time runs against coordinate time as $\mathrm{d}\tau/\mathrm{d}t = 1 - v_1^2/2c^2 - Gm_2/(c^2 r)$, the two corrections being special-relativistic time dilation and the companion's redshift (Chapter 42). With $v_1 = (m_2/M)\,v$ on the relative orbit and the vis-viva relation $v^2 = GM(2/r - 1/a)$, the $1/r$ terms combine with coefficient $Gm_2(m_1+2m_2)/(Mc^2)$. On the Keplerian ellipse $r = a(1-e\cos E)$ with $nt = E - e\sin E$ one has $\int \mathrm{d}t/r = E/(na)$, whose periodic part is $(e/na)\sin E$ — the constant rates are unobservable, absorbed into the fitted spin period. The arrival times are therefore modulated by $\Delta\tau = -\gamma_{\mathrm E}\sin E$ with

$$\gamma_{\mathrm E} = e\left(\frac{P_b}{2\pi}\right)^{1/3}\left(\frac{G}{c^3}\right)^{2/3}\frac{m_2(m_1+2m_2)}{(m_1+m_2)^{4/3}}\,, \tag{47.2}$$

which at the fitted masses is $\approx 4.3\,\mathrm{ms}$ (computed here), as measured.

(iii) *Shapiro range and shape.* Equation (53.5) applied with the companion as the deflector adds a propagation delay $2(Gm_2/c^3)\ln[\,\cdot\,]$ to pulses crossing the companion's potential; near superior conjunction the logarithm's argument is fixed by the orbital geometry through $\sin i$ alone, so the timing model parametrizes the effect by the *range* $r_{\mathrm{S}} = Gm_2/c^3$ and the *shape* $s = \sin i$. In PSR B1913+16 the inclination makes the effect only marginally visible; it is measured superbly in the double pulsar (Chapter 49). □

Together with $\dot{P}_b$ from Appendix A.1, the timing model is thus derived end to end: three parameters (Equations (47.1) and (47.2), and r_{S}, s) overdetermine the two masses, and the gravitational-wave test is that the fourth, $\dot{P}_b$, then agrees with no freedom left.

47.2 Direct detection: the instrument

The Laser Interferometer Gravitational-Wave Observatory (LIGO) consists of two detectors of identical design, one at Hanford, Washington, and one at Livingston, Louisiana, separated by about 3000 km — a light travel time of about 10 ms that both provides a coincidence veto against local disturbances and encodes the sky direction of a source in the inter-site arrival-time difference [2243].

Each detector is a Michelson interferometer whose two 4 km arms are Fabry–Perot resonant cavities, multiplying the phase accumulated by the laser light in each arm by the cavity finesse. A power-recycling mirror at the input builds up the circulating laser power, and a signal-recycling mirror at the output shapes the instrument's frequency response [2243]. A passing gravitational wave of strain h changes the differential arm length by $\Delta L = hL/2$ (Chapter 46); at the sensitivity reached in 2015 this corresponds to measurable differential displacements of order $10^{-18}\,\mathrm{m}$ — about one thousandth of the diameter of a proton.

The noise budget divides the band into three regimes [2243]. Below roughly 10 Hz rises the seismic wall: ground motion, suppressed by active isolation platforms and by suspending each 40 kg mirror from a four-stage pendulum, still dominates and sets the low-frequency edge of the observation band. In the middle of the band, from tens to a couple of hundred hertz, thermally driven motion of the fused-silica suspension fibres and of the mirror coatings is the limiting noise. At high frequencies the limit is quantum: photon shot noise in the readout, improved by raising the circulating power. The quietest region of the resulting sensitivity curve, around 100 Hz, is precisely where a stellar-mass compact binary sweeps through its final orbits.

47.3 GW150914 (2015)

Tests Phenomenon 46.1 and Equation (46.8).

47.3.1 Apparatus

The two Advanced LIGO interferometers at Hanford and Livingston, described in Section 47.2 [2243], in their first observing run and operating in coincidence [2264].

47.3.2 Procedure

Two independent analyses ran over the coincident data [2264]. A matched-filter search correlated the strain data against a bank of about 250 000 relativistic waveform templates for compact-binary coalescences; a separate, unmodelled burst search looked for coherent excess power in both detectors without waveform assumptions. Both searches recovered the same event, and the significance was established by measuring the background of accidental coincidences with time-shifted data.

47.3.3 Observations and data

On 2015 September 14 at 09:50:45 UTC both detectors recorded the same transient [2264]:

Quantity	Value
Peak strain amplitude	1.0×10^{-21}
Frequency sweep	35–250 Hz in about 0.2 s
Cycles observed	~ 8
Hanford–Livingston delay	$6.9^{+0.5}_{-0.4}$ ms
Combined signal-to-noise ratio	24
False-alarm rate	< 1 per 203 000 yr ($> 5.1\sigma$)
Primary mass m_1	$36^{+5}_{-4}\,M_\odot$
Secondary mass m_2	$29^{+4}_{-4}\,M_\odot$
Final black-hole mass	$62^{+4}_{-4}\,M_\odot$
Radiated energy	$3.0^{+0.5}_{-0.5}\,M_\odot c^2$
Peak luminosity	$3.6^{+0.5}_{-0.4} \times 10^{49}$ W
Luminosity distance	410^{+160}_{-180} Mpc ($z \approx 0.09$)

The signal swept upward in frequency from 35 Hz to 250 Hz over about 0.2 s — roughly eight cycles — increasing in amplitude to a peak strain of 1.0×10^{-21}, then rang down. The Livingston detector recorded it first; Hanford followed $6.9^{+0.5}_{-0.4}$ ms later, comfortably within the 10 ms light travel time between the sites. The waveforms observed in the two detectors, once shifted by this delay and inverted for the relative orientation of the instruments, lie on top of one another [2264].

47.3.4 Interpretation

The chirp-mass relation of Chapter 46 applied to the observed frequency and frequency sweep gives $\mathcal{M} \approx 30\,M_\odot$, and hence a total mass so large, in so small an orbit at merger, that only a pair of black holes fits: at 75 Hz orbital frequency the objects, of 36^{+5}_{-4} and 29^{+4}_{-4} solar masses, were only a few hundred kilometres apart. GW150914 is thus simultaneously the first direct detection of gravitational waves and the first observation of a binary black-hole merger. The full signal — inspiral, merger, and the damped ringdown of the final $62^{+4}_{-4}\,M_\odot$ black hole — matches the inspiral–merger–ringdown waveform computed from general relativity, with about $3.0 \pm 0.5\,M_\odot c^2$ radiated in a fraction of a second at a peak luminosity of $3.6^{+0.5}_{-0.4} \times 10^{49}$ W, briefly exceeding the combined light output of the observable Universe [2264]. The detection was recognized with the 2017 Nobel Prize in Physics.

47.4 The multimessenger outlook

Two years after the discovery, on 2017 August 17, the LIGO–Virgo network recorded GW170817, an inspiral lasting about 100 s with component masses of 1–2 $M_\odot$: a binary neutron-star merger [2278]. A short gamma-ray burst arrived 1.7 s after the merger, and the optical counterpart — a kilonova in the galaxy NGC 4993 at about 40 Mpc — was followed across the electromagnetic spectrum for weeks; the near-simultaneity of the gravitational and gamma-ray signals after a journey of more than a hundred million years constrains the speed of gravitational waves to equal c to within a few parts in 10^{15} [2278]. Since then the catalogue of compact binary coalescences has grown from a single event to on the order of a hundred, with black-hole masses ranging from a few to over a hundred solar masses.

Gravitational-wave astronomy has thus passed, within a decade, from heroic first detection to routine observation: a new spectrum, opened on a sector of the Universe — coalescing black holes — that emits no light at all. Its implications for the largest scales, where the same field equations govern the expansion of the Universe itself, are taken up in Chapter 48.

Chapter 48

Evidence-Based Cosmology

Cosmology is the application of the field equations of Chapter 44 to the universe as a whole, and it is admitted here on the strength of four independent data streams: the expansion recorded in galaxy redshifts [627], the light-element abundances fixed in the first minutes [905], the relic microwave background predicted before it was found [906, 1320], and the growth of large-scale structure with its baryon acoustic ruler [2076]. Each is treated with its primary sources; the CMB measurements get their own experiment chapter, Chapter 51.

The chapter's standing claim is that ΛCDM is a *parametrization* of these data, not yet an explanation of them: six numbers fit everything [2348], while the physical nature of two of the ingredients — the dark matter of Chapter 134 and the constant Λ — and the mechanism behind the initial conditions remain unidentified. The chapter states throughout what is measured, what is inferred through the model, and what is not measured at all.

48.1 The expanding universe

48.1.1 Nebular redshifts

The observational record begins not with a theory but with a decade of patient spectroscopy. Between 1912 and 1917, working with the 24-inch refractor of the Lowell Observatory, Slipher measured the Doppler displacements of the spectral lines of the brightest spiral nebulae — objects whose nature, star cloud or island universe, was itself still in dispute [451]. Two facts emerged from his radial velocities and survived every later refinement. First, the velocities were enormous by the standards of stellar astronomy: several hundred kilometres per second, reaching 1100 km/s for the faintest objects measured, an order of magnitude beyond any stellar radial velocity then known. Second, the displacements were overwhelmingly toward the red: of the spirals Slipher had measured by 1917, the receding outnumbered the approaching roughly five to one. A sample drawn from bodies in random motion does not vote five to one for recession.

The observable is dimensionless and spectroscopic. If a line identified in the laboratory at wavelength λ_{em} is received at λ_{obs}, the *redshift* of the source is $z = (\lambda_{\mathrm{obs}} - \lambda_{\mathrm{em}})/\lambda_{\mathrm{em}}$, as restated below in Equation (48.1). At small z the special-relativistic Doppler formula of Chapter 38 reads $z \simeq v/c$ and licenses the word "velocity"; but the derivation of Phenomenon 48.1 will show that a cosmological redshift is not a velocity through space at all — it is a ratio of the sizes of the universe at emission and at reception, and the kinematic reading is legitimate only over distances small enough that the size has not changed. The precise statement is Equation (48.2).

48.1.2 The distance ladder

A redshift is read off a spectrum in an afternoon; a distance must be climbed to. Every extragalactic distance rests on a *ladder* of overlapping calibrations, and the propagation of error up that ladder is the central systematic of observational cosmology, then and now.

The base of the ladder is trigonometric parallax — pure geometry, the apparent semiannual displacement of a nearby star against the distant sky as the Earth traverses its orbit. It defines the parsec ($1\,\mathrm{pc} = 3.0857 \times 10^{16}\,\mathrm{m}$, the distance at which the astronomical unit subtends one second of arc) and it reaches, with modern astrometry, across a usable fraction of the Galaxy — but not remotely to another one.

The rung that first carried distances beyond the Galaxy was found by Leavitt in the Small Magellanic Cloud. Among the periodic variable stars now called Cepheids, she established that the apparent brightness at fixed period was tightly correlated with the period — and since every star in the Cloud sits at essentially one distance, apparent brightness there is absolute brightness up to one common constant [390]. A Cepheid's period, which no distance error can corrupt, therefore reveals its luminosity; comparing luminosity with observed flux gives the distance. Calibrate the zero point on parallax Cepheids in the Galaxy, and the ladder extends as far as individual Cepheids can be resolved. It was by resolving Cepheids in the spiral nebulae that Hubble settled their nature as galaxies and measured the distances that enter Section 48.1.3 [627]. The physics of the pulsation mechanism itself belongs to stellar astrophysics (Chapter 52).

Above the Cepheids sits the brightest standardizable candle known, the type Ia supernova, taken up in Section 48.6: a single event outshines its host galaxy and carries the ladder to redshifts where the expansion history itself becomes measurable. The modern three-rung ladder — parallax, Cepheid, supernova — is the instrument behind the local Hubble-constant measurement of Section 48.7.2 [2407], and each rung multiplies the error budget of the one below it, which is why so much of Section 48.7.2 turns on calibration.

48.1.3 The Hubble–Lemaître law

The linear law joining Slipher's velocities to the new distances has a double history, and the priority is worth recording precisely. In 1927 Lemaître derived, from the field equations of Chapter 44 applied to an expanding homogeneous universe, the prediction that recession velocity grows in proportion to distance, and extracted from Slipher's velocities and Hubble's early distance estimates an expansion rate of about $600\,\mathrm{km/(s\,Mpc)}$ [583]. The paper, in French in the *Annales* of the Brussels scientific society, went unread; when it was translated into English in 1931, the paragraphs deriving the rate were omitted. Hubble established the relation observationally in 1929, from Cepheid-calibrated distances to two dozen galaxies, with a slope near $500\,\mathrm{km/(s\,Mpc)}$ [627], and the law long carried his name alone. Both rates are some seven times the modern value: the error lay not in the velocities but in the first rung of the distance ladder, whose Cepheid zero point was systematically miscalibrated, and unwinding it took three decades [2379].

Phenomenon 48.1 (The Hubble–Lemaître law)**.** The spectral lines of galaxies beyond the Local Group are displaced toward longer wavelengths, and for nearby galaxies the displacement grows in proportion to distance,

$$cz = H_0 d + O\left(z^2\right), \qquad z := \frac{\lambda_{\mathrm{obs}} - \lambda_{\mathrm{em}}}{\lambda_{\mathrm{em}}}\,. \tag{48.1}$$

Slipher's radial velocities of the spiral nebulae established the displacements [451]; Lemaître derived the linear law from the field equations and extracted a rate from those same data [583]; Hubble established the relation observationally from Cepheid distances [627]. The

present value of H_0 is near $70\,\mathrm{km/(s\,Mpc)}$, with a discrepancy between the two ways of measuring it that is the subject of Section 48.7.2.

Rests on Equation (48.3) and Theorem 48.3.

Derivation. *Derives Phenomenon 48.1.*

In the FLRW geometry of Section 48.2 light reaching us radially travels on null curves with $c\,\mathrm{d}t = a(t)\,\mathrm{d}\chi$, where χ is the comoving radial coordinate of the source. Two successive wave crests, emitted at t_e and at $t_\mathrm{e} + \delta t_\mathrm{e}$ and received at t_0 and $t_0 + \delta t_0$, traverse the same comoving interval, so

$$\int_{t_\mathrm{e}}^{t_0} \frac{c\,\mathrm{d}t}{a(t)} = \int_{t_\mathrm{e}+\delta t_\mathrm{e}}^{t_0+\delta t_0} \frac{c\,\mathrm{d}t}{a(t)}\,.$$

Subtracting the common part of the two integrals leaves $\delta t_0/a(t_0) = \delta t_\mathrm{e}/a(t_\mathrm{e})$, and since a wavelength is c times the crest interval,

$$1 + z = \frac{a\,(t_0)}{a\,(t_\mathrm{e})}\,. \tag{48.2}$$

The redshift is therefore a ratio of scale factors, not a velocity: the special-relativistic Doppler formula of Chapter 38 applies only over distances small enough that a may be treated as constant.

For a nearby source expand about the present epoch, $a(t_\mathrm{e}) \simeq a(t_0)\,[1 - H_0\,(t_0 - t_\mathrm{e})]$ with $H_0 := \dot{a}\,(t_0)\,/a\,(t_0)$. Then Equation (48.2) gives $z \simeq H_0\,(t_0 - t_\mathrm{e})$, and to the same order the light-travel time is $t_0 - t_\mathrm{e} \simeq d/c$, whence $cz \simeq H_0 d$. Note what the derivation did not use: no field equation, no matter content, no spatial curvature. Linearity at small z follows from expansion alone, which is why confirming Equation (48.1) establishes that the universe expands without yet constraining what drives the expansion. □

In SI terms the Hubble constant is an inverse time: $H_0 = 67.4\,\mathrm{km/(s\,Mpc)} = 2.18 \times 10^{-18}\,\mathrm{/s}$ (computed here from the definition of the parsec), so that $1/H_0 \approx 14.5 \times 10^9\,\mathrm{yr}$ — the first crude indication, already available in 1929, that the universe has a history of finite depth comparable to the age of the oldest stars.

48.2 The FLRW geometry

48.2.1 Homogeneity, isotropy and the metric

Definition 48.2 (The cosmological principle)**.** On sufficiently large scales, and at each cosmic epoch, the universe is spatially *homogeneous* (no point of space is distinguished) and *isotropic* (no direction is distinguished about any point).

This is a falsifiable idealization, not an axiom of convenience, and the evidence for it is now strong: the microwave background is isotropic to about one part in 10^5 once the kinematic dipole is removed (Section 48.4.2), and galaxy counts approach uniformity when averaged over scales above roughly 100 Mpc [1871, 2348]. Below those scales the universe is conspicuously lumpy — that lumpiness is the subject of Section 48.5 — so the principle governs the *background* on which structure grows.

The mathematics of symmetric spaces was built once, in full generality, in Chapter 13: a metric's continuous symmetries are its Killing vectors (Definition 13.139), a D-dimensional space admits at most $D(D+1)/2$ of them, and a space admitting the full complement has curvature of constant-curvature form (Theorem 13.160). Here that machinery is instantiated on the spatial sections of spacetime.

Theorem 48.3 (The Robertson–Walker metric)**.** *A spacetime obeying Definition 48.2 — foliated by spacelike hypersurfaces each homogeneous and isotropic — admits coordinates (t, r, θ, φ) in which the metric takes the form*

$$\mathrm{d}s^2 = -c^2\mathrm{d}t^2 + a^2(t)\left[\frac{\mathrm{d}r^2}{1-kr^2} + r^2\left(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2\right)\right], \qquad k \in \{-1, 0, +1\}\,, \tag{48.3}$$

with r dimensionless, $a(t) > 0$ a function of t alone carrying the dimension of length, and k the sign of the spatial curvature. The uniqueness of this family was established group-theoretically by Robertson and Walker [758, 804].

Rests on Theorem 13.160, Proposition 13.162, and Remark 13.161.

Derivation. *Derives Theorem 48.3.*

Step 1: the slicing and cosmic time. Let the homogeneous slices be labelled by a parameter t and let x^i be coordinates within each slice, carried from slice to slice along the curves of constant x^i. In these coordinates the metric has blocks g_{00}, g_{0i}, g_{ij}. The vector field g_{0i} restricted to a slice is a spatial vector attached to every point; isotropy about every point forbids any nonvanishing spatial vector field defined by the geometry, so $g_{0i} = 0$: the slices are orthogonal to the curves of constant x^i, whose tangents define the *comoving observers*. Homogeneity makes g_{00} a function of t alone, and rescaling t absorbs it: $g_{00} = -c^2$. The label t is then the proper time of every comoving observer, synchronized across each slice — *cosmic time*.

Step 2: each slice has constant curvature. Each slice is a three-dimensional Riemannian space isotropic about every point. By Schur's argument (Remark 13.161), pointwise isotropy in $D = 3 > 2$ already forces the curvature into the maximally symmetric form Equation (13.318) with a single constant K over the slice: the slice is a space of constant curvature, of positive, zero or negative sign.

Step 3: the radial form of a constant-curvature 3-metric. For $K > 0$ the slice is (locally) the 3-sphere of radius $\ell = K^{-1/2}$, realizable by Proposition 13.162 as the quadric $X^2 + Y^2 + Z^2 + W^2 = \ell^2$ in Euclidean 4-space. Introduce on it the radius ρ of the 2-sphere orbits, so that $X^2 + Y^2 + Z^2 = \rho^2$ and $W^2 = \ell^2 - \rho^2$. Then $W\,\mathrm{d}W = -\rho\,\mathrm{d}\rho$, and the induced line element is

$$\mathrm{d}l^2 = \mathrm{d}\rho^2 + \rho^2\mathrm{d}\Omega^2 + \mathrm{d}W^2 = \frac{\mathrm{d}\rho^2}{1-\rho^2/\ell^2} + \rho^2\mathrm{d}\Omega^2\,,$$

with $\mathrm{d}\Omega^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2$. For $K < 0$ the same computation on the quadric of Proposition 13.162 with $\sigma = -1$ (in signature $(3,1)$) flips the sign under ρ^2/ℓ^2; for $K = 0$ the slice is flat and the line element is $\mathrm{d}\rho^2 + \rho^2\mathrm{d}\Omega^2$. Writing $\rho = \ell r$ with r dimensionless unifies the three cases into the bracket of Equation (48.3) with $k = \operatorname{sgn} K$ and an overall factor ℓ^2.

Step 4: the scale factor. The one geometric datum distinguishing slice from slice is the curvature radius ℓ, which homogeneity makes a single number per slice but which may vary with t: call it $a(t)$. Isotropy forbids any direction-dependent rescaling between slices (an anisotropic map of one slice onto the next would define preferred directions), and the sign k cannot change continuously. The metric is therefore Equation (48.3); for $k = 0$ the normalization of a is conventional, since only $\dot a/a$ and $\ddot a/a$ will appear in observables. That this family is the unique one — that no further functional freedom survives the symmetry — is the content of the group-theoretic classification of Robertson and Walker [758, 804], to which we refer for the completeness argument. □

Comoving coordinates deserve one dynamical remark before use: an object released at rest in them stays at rest (its worldline is a geodesic, by the isotropy of Equation (48.3) about it), and an object moving through them slows down.

Proposition 48.4 (Peculiar momentum decays with the expansion)**.** *Let a free particle move through the flat ($k = 0$) FLRW geometry with physical momentum p measured by the comoving observer it passes. Then along its geodesic*

$$p(t)\, a(t) = const\,, \qquad i.e. \qquad p \propto \frac{1}{a}\,. \tag{48.4}$$

Rests on Proposition 13.141 and Equation (48.3).

Derivation. *Derives Proposition 48.4.*

For $k = 0$ the spatial translations ∂_i are Killing vectors of Equation (48.3) (they preserve the flat slice metric, whose overall factor $a^2(t)$ they do not touch), so by Proposition 13.141, for the translation $\boldsymbol{\xi} = \partial_x$ along any fixed comoving direction x, the quantity $\xi_\mu u^\mu = g_{xx} u^x = a^2 \frac{\mathrm{d}x}{\mathrm{d}\tau}$ is constant along the geodesic. The physical momentum component measured locally is $p_x = m\, a \frac{\mathrm{d}x}{\mathrm{d}\tau}$ (the proper distance swept per proper time is $a\,\mathrm{d}x$), so $p_x a = m\, a^2 \frac{\mathrm{d}x}{\mathrm{d}\tau}$ is the conserved quantity, which is Equation (48.4). For a photon the same argument runs with the affine parameter in place of τ, and $p \propto 1/a$ reproduces the redshift Equation (48.2), since $p = h/\lambda$. Peculiar velocities of galaxies decay the same way, which is why the comoving frame is not merely a convention but an attractor. □

48.2.2 The Friedmann equations

Symmetry fixed the metric up to one function $a(t)$ and one sign k; the field equations of Chapter 44 now fix the dynamics of a. The same symmetry first constrains the source: isotropy about every comoving observer forces the stress–energy tensor to have no energy flux and no anisotropic stress in the comoving frame — the only tensors available are $g_{\mu\nu}$ and the observer 4-velocity u^μ — so it must take the perfect-fluid form

$$T_{\mu\nu} = (\varepsilon + p)\, \frac{u_\mu u_\nu}{c^2} + p\, g_{\mu\nu}\,, \tag{48.5}$$

with $\varepsilon(t)$ the energy density ($\mathrm{J/m^3}$) and $p(t)$ the pressure (Pa), both spatially constant by homogeneity.

Theorem 48.5 (The Friedmann equations)**.** *For the metric Equation (48.3) sourced by Equation (48.5), the field equations with cosmological constant Λ reduce to*

$$H^2 := \left(\frac{\dot a}{a}\right)^2 = \frac{8\pi G}{3c^2}\,\varepsilon - \frac{kc^2}{a^2} + \frac{\Lambda c^2}{3}\,, \tag{48.6}$$

$$\frac{\ddot a}{a} = -\frac{4\pi G}{3c^2}\,(\varepsilon + 3p) + \frac{\Lambda c^2}{3}\,, \tag{48.7}$$

together with the continuity equation

$$\dot\varepsilon + 3H\,(\varepsilon + p) = 0\,. \tag{48.8}$$

The first two were obtained from the field equations by Friedmann, for positive and for negative spatial curvature [490, 513], and independently by Lemaître [583].

Rests on Equations (48.3) and (48.5) and Postulate 44.3.

Derivation. *Derives Theorem 48.5.*

Write the metric as $g_{00} = -c^2$, $g_{ij} = a^2(t)\gamma_{ij}$, where γ_{ij} is the time-independent bracket of Equation (48.3): a 3-metric of constant curvature k, whose Ricci tensor is $R^{(3)}_{ij} = 2k\gamma_{ij}$ by Equation (13.318) in $D = 3$. The nonvanishing Christoffel symbols of Theorem 13.150 involving time are, by direct computation from $\Gamma^\lambda{}_{\mu\nu} = \frac{1}{2} g^{\lambda\sigma}(\partial_\mu g_{\sigma\nu} + \partial_\nu g_{\sigma\mu} - \partial_\sigma g_{\mu\nu})$,

$$\Gamma^t{}_{ij} = \frac{a\dot a}{c^2}\,\gamma_{ij}\,, \qquad \Gamma^i{}_{tj} = \frac{\dot a}{a}\,\delta^i{}_j\,, \tag{48.9}$$

plus the purely spatial symbols of γ_{ij}. Assembling the Ricci tensor (Definition 13.153) from these,

$$R_{tt} = -3\,\frac{\ddot{a}}{a}\,, \qquad R_{ij} = \left[\frac{a\ddot{a} + 2\dot{a}^2}{c^2} + 2k\right]\gamma_{ij}\,,$$

and the scalar

$$R = g^{tt}R_{tt} + g^{ij}R_{ij} = \frac{6}{c^2}\left[\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2} + \frac{kc^2}{a^2}\right].$$

The Einstein tensor components follow:

$$G_{tt} = 3\left[\frac{\dot{a}^2}{a^2} + \frac{kc^2}{a^2}\right], \qquad G_{ij} = -\frac{1}{c^2}\left[2a\ddot{a} + \dot{a}^2 + kc^2\right]\gamma_{ij}\,.$$

In the comoving frame $u^\mu = (1,0,0,0)$, $u_t = -c^2$, so Equation (48.5) gives $T_{tt} = \varepsilon c^2$ and $T_{ij} = p\,a^2\gamma_{ij}$. The tt component of the field equations $G_{\mu\nu} + \Lambda g_{\mu\nu} = (8\pi G/c^4)\,T_{\mu\nu}$ (Chapter 44) reads

$$3\left[\frac{\dot{a}^2}{a^2} + \frac{kc^2}{a^2}\right] - \Lambda c^2 = \frac{8\pi G}{c^2}\,\varepsilon\,,$$

which is Equation (48.6). The ij components, after dividing out $a^2\gamma_{ij}$ and eliminating $\dot{a}^2/a^2 + kc^2/a^2$ with Equation (48.6), collapse to Equation (48.7).

For Equation (48.8), impose $\nabla_\mu T^{\mu t} = 0$ — a consequence of the field equations via the Bianchi identities (Chapter 44), not a separate assumption. With $T^{tt} = \varepsilon/c^2$ and $T^{ij} = (p/a^2)\gamma^{ij}$,

$$\nabla_\mu T^{\mu t} = \partial_t\frac{\varepsilon}{c^2} + \Gamma^{\mu}{}_{\mu t}\frac{\varepsilon}{c^2} + \Gamma^{t}{}_{ij}\,T^{ij} = \frac{1}{c^2}\left[\dot{\varepsilon} + 3H\,(\varepsilon + p)\right] = 0\,,$$

using $\Gamma^{\mu}{}_{\mu t} = 3\dot{a}/a$ and Equation (48.9). Only two of the three equations are independent: differentiating Equation (48.6) and using Equation (48.8) reproduces Equation (48.7). □

Definition 48.6 (Critical density and the density parameters)**.** The *critical density* at expansion rate H is the energy density that makes the $k = 0$, Λ-free universe balance in Equation (48.6):

$$\varepsilon_{\mathrm{c}} := \frac{3H^2c^2}{8\pi G}\,, \qquad \rho_{\mathrm{c}} := \frac{\varepsilon_{\mathrm{c}}}{c^2} = \frac{3H^2}{8\pi G}\,. \tag{48.10}$$

Each component's *density parameter* is its present share, $\Omega_i := \varepsilon_i(t_0)/\varepsilon_{\mathrm{c}}(t_0)$, with the conventions $\Omega_\Lambda := \Lambda c^2/(3H_0^2)$ and $\Omega_k := -kc^2/(a_0^2H_0^2)$, in terms of which Equation (48.6) evaluated today reads

$$\Omega_{\mathrm{r}} + \Omega_{\mathrm{m}} + \Omega_k + \Omega_\Lambda = 1\,. \tag{48.11}$$

For $H_0 = 67.4\,\mathrm{km/(s\,Mpc)}$ the critical density is $\rho_{\mathrm{c}} = 8.5\times10^{-27}\,\mathrm{kg/m^3}$ (computed here), about five hydrogen atoms per cubic metre — the gulf between that number and any laboratory vacuum is a useful reminder of how empty the universe is on average.

48.2.3 Distances and horizons

In an expanding curved geometry "distance" must be defined operationally, and the two definitions that match what telescopes actually do — comparing fluxes and comparing angles — differ from each other and from the coordinate separation. All are built on the comoving radial coordinate accumulated by a light ray. Define

$$\chi := \int_0^r \frac{\mathrm{d}r'}{\sqrt{1 - kr'^2}}\,, \qquad S_k(\chi) := \begin{cases} \sin\chi & k = +1\,,\\ \chi & k = 0\,,\\ \sinh\chi & k = -1\,, \end{cases} \tag{48.12}$$

so that $r = S_k(\chi)$ and the metric reads $\mathrm{d}s^2 = -c^2\mathrm{d}t^2 + a^2[\mathrm{d}\chi^2 + S_k^2(\chi)\,\mathrm{d}\Omega^2]$. A radial null ray obeys $c\,\mathrm{d}t = a\,\mathrm{d}\chi$, so a source seen today at redshift z sits at

$$\chi(z) = \frac{c}{a_0}\int_0^z \frac{\mathrm{d}z'}{H(z')}\,, \qquad H(z) = H_0\,E(z)\,, \tag{48.13}$$

where the dimensionless expansion history

$$E(z) = \sqrt{\Omega_\mathrm{r}(1+z)^4 + \Omega_\mathrm{m}(1+z)^3 + \Omega_k(1+z)^2 + \Omega_\Lambda} \tag{48.14}$$

follows from Equation (48.6) once the scaling of each component with a is known — derived in Section 48.3.1 below.

Proposition 48.7 (Luminosity distance)**.** *Let a source of intrinsic luminosity L (W) at redshift z be observed with energy flux F (W/m^2). Then the* luminosity distance $d_\mathrm{L} := \sqrt{L/(4\pi F)}$ *evaluates to*

$$d_\mathrm{L} = (1+z)\,a_0\,S_k(\chi(z))\,. \tag{48.15}$$

Rests on Equations (48.2) and (48.13) and Theorem 48.3.

Derivation. *Derives Proposition 48.7.*

The photons emitted in all directions at comoving radius χ are, at reception, spread over a sphere whose proper area is $4\pi a_0^2 S_k^2(\chi)$ (set $\mathrm{d}t = \mathrm{d}\chi = 0$ in the metric and integrate the angular part at the observer's epoch). Two further factors of $(1+z)$ deplete the flux: each photon arrives with its energy degraded by $1+z$ (Equation (48.2) applied to $E = h\nu$), and the arrival *rate* of photons is diluted by the same factor (the crest-interval argument in the derivation of Phenomenon 48.1 applies to any clock, photon spacing included). Hence

$$F = \frac{L}{4\pi a_0^2 S_k^2(\chi)\,(1+z)^2}\,,$$

and solving $F = L/(4\pi d_\mathrm{L}^2)$ for d_L gives Equation (48.15). □

Corollary 48.8 (Angular-diameter distance and the duality relation)**.** *An object of proper transverse size ℓ at redshift z subtends the angle $\theta = \ell/d_\mathrm{A}$ with*

$$d_\mathrm{A} = a(t_\mathrm{e})\,S_k(\chi(z)) = \frac{d_\mathrm{L}}{(1+z)^2}\,. \tag{48.16}$$

Rests on Equation (48.15) and Proposition 48.7.

Derivation. *Derives Corollary 48.8.*

The proper size ℓ was laid down at emission: setting $\mathrm{d}t = \mathrm{d}\chi = 0$ *at the emission epoch*, the transverse proper length subtending coordinate angle θ at comoving radius χ is $\ell = a(t_\mathrm{e})S_k(\chi)\,\theta$, whence the first equality; the second follows from Equation (48.15) and $a_0/a(t_\mathrm{e}) = 1+z$. The relation $d_\mathrm{L} = (1+z)^2 d_\mathrm{A}$ holds in any metric theory with photon-number conservation, which makes it a test of the framework itself rather than of a parameter set. □

Two horizons bound what can be seen and what can be reached. The *particle horizon* is the comoving radius light can have crossed since the initial time,

$$\chi_\mathrm{p}(t) = \int_0^t \frac{c\,\mathrm{d}t'}{a(t')}\,, \tag{48.17}$$

finite whenever a grows fast enough near $t = 0$ — in the radiation era $a \propto t^{1/2}$ and the integral converges at the lower end, so at every epoch there *is* a finite sphere of causal

contact, a fact that becomes the horizon problem of Section 48.8. Today the proper particle horizon is about 14 Gpc (computed here from Equation (48.14) with the parameters of Table 48.1). Complementarily, with $\Lambda > 0$ the future integral $\int_t^\infty c\,\mathrm{d}t'/a(t')$ converges (exponential expansion), so an *event horizon* exists: comoving regions beyond it can never be signalled, and galaxies presently leave our future light cone [1871]. The Hubble radius $c/H_0 \approx 4.5$ Gpc (computed) is not a horizon but a curvature scale; it enters the perturbation theory of Section 48.5.1 as the boundary of the Newtonian regime.

48.3 The thermal history

48.3.1 Radiation, matter and Λ eras

Proposition 48.9 (Scaling of the energy components)**.** *Let a component have equation of state $p = w\varepsilon$ with w constant. Then Equation (48.8) integrates to*

$$\varepsilon(a) = \varepsilon_0 \left(\frac{a_0}{a}\right)^{3(1+w)} , \tag{48.18}$$

so nonrelativistic matter ($w = 0$) dilutes as a^{-3}, radiation ($w = 1/3$) as a^{-4}, and the Λ term ($w = -1$, $\varepsilon_\Lambda = \Lambda c^4/8\pi G$ constant) not at all.

Rests on Equation (48.8).

Derivation. Derives Proposition 48.9.

With $p = w\varepsilon$, Equation (48.8) reads $\mathrm{d}\ln\varepsilon = -3(1+w)\,\mathrm{d}\ln a$, which is Equation (48.18). The physics of the two nontrivial cases: matter dilutes with the volume, a^{-3}; radiation dilutes with the volume *and* each quantum loses energy as $1/a$ by Equation (48.4), giving the fourth power. The constancy of the Λ term is what makes it inevitable that, given enough expansion, it dominates — the ordering of the eras below is not an accident of initial conditions. □

Because the four terms of Equation (48.14) scale with four different powers, the history divides into eras with sharp crossovers. Radiation–matter equality sits at $1 + z_{\mathrm{eq}} = \Omega_{\mathrm{m}}/\Omega_{\mathrm{r}} \approx 3400$ (computed here from the densities of Table 48.1, with the photon density from the measured T_0 and the standard three neutrino species); matter–Λ equality at $1 + z = (\Omega_\Lambda/\Omega_{\mathrm{m}})^{1/3}$, i.e. $z \approx 0.30$, and the expansion began accelerating (Equation (48.7) changing sign) at $z \approx 0.6$, both computed from the same table. Solving Equation (48.6) in each pure era gives $a \propto t^{1/2}$ (radiation), $a \propto t^{2/3}$ (matter), and $a \propto \exp\left(\sqrt{\Lambda/3}\,ct\right)$ (Λ) — the last being the reason for the event horizon of Section 48.2.3.

Temperature. The relic radiation cools as $T \propto 1/a$ (Equation (48.24), derived with the CMB in Section 48.4.1); running that backwards makes the early universe arbitrarily hot, and equilibrium thermodynamics (Chapter 120) governs the plasma. Two workhorse relations follow. First, for the coupled relativistic plasma the comoving entropy is conserved: the expansion of Equation (48.8) is adiabatic (no heat crosses the boundary of a comoving volume — there is nowhere for it to come from, by homogeneity), so $s\,a^3 = \text{const}$ with $s \propto g_* T^3$ the entropy density of the relativistic species (Chapter 120), g_* counting their effective degrees of freedom. While g_* is constant this reproduces $T \propto 1/a$; when a species annihilates, its entropy is inherited by the rest, and the photon temperature briefly falls more slowly than $1/a$.

The one clean application is a prediction. Neutrinos decouple from the plasma just before electrons and positrons annihilate, so the $e^\pm$ entropy goes to the photons alone. Before annihilation the electromagnetic sector holds $g_* = 2 + \frac{7}{8} \times 4 = \frac{11}{2}$ (photons plus $e^\pm$);

after, $g_* = 2$. Conservation of $g_*(Ta)^3$ across the transition gives $(T_\gamma a)^3_{\text{after}} = \frac{11}{4}(Ta)^3_{\text{before}}$, while the decoupled neutrinos keep $(T_\nu a)$ fixed, so

$$\frac{T_\nu}{T_\gamma} = \left(\frac{4}{11}\right)^{1/3}, \qquad T_{\nu,0} = 1.95\,\text{K} \quad \text{(computed)}\,. \tag{48.19}$$

The relic neutrino sea itself has never been detected directly; its reality is attested indirectly, through the radiation density it contributes at nucleosynthesis (Section 48.3.2) and in the CMB damping tail [2348] — an honest amber, recorded as such.

Second, in the radiation era Equation (48.6) with $\varepsilon = \frac{g_*}{2}\, a_\text{B} T^4$ ($a_\text{B} = 4\sigma/c$ the radiation constant, Chapter 68) and $a \propto t^{1/2}$ gives the time–temperature relation

$$t = \left(\frac{3c^2}{16\pi G\, g_*\, a_\text{B}}\right)^{1/2} T^{-2}\,, \tag{48.20}$$

so $T = 1 \times 10^{10}\,\text{K}$ is reached at $t \approx 1\,\text{s}$ (with $g_* = 10.75$: photons, $e^\pm$, three neutrino species) and $T = 1 \times 10^9\,\text{K}$ at $t \approx 3\,\text{min}$ (with $g_* = 3.36$ after annihilation); both computed here. The first minutes are nuclear physics territory, taken up next.

Recombination. The plasma remains ionized long after $k_\text{B}T$ falls below the hydrogen binding energy of 13.6 eV, because photons outnumber baryons by $\eta^{-1} \approx 1.6 \times 10^9$ (Section 48.3.2) and the Wien tail keeps ionizing. The ionization balance — the Saha equation [470], an application of the chemical equilibrium of Chapter 120 — drops the free-electron fraction steeply only once $k_\text{B}T \approx 0.26\,\text{eV}$, i.e. $T \approx 3000\,\text{K}$, at $z_* \approx 1090$ (the precise value, $z_* = 1089.9$, is quoted from the fit of Table 48.1). The photons then fly free: that release is the last-scattering surface whose image is the microwave background of Section 48.4.

48.3.2 Big-Bang nucleosynthesis

The proposal that the light elements were assembled in the hot first minutes is the alpha–beta–gamma paper of 1948 [905]; the governing role of the neutron-to-proton ratio and its weak-interaction freeze-out was worked out by Hayashi [960]; and the full reaction network in the modern sense — a stiff system of coupled rate equations integrated through the expansion — was first computed by Wagoner, Fowler and Hoyle [1361], whose descendants remain in use [2357]. The heavier elements are *not* made here: there is no stable nucleus at mass 5 or 8, and the low density starves the triple-α process that stars use to jump the gap (Chapter 52, [1044]); primordial synthesis stalls at ^{7}Li.

Phenomenon 48.10 (A primordial floor of light elements)**.** The least processed material accessible to observation — metal-poor extragalactic gas clouds, and the absorption systems seen against high-redshift quasars — carries a common floor of light elements that stellar processing cannot produce: a helium mass fraction close to 0.25, a deuterium abundance D/H of a few parts in 10^5, and traces of ^{3}He and ^{7}Li. In the hot-big-bang picture these abundances form a one-parameter family governed by the ratio of baryons to photons alone [905, 2357], and the value of that ratio which fits them agrees with the entirely independent determination from the microwave-background power spectrum [2348]. Deuterium is the sharpest of the four: it is destroyed in stellar interiors and made nowhere else, so any observed deuterium is a lower bound on the primordial value.

Rests on Equation (48.20) and Theorem 48.5.

Derivation. *Derives Phenomenon 48.10.*

Step 1: freeze-out of the neutron fraction. Above $k_\text{B}T \approx 1\,\text{MeV}$ the weak reactions $n + \nu_e \leftrightarrow p + e^-$ and $n + e^+ \leftrightarrow p + \bar{\nu}_e$ (Chapter 107) hold neutrons and protons in chemical

equilibrium, so their ratio is the Boltzmann factor of the mass difference $\Delta mc^2 = 1.293\,\mathrm{MeV}$:

$$\frac{n}{p} = \exp\left(-\frac{\Delta m\, c^2}{k_{\mathrm{B}} T}\right) . \tag{48.21}$$

The interconversion rate per nucleon scales as $\Gamma \sim \left[G_{\mathrm{F}}/(\hbar c)^3\right]^2 (k_{\mathrm{B}}T)^5/\hbar$ (the Fermi coupling squared times the phase space of the five-dimensional final-state integral, Chapter 107), while the expansion rate scales as $H \sim \sqrt{g_* G/(\hbar^3 c^5)}\,(k_{\mathrm{B}}T)^2$ by Equation (48.6); their ratio falls as T^3, so equilibrium is abruptly lost. Carrying the numerical factors of the full rates through (we import them from the standard treatment [960, 2357]), $\Gamma = H$ at $k_{\mathrm{B}}T_{\mathrm{f}} \approx 0.8\,\mathrm{MeV}$, where Equation (48.21) gives $n/p \approx 1/5$; residual out-of-equilibrium conversions push the ratio to about $1/6$ over the following seconds.

Step 2: the deuterium bottleneck. Fusion must proceed through deuterium, $p + n \to \mathrm{D} + \gamma$, whose binding energy is only $B_{\mathrm{D}} = 2.224\,\mathrm{MeV}$. Although $k_{\mathrm{B}}T < B_{\mathrm{D}}$ already at freeze-out, each baryon is bathed in $\eta^{-1} \approx 1.6 \times 10^9$ photons, and photodissociation wins as long as the number of photons in the Wien tail above B_{D} exceeds the number of baryons — roughly, while $\eta^{-1}\exp\left(-B_{\mathrm{D}}/k_{\mathrm{B}}T\right) > 1$. Solving with $\eta = 6.1 \times 10^{-10}$ gives $k_{\mathrm{B}}T \approx B_{\mathrm{D}}/21 \approx 0.1\,\mathrm{MeV}$; the full rate balance places the breakout slightly lower, near $k_{\mathrm{B}}T \approx 0.08\,\mathrm{MeV}$, i.e. $T \approx 1 \times 10^9\,\mathrm{K}$, reached at $t \approx 3\,\mathrm{min}$ by Equation (48.20). The delay matters because free neutrons decay with mean life $\tau_n = 878.4\,\mathrm{s}$ (Chapter 107): by breakout the ratio has fallen to $n/p \approx 1/7$.

Step 3: helium. Once deuterium survives, the chain $\mathrm{D}(p,\gamma)^3\mathrm{He}$, $\mathrm{D}(\mathrm{D},n)^3\mathrm{He}$, $^3\mathrm{He}(\mathrm{D},p)^4\mathrm{He}$ runs to completion in minutes, because ^{4}He is by far the most bound light nucleus (Chapter 107). To first approximation *every surviving neutron ends in helium*: with $x := n/p$ at breakout, the helium mass fraction is

$$Y_{\mathrm{p}} = \frac{2x}{1+x} \approx 0.25 \quad \text{for } x = \tfrac{1}{7} . \tag{48.22}$$

The estimate is robust precisely because it rests on a counting argument, not on cross sections; the full network sharpens it to $Y_{\mathrm{p}} = 0.2469 \pm 0.0002$ at the CMB baryon density [2357].

Step 4: the deuterium residue and the baryometer. A trace of deuterium fails to burn, at a level set by the competition between the burning rate (proportional to the baryon density) and the expansion: a *higher* baryon density burns deuterium more completely, so D/H is a steeply decreasing function of η — the baryometer. The network prediction at the CMB-determined density lies between 2.5 and 2.6 parts in 10^5, the spread reflecting nuclear-rate inputs [2357]; the measurement, from damped Lyman-α absorbers along quasar sightlines, is $\mathrm{D/H} = (2.527 \pm 0.030) \times 10^{-5}$ [2308]. The measured helium fraction in metal-poor H II regions, $Y_{\mathrm{p}} = 0.2449 \pm 0.0040$ [2250], agrees with Equation (48.22) and its refinement. The full integration of the coupled rate network through the expansion — dozens of reactions, evaluated against measured cross sections — is imported here by reference [1361, 2357] rather than restated; the analytic skeleton above is what makes its output intelligible. □

The baryon-to-photon ratio used above, $\eta = 6.1 \times 10^{-10}$, is computed here from the CMB baryon density $\Omega_{\mathrm{b}}h^2$ of Table 48.1 and the photon density implied by the measured T_0 — and the point of Phenomenon 48.10 is that the abundances measured in gas clouds return the same number from entirely different physics at an epoch separated by a factor of 10^9 in temperature.

Remark 48.11 (The lithium discrepancy). The account above is honest only if its one failure is stated: the same network that gets D and ^{4}He right predicts a primordial ^{7}Li abundance about a factor of three above what is measured on the Spite plateau of metal-poor halo stars [2357]. Whether the fault lies in stellar depletion of lithium, in the astrophysics of the measurement, or in the network itself is not settled; the discrepancy is recorded here as an open defect of the concordance, not explained away.

48.3.3 The prediction of the relic radiation

The hot early phase required by Section 48.3.2 does not switch itself off: if the universe was once a thermal plasma, its radiation must still be here, cooled by the expansion but preserving its thermal form (the proof of that preservation is given with Phenomenon 48.12 below). In 1948 Gamow set out the framework in which nucleosynthesis fixes the conditions at $T \sim 10^9\,\mathrm{K}$ [914], and Alpher and Herman, correcting and completing his estimate, drew the explicit conclusion: a residual blackbody radiation should fill the universe today, at a temperature they put at about 5 K [906].

The structure of their inference deserves to be exhibited in modern numbers, because it is a genuine prediction — made seventeen years before the discovery, and not being searched for when the discovery came. The deuterium bottleneck fixes the baryon density *at* $T \approx 1\times10^9\,\mathrm{K}$: capture must win against expansion, which by the cross sections requires $\rho_\mathrm{b} \sim 1\times10^{-2}\,\mathrm{kg/m^3}$ there (computed here from the modern network normalization; Alpher and Herman's value was cruder). Astronomy supplies the *present* mean baryon density, $\rho_{\mathrm{b},0} \sim 4\times10^{-28}\,\mathrm{kg/m^3}$. Since $\rho_\mathrm{b} \propto a^{-3}$ while $T \propto a^{-1}$ (Proposition 48.9 and Equation (48.24)), the expansion factor between the two epochs is $(\rho_\mathrm{b}/\rho_{\mathrm{b},0})^{1/3} \approx 4\times10^8$, and the present radiation temperature must be

$$T_0 \approx \frac{1\times10^9\,\mathrm{K}}{4\times10^8} \approx 2.5\,\mathrm{K}\,. \tag{48.23}$$

With the modern inputs the estimate lands on the measured value; with the 1948 inputs it gave 5 K — the right physics and the right order of magnitude, published in *Nature*, and then forgotten for seventeen years. When Penzias and Wilson found the radiation in 1965 (Section 48.4.1) they were unaware of the prediction, and the interpreting paper [1305] cited the hot-big-bang logic afresh. As a case study in how evidence accumulates — prediction, neglect, independent rediscovery — cosmology has no better example (Chapter 1).

48.4 The cosmic microwave background

48.4.1 Discovery

In 1964 Penzias and Wilson, commissioning the 6 m horn antenna at Holmdel for radio astronomy, found an excess antenna temperature of $(3.5 \pm 1.0)\,\mathrm{K}$ at 4080 MHz that no accounting could remove: it was independent of direction, of season, and of every instrumental cause they could test, down to the famous evicted pigeons [1320]. The interpretation — that this is the cooled relic of the hot early universe — was supplied in the companion paper by Dicke, Peebles, Roll and Wilkinson [1305], whose own purpose-built radiometer was months from completion. The spectrum was finally measured absolutely from orbit by COBE/FIRAS, and it is the most perfect Planck spectrum known (Chapter 68); the instruments, data and error budgets belong to the experiment chapter, Chapter 51.

Phenomenon 48.12 (The relic microwave background)**.** The whole sky radiates in the microwave band with a spectrum indistinguishable from a Planck spectrum, at a temperature $T_0 = 2.725\,48\,\mathrm{K}$ known to $0.000\,57\,\mathrm{K}$ [2144], and isotropic to about one part in 10^5 once the dipole of Section 48.4.2 is removed. It was found as an irreducible excess antenna temperature at 4.08 GHz that no instrumental or local source would account for [1320], and identified in the companion paper as the relic of a hot early phase [1305] — a state of affairs predicted seventeen years earlier [906]. Absolute spectrophotometry from orbit found the departures from the Planck form to be below 10^{-4} of the peak intensity [1834, 1922], making this the closest approach to a blackbody ever measured anywhere, laboratory sources included.

Rests on Equation (48.2) *and Theorem 48.3.*

Derivation. *Derives Phenomenon 48.12.*

What must be shown is that a thermal spectrum survives free expansion with its temperature as the only changing parameter — otherwise the observed Planck form could not be a relic, the universe having expanded by a factor of order 10^3 since the photons last scattered. Let the radiation be in equilibrium at temperature T_e when the scale factor is a_e, so that the mean occupation number of a mode of frequency ν is the Planck value of Chapter 68,

$$f(\nu) = \frac{1}{\exp\left(h\nu/\left(k_\mathrm{B}T_\mathrm{e}\right)\right) - 1}\,.$$

Now expand freely to scale factor a. Two things happen, and only two. Every mode redshifts, $\nu \to \nu' = \nu\, a_\mathrm{e}/a$, by Equation (48.2) applied to the mode itself; and the occupation number of each mode is unchanged, since with no emission, absorption or scattering the photons are neither created nor destroyed while the modes themselves are simply carried along by the expansion. Hence

$$f'\left(\nu'\right) = f(\nu) = \frac{1}{\exp\left(h\nu' a/\left(a_\mathrm{e}k_\mathrm{B}T_\mathrm{e}\right)\right) - 1} = \frac{1}{\exp\left(h\nu'/\left(k_\mathrm{B}T\right)\right) - 1}\,,$$

which is again of Planck form, with

$$T = T_\mathrm{e}\frac{a_\mathrm{e}}{a}\,, \qquad \text{equivalently} \qquad T(z) = T_0\left(1+z\right)\,. \tag{48.24}$$

The spectrum is preserved exactly and the single parameter T scales as $1/a$. Two consequences follow. The measured T_0 fixes the radiation temperature at every earlier epoch, which is what makes the thermal history of Section 48.3 calculable; and any measured departure from the Planck form would be a record of energy injected after thermalization ceased, so the spectral limits quoted above are constraints on the entire history since then. □

48.4.2 Anisotropies

The first anisotropy seen was the *dipole*: one side of the sky is hotter than the other by 3.4 mK, detected from a U-2 aircraft in 1977 [1610] and measured by FIRAS at (3.372 ± 0.014) mK [1922]. It is kinematic: a Doppler modulation of Equation (48.24) by our own motion, $\Delta T/T_0 = v/c$, giving $v \approx 370$ km/s (computed) for the barycentre of the Solar System relative to the frame in which the radiation is isotropic — the comoving frame of Section 48.2.1 made tangible. It is removed before the cosmological analysis begins.

Phenomenon 48.13 (The anisotropy spectrum of the relic radiation)**.** Beneath the dipole, the microwave sky carries temperature fluctuations of about one part in 10^5: an rms of roughly 30 µK on ten-degree scales, first detected by the COBE differential radiometers [1858]. At angular scales below a degree the fluctuation power is organized into a series of acoustic peaks, the first near multipole $\ell \approx 220$, measured with high precision by the Planck satellite [2348]. The large-angle plateau was predicted as the gravitational imprint of density perturbations on the last-scattering surface [1357], and the peak structure as the frozen phases of sound waves in the pre-recombination plasma [1431, 1434] — both before any anisotropy had been seen. The apparatus, maps and likelihoods are the subject of Chapter 51.

Rests on Equation (48.24) and Phenomenon 48.12.

Derivation. *Derives Phenomenon 48.13.*

Two mechanisms carry the primordial perturbations onto the sky, and each is derivable in outline here.

The Sachs–Wolfe plateau. Consider a large-scale density perturbation at last scattering — large enough that no causal process has acted on it (Equation (48.17)), so only gravity

speaks. Let Φ be its Newtonian potential ($\Phi < 0$ in an overdensity). Photons climbing out of the well are gravitationally redshifted (Chapter 42): $\Delta T/T|_{\rm grav} = \Phi/c^2$. But the well also retards the local clocks: the proper time elapsed at coordinate time t is shifted by $\delta\tau/\tau = \Phi/c^2$, so the plasma in the well reaches its recombination temperature *later* in cosmic time, by $\delta t/t = -\Phi/c^2$; at that later time the scale factor is larger by $\delta a/a = \frac{2}{3}\,\delta t/t$ (matter era, $a \propto t^{2/3}$), and photons released at fixed local temperature from a larger a suffer less subsequent cooling, arriving hotter by $\Delta T/T|_{\rm delay} = -\frac{2}{3}\Phi/c^2$. The sum is

$$\frac{\Delta T}{T} = \frac{\Phi}{c^2} - \frac{2}{3}\frac{\Phi}{c^2} = \frac{\Phi}{3c^2}\,, \tag{48.25}$$

cold spots over overdensities, at one third of the naive gravitational redshift. The bookkeeping above is heuristic in its treatment of time; the gauge-consistent computation, which confirms the factor 1/3 for adiabatic perturbations in the matter era, is Sachs and Wolfe's [1357] and is imported by reference. With $\Delta T/T \sim 10^{-5}$, Equation (48.25) measures the depth of the primordial potentials, $\Phi/c^2 \sim 3 \times 10^{-5}$ — the normalization every structure-formation calculation in Section 48.5 inherits.

The acoustic peaks. Inside the horizon the pre-recombination plasma is a single tightly coupled fluid, and perturbations in it oscillate as sound waves (the restoring force is photon pressure; the derivation of the sound speed is given with Phenomenon 48.15). All modes of a given wavenumber k start their oscillation together — at horizon entry, with the same phase, because they share the same super-horizon initial condition — so at the instant of decoupling the modes with $k\,r_{\rm s} = n\pi$, where $r_{\rm s}$ is the comoving sound horizon (Equation (48.34)), are caught at the extrema of their oscillation. Those wavenumbers are imprinted as excess variance: projected on the sky through the angular-diameter distance of Corollary 48.8, they appear at multipoles

$$\ell_n \approx n\,\frac{\pi}{\theta_*}\,, \qquad \theta_* = \frac{r_{\rm s}(z_*)}{(1+z_*)\,d_{\rm A}(z_*)}\,, \tag{48.26}$$

up to an order-unity shift from the projection geometry and from the gravitational driving of the oscillations. Computing θ_* here from Equations (48.13) and (48.34) with the parameters of Table 48.1 gives $\theta_* = 1.040 \times 10^{-2}$ rad, against the measured 1.0411×10^{-2} [2348] — agreement at the level of a part in a thousand, which is the concordance of Section 48.7 in miniature. The measured first peak sits at $\ell_1 \approx 220$. On scales smaller still the peaks die away: photons random-walk out of wavelengths shorter than their diffusion length before decoupling completes, erasing the fluctuations — Silk damping, predicted in 1968 [1383] and measured in the high-ℓ tail [2348]. □

What the peak pattern buys, quantitatively, is leverage on nearly every parameter of Section 48.7: the sound horizon is calculable from pre-recombination physics, the peak angle measures the geometry through Equation (48.26), the relative peak heights measure the baryon and matter densities (baryons load the oscillating fluid asymmetrically; matter sets the epoch of equality and the driving). The extraction, with the instruments and likelihoods behind it, is Chapter 51.

48.5 Large-scale structure

48.5.1 Growth of perturbations

The universe of Definition 48.2 is smooth; the universe outside the window is not. The bridge is gravitational instability: the fluctuations of 10^{-5} measured on the last-scattering surface grow under their own gravity into the galaxies and clusters of today. The instability of a self-gravitating medium was analysed by Jeans for a static background [306]; the general-relativistic perturbation theory of an expanding universe is Lifshitz's [892]. On scales

well inside the Hubble radius and for nonrelativistic matter, Newtonian fluid mechanics (Chapter 31) suffices, and that is the regime derived here; the relativistic treatment is imported by reference where super-horizon scales are concerned [892].

Theorem 48.14 (Linear growth of density perturbations)**.** *Let $\delta := \delta\rho/\bar\rho$ be the fractional density perturbation of a pressureless matter component in an FLRW background, on scales well inside the Hubble radius. To linear order each Fourier mode $\delta_{\boldsymbol{k}}$ (comoving wavevector $\boldsymbol{k}$) obeys*

$$\ddot\delta_{\boldsymbol{k}} + 2H\dot\delta_{\boldsymbol{k}} = \left(4\pi G\bar\rho - \frac{c_s^2 k^2}{a^2}\right)\delta_{\boldsymbol{k}}\,, \tag{48.27}$$

with c_s the sound speed of the medium. In the matter era the pressureless growing mode is

$$\delta \propto a\,, \tag{48.28}$$

power-law growth, not the exponential growth of the static case.
Rests on Equations (31.10), (31.19) and (48.6) and Theorem 48.5.

Derivation. *Derives Theorem 48.14.*

Start from the continuity and Euler equations of Chapter 31 (Equations (31.10) and (31.19)) with the gravitational force $-\nabla\Phi$, and the field equation of Newtonian gravity in local form, $\nabla^2\Phi = 4\pi G\rho$ (Chapter 27). The background solution is the expansion itself: $\bar\rho(t) \propto a^{-3}$, velocity field $\bar{\boldsymbol{v}} = H\boldsymbol{r}$, and $\bar\Phi = \frac{2}{3}\pi G\bar\rho r^2$, which satisfies the three equations by virtue of Equations (48.6) and (48.7) restricted to their Newtonian content.

Perturb: $\rho = \bar\rho(1+\delta)$, $\boldsymbol{v} = H\boldsymbol{r} + \boldsymbol{u}$, $\Phi = \bar\Phi + \phi$, and pass to comoving coordinates $\boldsymbol{x} = \boldsymbol{r}/a$, in which $\nabla_r = a^{-1}\nabla_x$ and the time derivative at fixed $\boldsymbol{x}$ replaces that at fixed $\boldsymbol{r}$ via $\partial_t|_r = \partial_t|_x - H\boldsymbol{x}\cdot\nabla_x$. To first order in $(\delta, \boldsymbol{u}, \phi)$ the three equations become

$$\dot\delta + \frac{1}{a}\nabla_x\cdot\boldsymbol{u} = 0\,, \tag{48.29}$$

$$\dot{\boldsymbol{u}} + H\boldsymbol{u} = -\frac{1}{a}\nabla_x\phi - \frac{c_s^2}{a}\nabla_x\delta\,, \tag{48.30}$$

$$\nabla_x^2\phi = 4\pi G\bar\rho\, a^2\delta\,, \tag{48.31}$$

where the pressure term wrote $\nabla p = c_s^2\bar\rho\,\nabla\delta$. Take ∂_t of Equation (48.29), insert Equation (48.30), eliminate $\nabla_x\cdot\boldsymbol{u}$ with Equation (48.29) again and ϕ with Equation (48.31), and Fourier-transform in $\boldsymbol{x}$: the result is Equation (48.27). The Hubble term $2H\dot\delta$ — absent in the static case — acts as friction: expansion carries matter away from the well as fast as gravity gathers it.

Setting $H = 0$, $\bar\rho$ constant recovers Jeans's dichotomy [306]: modes with $k < k_{\mathrm{J}}$, where

$$\frac{c_s^2 k_{\mathrm{J}}^2}{a^2} = 4\pi G\bar\rho\,, \tag{48.32}$$

grow exponentially at rate $\sqrt{4\pi G\bar\rho}$, shorter modes oscillate as sound. In the expanding matter era take $c_s \to 0$, $a \propto t^{2/3}$, so $H = 2/(3t)$ and $4\pi G\bar\rho = \frac{3}{2}H^2 = 2/(3t^2)$ (Einstein–de Sitter values from Equation (48.6)); the ansatz $\delta \propto t^n$ gives $3n^2 + n - 2 = 0$, i.e. $n = 2/3$ or $n = -1$. The growing mode is $\delta \propto t^{2/3} \propto a$, which is Equation (48.28). During radiation domination the rapid expansion (H set by the radiation, not by the matter) overwhelms the self-gravity of the matter and growth stalls logarithmically; once Λ dominates, growth stops [1871]. □

Theorem 48.14 carries an arithmetic consequence that is one of the strongest arguments in this book. From recombination to today the scale factor grows by $1 + z_* \approx 1100$, so a baryonic fluctuation of the measured amplitude $\sim 10^{-5}$ (Phenomenon 48.13) can have

grown by at most that factor — to 10^{-2}, and less once the stalls at both ends are counted. Galaxies, with $\delta \gg 1$, could not exist. The resolution is a matter component that does not couple to the photons: its perturbations, unsupported by radiation pressure, began growing at matter–radiation equality ($z_{\mathrm{eq}} \approx 3400$, Section 48.3.1) and had dug potential wells well before recombination; the baryons, released at z_*, fell into wells already prepared [1699]. This is the structure-formation argument for dark matter cited in Phenomenon 48.16.

The initial spectrum feeding Equation (48.27) was guessed on general grounds before it was measured: Harrison and Zel'dovich argued independently that the only spectrum injecting equal potential fluctuations on every scale — the only one with no built-in preferred length — has spectral index $n_s = 1$ [1424, 1491]. The measured value, $n_s = 0.9649 \pm 0.0042$ [2348], is close to but significantly below that: a small tilt, whose possible origin is taken up in Section 48.8.

48.5.2 Baryon acoustic oscillations

The sound waves that produce the CMB peaks (Phenomenon 48.13) do not vanish at recombination: they freeze into the *matter* distribution too, and their imprint is measurable in galaxy surveys billions of years later — a ruler of known length available at many redshifts.

Phenomenon 48.15 (A standard ruler in the galaxy distribution)**.** The two-point correlation function of galaxies carries a single narrow excess at a comoving separation of about 150 Mpc, riding on an otherwise smooth, nearly power-law clustering. It was first detected in the luminous-red-galaxy sample of the Sloan survey [2076]. The feature sits at the comoving sound horizon frozen in when the photons decoupled from the baryons — the same length that sets the angular spacing of the acoustic peaks in the microwave background [2348] — so it is a ruler of calculable length laid down at a known redshift. Measuring its apparent size along and across the line of sight at several redshifts maps the expansion history geometrically, with no standard candle and no distance ladder involved.

Rests on Equations (48.16) *and* (48.34) *and Corollary 48.8.*

Derivation. *Derives Phenomenon 48.15.*

Step 1: the sound speed of the coupled fluid. Before recombination, Thomson scattering ties the baryons to the photons into a single fluid whose pressure is supplied almost entirely by the photons, $p_\gamma = \varepsilon_\gamma/3$ (Chapter 68), and whose inertia is shared. For adiabatic perturbations the photon and baryon densities fluctuate together (equal number-density contrasts, so $\delta\varepsilon_\gamma/\varepsilon_\gamma = \frac{4}{3}\,\delta\rho_{\mathrm{b}}/\rho_{\mathrm{b}}$), and the sound speed follows from $c_s^2 = c^2\,\delta p/\delta\varepsilon$:

$$c_s^2 = \frac{c^2}{3\,(1+R)}\,, \qquad R := \frac{3\varepsilon_{\mathrm{b}}}{4\varepsilon_\gamma} \propto a\,, \tag{48.33}$$

since only the photons push while both components weigh. Deep in the radiation era $R \ll 1$ and $c_s \to c/\sqrt{3}$; by recombination R is of order unity and the fluid has audibly slowed.

Step 2: the sound horizon. A pressure wave launched at the initial time has travelled, by decoupling, the comoving distance

$$r_{\mathrm{s}} = \int_{t_i}^{t_{\mathrm{d}}} \frac{c_s(t)\,\mathrm{d}t}{a(t)/a_0} = \int_{z_{\mathrm{d}}}^{\infty} \frac{c_s(z)\,\mathrm{d}z}{H(z)}\,, \tag{48.34}$$

the acoustic analogue of Equation (48.17). Evaluating the integral here with Equations (48.14) and (48.33) and the densities of Table 48.1, at the drag epoch $z_{\mathrm{d}} \approx 1060$ (when the baryons, outnumbered 10^9 to one, are finally released by the photons — slightly after the photons are released by the baryons), gives $r_{\mathrm{d}} = 147$ Mpc comoving, in agreement with the fitted value $r_{\mathrm{d}} = (147.09 \pm 0.26)$ Mpc quoted by Planck [2348].

Step 3: survival as a bump. Picture a single pointlike primordial overdensity: dark matter, baryons, photons and neutrinos superposed. The photon–baryon component launches a

spherical sound wave; the dark matter, pressureless, stays and grows by Theorem 48.14. At the drag epoch the wave stalls: the pressure that drove it vanishes with the coupling, and the baryon shell is stranded at radius r_{d}. Thereafter both the central dark-matter peak and the baryon shell grow by the same linear theory — Equation (48.27) is linear, so the configuration is preserved up to overall amplitude, and gravity gradually shares the shell between the components. Since galaxies form where matter is dense, pairs of galaxies separated by r_{d} are slightly more common than the smooth clustering predicts: the correlation function acquires a bump at r_{d}, of relative amplitude set by the baryon fraction $\Omega_{\mathrm{b}}/\Omega_{\mathrm{m}} \approx 1/6$ — a percent-level feature, which is why finding it took a survey of 46 748 luminous red galaxies over $0.72\,h^{-3}\,\mathrm{Gpc}^3$ [2076]. Nonlinear evolution at late times broadens the bump slightly but shifts its centre only at the sub-percent level, which is what qualifies it as a standard ruler [2076, 2348]. □

Used as a ruler, the feature measures $d_{\mathrm{A}}(z)$ transverse to the line of sight and $c/H(z)$ along it (Corollary 48.8); anchored to the same r_{d} that the CMB calibrates, BAO surveys extend the geometric measurement from z_* down through the era of Λ domination, and they are the third leg — with the CMB and the supernovae — of every concordance fit [2348].

48.5.3 Evidence for dark matter

The dark-matter inference is often told as one discovery; it is better told as three independent measurements that agree on a number. Zwicky, applying the virial theorem to the Coma cluster in 1933, found the velocity dispersion of the member galaxies to imply a binding mass vastly exceeding the luminous one [729]. Rubin and Ford, four decades later, traced the rotation of M31 through the emission lines of its H II regions and found no Keplerian decline [1432], a result their survey of field spirals made general [1658]. And the microwave background requires, through the peak structure of Phenomenon 48.13 and the growth argument of Section 48.5.1, a gravitating component that does not scatter light, at five times the baryon density [2348]. Gravitational lensing supplies the most direct image: in the merging cluster 1E 0657−56 the X-ray–emitting gas — most of the baryonic mass — was stripped and slowed by the collision, while the lensing mass sailed through with the galaxies, mapping a dominant collisionless component spatially separated from the baryons [2062, 2093].

Phenomenon 48.16 (Flat rotation curves and the missing mass)**.** The orbital speed of gas and stars in a spiral galaxy does not decline beyond the visible disc: it stays nearly constant out to the largest radius at which any tracer can be found [1432]. The same discrepancy appears on the scale of clusters, where the velocity dispersion of the member galaxies implies a binding mass far above the luminous one [729], and again in the microwave background and in the growth of structure, both of which require a matter component that neither emits nor scatters radiation [2348]. The three arguments are independent, and they agree on the amount.

Rests on Equation (48.27) *and Theorem 48.14.*

Derivation. *Derives Phenomenon 48.16.*

For a test particle on a circular orbit of radius r inside a spherically symmetric mass distribution, Newtonian dynamics gives

$$\frac{v^2}{r} = \frac{GM(r)}{r^2}\,, \qquad \text{that is} \qquad M(r) = \frac{v^2 r}{G}\,,$$

where $M(r)$ is the mass interior to r. Were the luminous matter all the matter, $M(r)$ would be essentially constant outside the optical disc and v would fall off as $r^{-1/2}$, the Keplerian

behaviour familiar from the solar system. The observed constancy of v instead forces

$$M(r) \propto r\,, \qquad \rho(r) = \frac{1}{4\pi r^2}\frac{\mathrm{d}M}{\mathrm{d}r} \propto \frac{1}{r^2}\,, \tag{48.35}$$

an enclosed mass still growing linearly at radii where the surface brightness has long since fallen away exponentially. The inference is purely kinematic: it uses only Newtonian gravity in the weak-field, slow-motion regime together with the assumption of a roughly spherical halo, and it fixes how much unseen mass there is without saying anything whatever about what it is made of.

The cluster version is the same argument with the virial theorem in place of the circular orbit, and the theorem is one line from Newton's equations (Chapter 19). For N bodies with positions $\boldsymbol{r}_i$ and momenta $\boldsymbol{p}_i$, let $\mathcal{G} := \sum_i \boldsymbol{p}_i \cdot \boldsymbol{r}_i$; then $\dot{\mathcal{G}} = 2T + \sum_i \boldsymbol{F}_i \cdot \boldsymbol{r}_i = 2T + U$, the last step by Euler's homogeneous-function identity applied to the gravitational potential energy U, homogeneous of degree -1 in the positions. For a bound system $\mathcal{G}$ stays finite, so the long-time average of $\dot{\mathcal{G}}$ vanishes: $2\langle T\rangle + \langle U\rangle = 0$. A cluster of radius R whose galaxies move with velocity dispersion σ therefore has mass of order $M \sim \sigma^2 R/G$. For Coma, $\sigma \approx 1000\,\mathrm{km/s}$ and R of a few megaparsecs give a mass one to two orders of magnitude above what the starlight accounts for — Zwicky's 1933 arithmetic, essentially unchanged [729]. □

What the particle might be — and the searches that have so far excluded much of the candidate space — is deliberately not discussed here: the evidence above is gravitational and belongs to this chapter; the particle physics is a frontier and belongs to Chapter 134, under the standards of Chapter 1.

48.6 The accelerating universe

48.6.1 Type Ia supernovae

A type Ia supernova is the thermonuclear disruption of a white dwarf driven over its stability limit by accretion (Chapter 52); because the igniting mass is nearly universal, so is the luminosity, and what scatter remains is correlated with the light-curve's decline rate — broader is brighter — tightly enough that a measured light curve standardizes the peak magnitude to about 0.15 magnitudes [1873]. That makes the events standardizable candles visible across half the observable universe, and in the late 1990s two independent teams pushed the Hubble diagram to $z \approx 0.5$–1 expecting to measure the deceleration of the expansion [1962, 1981]. Both found the opposite sign.

Phenomenon 48.17 (The expansion is accelerating)**.** Type Ia supernovae near $z \approx 0.5$, standardized through the correlation between light-curve width and peak luminosity, are observed systematically fainter — and so at systematically larger luminosity distance — than a matter-dominated, decelerating universe predicts, by an amount that grows with redshift [1962, 1981]. Read through the FLRW distance relations of Section 48.2.3, the observation says that $\ddot{a} > 0$ at the present epoch, that is that the deceleration parameter

$$q_0 := -\left.\frac{\ddot{a}a}{\dot{a}^2}\right|_{t_0} \tag{48.36}$$

is negative. The concordance fit, which now folds in the microwave background and the acoustic ruler of Phenomenon 48.15, attributes about 69% of the present energy budget to a smooth component whose equation of state is consistent with $w = -1$ and about 31% to matter [2348]. What has been measured is an expansion history; no mechanism has been measured.

Rests on Equations (48.7) *and* (48.15)*, Proposition 48.7, and Theorem 48.5.*

Derivation. *Derives Phenomenon 48.17.*

Step 1: the kinematic distance–redshift relation. Expand the scale factor about the present,

$$a(t) = a_0 \left[1 + H_0 \, (t - t_0) - \frac{q_0}{2} H_0^2 \, (t - t_0)^2 + \cdots \right] ,$$

which *defines* q_0 via Equation (48.36) and uses no field equation. Inverting Equation (48.2) order by order gives the look-back time in terms of z, and inserting it into the null-ray integral $\chi = \int c \, \mathrm{d}t / a$ and then into Equation (48.15) (curvature enters only at third order) yields

$$d_{\mathrm{L}}(z) = \frac{cz}{H_0} \left[1 + \frac{1 - q_0}{2} \, z + O\!\left(z^2\right) \right] . \tag{48.37}$$

The first term is Equation (48.1); the second is where the dynamics hides. At $z = 0.1$ the two-term formula agrees with the exact integral for the concordance parameters to a quarter of a percent (computed here), so the expansion is trustworthy where the calibrating supernovae live and begins to bend measurably by $z \approx 0.5$.

Step 2: magnitudes. Optical astronomy measures the *distance modulus*

$$\mu := m - M = 5 \log_{10} \frac{d_{\mathrm{L}}}{10 \, \mathrm{pc}} , \tag{48.38}$$

so a fractional distance excess ϵ registers as $\Delta\mu = (5/\ln 10) \, \epsilon \approx 2.17 \, \epsilon$ magnitudes. By Equation (48.37) a change of q_0 shifts the modulus at redshift z by $\Delta\mu \approx 2.17 \, z \, |\Delta q_0| \, /2$: distinguishing the matter-only Einstein–de Sitter value $q_0 = +\frac{1}{2}$ from an accelerating $q_0 \approx -0.5$ requires photometry good to a few tenths of a magnitude at $z \approx 0.5$ — exactly what standardized type Ia photometry provides.

Step 3: what was measured. Both teams found the high-redshift supernovae *fainter* than any decelerating model allows. Against the exact integrals of Equation (48.13) (computed here at $z = 0.5$): the concordance universe places a supernova 0.40 magnitudes fainter than Einstein–de Sitter, 0.19 fainter than an open $\Omega_{\mathrm{m}} = 0.2$ universe, and 0.12 fainter than an empty coasting one — and the data preferred distances near the concordance values, 10–15% beyond the open model [1962], with the 42-supernova fit of the second team giving $\Omega_{\mathrm{m}} \approx 0.28$ under flatness [1981]. Through Equations (48.6) and (48.7), evaluated today,

$$q_0 = \frac{\Omega_{\mathrm{m}}}{2} + \Omega_{\mathrm{r}} - \Omega_\Lambda ,$$

so the measured $\Omega_{\mathrm{m}} \approx 0.3$, $\Omega_\Lambda \approx 0.7$ give $q_0 \approx -0.53$ (computed): the expansion accelerates. The systematics that could have mimicked the signal — grey dust along the line of sight, luminosity evolution between the young universe and the old — were the subject of a decade of scrutiny and are bounded by the later data: the Hubble diagram now extends beyond $z = 1$ into the epoch where the matter term of Equation (48.14) dominates and the model predicts the faintness trend must *reverse* into relative brightening, which is observed [2402]. Dust and evolution do not reverse sign on cue. □

48.6.2 The cosmological constant as dark energy

The minimal reading of Phenomenon 48.17 is already in the field equations. The constant Λ was introduced by Einstein in 1917 to allow a static universe [445] — a motivation the redshifts of Section 48.1 demolished — but the term itself is not optional decoration: it is the one addition the structure of the field equations permits (Chapter 44), and the data now demand it. With $\Lambda > 0$, Equation (48.7) turns positive once matter dilutes sufficiently, and the fit of Table 48.1 gives (computed here from Ω_Λ and H_0)

$$\Lambda = \frac{3 \Omega_\Lambda H_0^2}{c^2} = 1.1 \times 10^{-52} / \mathrm{m}^2 , \qquad \varepsilon_\Lambda = \frac{\Lambda c^4}{8 \pi G} = 5.2 \times 10^{-10} \, \mathrm{J/m}^3 , \tag{48.39}$$

about 3.3 GeV per cubic metre: two protons' worth of rest energy in every cubic metre of vacuum. Interpreted as a fluid, the Λ term has $w = -1$ exactly (Proposition 48.9); the fitted equation of state, from the combination of CMB, BAO and supernovae, is consistent with -1 at the three-percent level [2348, 2402]. Nothing in the data yet distinguishes a true constant from a slowly varying impostor.

Two honest difficulties frame the subject. First, the *smallness problem*: quantum field theory assigns the vacuum an energy density, and every naive estimate of it — cutting the zero-point sum off at any scale from the electroweak to the Planck scale — exceeds Equation (48.39) by some 55 to 120 orders of magnitude [1828]. Why the measured value is not zero yet absurdly small compared to its natural scale is unexplained; Weinberg's review remains the standard statement of how resistant the problem is to every class of mechanism proposed. Second, the *anthropic bound*: Weinberg observed, a decade before the acceleration was found, that a Λ much larger than the matter density at the epoch of structure formation would have prevented galaxies from forming at all, so observers can only find themselves in universes with Λ at most of roughly the observed order [1799]. Whether that observation is an explanation is a question about scientific method rather than about data; this treatise records it as an argument, notes that it predicted the right order of magnitude, and does not admit it as evidence (Chapter 1).

What is measured, in sum: an expansion history $H(z)$, consistent across three independent probes with a constant vacuum energy of the value Equation (48.39). What is not measured: any property of the component beyond its density and its pressure, or any mechanism setting either. "Dark energy" is a name for the gap between those two sentences.

48.7 The ΛCDM parametrization

48.7.1 Six numbers

The base model that fits every data stream of this chapter is defined by Equation (48.3) with $k = 0$, the Friedmann dynamics of Theorem 48.5 sourced by baryons, cold dark matter, radiation and Λ, and a power-law spectrum of adiabatic initial perturbations. Six sampled numbers specify it: two densities, one angle, one optical depth, and the amplitude and tilt of the initial spectrum. Everything else — the Hubble constant included — is derived. Table 48.1 lists the six with the 2018 Planck values, and a selection of the derived quantities this chapter has used; here $h := H_0/(100\,\mathrm{km/(s\,Mpc)})$.

The model's economy is its strongest and its weakest feature at once. Strongest: six numbers, fitted to the microwave background alone, then *predict* the BAO scale in galaxy surveys, the supernova Hubble diagram, the light-element abundances through $\Omega_\mathrm{b}h^2$, and the broad shape of the matter power spectrum — and the predictions land (Phenomena 48.10, 48.15 and 48.17). Weakest: of the six, only $\Omega_\mathrm{b}h^2$ names physics whose microscopic identity is known. The model does not say what the cold component is, why Λ has the value Equation (48.39), or what set A_s and n_s. It is a parametrization whose parameters are measured superbly and explained not at all; they take their place in the ledger of unexplained constants in Appendix C.

48.7.2 The Hubble tension

Phenomenon 48.18 (The Hubble tension)**.** The two best determinations of the present expansion rate disagree. Calibrating type Ia supernovae on the Cepheid distance ladder gives $H_0 = 73.0\,\mathrm{km/(s\,Mpc)}$ with an uncertainty near $1.0\,\mathrm{km/(s\,Mpc)}$ [2407]; fitting the microwave-background power spectra within the same six-parameter model that fits everything else in this chapter gives $H_0 = 67.4\,\mathrm{km/(s\,Mpc)}$ with an uncertainty near $0.5\,\mathrm{km/(s\,Mpc)}$ [2348]. The two differ by about five times their combined uncertainty. The disagreement has

Table 48.1: The six sampled parameters of the base ΛCDM model, and selected derived quantities, from the Planck 2018 fit to the temperature, polarization and lensing power spectra [2348]. All uncertainties are the quoted 68% intervals. Every number in this table is a fit through the model; none is a direct measurement of the quantity named.

Parameter	Symbol	Value
Baryon density	$\Omega_{\mathrm{b}}h^2$	$0.022\,37 \pm 0.000\,15$
Cold-dark-matter density	$\Omega_{\mathrm{c}}h^2$	0.1200 ± 0.0012
Acoustic angular scale	$100\,\theta_{\mathrm{MC}}$	$1.040\,92 \pm 0.000\,31$
Reionization optical depth	τ	0.0544 ± 0.0073
Primordial amplitude	$\ln(10^{10}A_{\mathrm{s}})$	3.044 ± 0.014
Scalar spectral index	n_{s}	0.9649 ± 0.0042
Hubble constant	H_0	$(67.36 \pm 0.54)\,\mathrm{km/(s\,Mpc)}$
Matter fraction	Ω_{m}	0.3153 ± 0.0073
Dark-energy fraction	Ω_Λ	0.6847 ± 0.0073
Fluctuation amplitude	σ_8	0.8111 ± 0.0060
Age of the universe	t_0	$(13.797 \pm 0.023)\,\mathrm{Gyr}$
Last-scattering redshift	z_*	1089.92 ± 0.25
Sound horizon, drag epoch	r_{d}	$(147.09 \pm 0.26)\,\mathrm{Mpc}$

survived a decade of scrutiny of both error budgets and of the rungs of the ladder, and it is at present unresolved (Chapter 133). It is recorded here as a measurement in conflict — one of the two determinations, or the model connecting them, is wrong — and not as evidence for any particular resolution.

Rests on Equations (48.15) *and* (48.26)*, Phenomenon 48.13, and Proposition 48.7.*

Derivation. *Derives Phenomenon 48.18.*

What must be exhibited is where each number comes from, since the conflict lives entirely in the inference chains.

The ladder value. The chain of Section 48.1.2: geometric anchors (parallaxes, the megamaser distance to NGC 4258, detached eclipsing binaries in the LMC) calibrate the Cepheid period–luminosity law; Cepheids in 42 host galaxies calibrate the peak luminosity of type Ia supernovae; the calibrated supernovae, read through Equation (48.38) and Equation (48.37) in the redshift range where the q_0 correction is small, give $H_0 = (73.04 \pm 1.04)\,\mathrm{km/(s\,Mpc)}$ [2407]. The measurement is local ($z \lesssim 0.15$) and nearly model-independent: no assumption about early-universe physics enters.

The CMB value. The chain of Phenomenon 48.13: the peak spacing measures θ_* to three parts in 10^4 (Table 48.1); the sound horizon $r_{\mathrm{s}}(z_*)$ is *computed* from Equation (48.34), whose only inputs are the densities $\Omega_{\mathrm{b}}h^2$ and $\Omega_{\mathrm{m}}h^2$ — both fixed by the peak heights — and standard pre-recombination physics; the ratio then fixes the comoving distance to last scattering through Equation (48.26), and that distance is the integral Equation (48.13) of $c/H(z)$ over the *entire* expansion history. Within ΛCDM — flat, with constant Λ — the integral has no freedom left once the densities are set, and H_0 comes out at $(67.36 \pm 0.54)\,\mathrm{km/(s\,Mpc)}$ [2348]. The value is thus an *inference through the model*, anchored at $z = 1090$ and extrapolated across the whole history; the BAO ruler of Phenomenon 48.15, calibrated by the same r_{d}, confirms the extrapolation at intermediate redshifts.

The comparison. The difference is $5.7\,\mathrm{km/(s\,Mpc)}$ against a combined uncertainty of $1.2\,\mathrm{km/(s\,Mpc)}$: 4.8σ as computed here from the two quoted errors, "about five sigma" as commonly stated [2407]. For the disagreement to be an accident of errors, one budget must be wrong by five times its stated size. The candidate systematics have been hunted for a decade: Cepheid crowding photometry, metallicity terms and anchor distances on the ladder

side — partially checked by the independent tip-of-the-red-giant-branch calibration, which lands between the two values, near 70 km/(s Mpc) with larger uncertainty [2379] — and foregrounds and likelihood choices on the CMB side, where independent instruments and analyses reproduce the low value [2348]. The third logical possibility is the model itself: the CMB chain rests on the computed r_s, so any new physics that shrinks the sound horizon by a few percent — extra relativistic energy density before recombination, for instance — would raise the inferred H_0. No such extension is currently supported by the data it would have to leave undisturbed. The tension stands, and this treatise records it as standing (Chapter 133). □

48.8 Inflation: the evidence status

48.8.1 The proposal

The hot big bang of this chapter is spectacularly successful from one second onward and silent about its own initial conditions. Two of those conditions are quantitatively strange, and the arithmetic deserves to be shown.

The horizon problem. The particle horizon at last scattering, Equation (48.17) evaluated through the radiation and matter eras, is a comoving 280 Mpc (computed here); the comoving distance to the last-scattering surface is 13.9 Gpc (computed, Equation (48.13)). A causally connected patch therefore has an angular radius of about 1.2° on the sky, and the visible last-scattering surface comprises on the order of 10^4 such regions that, within the hot big bang alone, have never exchanged a signal (computed). Yet Phenomenon 48.12 shows them at a common temperature to a part in 10^5. Equilibrium without contact is not impossible as an initial condition — initial conditions are free — but it is unexplained structure.

The flatness problem. Write Equation (48.6) as $|\Omega(t) - 1| = |k|\,c^2/(a^2H^2)$: the deviation from critical density scales as the inverse square of aH, which *grows* throughout radiation and matter domination. Running the measured bound backwards (computed here from Equation (48.14)): today's $|\Omega - 1| < 0.002$ (Section 48.8.2) was $\sim 10^{-6}$ at z_{eq} and below 10^{-17} at the weak freeze-out that opens nucleosynthesis ($t \approx 1$ s, Section 48.3.2). The hot big bang must be *handed* a universe tuned to critical density to seventeen decimal places for one to be here measuring it.

Guth's 1981 observation is that a single mechanism voids both problems [1670]: a phase of accelerated expansion *before* the radiation era.

Proposition 48.19 (Accelerated expansion shrinks the comoving Hubble radius)**.** *The comoving Hubble radius $c/(aH) = c/\dot{a}$ decreases exactly when $\ddot{a} > 0$.*

Rests on Equation (48.7).

Derivation. *Derives Proposition 48.19.*

$\frac{\mathrm{d}}{\mathrm{d}t}\,(c/\dot{a}) = -c\,\ddot{a}/\dot{a}^2$, negative iff $\ddot{a} > 0$. During such a phase $|\Omega - 1| = |k|\,c^2/\dot{a}^2$ is driven *toward* zero rather than away — flatness becomes an attractor — and comoving regions vastly larger than the instantaneous Hubble radius were inside it, in causal contact, before the phase began: the uniformity of the last-scattering surface is inherited from a causally connected past. Sixty-odd e-foldings of such expansion suffice to bring the whole presently observable volume within one pre-inflationary causal patch and to flatten it beyond the measured bounds [1670]; the counting is standard and we do not repeat it. □

Guth's own realization stalled in its exit from the accelerated phase; the workable slow-roll versions came a year later [1677, 1694]. What made the framework more than a cure for two aesthetic complaints is a by-product: the quantum fluctuations of the field driving the phase are stretched to super-horizon scales and become a nearly scale-invariant, slightly tilted spectrum of density perturbations — computed by Mukhanov and Chibisov

in 1981 [1672], eleven years before COBE saw any anisotropy at all (Phenomenon 48.13). A framework that predicted the statistical character of the seeds of all structure, in advance, has earned its place in this chapter.

48.8.2 Measured and unmeasured

The discipline of Chapter 1 requires the balance sheet to be explicit.

Measured, and consistent with the framework. Spatial curvature: the CMB combined with BAO gives $\Omega_k = 0.0007 \pm 0.0019$ — flat to two parts in a thousand [2348], where inflation predicts flatness to experimental precision. The spectral tilt: $n_s = 0.9649 \pm 0.0042$, eight standard deviations below exact scale invariance (computed from the quoted values), with the sign and rough size that generic slow roll predicts [1672, 2348]. Adiabaticity and Gaussianity: the fluctuations are adiabatic and Gaussian to the limits of measurement [2348], as the simplest single-field realizations require.

Not measured. The distinguishing prediction of the framework — the one signal no alternative shares — is a background of primordial gravitational waves, imprinted as B-mode polarization in the CMB. None has been detected: the tensor-to-scalar ratio is bounded at $r < 0.036$ at 95% confidence [2369]. With no tensor signal there is no measurement of the energy scale of the proposed phase, no identification of the field that drove it, and no test of the mechanism as opposed to its outputs. The consistency successes above are real but not exclusive: they check predictions that some alternative histories could also produce, whereas the tensor background is the framework's own signature.

The verdict, in this treatise's terms: inflation is mainstream cosmology and belongs in this chapter as the leading account of the initial conditions — an account whose generic outputs (flatness, tilt, adiabatic Gaussian perturbations) are measured and agree, and whose distinguishing prediction remains untested. It is reported in exactly those terms, and its speculative extensions — which trade in what cannot be observed — are excluded from this book by the scope rule of Chapter 1 (Chapter 133 records what a future B-mode detection, or a definitive null, would each settle).

Chapter 49

Compact Stars and Relativistic Astrophysics

A star that has exhausted its nuclear fuel can no longer hold itself up by thermal pressure, and what remains is a contest between gravity and quantum mechanics: the degeneracy pressure of fermions, first invoked for white dwarfs by Fowler [541], is the only cold support matter possesses, and general relativity sets a ceiling on how much of it gravity will tolerate. This chapter follows that contest through the Tolman–Oppenheimer–Volkoff equations [845, 848], the white-dwarf mass limit of Chandrasekhar [676], the neutron stars predicted by Baade and Zwicky [730] and found as pulsars [1373], up to the maximum masses and radii that pulsar timing, X-ray pulse-profile modelling and the binary merger GW170817 [2278] now measure.

The chapter is the meeting point of three others. The stellar models whose endpoints these objects are belong to Chapter 52; the field equations that govern their interiors are those of Chapter 44; and the horizon that forms when every equilibrium fails is the subject of Chapter 45, with its observational record in Chapter 50. The standard monograph is [1727].

49.1 White dwarfs

49.1.1 The observational puzzle: Sirius B

The companion of Sirius was found by Bessel in 1844 from the wobble it imprints on the bright star's proper motion, and seen telescopically in 1862; its mass, from the astrometric orbit, is close to the Sun's. The surprise came in 1915, when Adams obtained its spectrum and found not the cool red star its faintness suggested but a white-hot one [423]. A hot surface radiating so little light must be small: the Stefan–Boltzmann law forces a radius near the Earth's, and therefore a mean density of order $10^{9}\,\mathrm{kg/m^{3}}$ — matter in a state no classical equation of state allows. The gravitational redshift of Sirius B, the classical test it later furnished, is treated with the other tests in Chapter 42.

Phenomenon 49.1 (Matter at a billion kilograms per cubic metre)**.** The faint companion of Sirius shows the spectrum of a hot white star, yet its luminosity is some ten thousand times below its primary's, which for that surface temperature fixes its radius near the Earth's; its mass, from the astrometric orbit, is close to the Sun's [423]. The implied mean density is of order $10^{9}\,\mathrm{kg/m^{3}}$, a million times that of ordinary solids. Thousands of white dwarfs are now catalogued and they occupy the same narrow band of the mass–radius plane. No classical equation of state supports matter in this state; at such densities the electrons are degenerate and the support is quantum-mechanical, surviving to zero temperature [541].

Rests on Proposition 49.2 and Phenomenon 83.1.

Derivation. *Derives Phenomenon 49.1.*

What must be checked is that the electrons really are degenerate at this density — that the exclusion principle of Chapter 83, and not thermal agitation, sets the pressure. Take $\rho = 10^9\,\mathrm{kg/m^3}$ of fully ionized material with two nucleons per electron, so that

$$n_\mathrm{e} = \frac{\rho}{2m_\mathrm{u}} = \frac{10^9\,\mathrm{kg/m^3}}{2 \times 1.661 \times 10^{-27}\,\mathrm{kg}} \approx 3.0 \times 10^{35}/\mathrm{m^3}\,.$$

The Fermi energy of a free electron gas at that density, from Chapter 120, is

$$E_\mathrm{F} = \frac{\hbar^2}{2m_\mathrm{e}} \left(3\pi^2 n_\mathrm{e}\right)^{2/3} \approx 2.6 \times 10^{-14}\,\mathrm{J} \approx 160\,\mathrm{keV}\,,$$

whereas the interior of a white dwarf, at a temperature of order $10^7\,\mathrm{K}$, has $k_\mathrm{B}T \approx 1.4 \times 10^{-16}\,\mathrm{J} \approx 0.9\,\mathrm{keV}$. The ratio $E_\mathrm{F}/\left(k_\mathrm{B}T\right) \approx 200$ settles the question: essentially every state below the Fermi level is occupied, the gas is degenerate, and the pressure it exerts does not vanish as the star cools. That is why a white dwarf can sit in equilibrium with no energy source whatever, which no thermally supported star can do.

The same arithmetic carries a warning. The Fermi energy already reaches about a third of the electron rest energy $m_\mathrm{e}c^2 = 511\,\mathrm{keV}$, so the non-relativistic formula used above is only an estimate, and a denser — that is, a more massive — white dwarf will be relativistic. That is the regime of Section 49.1.3, and it is where the mass limit comes from. □

49.1.2 Electron degeneracy pressure

Fowler resolved the paradox within a year of the new statistics [537, 539]: the electrons of a white dwarf form a degenerate Fermi gas in the sense of Chapter 120, and the pressure of that gas at zero temperature is what carries the star [541]. The two limits of that pressure — the non-relativistic $P \propto n^{5/3}$ and the ultrarelativistic $P \propto n^{4/3}$ — control everything in this chapter, so we derive them in full.

Proposition 49.2 (Ground-state pressure of the ideal Fermi gas)**.** *A gas of spin-$\frac{1}{2}$ fermions of mass m at number density n and zero temperature fills all momentum states up to the Fermi momentum*

$$p_\mathrm{F} = \hbar \left(3\pi^2 n\right)^{1/3}\,, \tag{49.1}$$

and exerts a pressure that survives at zero temperature. In the non-relativistic regime $p_\mathrm{F} \ll mc$,

$$P = \frac{\left(3\pi^2\right)^{2/3}}{5} \frac{\hbar^2}{m}\, n^{5/3} = \frac{2}{5}\, n E_\mathrm{F}\,, \qquad E_\mathrm{F} = \frac{\hbar^2}{2m} \left(3\pi^2 n\right)^{2/3}\,, \tag{49.2}$$

while in the ultrarelativistic regime $p_\mathrm{F} \gg mc$,

$$P = \frac{\left(3\pi^2\right)^{1/3}}{4} \hbar c\, n^{4/3} = \frac{1}{4}\, n E_\mathrm{F}\,, \qquad E_\mathrm{F} = \hbar c \left(3\pi^2 n\right)^{1/3}\,. \tag{49.3}$$

Rests on Phenomenon 83.1 and Theorem 40.5.

Proof. *Derives Proposition 49.2.*

Free-particle states occupy phase space in cells of volume $(2\pi\hbar)^3$, two spin orientations per cell (Chapters 83 and 120). At zero temperature the exclusion principle fills the states of lowest energy: a sphere in momentum space of radius p_F fixed by counting,

$$n = \frac{2}{(2\pi\hbar)^3} \cdot \frac{4\pi}{3} p_\mathrm{F}^3 = \frac{p_\mathrm{F}^3}{3\pi^2\hbar^3}\,,$$

which is Equation (49.1). The energy density is the sum of single-particle energies $\varepsilon(p)$ over the filled sphere,

$$u = \frac{2}{(2\pi\hbar)^3}\int_0^{p_\mathrm{F}} \varepsilon(p)\, 4\pi p^2\,\mathrm{d}p = \frac{1}{\pi^2\hbar^3}\int_0^{p_\mathrm{F}} \varepsilon(p)\, p^2\,\mathrm{d}p\,.$$

With $\varepsilon = p^2/2m$ this gives $u = (3/5)\,nE_\mathrm{F}$ with $E_\mathrm{F} = p_\mathrm{F}^2/2m$; with $\varepsilon = pc$ it gives $u = (3/4)\,nE_\mathrm{F}$ with $E_\mathrm{F} = p_\mathrm{F}c$.

The pressure follows thermodynamically, with no kinetic argument needed. At zero temperature the total energy of N particles in volume V is $E = Vu(N/V)$, and

$$P = -\left.\frac{\partial E}{\partial V}\right|_N = -u + n\,\frac{\mathrm{d}u}{\mathrm{d}n}\,.$$

For any power law $u \propto n^\gamma$ this is $P = (\gamma - 1)\,u$. Non-relativistically $\gamma = 5/3$, so $P = \frac{2}{3}u = \frac{2}{5}nE_\mathrm{F}$, which is Equation (49.2); ultrarelativistically $\gamma = 4/3$, so $P = \frac{1}{3}u = \frac{1}{4}nE_\mathrm{F}$, which is Equation (49.3). Substituting Equation (49.1) gives the explicit coefficients. Note what happened between the two limits: relativity does not remove the pressure, it *softens* it, from $n^{5/3}$ to $n^{4/3}$ — one power of $n^{1/3}$, lost because the velocity saturates at c and can no longer grow with the Fermi momentum. That lost third of a power is the whole story of the Chandrasekhar limit. □

In a white dwarf the electrons supply the pressure and the nuclei the mass. For a composition with mean molecular weight per electron μ_e — the number of nucleons per electron, equal to 2 for the helium, carbon and oxygen that white dwarfs are made of — the mass density is $\rho = \mu_\mathrm{e} m_\mathrm{u} n_\mathrm{e}$, and Equation (49.2) becomes a polytrope $P = K_{5/3}\,\rho^{5/3}$ with

$$K_{5/3} = \frac{(3\pi^2)^{2/3}}{5}\,\frac{\hbar^2}{m_\mathrm{e}\,(\mu_\mathrm{e} m_\mathrm{u})^{5/3}}\,. \tag{49.4}$$

For $\mu_\mathrm{e} = 2$ this evaluates (computed from the CODATA constants) to a pressure of $3.2 \times 10^{21}\,\mathrm{Pa}$ at the Sirius B density $\rho = 10^9\,\mathrm{kg/m^3}$ — some ten orders of magnitude beyond the pressure at the centre of the Earth, from a gas at zero temperature. A star supported by a polytropic pressure is an exactly solvable structure problem, and the machinery deserves stating once, in the form every later section will use.

Proposition 49.3 (Lane–Emden form of hydrostatic equilibrium; restated from the stellar-structure chapter)**.** *A self-gravitating Newtonian fluid sphere with the polytropic equation of state $P = K\rho^{1+1/n}$ has density profile $\rho(r) = \rho_\mathrm{c}\,\theta^n(\xi)$, where $r = a\xi$,*

$$a^2 = \frac{(n+1)\,K}{4\pi G}\,\rho_\mathrm{c}^{\frac{1}{n}-1}\,, \tag{49.5}$$

and θ solves the Lane–Emden equation

$$\frac{1}{\xi^2}\frac{\mathrm{d}}{\mathrm{d}\xi}\left(\xi^2\frac{\mathrm{d}\theta}{\mathrm{d}\xi}\right) = -\theta^n\,, \qquad \theta(0) = 1\,, \quad \theta'(0) = 0\,. \tag{49.6}$$

The surface is the first zero ξ_1 of θ, and the radius and total mass are

$$R = a\,\xi_1\,, \qquad M = 4\pi a^3 \rho_\mathrm{c}\,\xi_1^2\,\left|\theta'(\xi_1)\right|\,. \tag{49.7}$$

Rests on Equation (31.13), Theorem 52.6, and Proposition 52.1.

Proof. *Derives Proposition 49.3.*

This is Theorem 52.6 in the variables of this chapter; the short derivation is repeated so that the Chandrasekhar argument can lean on the surface-slope mass formula Equation (49.7) without a forward excursion. Hydrostatic equilibrium (Proposition 31.16, specialized to the self-gravitating sphere as in Section 52.1.1) reads $\mathrm{d}P/\mathrm{d}r = -Gm\rho/r^2$ with $\mathrm{d}m/\mathrm{d}r = 4\pi r^2\rho$. Eliminating m by differentiating the first and substituting the second,

$$\frac{1}{r^2}\frac{\mathrm{d}}{\mathrm{d}r}\left(\frac{r^2}{\rho}\frac{\mathrm{d}P}{\mathrm{d}r}\right) = -4\pi G\rho\,.$$

Insert $P = K\rho^{1+1/n}$ and $\rho = \rho_\mathrm{c}\theta^n$: the left side becomes $\left[(n+1)\,K\rho_\mathrm{c}^{1/n}/r^2\right]\mathrm{d}\left(r^2\,\mathrm{d}\theta/\mathrm{d}r\right)/\mathrm{d}r$, and dividing by $4\pi G\rho_\mathrm{c}$ and rescaling $r = a\xi$ with Equation (49.5) leaves exactly Equation (49.6). The centre is regular ($\theta'(0) = 0$) because $m \propto r^3$ there. For the mass, use the equation itself backwards:

$$M = 4\pi a^3\rho_\mathrm{c}\int_0^{\xi_1}\theta^n\xi^2\,\mathrm{d}\xi = -4\pi a^3\rho_\mathrm{c}\int_0^{\xi_1}\frac{\mathrm{d}}{\mathrm{d}\xi}\left(\xi^2\frac{\mathrm{d}\theta}{\mathrm{d}\xi}\right)\mathrm{d}\xi = 4\pi a^3\rho_\mathrm{c}\,\xi_1^2\,|\theta'(\xi_1)|\,,$$

since $\theta'(\xi_1) < 0$. No integration of the density profile is ever needed: the surface slope carries the whole mass integral. □

Remark 49.4 (The two Lane–Emden constants this chapter needs). Equation (49.6) has closed-form solutions only for $n = 0, 1, 5$; for the two indices that matter here it is integrated numerically, and we quote the constants from the standard tabulation [831]:

n	ξ_1	$\xi_1^2\,\lvert\theta'(\xi_1)\rvert$
3/2	3.653 75	2.714 06
3	6.896 85	2.018 24

The general theory of polytropes, including these integrations, belongs to Section 52.1.2.

Proposition 49.5 (White-dwarf mass–radius relation). *A non-relativistic white dwarf ($P = K_{5/3}\rho^{5/3}$, polytropic index $n = 3/2$) obeys*

$$R \propto M^{-1/3}\,, \qquad R \approx 8.9\times10^6\,\mathrm{m}\left(\frac{M}{M_\odot}\right)^{-1/3} \quad \text{for } \mu_\mathrm{e} = 2\,. \tag{49.8}$$

Adding mass shrinks *a white dwarf — the opposite of every object held up by thermal or material pressure.*

Rests on Equations (49.2) and (49.7).

Proof. *Derives Proposition 49.5.*

For $n = 3/2$, Equation (49.5) gives $a \propto \rho_\mathrm{c}^{-1/6}$, so Equation (49.7) gives $M \propto a^3\rho_\mathrm{c} \propto \rho_\mathrm{c}^{1/2}$ and $R \propto \rho_\mathrm{c}^{-1/6}$: eliminating the central density, $R \propto M^{-1/3}$. Restoring the constants (Equation (49.4) and Remark 49.4),

$$R = \xi_1\left(\frac{5K_{5/3}}{8\pi G}\right)^{1/2}\rho_\mathrm{c}^{-1/6}\,, \qquad M = 4\pi\,\xi_1^2\,|\theta'(\xi_1)|\left(\frac{5K_{5/3}}{8\pi G}\right)^{3/2}\rho_\mathrm{c}^{1/2}\,,$$

and eliminating ρ_c between them gives, for $\mu_\mathrm{e} = 2$, the figure quoted (computed here from the constants; e.g. $M = 0.6\,M_\odot$ gives $\rho_\mathrm{c} \approx 1.5\times10^9\,\mathrm{kg/m^3}$ and $R \approx 1.05\times10^7\,\mathrm{m}$ — precisely the density regime the Sirius B puzzle demanded). The formula overestimates the radius of the more massive white dwarfs, whose electrons are already partly relativistic and whose true radius therefore falls faster than $M^{-1/3}$; the exact interpolating equation of state joins this curve to the terminating sequence of Section 49.1.3. □

49.1.3 The Chandrasekhar mass limit

The inverse mass–radius relation carries its own death sentence. Compression raises the Fermi momentum, and once $p_{\mathrm{F}} \gtrsim m_{\mathrm{e}}c$ the equation of state softens from $\rho^{5/3}$ to the ultrarelativistic $\rho^{4/3}$ of Equation (49.3) — the polytropic index reaches $n = 3$, and at $n = 3$ the Lane–Emden scaling produces a mass that does not depend on the central density at all. That mass is a *limit*: below it equilibria exist, above it none do [676]. Landau's contemporaneous argument [702] reaches the same scale from the energy of a relativistic degenerate gas, with no structure equation solved, and we give it first.

Phenomenon 49.6 (A maximum mass for a cold degenerate star)**.** No white dwarf has been measured above about $1.4\,M_{\odot}$. The observed mass–radius relation does not continue indefinitely: radius falls as mass rises and the sequence terminates [676]. The same ceiling is what makes thermonuclear supernovae reproducible. A white dwarf pushed across it by accretion from a companion has no equilibrium left to settle into, ignites its carbon degenerately, and releases a nearly fixed amount of energy — which is why type Ia events can serve as the standardizable candles of Chapter 48.

Rests on Proposition 49.2 and Theorems 44.27 and 49.7.

Derivation. *Derives Phenomenon 49.6.*

The existence of the limit, and its scale, follow from comparing two energies, with no structure equation solved [702]. Let the star hold N electrons within a radius R, with μ_{e} nucleons per electron, so that its mass is $M = N\mu_{\mathrm{e}}m_{\mathrm{u}}$ and the electron number density is $n \sim N/R^3$.

Once the electrons are relativistic — the regime Phenomenon 49.1 showed to be near — the Fermi energy is $E_{\mathrm{F}} \sim \hbar c\, n^{1/3} \sim \hbar c\, N^{1/3}/R$, so the kinetic energy of the gas is

$$E_{\mathrm{kin}} \sim N E_{\mathrm{F}} \sim \frac{\hbar c\, N^{4/3}}{R}\,,$$

while the gravitational energy is

$$E_{\mathrm{grav}} \sim -\frac{GM^2}{R} = -\frac{G\,(\mu_{\mathrm{e}}m_{\mathrm{u}})^2\,N^2}{R}\,.$$

Both vary as $1/R$, and that is the decisive fact: contracting the star changes the two terms in exactly the same proportion, so no radius is singled out and equilibrium cannot be reached by adjusting R. The sign of the total energy depends on N alone. It turns negative — unbounded contraction, with no configuration to stop at — once

$$G\,(\mu_{\mathrm{e}}m_{\mathrm{u}})^2\,N^2 > \hbar c\, N^{4/3}\,, \qquad \text{that is} \qquad N > N_{\max} \sim \left(\frac{\hbar c}{G}\right)^{3/2} \frac{1}{(\mu_{\mathrm{e}}m_{\mathrm{u}})^3}\,.$$

The corresponding mass is

$$M_{\max} \sim N_{\max}\mu_{\mathrm{e}}m_{\mathrm{u}} = \frac{1}{\mu_{\mathrm{e}}^2 m_{\mathrm{u}}^2}\left(\frac{\hbar c}{G}\right)^{3/2}\,, \tag{49.9}$$

which for $\mu_{\mathrm{e}} = 2$ evaluates to $9.3 \times 10^{29}\,\mathrm{kg}$, about $0.47\,M_{\odot}$. What the argument establishes without any coefficient at all is the substance of the phenomenon: a limit exists, it does not depend on the radius, and it is assembled out of $\hbar$, c, G and the nucleon mass — a stellar mass written in fundamental constants. The exact coefficient, close to three, is supplied by the $n = 3$ polytrope in Theorem 49.7 below. □

Theorem 49.7 (The Chandrasekhar mass)**.** *For the ultrarelativistic equation of state* $P = K_{4/3}\,\rho^{4/3}$ *with*

$$K_{4/3} = \frac{(3\pi^2)^{1/3}}{4}\,\frac{\hbar c}{(\mu_{\mathrm{e}} m_{\mathrm{u}})^{4/3}}\,, \tag{49.10}$$

the polytropic mass Equation (49.7) *is independent of the central density and equals*

$$M_{\mathrm{Ch}} = 4\pi\,\xi_1^2\,|\theta'(\xi_1)|\left(\frac{K_{4/3}}{\pi G}\right)^{3/2} = \frac{5.82}{\mu_{\mathrm{e}}^2}\,M_\odot = 1.46\,M_\odot \quad \textit{for } \mu_{\mathrm{e}} = 2\,. \tag{49.11}$$

No cold star supported by electron degeneracy can exceed it.
Rests on Equations (49.3) *and* (49.7) *and Propositions 49.2 and 49.3.*

Proof. *Derives Theorem 49.7.*

$P = K\rho^{4/3}$ is the polytrope $n = 3$. Equation (49.5) then gives $a = (K/\pi G)^{1/2}\,\rho_{\mathrm{c}}^{-1/3}$, so in Equation (49.7) the central density cancels identically:

$$M = 4\pi a^3 \rho_{\mathrm{c}}\,\xi_1^2\,|\theta'(\xi_1)| = 4\pi\left(\frac{K}{\pi G}\right)^{3/2}\xi_1^2\,|\theta'(\xi_1)|\,.$$

The $n = 3$ sequence is therefore a sequence of one mass at every central density: compressing the star ($R = a\xi_1 \propto \rho_{\mathrm{c}}^{-1/3} \to 0$) changes nothing in the balance, which is the structural restatement of the $1/R$ degeneracy in Landau's argument. A star lighter than M has a subrelativistic core, a stiffer effective $n < 3$, and finds an equilibrium radius; a star heavier has none. Inserting Equation (49.10) with $\mu_{\mathrm{e}} = 2$ and $\xi_1^2\,|\theta'(\xi_1)| = 2.018\,24$ (Remark 49.4),

$$M_{\mathrm{Ch}} = 2.90 \times 10^{30}\,\mathrm{kg} = 1.46\,M_\odot\,,$$

computed here from the CODATA constants; it exceeds the dimensional estimate Equation (49.9) by the factor $\frac{1}{2}\sqrt{3\pi}\,\xi_1^2\,|\theta'(\xi_1)| \approx 3.1$. Chandrasekhar's 1931 paper [676] quotes $0.91\,M_\odot$ because it took $\mu_{\mathrm{e}} = 2.5$, the then-standard guess at stellar composition; the formula is the same, and with the modern $\mu_{\mathrm{e}} = 2$ of helium, carbon and oxygen it gives the value above. General-relativistic corrections and electron capture shave a few per cent off the Newtonian figure, which is why the limit is customarily quoted as $\approx 1.4\,M_\odot$ [831, 1727]. □

49.1.4 White-dwarf cooling and ages

A white dwarf has no fuel: it shines by leaking the thermal energy of its ions through a thin insulating envelope, and its luminosity is therefore a clock. Mestel's theory [1007] turns the statement into a power law, and the population of the Galactic disc into a datable sample.

Phenomenon 49.8 (The white-dwarf luminosity function has an edge)**.** White dwarfs are observed at every luminosity from about $10^{-1}L_\odot$ down to about $10^{-4.5}L_\odot$ — and then stop. The number of white dwarfs per unit luminosity rises steadily toward the faint end and falls off abruptly below $\log_{10}(L/L_\odot) \approx -4.5$ [1801]. Fainter, older white dwarfs do not exist to be seen: the cutoff is the age of the population. Read through cooling theory it dates the local Galactic disc at about (9 ± 2) Gyr [1801], consistent with every other chronometer of Chapter 48. In the cooling sequence itself, *Gaia* photometry of over ten thousand white dwarfs shows a pile-up of stars at the luminosity where the core crystallises — the latent heat of freezing stalls the cooling, and stars accumulate there like water at its freezing point [2341].
Rests on Propositions 31.16, 49.2 and 52.9.

Derivation. *Derives Phenomenon 49.8.*

Two facts organize the problem. First, the degenerate electrons conduct heat so well that the interior is nearly isothermal at a single T_{c}, and their heat capacity is suppressed by the degeneracy factor T/T_{F} (Chapter 120), so the heat reservoir is the *ions*:

$$U = \frac{3}{2}\,\frac{M}{A m_{\mathrm{u}}}\,k_{\mathrm{B}}T_{\mathrm{c}}\,,$$

with A the mean nucleon number ($A \approx 14$ for a carbon–oxygen mixture). Second, the leak is a thin non-degenerate envelope in radiative equilibrium: photons diffuse with mean free path $1/(\kappa\rho)$, giving the radiative-transfer relation

$$L = -\frac{16\pi a c r^2 T^3}{3\kappa\rho}\,\frac{\mathrm{d}T}{\mathrm{d}r}\,,$$

with a the radiation constant and $\kappa = \kappa_0 \rho T^{-7/2}$ the Kramers opacity of Chapter 52. Dividing hydrostatic equilibrium (Equation (31.13), with $m \approx M$ in the thin envelope) by that relation eliminates r, and the ideal gas law of the envelope, $\rho = \mu m_{\mathrm{u}} P/(k_{\mathrm{B}}T)$ with μ its mean molecular weight, closes the system:

$$\frac{\mathrm{d}P}{\mathrm{d}T} = \frac{16\pi a c G M}{3\kappa L}\,T^3 = \frac{16\pi a c G M k_{\mathrm{B}}}{3\kappa_0 \mu m_{\mathrm{u}} L}\,\frac{T^{15/2}}{P} \quad\Longrightarrow\quad P^2 \propto \frac{M}{L}\,T^{17/2} \quad\Longrightarrow\quad \rho^2 \propto \frac{M}{L}\,T^{13/2}\,.$$

The envelope ends where the electrons turn degenerate, $k_{\mathrm{B}}T \approx E_{\mathrm{F}} \propto \rho^{2/3}$, i.e. $\rho \propto T^{3/2}$; and because the degenerate interior is isothermal, the temperature there is T_{c} itself. Setting $\rho^2 \propto T_{\mathrm{c}}^3$ equal to $(M/L)\,T_{\mathrm{c}}^{13/2}$ gives Mestel's law

$$L \propto M\,T_{\mathrm{c}}^{7/2}\,. \tag{49.12}$$

Now the clock: $-\mathrm{d}U/\mathrm{d}t = L$ reads $T_{\mathrm{c}}^{-7/2}\,\mathrm{d}T_{\mathrm{c}} \propto -\mathrm{d}t$, so $T_{\mathrm{c}} \propto t^{-2/5}$ and

$$L \propto t^{-7/5}\,, \qquad t = \frac{2}{5}\,\frac{U}{L} \propto \left(\frac{L}{M}\right)^{-5/7}\,. \tag{49.13}$$

Cooling decelerates: each decade down in luminosity takes about $10^{5/7} \approx 5$ times longer than the last, which is why the luminosity function *rises* toward the faint end — stars pile up where they cool slowly — and why its termination is sharp. The absolute age at the cutoff requires the calibrated constant in Equation (49.12) together with the crystallisation and phase-separation corrections, and we quote the result rather than the numerics: $(9 \pm 2)\,\mathrm{Gyr}$ for the local disc [1801]. Crystallisation itself was predicted theoretically in the 1960s [1386]; its latent heat, $\sim k_{\mathrm{B}}T$ per ion, interrupts Equation (49.13) for of order a gigayear, and the resulting traffic jam in the cooling sequence is what *Gaia* resolved [2341]. □

49.2 Neutron stars

49.2.1 The Baade–Zwicky hypothesis

Within two years of the discovery of the neutron [692], Baade and Zwicky proposed that a supernova is the transition of an ordinary star into a star made of neutrons — packed at nuclear density, bound by gravity, and only a few kilometres across — and that the energy of the explosion is the gravitational binding energy released in the collapse [730]. The proposal was quantitative and, as Phenomenon 49.14 will show, correct in every part. Collapsing $1.4\,M_{\odot}$ to a radius of 12 km releases $\sim \frac{3}{5}GM^2/R \approx 2.6 \times 10^{46}\,\mathrm{J}$ (Equation (49.23) below) — about ten per cent of the star's rest energy, and four orders of magnitude more than the $10^{42}\,\mathrm{J}$ a supernova radiates as light. The visible fireworks are a rounding error on the energy budget; the budget itself was verified, neutrino by neutrino, in 1987. The prediction of the compact remnant waited thirty-four years for its confirmation: a pulsar sitting inside the Crab supernova remnant of AD 1054 [1384].

49.2.2 The Tolman–Oppenheimer–Volkoff equations

A neutron star is relativistic in a way no white dwarf is: its compactness $GM/\left(Rc^2\right)$ is of order 0.2 rather than 10^{-4}, so Newtonian hydrostatics (Proposition 31.16 and Section 52.1.1) is not a first approximation but a wrong theory. The correct structure equations follow from the field equations of Chapter 44,

$$G_{\mu\nu} \equiv R_{\mu\nu} - \tfrac{1}{2} g_{\mu\nu} R = \frac{8\pi G}{c^4}\, T_{\mu\nu}\,, \tag{49.14}$$

applied to a static, spherically symmetric perfect fluid [845, 848]. This is the chapter's central derivation, and we give it in full.

The most general static, spherically symmetric line element can be written

$$\mathrm{d}s^2 = -\mathrm{e}^{2\alpha(r)} c^2 \mathrm{d}t^2 + \mathrm{e}^{2\beta(r)} \mathrm{d}r^2 + r^2 \left(\mathrm{d}\theta^2 + \sin^2\theta\, \mathrm{d}\varphi^2\right)\,, \tag{49.15}$$

and the matter is a perfect fluid at rest in these coordinates,

$$T^{\mu\nu} = \left(\rho + \frac{P}{c^2}\right) u^\mu u^\nu + P\, g^{\mu\nu}\,, \qquad u^\mu = \left(\mathrm{e}^{-\alpha}, 0, 0, 0\right) \ \text{in}\ (t, r, \theta, \varphi)\,, \tag{49.16}$$

with $\rho(r)$ the mass density, $P(r)$ the pressure, and the normalization $u^\mu u_\mu = g_{tt}\,\mathrm{e}^{-2\alpha} = -c^2$ (Section 44.2.1). In mixed components $T^\mu{}_\nu = \mathrm{diag}\left(-\rho c^2, P, P, P\right)$.

Theorem 49.9 (Tolman–Oppenheimer–Volkoff equations)**.** *Define the mass function $m(r)$ by $\mathrm{e}^{-2\beta} = 1 - 2Gm/\left(rc^2\right)$. Then the field equations Equation (49.14) for Equations (49.15) and (49.16) reduce to*

$$\frac{\mathrm{d}m}{\mathrm{d}r} = 4\pi r^2 \rho\,, \tag{49.17}$$

$$\frac{\mathrm{d}P}{\mathrm{d}r} = -\,\frac{G\left(\rho + \dfrac{P}{c^2}\right)\left(m + \dfrac{4\pi r^3 P}{c^2}\right)}{r^2\left(1 - \dfrac{2Gm}{rc^2}\right)}\,, \tag{49.18}$$

$$\frac{\mathrm{d}\alpha}{\mathrm{d}r} = -\,\frac{1}{\rho c^2 + P}\,\frac{\mathrm{d}P}{\mathrm{d}r}\,. \tag{49.19}$$

At the surface $r = R$, where $P = 0$, the solution matches the exterior Schwarzschild geometry of Chapter 45 with total mass $M = m(R)$.

Rests on Equations (49.14) and (49.16), Postulate 44.3, and Definition 44.16.

Proof. *Derives Theorem 49.9.*

The curvature of the metric Equation (49.15) is computed, Christoffel symbols to Ricci tensor, in Chapter 45, where the vacuum case yields the Schwarzschild solution; the two Einstein-tensor components needed here are [848, 1509]

$$G^t{}_t = -\frac{1}{r^2}\frac{\mathrm{d}}{\mathrm{d}r}\left[r\left(1 - \mathrm{e}^{-2\beta}\right)\right]\,,$$
$$G^r{}_r = -\frac{1}{r^2}\left(1 - \mathrm{e}^{-2\beta}\right) + \frac{2}{r}\,\mathrm{e}^{-2\beta}\,\alpha'\,,$$

with the prime denoting $\mathrm{d}/\mathrm{d}r$. The angular components carry no new information: by the contracted Bianchi identity (Section 44.3) they are consequences of these two together with stress–energy conservation, which we impose explicitly below.

The tt equation. With $T^t{}_t = -\rho c^2$, Equation (49.14) reads $\mathrm{d}\left[r\left(1 - \mathrm{e}^{-2\beta}\right)\right]/\mathrm{d}r = \left(8\pi G/c^2\right)\rho r^2$. Substituting the definition $r\left(1 - \mathrm{e}^{-2\beta}\right) = 2Gm/c^2$ turns this into Equation (49.17). Regularity at the centre requires $m(0) = 0$, so $m(r)$ is fixed with no further

constant. Note what m is and is not: $M = m(R)$ is the mass that governs the exterior orbits — the mass a distant satellite weighs — but it is *not* the integral of ρ over proper volume, which carries an extra factor $\mathrm{e}^{\beta} > 1$. The deficit is the gravitational binding energy, already subtracted; general relativity weighs the star bound.

The rr equation. With $T^{r}{}_{r} = P$ and $1 - \mathrm{e}^{-2\beta} = 2Gm/(rc^2)$,

$$\frac{8\pi G}{c^4}P = -\frac{2Gm}{r^3c^2} + \frac{2}{r}\left(1 - \frac{2Gm}{rc^2}\right)\alpha' \quad\Longrightarrow\quad \alpha' = \frac{\dfrac{Gm}{c^2} + \dfrac{4\pi G r^3 P}{c^4}}{r^2\left(1 - \dfrac{2Gm}{rc^2}\right)}\,.$$

Conservation. The fluid obeys $\nabla_\mu T^{\mu}{}_{\nu} = 0$ (Section 44.2.2); take the $\nu = r$ component. For the static diagonal stress tensor,

$$\nabla_\mu T^{\mu}{}_{r} = \partial_r T^{r}{}_{r} + \Gamma^{\mu}{}_{\mu\lambda}T^{\lambda}{}_{r} - \Gamma^{\lambda}{}_{\mu r}T^{\mu}{}_{\lambda} = P' + \Gamma^{t}{}_{tr}\left(P + \rho c^2\right) = P' + \left(\rho c^2 + P\right)\alpha'\,,$$

because $\Gamma^{t}{}_{tr} = \alpha'$ while the spatial Christoffel terms multiply $P - P = 0$. Setting this to zero gives Equation (49.19): pressure gradients are what hold the fluid static against the gravitational potential α. Substituting α' from the rr equation yields Equation (49.18).

Matching. At $r = R$ the pressure vanishes and Equation (49.17) makes m constant; the metric functions become $\mathrm{e}^{-2\beta} = 1 - 2GM/(rc^2)$ and, by integrating α' in vacuum, $\mathrm{e}^{2\alpha} = 1 - 2GM/(rc^2)$ — the Schwarzschild exterior of Chapter 45, as it must be by Birkhoff's theorem there. Given an equation of state $P(\rho)$, the system Equations (49.17) and (49.18) integrates outward from a chosen central density ρ_{c} until P reaches zero: one equilibrium star per central density, and the mass–radius *curve* is the image of that one-parameter family. □

Remark 49.10 (Newtonian limit, and why relativity lowers the ceiling). When $P \ll \rho c^2$ and $2Gm \ll rc^2$, Equation (49.18) reduces to $\mathrm{d}P/\mathrm{d}r = -Gm\rho/r^2$ — hydrostatic equilibrium exactly as in Proposition 31.16 and Section 52.1.1. The three relativistic corrections are the three parenthesized factors, and each has a sign: pressure adds to the gravitating density $(\rho + P/c^2)$, pressure gravitates as a source $(m + 4\pi r^3 P/c^2)$, and the denominator $1 - 2Gm/(rc^2)$ strengthens gravity as compactness grows. All three make gravity *stronger* than Newton at the same P and ρ. Pressure, the agent of support, is also a source of the field it fights — so squeezing harder eventually recruits gravity faster than support, and equilibrium sequences terminate at finite mass even for matter far stiffer than a degenerate electron gas. The Chandrasekhar limit was an accident of special relativity in the equation of state; the neutron-star maximum mass is general relativity's own.

Example 49.11 (The uniform-density star)**.** For constant ρ, $m = \frac{4}{3}\pi r^3\rho = Mr^3/R^3$ and Equation (49.18) separates; partial fractions and the boundary condition $P(R) = 0$ give (verified by substitution)

$$P(r) = \rho c^2\,\frac{\sqrt{1 - \dfrac{r_{\mathrm{s}}r^2}{R^3}} - \sqrt{1 - \dfrac{r_{\mathrm{s}}}{R}}}{3\sqrt{1 - \dfrac{r_{\mathrm{s}}}{R}} - \sqrt{1 - \dfrac{r_{\mathrm{s}}r^2}{R^3}}}\,, \qquad r_{\mathrm{s}} \equiv \frac{2GM}{c^2}\,, \tag{49.20}$$

with central value

$$P_{\mathrm{c}} = \rho c^2\,\frac{1 - \sqrt{1 - r_{\mathrm{s}}/R}}{3\sqrt{1 - r_{\mathrm{s}}/R} - 1}\,. \tag{49.21}$$

For a star of $1.4\,M_\odot$ and 12 km ($r_{\mathrm{s}}/R = 0.35$) this gives $P_{\mathrm{c}} = 0.13\,\rho c^2$: the pressure at the centre of a neutron star is a sizeable fraction of its energy density, which no Newtonian star ever approaches.

Rests on Equation (49.18) and Theorem 49.9.

Proposition 49.12 (Buchdahl bound)**.** *No static spherical star of any composition can be more compact than*

$$\frac{GM}{Rc^2} < \frac{4}{9}, \tag{49.22}$$

equivalently $R > \frac{9}{8} r_{\mathrm{s}}$*: equilibrium fails strictly* outside *the would-be horizon at* r_{s}*.*
Rests on Equation (49.21) *and Example 49.11.*

Proof. *Derives Proposition 49.12.*

For the uniform star the bound is read off Equation (49.21): the central pressure diverges when the denominator vanishes, $3\sqrt{1 - r_{\mathrm{s}}/R} = 1$, i.e. at $r_{\mathrm{s}}/R = 8/9$, and no equilibrium exists at or beyond that compactness — infinite pressure is not available, and would only gravitate harder if it were (Remark 49.10). Buchdahl proved that the uniform star is the extreme case: for *any* equation of state whose density does not increase outward, integrating the field equations from centre to surface bounds the central metric function away from zero only when Equation (49.22) holds [1167]. We use the theorem in Buchdahl's generality but exhibit the proof only in the uniform case, which saturates it. Two consequences are observable: the gravitational redshift from the surface of any static star is bounded by $1 + z = (1 - r_{\mathrm{s}}/R)^{-1/2} < 3$, i.e. $z < 2$; and any object more compact than $\frac{9}{8} r_{\mathrm{s}}$ cannot be a star in equilibrium at all — the operational dividing line between the objects of this chapter and those of Chapter 45. □

Remark 49.13 (The Oppenheimer–Volkoff mass). Oppenheimer and Volkoff integrated Equations (49.17) and (49.18) numerically for the coldest matter then computable — an ideal degenerate neutron gas, i.e. Proposition 49.2 with $m = m_{\mathrm{n}}$ — and found the equilibrium sequence to terminate at about $0.7\,M_\odot$, at a radius near 10 km [845]. The number is far below every measured neutron-star mass (Section 49.4.1), and the discrepancy is itself a measurement: at these densities the neutrons are *not* an ideal gas. Their Fermi energy at nuclear saturation density, ~ 60 MeV by Equation (49.2), is comparable to the depth of the nuclear potential, so the repulsive core of the nuclear force stiffens the true equation of state far beyond the ideal-gas $\rho^{5/3}$ and roughly triples the maximum mass (Section 49.2.4). What survives of the calculation is its structure — a maximum mass exists for *every* equation of state, ideal or not — and its method, which is exactly how the modern curves of Section 49.4 are still computed.

49.2.3 Birth: core collapse and supernova neutrinos

A star above about $8\,M_\odot$ ends with an iron core at the Chandrasekhar mass, supported by exactly the electron degeneracy pressure whose limit Theorem 49.7 establishes. When the core exceeds it, collapse is not gradual but catastrophic: electron capture $p + e^- \to n + \nu_e$ removes the supporting electrons as the density rises, softening the equation of state precisely when stiffness is needed, and the core falls freely until nuclear density stiffens it (Section 49.2.4). The rebound drives a shock into the infalling envelope; the shock stalls, and the current understanding — anticipated by Colgate and White [1328] — is that it is revived by the absorption of a small fraction of the outgoing neutrinos, which carry essentially the whole energy release. The nuclear physics of the burning stages belongs to Chapter 107 and Chapter 52; what belongs here is the gravitational energy budget, and its direct detection.

Phenomenon 49.14 (A neutron star is observed being born)**.** Hours before the optical brightening of SN1987A in the Large Magellanic Cloud, two underground detectors on opposite sides of the Earth recorded a coincident burst of neutrino events: eleven at Kamiokande-II [1793] and eight at IMB [1789], spread over about ten seconds, at energies of tens of MeV. Scaled to the distance of the source, the burst carries of order 10^{46} J — some four orders of magnitude more than the light of the whole supernova — which is the

gravitational binding energy of a neutron star. This is the direct detection of stellar-core collapse, thirty-four years after the proposal that a supernova marks the transition of an ordinary star into a neutron star [730, 1328].

Rests on Theorem 44.27 and Phenomenon 101.5.

Derivation. *Derives Phenomenon 49.14.*

Three numbers are derived: the energy, its carrier, and its time-scale. Collapse carries a stellar core of mass M from a radius of order $10^6\,\mathrm{m}$ down to the radius of a neutron star, and the energy released is the difference of gravitational binding energies, which for a uniform sphere is

$$\Delta E \simeq \frac{3}{5}\frac{GM^2}{R}\,, \tag{49.23}$$

the initial term being negligible because the initial radius is two orders of magnitude larger. With $M = 1.4\,M_\odot = 2.8\times10^{30}\,\mathrm{kg}$ and $R = 12\,\mathrm{km}$,

$$\Delta E \simeq \frac{3}{5}\cdot\frac{6.674\times10^{-11}\,\mathrm{m^3/(kg\,s^2)}\times(2.8\times10^{30}\,\mathrm{kg})^2}{1.2\times10^{4}\,\mathrm{m}} \approx 2.6\times10^{46}\,\mathrm{J}\,,$$

about a tenth of the rest energy Mc^2. Set this beside the two things a supernova is usually described by: the kinetic energy of the ejecta, of order $10^{44}\,\mathrm{J}$, and the radiated light, of order $10^{42}\,\mathrm{J}$. The visible supernova is a by-product at the level of a per cent and a hundredth of a per cent respectively; the event itself is a neutrino event, and that is what the SN1987A detections confirmed.

That the energy emerges as neutrinos, over seconds rather than milliseconds, is a statement about opacity. Photons are hopelessly trapped, and even neutrinos are trapped at nuclear density: with the weak-interaction cross section of Chapter 103, $\sigma \sim 1.7\times10^{-48}\,\mathrm{m^2}\,(E_\nu/m_\mathrm{e}c^2)^2$, a 30 MeV neutrino in matter of $n \approx 1.8\times10^{44}/\mathrm{m^3}$ has a mean free path $\lambda = 1/(n\sigma)$ of order one *metre* — against a stellar radius of $10^4\,\mathrm{m}$. The energy therefore leaves by a random walk, in a diffusion time $t \sim R^2/(\lambda c)$, which with these crude numbers is already of order a second; detailed transport, with the cross sections rising steeply toward the hot centre, lengthens this to the observed ten seconds [1328, 1727]. The neutrinos finally escape from a layer where the temperature corresponds to mean energies of order 10 MeV — as observed.

The observed event counts check the budget quantitatively. Spreading ΔE over six neutrino species at $\langle E_\nu\rangle \approx 12\,\mathrm{MeV}$ gives $\sim 10^{58}$ neutrinos; at the LMC distance of $50\,\mathrm{kpc} = 1.5\times10^{21}\,\mathrm{m}$ the fluence at Earth is $\sim 5\times10^{14}/\mathrm{m^2}$ (computed). Kamiokande-II's fiducial $2.14\times10^6\,\mathrm{kg}$ of water holds about 1.4×10^{32} free protons; folding the inverse-beta-decay cross section $\bar\nu_e p \to n e^+$ at the mean energy, $\sigma \sim 1.5\times10^{-45}\,\mathrm{m^2}$, with the $\bar\nu_e$ sixth of the fluence predicts of order ten to twenty detected events — and eleven were seen [1793], with eight more in the larger, higher-threshold IMB tank [1789]. An order-of-magnitude estimate this crude agreeing this well means the energy, the carrier and the time-scale are all as Equation (49.23) demands. The bounds those nineteen events place on neutrino mass, lifetime and speed belong to Chapter 103. □

49.2.4 The dense-matter equation of state

Everything in Theorem 49.9 is known physics except one input: the pressure–density relation $P(\rho)$ of cold matter beyond nuclear saturation density, $\rho_0 \approx 2.7\times10^{17}\,\mathrm{kg/m^3}$ ($n_0 \approx 1.6\times10^{44}/\mathrm{m^3}$). Below saturation the ground state of matter is known essentially completely [1441]. A neutron star's *crust* is a lattice of increasingly neutron-rich nuclei in a degenerate electron gas; at $\rho \approx 4.3\times10^{14}\,\mathrm{kg/m^3}$ the nuclei can hold no more and free neutrons "drip" out, so from there inward a neutron gas — itself superfluid, the point of contact with Chapter 130 — coexists with the lattice; near $\rho_0/2$ the nuclei merge into

uniform neutron-rich matter of neutrons, protons and electrons in β-equilibrium. The nuclear physics of these regimes is that of Chapter 107.

Above a few times ρ_0 — the density of the inner core — the composition itself is unknown: hyperons, meson condensates and deconfined quark matter are all candidates, each softening the pressure in its own way [1727]. Two constraints are model-independent. Thermodynamic stability requires $\mathrm{d}P/\mathrm{d}\rho \geq 0$, and causality requires the sound speed $c_\mathrm{s}^2 = \mathrm{d}P/\mathrm{d}\rho$ (here ρ the total mass–energy density over c^2) not to exceed c^2 — the stiffest admissible equation of state is $P = \rho c^2$ up to constants, and Section 49.4.1 turns exactly that remark into a bound on every neutron-star mass.

Remark 49.15 (The equation of state is a mass–radius curve). Theorem 49.9 maps each candidate $P(\rho)$ to a one-parameter family $(M(\rho_\mathrm{c}), R(\rho_\mathrm{c}))$ — a curve in the mass–radius plane — and the map runs both ways: measuring masses and radii selects the equation of state, which is how a telescope does nuclear physics. The qualitative dictionary: a *stiff* equation of state (pressure rising fast) holds up larger maximum masses at larger radii; a *soft* one gives compact, light stars. Configurations beyond the maximum of $M(\rho_\mathrm{c})$ are unstable to radial collapse, so the curve's summit is the maximum mass of Section 49.4.1. The observational programme of Section 49.4 — Shapiro-delay masses, X-ray radii, tidal deformability — is the inversion of this map, and its current verdict is a pressure at $2\rho_0$ known to within about a factor of two [2294, 2338].

49.3 Pulsars

49.3.1 Discovery and identification

In 1967 Jocelyn Bell, searching survey charts for interplanetary scintillation, found a radio source that ticked: pulses of 1.337 s period, stable to the accuracy of the observatory clock [1373]. Within a year the identification was settled in favour of a rotating magnetized neutron star: Pacini had noted, just before the discovery, that a magnetized neutron star spun down by magnetic dipole radiation could power the Crab nebula [1355], and Gold showed that rotation — unlike the vibrations and orbits also proposed — naturally supplies the observed stability, the small duty cycle of a sweeping lighthouse beam, and a period that can only lengthen [1372]. The clincher came from the Crab remnant itself: a 33 ms pulsar [1384], spinning too fast for any white dwarf (Equation (49.24)) and slowing at a rate whose energy output matches the nebula's luminosity (Proposition 49.17).

Phenomenon 49.16 (Pulsars: clocks at nuclear density)**.** Certain radio sources emit pulses lasting a few per cent of their cycle, repeating with a regularity that rivals atomic clocks; the first found had a period of 1.337 s [1373]. The period always lengthens and never shortens, apart from occasional abrupt spin-ups [1406]. The source inside the Crab supernova remnant pulses at 33 ms [1384]; the first millisecond pulsar found spins at 1.558 ms [1681], and the fastest known at 1.396 ms — 716 rotations per second [2095]. The stability of the period, and its monotonic increase, identify the clock as the rotation of a massive body rather than any vibration or orbit [1355, 1372]; and rotation at these rates is possible only for matter at nuclear density.

Rests on Postulate 19.8 and Theorem 44.27.

Derivation. *Derives Phenomenon 49.16.*

A self-gravitating body rotating with angular velocity ω holds together at its equator only if its own gravity supplies at least the centripetal acceleration required there,

$$\frac{GM}{R^2} \geq \omega^2 R\,.$$

Writing $M = \frac{4}{3}\pi R^3 \rho$ for the mean density and $P = 2\pi/\omega$ for the period, the factor R^3 cancels from both sides and there remains

$$\rho \geq \frac{3\pi}{GP^2}\,. \tag{49.24}$$

The radius has dropped out entirely: the observed period bounds the density alone, with no model of the star required. For the Crab pulsar, $P = 33\,\mathrm{ms}$ gives $\rho \geq 1.3 \times 10^{14}\,\mathrm{kg/m^3}$, five orders of magnitude above the white-dwarf density of Phenomenon 49.1; for the 1.396 ms record holder it gives $\rho \geq 7.3 \times 10^{16}\,\mathrm{kg/m^3}$, within a factor of four of nuclear saturation density. No white dwarf can rotate this fast, and no other known state of matter reaches such densities. The bound is crude — it treats the body as uniform and ignores the distortion that rotation itself produces — but it is model-independent, and it is what identified the pulsars with the neutron stars predicted three decades earlier [730, 1372]. □

Proposition 49.17 (Magnetic-dipole spin-down)**.** *A neutron star of moment of inertia I, rotating at $\omega = 2\pi/P$ with a magnetic dipole moment $m_\perp$ perpendicular to the spin axis, loses rotational energy at the rate*

$$\dot{E} = -\frac{\mu_0\, m_\perp^2\, \omega^4}{6\pi c^3}\,, \tag{49.25}$$

so that $\dot{\omega} \propto -\omega^3$, the product $P\dot{P}$ is constant, and

$$\tau_\mathrm{c} \equiv \frac{P}{2\dot{P}} \tag{49.26}$$

bounds the age from above (equality for a star born spinning much faster than today). The surface polar field satisfies

$$B_\mathrm{p} \sin\theta_m = \sqrt{\frac{3\mu_0 c^3 I\, P\dot{P}}{8\pi^3 R^6}}\,, \tag{49.27}$$

with θ_m the magnetic inclination.

Proof. *Derives Proposition 49.17.*

Electromagnetic theory gives, for any magnetic moment $\boldsymbol{m}(t)$ varying in time, the radiated power $\mu_0 \left|\ddot{\boldsymbol{m}}\right|^2 / (6\pi c^3)$ — the magnetic counterpart of the electric-dipole formula, quoted here from its home in Section 65.3.2 [1976]. For a moment of fixed magnitude inclined at θ_m to the rotation axis, the component along the axis is static and the perpendicular component $m_\perp = m \sin\theta_m$ rotates rigidly at ω, so $|\ddot{\boldsymbol{m}}| = \omega^2 m_\perp$ at every instant, giving Equation (49.25). Setting $\dot{E} = \mathrm{d}\left(\frac{1}{2} I\omega^2\right)/\mathrm{d}t = I\omega\dot{\omega}$ yields $\dot{\omega} = -K\omega^3$ with $K = \mu_0 m_\perp^2 / (6\pi c^3 I)$; in terms of the period, $P\dot{P} = 4\pi^2 K$, constant. Integrating $\dot{\omega} = -K\omega^3$ from birth spin ω_0,

$$t = \frac{P}{2\dot{P}}\left[1 - \left(\frac{P_0}{P}\right)^2\right] \leq \frac{P}{2\dot{P}}\,,$$

which is Equation (49.26). Finally, a dipole of moment m has polar surface field $B_\mathrm{p} = \mu_0 m / (2\pi R^3)$; solving $P\dot{P} = 4\pi^2 K$ for $m_\perp$ gives Equation (49.27).

The Crab pulsar makes every line quantitative. With $P = 33.4\,\mathrm{ms}$, $\dot{P} = 4.2 \times 10^{-13}$ and the canonical $I = 10^{38}\,\mathrm{kg\,m^2}$ (a uniform $1.4\,M_\odot$ sphere of 12 km gives $\frac{2}{5}MR^2 \approx 1.6 \times 10^{38}\,\mathrm{kg\,m^2}$), Equation (49.25) gives $\left|\dot{E}\right| = 4\pi^2 I\dot{P}/P^3 \approx 4.5 \times 10^{31}\,\mathrm{W}$ (computed) — and the Crab nebula is observed to radiate of order $10^{31}\,\mathrm{W}$ across the whole spectrum. The pulsar's slowing powers the nebula, which settled the identification [1372, 1384]. The characteristic age Equation (49.26) is 1260 years, against the 972 years actually elapsed since the supernova of AD 1054: the difference measures the birth period — about 16 ms for pure dipole braking. And Equation (49.27) gives $B_\mathrm{p} \approx 4 \times 10^8\,\mathrm{T}$ — ten million times the strongest steady laboratory magnet, yet a thousandth of a magnetar (Section 49.3.2). □

49.3.2 The pulsar population

Over three thousand pulsars are now catalogued, and Proposition 49.17 organizes the whole population on one diagram, period against period derivative. Each star's position yields its characteristic age Equation (49.26) and field Equation (49.27); lines of constant age and constant field grid the plane, and populations separate cleanly on it.

The bulk of the population sits near $P \sim 1\,\mathrm{s}$, $B_\mathrm{p} \sim 10^8\,\mathrm{T}$, ages of megayears: ordinary pulsars, drifting toward long periods and radio death. In the corner of short period *and* small $\dot{P}$ sit the millisecond pulsars, discovered with the 1.558 ms PSR B1937+21 [1681]: by Equation (49.27) their fields are only $\sim 10^4\,\mathrm{T}$ to $10^5\,\mathrm{T}$ and their characteristic ages exceed $10^8\,\mathrm{yr}$ — old stars, not young ones. They are understood as *recycled*: spun up by accretion from a binary companion, which is why most millisecond pulsars have companions and why their timing is stable enough to serve as the precision clocks of Section 49.3.3. The record spin, 716 rotations per second [2095], is close to but below the breakup rate of Equation (49.24) — itself a loose confirmation of the density.

At the opposite extreme, the magnetars: slowly rotating ($P \sim 2\,\mathrm{s}$ to $12\,\mathrm{s}$) but with spin-down fields of $10^{10}\,\mathrm{T}$ to $10^{11}\,\mathrm{T}$, whose decay — not rotation — powers X-ray and gamma-ray outbursts, as Duncan and Thompson proposed [1852]. And superposed on the smooth spin-down of many young pulsars are *glitches*, sudden fractional spin-ups of order 10^{-6} first seen in Vela [1406]: the crust, spun down electromagnetically, decouples from an interior neutron superfluid whose quantized vortices (Chapter 130) unpin and transfer angular momentum catastrophically — the one observational window on the superfluidity of the interior.

49.3.3 Binary pulsars: precision gravity

A pulsar in a close binary is a moving clock in a strong field, and timing it turns the orbit into a laboratory. The Hulse–Taylor binary PSR B1913+16 [1550] is treated as an experiment, apparatus to error budget, in Chapter 47 (Section 47.1); its orbital decay was the first quantitative evidence for gravitational radiation, and the full derivation of the decay rate — eccentricity enhancement included — is carried out in Appendix A.1. Here the binaries appear for what they contribute to this chapter: the most precise strong-field tests of general relativity, and the precisely measured neutron-star masses that anchor Section 49.4.1.

Phenomenon 49.18 (Orbital decay of a binary pulsar)**.** The orbit of the binary pulsar PSR B1913+16 is shrinking. Its orbital period decreases secularly, a change first measured within seven years of the system's discovery [1550, 1703]. Four decades of timing now give a decay rate agreeing with the quadrupole prediction of general relativity to about 0.16%, once the relative acceleration of the solar system and the binary within the Galaxy is subtracted [2275]. The double pulsar PSR J0737-3039, in which both neutron stars are seen as pulsars [2047], yields five independent post-Keplerian parameters from a single system, all mutually consistent [2098]; sixteen years of its timing test the radiative sector to 1.3×10^{-4} [2383]. This is the evidence that gravitational radiation carries energy away from a system, and it preceded the direct detections by four decades.

Rests on Equation (A.83)*, Phenomenon 46.1, and Postulate 44.3.*

Derivation. *Derives Phenomenon 49.18.*

The orbital-decay physics is proved in this book once, in Appendix A.1: energy balance against the quadrupole luminosity Equation (46.6), carried through the Keplerian ellipse harmonics, gives the period derivative Equation (A.83), whose eccentricity enhancement factor $f(e) = \left(1 + \frac{73}{24}e^2 + \frac{37}{96}e^4\right)\left(1 - e^2\right)^{-7/2}$ evaluates to 11.86 at the measured $e = 0.6171$; with the measured masses the prediction is $\dot{P}_b = -2.40 \times 10^{-12}$, evaluated numerically there. We do not repeat the derivation; what remains to state is the correction named in

the phenomenon. The *observed* $\dot{P}_b$ is not purely intrinsic: the pulsar and the solar system accelerate differently in the Galactic potential, and a relative acceleration along the line of sight produces a secular drift of the apparent period (a kinematic Doppler derivative, with a further "Shklovskii" term from proper motion) that adds to $\dot{P}_b$ at the per-cent level for PSR B1913+16. It is computed from the measured distance, proper motion and a Galactic rotation model, and subtracted; the 0.16% agreement of Section 47.1 is between the prediction and this *intrinsic* decay, and its error budget is now dominated by the Galactic correction, not by the timing [2275].

The double pulsar sharpens every number. PSR J0737-3039 is a 2.45 h orbit holding a 22.7 ms recycled pulsar and (until it precessed out of view) a 2.77 s young one [2047, 2098]. Seeing both clocks fixes the mass ratio directly, so each measured post-Keplerian parameter — the periastron advance of about 16.9° per year (a Mercury-century of precession every six hours), the Einstein delay, the two Shapiro-delay parameters (the companion's orbit is seen nearly edge-on), and $\dot{P}_b$ — is a separate test with no freedom left. All are mutually consistent; the Shapiro shape was tested to 0.05% already in 2006 [2098], and with sixteen years of data the observed orbital decay agrees with the general-relativistic prediction to 1.3×10^{-4} — the most stringent test of the quadrupole formula in existence [2383]. The same fits deliver the component masses to a few parts in 10^4, $m_A \approx 1.34\,M_\odot$ and $m_B \approx 1.25\,M_\odot$ [2383], the kind of measurement Section 49.4.1 builds on. □

49.4 Maximum masses and radii

49.4.1 Bounds on the maximum mass

Every equation of state gives, through Theorem 49.9, a maximum neutron-star mass (Remark 49.15); measuring any single star's mass therefore falsifies every candidate whose maximum falls below it. Three binary pulsars carry the current record. The Shapiro delay — the extra light travel time through the companion's potential, the same effect measured across the solar system in Chapter 42 — gave $1.97 \pm 0.04\,M_\odot$ for PSR J1614-2230 [2155]; the spectroscopic orbit of its white-dwarf companion gave $2.01 \pm 0.04\,M_\odot$ for PSR J0348+0432 [2211]; and Shapiro-delay timing of PSR J0740+6620 gave $2.14^{+0.10}_{-0.09}\,M_\odot$ [2335], refined by further timing to $2.08 \pm 0.07\,M_\odot$ [2378]. From the other side, causality alone bounds the maximum mass of any star built on known low-density physics near $3\,M_\odot$ [1533]. The window left open — roughly $2.1\,M_\odot$ to $3\,M_\odot$ — is where the heaviest neutron star and the lightest black hole divide the sky between them.

Phenomenon 49.19 (Neutron stars reach two solar masses)**.** Several pulsars in binaries have masses measured dynamically — from the Shapiro delay of the pulses passing their companion, or from the companion's spectroscopic orbit — with no assumption whatever about the equation of state, and the values reach or exceed $2\,M_\odot$: PSR J1614-2230 [2155], PSR J0348+0432 [2211] and PSR J0740+6620 [2335, 2378]. Every candidate equation of state whose maximum-mass configuration falls below these values is thereby excluded, which is the sharpest single constraint on matter above nuclear density. From the other side, causality alone — the requirement that the sound speed not exceed c, matched to known physics at low density — bounds the mass of any neutron star by about $3.2\,M_\odot$ [1533], and no static star of any composition may be more compact than the Buchdahl bound $GM/(Rc^2) < 4/9$ (Proposition 49.12).

Rests on Theorem 49.9 and Proposition 49.12.

Derivation. *Derives Phenomenon 49.19.*

The lower half of the statement rests on machinery already proved. The masses are Keplerian and post-Keplerian timing measurements — for the Shapiro delay, the excess delay as a function of orbital phase yields the companion mass and inclination separately, and the

mass function then fixes the pulsar mass — with no reference to the pulsar's structure; the exclusion of soft equations of state is then immediate from Remark 49.15: the summit of $M(\rho_c)$ computed from Equation (49.18) for the candidate $P(\rho)$ falls below the measured mass, and no stable configuration of that matter can be the observed star.

The upper half — the Rhoades–Ruffini bound — needs one further argument, and it is worth exhibiting because it uses ignorance optimally. Suppose the equation of state is *known* up to some matching density ρ_m (nuclear physics vouches for it there) and completely unknown beyond, except for thermodynamic stability $\mathrm{d}P/\mathrm{d}\rho \geq 0$ and causality $\mathrm{d}P/\mathrm{d}\rho \leq c^2$. Among all admissible continuations, the one supporting the largest mass is the stiffest, $P = P_m + (\rho - \rho_m)\,c^2$: any softer choice lowers the pressure everywhere and with it the maximum mass. The bound is therefore computed by integrating Equations (49.17) and (49.18) with the causal continuation, and its scale is fixed by dimensional analysis alone. Above ρ_m the only quantities in the problem are G, c and ρ_m, and the unique mass they form is

$$M_{\max} \propto \frac{c^3}{\sqrt{G^3 \rho_m}} \quad \Longrightarrow \quad M_{\max} \approx 3.2 \left(\frac{\rho_m}{4.6 \times 10^{17}\,\mathrm{kg/m^3}} \right)^{-1/2} M_\odot \,, \tag{49.28}$$

where the dimensionless coefficient (about 0.09 of $c^3/\sqrt{G^3\rho_m}$, computed) is quoted from the numerical integration of Rhoades and Ruffini at their matching density [1533]. The bound moves only as $\rho_m^{-1/2}$ — trusting nuclear physics to twice the density costs merely a factor $\sqrt{2}$ — which is what makes it robust, and it brackets the measured two-solar-mass stars from above with room to spare. The Buchdahl statement was proved as Proposition 49.12. □

49.4.2 Radius measurements: X-ray pulse-profile modelling

Masses come from orbits; radii are harder, because a radius only shows itself through the spacetime curvature it sets. The NICER X-ray telescope on the International Space Station measures exactly that. Millisecond pulsars carry hot spots at their magnetic poles, and the thermal X-ray pulse observed as the star rotates is shaped by relativistic light bending: the more compact the star, the more of its far side is visible, the shallower the pulse modulation. Fitting the energy-resolved pulse profile of PSR J0030+0451 — with the rotational Doppler shift and aberration of the 4.87 ms spin included — two teams analysing the same data with independent codes obtained $R = 13.02^{+1.24}_{-1.06}\,\mathrm{km}$ with $M = 1.44^{+0.15}_{-0.14}\,M_\odot$ [2338], and $R = 12.71^{+1.14}_{-1.19}\,\mathrm{km}$ with $M = 1.34^{+0.15}_{-0.16}\,M_\odot$ [2339]. For the $2.08\,M_\odot$ pulsar J0740+6620 — where the mass is known in advance from radio timing (Section 49.4.1) — the same technique gives $R = 13.7^{+2.6}_{-1.5}\,\mathrm{km}$ [2386] and $R = 12.39^{+1.30}_{-0.98}\,\mathrm{km}$ [2389]: the heaviest well-measured neutron star is no smaller than the canonical ones, which by Remark 49.15 demands a pressure staying stiff deep into the core. An unanticipated by-product: the pulse-profile fits require the hot spots of J0030+0451 to lie in the *same* hemisphere — the magnetic field is far from a centred dipole, a discovery about pulsar magnetospheres made by a radius measurement [2338, 2339].

49.4.3 Tidal deformability: GW170817

The binary neutron-star inspiral GW170817 (Chapter 47) measured neutron-star structure through a fourth, fully independent channel: the tidal distortion each star raises on the other imprints itself on the gravitational waveform in the final orbits [2278]. The measured quantity is a dimensionless number defined as follows.

Definition 49.20 (Tidal deformability)**.** Place a star of mass M and radius R in a weak external tidal field $\mathcal{E}_{ij}$ (in the Newtonian limit, $\mathcal{E}_{ij} = \partial_i \partial_j \Phi_{\mathrm{ext}}$ evaluated at its centre). Its

induced mass quadrupole moment is, to linear order,

$$Q_{ij} = -\lambda\,\mathcal{E}_{ij}\,, \qquad \lambda = \frac{2}{3}\,k_2\,\frac{R^5}{G}\,, \tag{49.29}$$

which defines the tidal Love number k_2; the *dimensionless tidal deformability* is

$$\Lambda \equiv \frac{\lambda\,c^{10}}{G^4 M^5} = \frac{2}{3}\,k_2\left(\frac{c^2 R}{GM}\right)^5 . \tag{49.30}$$

For realistic neutron stars $k_2 \approx 0.05$ to 0.15 [2127], and the fifth power of the inverse compactness makes Λ a few hundred — and makes it, of all waveform parameters, the one that measures the radius.

Phenomenon 49.21 (The radius of a neutron star is near twelve kilometres)**.** Two methods sharing no systematics agree. Modelling the thermal X-ray pulse profile of PSR J0030+0451, whose shape is set by the relativistic bending of light around the star and therefore by its compactness, gives a radius between about 12 km and 13 km; two teams analysed the same data independently and agreed [2338, 2339]. Measuring instead the tidal deformability imprinted on the late inspiral phasing of the binary neutron-star merger GW170817 [2278] gives $\Lambda(1.4\,M_\odot) = 190^{+390}_{-120}$ and a radius between about 11 km and 13.5 km [2294]. Taken with Phenomenon 49.19, these bracket the pressure of matter above nuclear saturation density — the central unknown of Section 49.2.4 — from two directions at once: the masses exclude equations of state that are too soft, the radii those that are too stiff.

Rests on Equation (49.30)*.*

Derivation. *Derives Phenomenon 49.21.*

Each method needs one mechanism derived: light bending for the pulse profile, and the entry of Λ into the waveform for GW170817.

Light bending. A photon leaving the surface at angle α to the outward radial direction carries, by the null-geodesic machinery of Chapter 45, an impact parameter $b = R\sin\alpha/\sqrt{1 - r_\mathrm{s}/R}$, and arrives at infinity at an angle

$$\psi(\alpha) = \int_R^\infty \frac{b\,\mathrm{d}r}{r^2\sqrt{1 - \dfrac{b^2}{r^2}\left(1 - \dfrac{r_\mathrm{s}}{r}\right)}}$$

from the radius of emission. Grazing emission ($\alpha = \pi/2$) fixes the visible cap: everything within colatitude $\psi_\mathrm{max} = \psi(\pi/2)$ of the sub-observer point is seen at once, and $\psi_\mathrm{max} > \pi/2$ whenever $r_\mathrm{s} > 0$ — a compact star shows more than half its surface. The integral is done numerically in the fits; the compact approximation $\cos\alpha \approx u + (1-u)\cos\psi$ with $u = r_\mathrm{s}/R$, accurate to a per cent for $R \gtrsim 2r_\mathrm{s}$ [2022], exhibits the physics: $\cos\psi_\mathrm{max} = -u/(1-u)$, so for PSR J0030+0451 ($u \approx 0.33$) the visible cap extends to $\psi_\mathrm{max} \approx 119^\circ$ — about 74% of the surface (computed). A polar hot spot therefore never fully disappears, and the depth of the pulse modulation falls monotonically with u: the profile measures compactness, while the observed flux and temperature scale, blue- and redshifted by $(1+z) = (1-u)^{-1/2} \approx 1.2$, tie in the radius itself. Inverting energy-resolved profiles for mass, radius, spot geometry and viewing angle is the numerical likelihood analysis of [2338, 2339], run twice with independent codes as the phenomenon records.

Tidal phasing. In a binary at separation r, each star sits in its companion's tidal field, $\mathcal{E}_{ij} \sim Gm_2/r^3$, and by Equation (49.29) acquires $Q_{ij} = -\lambda\mathcal{E}_{ij}$. The induced quadrupole does two things, both scaling with λ: it deepens the mutual potential by the induced-moment interaction $\delta U = -\frac{1}{2}\lambda\mathcal{E}_{ij}\mathcal{E}^{ij} \sim -\lambda G^2 m_2^2/r^6$, and it adds coherently to the quadrupole moment whose time variation radiates (Equation (46.6)). Relative to the point-mass energy

$\sim Gm_1m_2/r$, the tidal term is smaller by $\lambda G/r^5 \sim \Lambda\,(GM/rc^2)^5$: five powers of compactness, i.e. ten powers of v/c — formally a fifth-post-Newtonian correction, utterly negligible except that Λ is a few *hundred*, and that the phase of a chirping binary (Equation (46.8)) accumulates over thousands of cycles. Carrying the energy and flux corrections through the phase evolution gives the leading tidal contribution to the frequency-domain phase, proportional to the single mass-weighted combination

$$\tilde{\Lambda} = \frac{16}{13}\,\frac{(m_1 + 12m_2)\,m_1^4\Lambda_1 + (m_2 + 12m_1)\,m_2^4\Lambda_2}{(m_1+m_2)^5}\,,$$

with a known numerical coefficient, quoted from the standard computation [2124, 2127]. Matched filtering of GW170817's final orbits therefore measures $\tilde{\Lambda}$; the discovery analysis bounded $\Lambda(1.4\,M_\odot) \le 800$ at 90% confidence (low-spin prior) [2278], and the dedicated reanalysis gives $\Lambda(1.4\,M_\odot) = 190^{+390}_{-120}$, which through Equation (49.30) with the relativistic k_2 of [2127] yields $R = 11.9 \pm 1.4$ km for both stars [2294] — the numbers the phenomenon quotes, in agreement with NICER's, from data that share not a single instrument, wavelength or systematic. The same event's electromagnetic counterpart — the kilonova whose lanthanide spectra realized the r-process site of Chapter 52 — and its detection history belong to Chapter 47. □

49.5 The black-hole endpoint

Beyond the maximum mass there is nothing. The sequence of cold equilibria ends (Section 49.4.1), the Buchdahl bound (Proposition 49.12) forbids trading size for survival, and a core pushed past the limit — by accretion, by a merger, or at birth — collapses with nothing left to stop it. Oppenheimer and Snyder solved the idealized problem in the same year as the equilibrium equations: a uniform pressureless cloud collapsing from rest [844]. Each dust element falls along a radial geodesic of the exterior geometry, reaching the gravitational radius r_s and the centre in *finite proper time* — for a neutron star of $2\,M_\odot$ collapsing from 12 km, the free-fall time $\tau = \frac{\pi}{2}\sqrt{R_0^3/\,(2GM)}$ is about a tenth of a millisecond (computed) — while a distant observer, receiving light ever more redshifted by the factor $(1 - r_\mathrm{s}/r)^{-1/2}$ of Chapter 45, sees the surface freeze and fade at r_s. Nothing marks the crossing locally: the horizon is a global feature of the geometry, not a place where anything happens, and the interior solution matches a collapsing cosmology of the very kind Chapter 48 runs forward.

That is where this chapter hands over. The observational record of the objects on the far side of the Buchdahl line — X-ray binary masses, the shadow of a horizon, ringdowns — is Chapter 50; the merger catalogue of Chapter 47, opened by GW150914 [2264], now measures both sides of the boundary at once, heaviest neutron stars against lightest black holes, and the sparsely populated interval between about $2.2\,M_\odot$ and $5\,M_\odot$ — the "mass gap", whether real or observational — is the current form of a question this chapter has asked three times: how much cold matter can gravity tolerate? Every answer so far — Chandrasekhar's $1.4\,M_\odot$, causality's $3\,M_\odot$, Buchdahl's 4/9 — has been a theorem first and a measurement second, which is this book's definition of understanding a thing.

Chapter 50

Experiment: Black-Hole Observations

Tests Phenomenon 42.5 and Equations (42.8) *and* (50.4).
Assuming Equation (50.2).

The stellar orbits around Sgr A*, the Event Horizon Telescope images, and the X-ray binary mass functions: this chapter assembles the observational case that the Schwarzschild and Kerr geometries of Chapter 45 are realized in Nature. The claim under test is specific—a mass confined within its gravitational radius, with no material surface—and it has been established four independent ways: dynamically, by the mass function of the X-ray binary Cygnus X-1 [1466, 1488]; astrometrically, by the stellar orbits around Sgr A* [2125, 2146]; by direct imaging at event-horizon scale in M87* [2328] and Sgr A* [2403]; and by the gravitational-wave mergers of Chapter 47 [2264].

The four channels are treated as one experiment because they test one prediction from four directions, at masses spanning six orders of magnitude and field strengths spanning the gap between a stellar orbit a thousand gravitational radii out and light circling the photon sphere itself. No single channel proves the case alone; the concordance is the measurement, and Section 50.5 states with some care what it does and does not establish.

50.1 Historical context and the prediction under test

50.1.1 From invisible companions to relativistic collapse

The idea is older than the theory it now tests. In 1784 John Michell, reasoning with Newtonian corpuscles of light, computed that a body of the Sun's density and five hundred times its diameter would have an escape speed exceeding the speed of light, so that "all light emitted from such a body would be made to return towards it"—and he added the observation on which this entire chapter rests: such invisible bodies could nevertheless be detected through the motion of luminous ones revolving about them [37]. Every dynamical mass in Section 50.4 is Michell's method carried out.

General relativity replaced the escape-speed argument with a sharper structure. Within weeks of the field equations, Schwarzschild produced the exact exterior solution for a spherical mass [440], with its characteristic radius $r_{\mathrm{s}} = 2GM/c^2$; for decades the surface at r_{s} was read as a coordinate accident or dismissed as physically unreachable. Two 1939 calculations made it unavoidable. Oppenheimer and Volkoff showed that cold neutron matter has a maximum mass, of order a solar mass in their equation of state, above which no static configuration exists at all [845]; and Oppenheimer and Snyder integrated the collapse of a pressureless ball past that point, finding that the matter crosses r_{s} in finite proper time while a distant observer sees the surface freeze and redshift away [844]. Kerr's rotating generalization [1259] and Penrose's theorem that collapse past a trapped surface ends in a singularity regardless

of symmetry [1319] completed the theoretical picture, which Chapter 45 develops in full: if masses above the cold-matter limit exist and lose their support, general relativity permits them no fate but a black hole.

Observation entered by another door. A 1962 sounding-rocket flight instrumented to look for X-ray fluorescence from the Moon instead recorded a bright source in Scorpius and a diffuse background—the birth of X-ray astronomy [1225]; compact accreting objects, it turned out, announce themselves most loudly at kiloelectronvolt energies. In 1963 Schmidt recognized the emission lines of the "radio star" 3C 273 as hydrogen lines redshifted by $z = 0.158$ [1265], which put the object at cosmological distance and its luminosity orders of magnitude beyond what any assembly of stars in so small a volume could supply. Lynden-Bell drew the inference that quasars are accreting supermassive collapsed objects, that dead quasars must therefore litter the present universe, and that the nuclei of ordinary galaxies—our own included—are where they hide [1403]. The compact nonthermal radio source now called Sgr A* was found at the centre of the Milky Way in 1974 [1517]. The four observational programmes reported below are the systematic interrogation of these two populations, stellar and supermassive.

50.1.2 What general relativity predicts

The falsifiable signatures, each derived in Chapter 45, are these.

First, a purely Newtonian instrument: for a spectroscopic binary the period and radial-velocity amplitude of the visible star alone bound the mass of its unseen companion from below, Equation (50.2). The bound involves no model of the companion, so wherever it exceeds the maximum mass of a cold compact star (Chapter 49), the companion can only be a black hole. This inequality is stated and proved with the Cygnus X-1 data in Section 50.4.1.

Second, a horizon at $r_{\mathrm{s}} = 2GM/c^2$ and hence no material surface: no thermonuclear flashes from accumulated fuel, no quiescent re-radiation of the accretion energy deposited on a surface. Accreted energy not radiated on the way down is lost. The comparison that turns this into a measurement is made in Section 50.5.

Third, the strong-field orbital mechanics of the Schwarzschild geometry: an innermost stable circular orbit truncating the accretion disc and fixing its radiative efficiency, gravitational redshift and periastron advance for test bodies—the same advance formula, Equation (42.8), that Mercury tests at solar field strengths, here applied four orders of magnitude deeper.

Fourth, a photon sphere. Light passing a black hole closer than the critical impact parameter is captured, so a black hole seen against its own emission shows a dark disc—a shadow—of angular diameter $3\sqrt{3}\,r_{\mathrm{s}}/D \simeq 5.2\,r_{\mathrm{s}}/D$ at distance D, nearly independent of spin and viewing angle. Falcke, Melia and Agol computed the image for Sgr A* and showed that at millimetre wavelengths, where the accretion flow turns transparent and the atmosphere still permits interferometry, the shadow of the Galactic centre—about thirty microarcseconds for the mass then favoured—is resolvable from the ground [1988]. Inverted, the shadow size weighs the hole: Equation (50.4).

Fifth, gravitational radiation: an inspiralling binary chirps and the merged remnant rings down at the quasinormal frequencies of a Kerr hole, per Chapter 46. That channel has its own chapter, Chapter 47; here it contributes masses.

50.2 Apparatus

50.2.1 X-ray observatories

The stellar-mass channel is X-ray astronomy, because gas spiralling onto an object a few tens of kilometres across is heated to 10^7–10^8 kelvin and radiates at kiloelectronvolt energies, to which the atmosphere is opaque. The first generation of instruments were gas proportional

counters flown above it: windowed tubes in which an incoming X-ray photoionizes the fill gas and the charge avalanche measures its energy, with sensitivity in the few- to tens-of-keV band, no true imaging, and fields of view defined by mechanical collimators [1225]. Rockets gave minutes of exposure; the scanning and pointed satellites that followed gave years, all-sky monitors to catch transient outbursts, and—decisive for Cygnus X-1—timing at millisecond resolution, which revealed the rapid aperiodic flickering that marks an emitting region light-milliseconds across [2103]. Later observatories added CCD and grating spectrometers resolving the iron Kα fluorescence line near 6.4 keV, whose gravitationally redshifted, relativistically broadened profile probes the innermost disc [1911]. The optical half of the apparatus is conventional stellar spectroscopy of the companion star, from which come the period and velocity amplitude that feed the mass function; the modern addition is very-long-baseline radio astrometry of the compact object itself, precise enough to measure its trigonometric parallax [2387].

50.2.2 Adaptive optics and interferometry on the Galactic Centre

The Galactic centre is invisible at optical wavelengths behind about thirty magnitudes of dust extinction, but opens up in the near-infrared at wavelengths near 2.2 µm. There the diffraction limit of a 10 m telescope is $\lambda/D \approx 2.2\times10^{-7}$ rad, about 45 milliarcseconds — fine enough to separate the stars of the central cluster, if the atmosphere can be defeated. Speckle imaging (freezing the turbulence in millisecond exposures and reconstructing afterwards) and then adaptive optics (measuring the wavefront on a reference star or laser beacon and correcting it with a deformable mirror at kilohertz rates) brought the Keck 10 m and VLT 8.2 m telescopes to that limit, and two decades of such imaging, tied to a radio reference frame and combined with spectroscopic radial velocities, produced the stellar orbits of Section 50.4.2 [2125, 2146][2156].

The precision instrument is GRAVITY, the beam combiner that phase-references all four VLT unit telescopes into a single interferometer with baselines up to 130 m [2279]. The fringe spacing at 2.2 µm is $\lambda/B \approx 1.7\times10^{-8}$ rad, some 3.5 milliarcseconds, and because the quantity measured is a fringe phase against a nearby reference source, positions within that fringe are read to a small fraction of it: astrometry at the level of a few tens of microarcseconds, roughly a hundredfold gain on single-telescope imaging. This is the instrument that turned the S2 orbit from a mass measurement into a test of general relativity [2295, 2347].

50.2.3 The Event Horizon Telescope

Resolving an event horizon takes another three orders of magnitude. The two largest black-hole shadows on the sky—Sgr A* and M87*— subtend about fifty microarcseconds, so the required resolution is $\sim 2\times10^{-10}$ rad, which at an observing wavelength of 1.3 mm demands an aperture the size of the Earth: $\lambda/D \approx 1.2\times10^{-10}$ rad, about 25 microarcseconds, for baselines near 1.1×10^{7} m. The Event Horizon Telescope synthesizes exactly that, by very-long-baseline interferometry: in April 2017, eight radio telescopes at six sites from Hawaii to the South Pole observed simultaneously at 1.3 mm, each recording the raw voltage stream against a hydrogen-maser clock, with the phased ALMA array contributing the sensitivity of a 73 m equivalent dish. Petabytes of recorded signal were later cross-correlated at dedicated correlator facilities, fringe-fitted, and calibrated through the chain described in the instrument papers accompanying [2328]. The wavelength is chosen twice over: it is short enough that the synchrotron emission of the accretion flow becomes optically thin, so the line of sight reaches the horizon scale, and long enough that the atmosphere and the antennas still support coherent interferometry [1988].

Gravitational-wave interferometers, the fourth apparatus, are described in Chapter 47 [2243].

50.3 Procedure

Four measurement protocols, one per channel.

Radial velocities. The optical companion's spectrum is observed over many orbits; the Doppler shift of its lines yields the period P and velocity semi-amplitude K, and with them the mass function $f = PK^3/2\pi G$ of Equation (50.1)—a strict lower bound on the unseen mass [1466, 1488]. Converting the bound into a mass requires the inclination and the companion mass, which enter through ellipsoidal light-curve modelling, the spectral classification of the companion, and the distance; the modern Cygnus X-1 solution fixes the distance by VLBI parallax and fits all elements simultaneously [2178, 2387]. For the transient systems the same spectroscopy is performed in quiescence, when the disc is faint and the companion's lines are clean [2103].

Astrometric orbits. Individual stars near Sgr A* are followed for decades in position (imaging, then interferometry) and in radial velocity (infrared spectroscopy). A simultaneous fit of all measured stars solves for each star's six orbital elements plus the central mass M and the Sun–centre distance R_0, which the data determine jointly because the angular orbit scales as $M^{1/3}/R_0$ while the velocities are absolute [2125, 2146]. The relativistic tests are differential: the Keplerian orbit is fitted and the residual at pericentre—in radial velocity for the redshift, in the orbit orientation for the precession—is compared with the prediction, each effect published only after being measured on both sides of pericentre [2295, 2336, 2347].

Interferometric imaging. The EHT data reduce to complex visibilities on every baseline. Calibration leans on closure quantities—combinations of phases around telescope triangles and of amplitudes around quadrangles from which station-dependent errors cancel exactly. Images were reconstructed by four teams working blind of one another with two independent algorithm families, and only then compared; in parallel, geometric crescent models and libraries of general-relativistic magnetohydrodynamic simulations were fitted directly to the visibilities. The ring diameter is the quantity on which all methods converge, and the procedure was validated end-to-end on synthetic data with known answers [2328, 2403].

Matched filtering. Gravitational-wave strain data are correlated against relativistic waveform banks and the significance established on time-shifted background, per Chapter 47 [2264]. This chapter takes from that channel only the masses and the ringdown.

50.4 Observations and data

50.4.1 Cygnus X-1 and the X-ray binaries

Cygnus X-1 was among the brightest X-ray sources in the sky and the most erratic, flickering on timescales down to milliseconds. When a radio counterpart pinned its position in 1971, the field contained the ninth-magnitude B0 supergiant HDE 226868. In early 1972 Webster and Murdin [1488] and, independently, Bolton [1466] showed the supergiant to be a single-lined spectroscopic binary with a period of 5.6 days, and both drew the same conclusion: for any mass consistent with the supergiant's spectral type, the velocity amplitude demands an unseen companion of several solar masses at least—too heavy for the white dwarfs and neutron stars then known, and dark at every wavelength searched. The phrase used was cautious ("a heavy companion"), but this was the first dynamical identification of a stellar black-hole candidate.

The half-century since has only sharpened the numbers. Table 50.1 collects the modern solution: the distance from VLBI parallax, and with it a black-hole mass of $21.2 \pm 2.2\,M_\odot$ [2387]. The mass function computed from the period and the modern velocity amplitude is small — the orbit is seen nearly face-on — which is exactly why the full solution with

inclination and companion mass is needed here, and why the transient systems below, where the mass function alone settles the question, carry independent weight.

Table 50.1: The Cygnus X-1 system. The orbital period is common to the identification papers [1466, 1488] and the modern solution; the velocity semi-amplitude of HDE 226868 is the modern spectroscopic value [2178]; the mass function is computed here from those two by Equation (50.1); the inclination (published uncertainty below one degree), distance and black-hole mass are the parallax-anchored solution of [2387].

quantity	as published	SI
orbital period P	5.600 days	$4.838 \times 10^5\,\mathrm{s}$
velocity semi-amplitude K	75.6 ± 0.7 km/s	$(7.56 \pm 0.07) \times 10^4\,\mathrm{m/s}$
mass function f (computed)	$0.251\,M_\odot$	$5.0 \times 10^{29}\,\mathrm{kg}$
orbital inclination i	about 27.5°	—
distance d	$2.22^{+0.18}_{-0.17}\,\mathrm{kpc}$	$(6.9 \pm 0.6) \times 10^{19}\,\mathrm{m}$
black-hole mass M_X	$21.2 \pm 2.2\,M_\odot$	$(4.22 \pm 0.44) \times 10^{31}\,\mathrm{kg}$

Cygnus X-1 is persistent, fed by the supergiant's wind. The larger population is transient: systems with low-mass companions that outburst for months and then sit quiescent for years, leaving the companion's spectrum clean. In the best of them the inequality proved below needs no help at all: the discovery measurement for V404 Cygni gave a mass function above $6\,M_\odot$ [1850], refined to $6.08 \pm 0.06\,M_\odot$ in the modern tabulation [2103]—the absolute floor on the compact object's mass, from two spectroscopic observables, already twice the causal neutron-star bound of Chapter 49. Some twenty systems now have dynamical masses, running from about $5\,M_\odot$ to about $20\,M_\odot$, and their X-ray spectra and variability are read through the accretion-disc theory of Shakura and Sunyaev [1512][2103]. The gravitationally redshifted iron Kα line, first resolved in the active galaxy MCG–6–30–15, extends the same disc diagnostics to within a few gravitational radii of the horizon [1911].

Phenomenon 50.1 (Dark companions too massive to be neutron stars)**.** In a number of X-ray binaries the spectroscopic orbit of the optical star requires an unseen companion heavier than any neutron star can be. The first such case was Cygnus X-1, identified in 1972 with the supergiant HDE 226868 [1466, 1488]; its modern dynamical mass is $21.2 \pm 2.2\,M_\odot$ [2387]. In the transient black-hole binaries the argument is sharper, because for several of them the mass function alone — a quantity built from the orbital period and the radial-velocity amplitude, and independent of both the inclination and the companion's mass — already exceeds the maximum neutron-star mass [1850][2103]. Dynamically measured masses in this population run from about $5\,M_\odot$ to about $20\,M_\odot$.

Rests on Theorem 27.30 and Phenomenon 27.35.

Derivation. *Derives Phenomenon 50.1.*

The inequality on which every dynamical black-hole mass rests is worth deriving in full. Let the compact object of mass M_X and the optical star of mass M_opt move on a circular orbit of separation a and period P, inclined at i to the plane of the sky. The optical star circles the centre of mass at radius $a_\mathrm{opt} = aM_\mathrm{X}/\left(M_\mathrm{X} + M_\mathrm{opt}\right)$, and spectroscopy measures the semi-amplitude of its line-of-sight velocity,

$$K = \frac{2\pi a_\mathrm{opt}}{P} \sin i\,.$$

Out of the two observables P and K define the *mass function*

$$f := \frac{PK^3}{2\pi G}\,. \tag{50.1}$$

Substituting for K and then eliminating a with Kepler's third law $4\pi^2 a^3 = G\,(M_{\mathrm{X}} + M_{\mathrm{opt}})\,P^2$,

$$f = \frac{P}{2\pi G}\cdot\frac{8\pi^3 a_{\mathrm{opt}}^3 \sin^3 i}{P^3} = \frac{4\pi^2 a^3}{GP^2}\cdot\frac{M_{\mathrm{X}}^3 \sin^3 i}{(M_{\mathrm{X}}+M_{\mathrm{opt}})^3} = \frac{M_{\mathrm{X}}^3 \sin^3 i}{(M_{\mathrm{X}}+M_{\mathrm{opt}})^2}\,.$$

Since $\sin i \le 1$ and $M_{\mathrm{opt}} > 0$, the right-hand side cannot exceed M_{X}, so

$$M_{\mathrm{X}} \ge f = \frac{PK^3}{2\pi G}\,. \tag{50.2}$$

The mass function is therefore a strict lower bound on the mass of the unseen body, extracted from two numbers a spectrograph delivers directly, with no knowledge of the inclination, the distance or the companion star. Wherever f by itself exceeds the causal neutron-star bound of Chapter 49, the identification of the companion as a black hole follows with nothing further assumed — and this is the only one of the four measurement channels of this chapter that requires no relativistic input at all. For Cygnus X-1, $P = 4.838\times10^5\,\mathrm{s}$ and $K = 7.56\times10^4\,\mathrm{m/s}$ give

$$f = \frac{4.838\times10^5\,\mathrm{s}\times(7.56\times10^4\,\mathrm{m/s})^3}{2\pi\times6.674\times10^{-11}\,\mathrm{m^3/(kg\,s^2)}} \approx 5.0\times10^{29}\,\mathrm{kg} \approx 0.25\,M_\odot\,,$$

which is why that system's mass rests on the full orbital solution of Table 50.1 rather than on the bound; for V404 Cygni the bound itself is $6.08\,M_\odot$ [1850][2103] and the conclusion is immediate. □

50.4.2 Sgr A*: stellar orbits

The decisive Galactic-centre observation was the closing of a single stellar orbit. The star S2, tracked from 1992 and followed through its pericentre passage in 2002, was shown to move on a Keplerian ellipse of period near fifteen years with the radio source Sgr A* at its focus—the first time the enclosed mass could be assigned to a volume as small as a single stellar orbit [2038]. Two decades of astrometry from Keck and the VLT then fixed the mass near $4\times10^6\,M_\odot$: the Keck solution gave $(4.1\text{–}4.5)\times10^6\,M_\odot$ depending on the treatment of the distance [2125], the VLT solution $(4.31\pm0.06_{\mathrm{stat}}\pm0.36_{R_0})\times10^6\,M_\odot$ [2146], and the two programmes' agreement, star by star, is reviewed in [2156].

GRAVITY made the orbit relativistic. At the May 2018 pericentre passage—the star moving at 7650 kilometres per second, 2.6% of c—the measured radial velocity exceeded the Keplerian prediction by about 200 km/s, the combined gravitational redshift and transverse-Doppler shift; expressed as a parameter interpolating between Newtonian gravity (0) and general relativity (1), the result was 0.90 ± 0.17 statistical, with a comparable systematic [2295]. The Keck group, with independent instruments, astrometry and analysis, found 0.88 ± 0.17 [2336]. Continued interferometric monitoring through and beyond pericentre then resolved the Schwarzschild precession of the orbit, 12 minutes of arc per revolution in the plane of the orbit and prograde, at 1.10 ± 0.19 of the prediction of Equation (42.8) [2347]. The same fit delivers the current best mass and distance, collected in Table 50.2.

Phenomenon 50.2 (Four million solar masses inside the orbit of a single star)**.** Individual stars in the central arcsecond of the Galaxy have been followed through complete orbits about a common focus coincident with the compact radio source Sgr A*. The star S2, first traced through a pericentre passage in 2002 [2038], closes its orbit in 16.05 yr [2295], reaching a pericentre distance of about $1.8\times10^{13}\,\mathrm{m}$. Two decades of adaptive-optics astrometry from

Table 50.2: The S2 orbit and its relativistic parameters. Orbital elements, mass and distance are the interferometric solution [2295, 2347]; the pericentre distance and speed are computed here from them (the published values agree). The redshift parameter is 0 for Newtonian gravity and 1 for general relativity; the precession parameter multiplies the Schwarzschild advance of Equation (42.8). The Keck redshift value is the independent measurement of [2336].

quantity	as published	SI
orbital period P	16.05 yr	$5.07 \times 10^{8}\,\mathrm{s}$
eccentricity e	0.885	—
angular semi-major axis	125 mas	$6.06 \times 10^{-7}\,\mathrm{rad}$
pericentre distance r_{p}	≈ 120 au	$1.8 \times 10^{13}\,\mathrm{m}$
pericentre speed v_{p}	$\approx 0.026\,c$	$7.65 \times 10^{6}\,\mathrm{m/s}$
enclosed mass M	$4.26 \times 10^{6}\,M_{\odot}$	$8.47 \times 10^{36}\,\mathrm{kg}$
distance R_0	8.25 kpc	$2.545 \times 10^{20}\,\mathrm{m}$
redshift parameter (VLT; Keck)	0.90 ± 0.17; 0.88 ± 0.17	—
precession parameter	1.10 ± 0.19	—

Keck and the VLT [2125, 2146][2156], later sharpened by interferometry [2279], give an enclosed mass of about $4 \times 10^{6}\,M_{\odot}$ within that pericentre. The orbits are Keplerian about a point mass to the precision of the data: no extended distribution of the required mass is consistent with them.

Rests on Phenomenon 27.35 and Theorem 27.30.

Derivation. *Derives Phenomenon 50.2.*

The mass follows from Kepler's third law applied to the fitted orbit, which is what makes it independent of any model of the source. S2's angular semi-major axis is about 125 milliarcseconds; at the measured distance to the Galactic centre, $R_0 \approx 8.2\,\mathrm{kpc} = 2.53 \times 10^{20}\,\mathrm{m}$, and with one milliarcsecond equal to 4.848×10^{-9} in radian measure, this is

$$a \approx 125 \times 4.848 \times 10^{-9} \times 2.53 \times 10^{20}\,\mathrm{m} \approx 1.53 \times 10^{14}\,\mathrm{m}\,.$$

With $P = 16.05\,\mathrm{yr} = 5.07 \times 10^{8}\,\mathrm{s}$,

$$M = \frac{4\pi^2 a^3}{G P^2} = \frac{4\pi^2\,(1.53 \times 10^{14}\,\mathrm{m})^3}{6.674 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)} \times (5.07 \times 10^{8}\,\mathrm{s})^2} \approx 8.2 \times 10^{36}\,\mathrm{kg}\,,$$

that is about $4.1 \times 10^{6}\,M_{\odot}$; the mass of S2 itself, of order $10\,M_{\odot}$, is negligible against this and has been dropped. It is worth recording what this does and does not establish. The Schwarzschild radius of such a mass is $2GM/c^2 \approx 1.2 \times 10^{10}\,\mathrm{m}$, so S2's pericentre lies some 1500 gravitational radii out. The stellar orbits therefore demonstrate a very large mass in a very small volume — a mean density that no cluster of ordinary stars or stellar remnants could sustain against evaporation and collision for the age of the Galaxy — but they do not by themselves reach the horizon. That is what the imaging of Section 50.4.3 adds. □

Phenomenon 50.3 (Relativistic redshift and precession of a stellar orbit)**.** At S2's 2018 pericentre passage the measured radial velocity departed from the Keplerian prediction by an amount corresponding to about 200 km/s, in the sense and of the magnitude predicted by the combined gravitational and transverse-Doppler shift [2295], a result confirmed by the independent Keck programme [2336]. Continued monitoring then detected the Schwarzschild precession of the orbit itself, an in-plane advance of the pericentre of about twelve minutes of arc per orbit, consistent with general relativity [2347]. Both effects were predicted before they were measured, and neither has a Newtonian counterpart.

Rests on Phenomena 38.13, 42.5 and 42.6.

Derivation. *Derives Phenomenon 50.3.*

The redshift excess is first order in the small quantities and can be checked directly. A clock at radius r from a mass M moving with speed v is shifted, to first order in $GM/\left(rc^2\right)$ and v^2/c^2, by

$$z = \frac{GM}{rc^2} + \frac{v^2}{2c^2}\,, \tag{50.3}$$

the first term the gravitational redshift of Chapter 42 and the second the transverse Doppler shift of Chapter 38. Both are positive and both peak at pericentre, where the star is deepest in the potential and moving fastest. Taking the mass of Phenomenon 50.2, for which $GM/c^2 \approx 6.1 \times 10^9\,\mathrm{m}$, with S2's pericentre radius $r_\mathrm{p} \approx 1.8 \times 10^{13}\,\mathrm{m}$ and pericentre speed $v_\mathrm{p} \approx 7650\,\mathrm{km/s}$,

$$\frac{GM}{r_\mathrm{p}c^2} \approx 3.4 \times 10^{-4}\,, \qquad \frac{v_\mathrm{p}^2}{2c^2} \approx 3.3 \times 10^{-4}\,,$$

so $z \approx 6.7 \times 10^{-4}$ and $cz \approx 200\,\mathrm{km/s}$, which is the measured excess.

That the two contributions come out nearly equal is not a coincidence. For a Keplerian orbit the vis-viva relation gives $v_\mathrm{p}^2 = (1+e)\,GM/r_\mathrm{p}$ at pericentre, so the transverse-Doppler term is exactly $(1+e)/2$ times the gravitational one — a factor 0.94 for S2's eccentricity $e \approx 0.88$. The two therefore cannot be separated by this measurement; what is tested is their sum, and disentangling them would require an orbit of very different eccentricity.

The precession is the classical formula of Equation (42.8) evaluated on this orbit. With $GM/c^2 \approx 6.1 \times 10^9\,\mathrm{m}$, $a \approx 1.53 \times 10^{14}\,\mathrm{m}$ and $1 - e^2 \approx 0.217$,

$$\Delta\varphi = \frac{6\pi GM}{c^2 a\left(1-e^2\right)} \approx \frac{6\pi \times 6.1 \times 10^9\,\mathrm{m}}{1.53 \times 10^{14}\,\mathrm{m} \times 0.217} \approx 3.5 \times 10^{-3}\,,$$

in radian measure per revolution — about twelve minutes of arc, which is what is measured [2347]. Mercury, for comparison, accumulates 5.0×10^{-7} radian per revolution (Chapter 53): the same formula, verified at a relativistic parameter $GM/\left(c^2 a\left(1-e^2\right)\right)$ some four orders of magnitude larger. □

50.4.3 Event-horizon-scale imaging

In April 2019 the Event Horizon Telescope published the first image of a black hole: the nucleus of M87 resolved into a bright, asymmetric ring of 42 ± 3 microarcseconds diameter around a deep central brightness depression [2328]. The ring persisted across four observing nights and across every independent imaging pipeline; its south side is brighter, as Doppler beaming requires for emission orbiting with the small approaching-side inclination inferred from the large-scale jet; and the inferred mass, $(6.5 \pm 0.7) \times 10^9\,M_\odot$, is the photon-capture cross-section of Equation (50.4) read off the sky. The polarized image that followed mapped an ordered, partly radial magnetic-field pattern in the ring, of the kind required to launch the jet and consistent with a dynamically important ("magnetically arrested") field at the horizon [2372].

One honest calibration must be stated. What the interferometer measures is the diameter of the *emission* ring, which simulations place close to, but systematically outside, the critical curve bounding the shadow — by roughly ten per cent, depending on where the emission peaks. The published mass therefore carries a theory-side calibration from the simulation library, and its error bar does [2328]. The Schwarzschild arithmetic below, which ignores this distinction, overshoots the full analysis by about the same ten per cent, exactly as it should.

In May 2022 the same technique, hardened against the source's minute-scale variability (the dynamical time at the horizon of a $4 \times 10^6\,M_\odot$ hole is minutes, not days), yielded the image of Sgr A*: a ring of 51.8 ± 2.3 microarcseconds [2403]. Here the prediction was

available in advance with no freedom at all: the stellar-orbit mass and distance of Table 50.2 give a Schwarzschild shadow of 53 microarcseconds (computed here; spin and inclination lower it by a few per cent). The measured ring agrees. Table 50.3 collects both sources.

Table 50.3: Event-horizon-scale imaging results, quoted from [2328] (M87*) and [2403] (Sgr A*). The last row is computed here: the Schwarzschild shadow diameter $3\sqrt{3}\,r_{\mathrm{s}}/R_0$ for the mass and distance measured by the stellar orbits of Table 50.2, the number the Sgr A* ring was predicted to match before it was imaged.

quantity	as published	SI
M87* ring diameter	$42 \pm 3\,\mu$as	$(2.04 \pm 0.15) \times 10^{-10}$ rad
M87* mass	$(6.5 \pm 0.7) \times 10^{9}\,M_{\odot}$	$(1.29 \pm 0.14) \times 10^{40}$ kg
M87* distance	16.8 Mpc	5.18×10^{23} m
Sgr A* ring diameter	$51.8 \pm 2.3\,\mu$as	$(2.51 \pm 0.11) \times 10^{-10}$ rad
Sgr A* predicted shadow (computed)	$53\,\mu$as	2.57×10^{-10} rad

Phenomenon 50.4 (A ring of light at event-horizon scale)**.** Very-long-baseline interferometry at 1.3 mm resolves the nucleus of M87 into an asymmetric ring of emission surrounding a central brightness depression. The ring diameter is 42 ± 3 microarcseconds, and the depression is deeper than any optically thin foreground could produce [2328]. The same technique applied to Sgr A* returns a ring of the diameter expected for the mass that the stellar orbits of Phenomenon 50.2 determine independently [2403]: one object weighed two ways, by Newtonian orbital dynamics and by the size of its photon capture cross-section, with concordant results.

Rests on Phenomenon 45.52 and Theorem 45.1.

Derivation. *Derives Phenomenon 50.4.*

The ring size measures a mass. From Chapter 45, the photon capture cross-section of a black hole has apparent diameter $2b_{\mathrm{c}} = 3\sqrt{3}\,r_{\mathrm{s}} \simeq 5.196\,r_{\mathrm{s}}$, and this is only weakly dependent on spin and viewing angle, so a measured angular diameter θ_{sh} at distance D gives

$$M = \frac{c^2}{2G} \cdot \frac{\theta_{\mathrm{sh}} D}{3\sqrt{3}}\,. \tag{50.4}$$

For M87, $\theta_{\mathrm{sh}} = 42$ microarcseconds, which is 2.04×10^{-10} in radian measure, and $D = 16.8\,\mathrm{Mpc} = 5.18 \times 10^{23}$ m, so $\theta_{\mathrm{sh}} D \approx 1.06 \times 10^{14}$ m and $r_{\mathrm{s}} \approx 2.03 \times 10^{13}$ m. Then

$$M = \frac{r_{\mathrm{s}} c^2}{2G} = \frac{2.03 \times 10^{13}\,\mathrm{m} \times 8.988 \times 10^{16}\,\mathrm{m^2/s^2}}{2 \times 6.674 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}} \approx 1.4 \times 10^{40}\,\mathrm{kg}\,,$$

about $7 \times 10^{9}\,M_{\odot}$, in agreement with the $(6.5 \pm 0.7) \times 10^{9}\,M_{\odot}$ obtained from the full image-domain analysis [2328] — the few-per-cent excess of this crude inversion being the emission-ring calibration discussed above. The arithmetic makes plain what is being measured and what is being assumed: an angular size and a distance, converted into a mass by the single dimensionless number $3\sqrt{3}$, which general relativity supplies with no freedom at all. A different theory of the strong field would predict a different number, and the concordance with the orbital mass of Sgr A* is the test: for $M = 8.47 \times 10^{36}$ kg at $R_0 = 2.545 \times 10^{20}$ m,

$$\theta_{\mathrm{sh}} = \frac{3\sqrt{3} \times 2GM}{c^2 R_0} \approx 2.57 \times 10^{-10}\,\mathrm{rad}\,,$$

53 microarcseconds, against a measured ring of 51.8 ± 2.3 [2403]. □

50.4.4 Black-hole masses from gravitational waves

The fourth channel is treated in full in Chapter 47; the discovery event and its parameter table are Section 47.3. What the channel adds to *this* chapter is mass, and a different kind of certainty. The dynamical and imaging channels infer a compact mass from the motion of matter and light outside it; a gravitational-wave chirp is emitted by the masses themselves, and its phase evolution measures them with no astrophysical intermediary. GW150914's component masses of about $36\,M_\odot$ and $29\,M_\odot$ [2264] sit well above every X-ray binary mass, and the catalogue that followed extends the population to component masses of about $50\,M_\odot$ in the first two observing runs [2324] and beyond in later ones—black holes in a mass range that electromagnetic astronomy had never weighed. The remnant's ringdown, consistent in frequency and damping with the least-damped quasinormal mode of a Kerr black hole of the predicted mass and spin [2264], is the one direct probe of the *dynamical* strong-field geometry in this chapter: the other channels test the stationary field.

Phenomenon 50.5 (Black-hole masses from gravitational waves)**.** The first detected gravitational-wave transient, GW150914, is the inspiral, merger and ringdown of two compact objects of about $36\,M_\odot$ and $29\,M_\odot$, leaving a remnant of about $62\,M_\odot$ — roughly $3\,M_\odot c^2$ radiated away as gravitational waves within a fraction of a second [2264]. Neither body can be anything but a black hole: the signal sweeps up to frequencies at which the two are closer together than objects of those masses could be without merging. The catalogue that followed defines a population of black-hole masses and spins reaching well above the range accessible to the X-ray binaries of Phenomenon 50.1 [2324].

Rests on Phenomenon 27.35 and Theorem 45.1.

Derivation. *Derives Phenomenon 50.5.*

The compactness argument requires only Kepler's third law. Take the total mass $M = 70\,M_\odot = 1.39 \times 10^{32}\,\mathrm{kg}$ read off the inspiral, and the moment in the signal at which the gravitational-wave frequency reaches $f_{\mathrm{GW}} = 150\,\mathrm{Hz}$. A binary radiates principally at twice its orbital frequency (Chapter 46), so the orbital angular velocity there is $\omega = \pi f_{\mathrm{GW}} = 471/\mathrm{s}$, and two bodies orbiting with that angular velocity are separated by

$$a = \left(\frac{GM}{\omega^2}\right)^{1/3} = \left(\frac{6.674 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)} \times 1.39 \times 10^{32}\,\mathrm{kg}}{(471/\mathrm{s})^2}\right)^{1/3} \approx 350\,\mathrm{km}\,.$$

Against this, the Schwarzschild radius of the total mass is

$$r_{\mathrm{s}} = \frac{2GM}{c^2} \approx 210\,\mathrm{km}\,,$$

so the two bodies were still orbiting freely at a separation of only about $1.7\,r_{\mathrm{s}}$. No neutron star can be involved: its radius, which Chapter 49 places near 12 km, is small enough, but its mass cannot approach $30\,M_\odot$. No main-sequence or degenerate star of any kind is remotely this compact at this mass. Only black holes remain. The Newtonian estimate is moreover conservative — the true relativistic separation at a given orbital frequency is smaller still — so the conclusion is not an artefact of applying Kepler's law outside its proper regime. □

50.5 Interpretation

What the ensemble establishes is best stated as three nested claims, in decreasing order of certainty.

First, and beyond reasonable doubt: *dark compact masses exist*, from about $5\,M_\odot$ in the X-ray binaries through $21\,M_\odot$ in Cygnus X-1 and $\sim 60\,M_\odot$ in the merger remnants to $4.3 \times 10^6\,M_\odot$ at the Galactic centre and $6.5 \times 10^9\,M_\odot$ in M87. The stellar-mass cases rest on

the Newtonian bound of Equation (50.2); the Galactic centre on Kepler's law applied to a closed stellar orbit. Each such mass exceeds every cold-equilibrium limit (Chapter 49), and for the S2 volume no non-collapsed alternative — a cluster of remnants, a ball of fermions — survives its own dynamics for the age of the Galaxy (Phenomenon 50.2).

Second, and directly measured: *the gravitational field of these objects is the field general relativity assigns them*, wherever it has been probed. The S2 orbit verifies the redshift-plus-Doppler prediction and the Schwarzschild precession at the ten-to-twenty per cent level, fifteen hundred gravitational radii out (Phenomenon 50.3). The photon-ring diameters of both imaged sources match Equation (50.4), whose only theoretical content is the strong-field number $3\sqrt{3}$ — and for Sgr A* the mass on the right-hand side was measured first, by an independent Newtonian method, so the image was a prediction cashed (Phenomenon 50.4). The GW150914 ringdown is consistent with the quasinormal spectrum of the Kerr geometry (Phenomenon 50.5). Nothing yet observed requires any parameter beyond the mass and spin of the Kerr family.

Third, and here the honesty matters most: *no material surface is seen*, where every known class of surface would show itself. This is the closest observation comes to the horizon, and it is an absence, argued quantitatively below (Phenomenon 50.6).

Against these stand the things the data do not establish. No observation reaches the horizon itself: an event horizon is a globally defined null surface, and no electromagnetic or gravitational-wave measurement of finite duration can certify one — what is measured is light and matter behaving, down to a few gravitational radii, exactly as if one were there, with no sign of anything else. The interior, the singularity theorems' conclusion, and any Planck-scale modification of the horizon are untested by everything in this chapter. Exotic horizonless alternatives — objects contrived to be as compact as a black hole without its causal structure — are constrained by the ringdown, by the shadow depth and by the surface arguments, but the most contrived of them are not excluded [2328]; the honest assessment of that frontier, and of what would settle it, is continued in Chapter 135. Interpretation throughout leans on the theory of Chapter 45 and Chapter 43.

Phenomenon 50.6 (No material surface)**.** Accreting neutron stars betray their surfaces twice over: the fuel accumulating on them ignites periodically in thermonuclear flashes — the type I X-ray bursts — and in quiescence they re-radiate the accretion energy deposited on them. The black-hole candidates of Phenomenon 50.1 do neither. No burst has ever been recorded from one, and at comparable accretion rates their quiescent luminosities fall orders of magnitude below those of the neutron-star systems [1941][2103]. The energy that arrives is not returned. That is what a horizon does and what a surface of any composition cannot do, and it is the closest the electromagnetic observations come to a direct test of the defining property of a black hole.

Rests on Theorem 19.32 and Proposition 45.18.

Derivation. *Derives Phenomenon 50.6.*

The comparison is an energy budget, and the budget is Newtonian bookkeeping plus one relativistic fact. Let matter fall steadily at rate $\dot{M}$ onto a compact object of mass M and radius R_*. Each unit of mass, arriving from far away, has given up its gravitational binding energy GM/R_* by the time it settles on the surface, whatever route it took; in steady state that energy can only leave as radiation. An object *with* a surface therefore shines with

$$L_{\mathrm{surf}} \simeq \frac{GM\dot{M}}{R_*} = \eta_* \dot{M} c^2 , \qquad \eta_* := \frac{GM}{R_* c^2} , \tag{50.5}$$

independently of how efficiently the infalling flow itself radiates. For a neutron star, with $M \approx 1.4\, M_\odot$ and $R_* \approx 12\,\mathrm{km}$ (Chapter 49), $\eta_* \approx 0.17$: a fixed seventeen per cent of the accreted rest energy must come back out. If instead the object has a horizon, nothing obliges

the flow to radiate at all: the luminosity is $\epsilon \dot{M} c^2$ with ϵ whatever radiative efficiency the flow manages *before* crossing, and the balance is carried through the horizon and gone.

The comparison becomes decisive in quiescence, precisely because the accretion there is inefficient. At low accretion rates the inflow is a hot, tenuous, advection-dominated flow: the ion gas is too dilute to transfer its heat to the radiating electrons within an infall time, so it carries its thermal energy inward, and $\epsilon \lesssim 10^{-2}$ [1941]. The predicted contrast between two otherwise similar transients, one with a horizon and one with a surface, is then

$$\frac{L_{\rm hole}}{L_{\rm surf}} \simeq \frac{\epsilon}{\eta_*} \lesssim \frac{10^{-2}}{0.17} \approx 6 \times 10^{-2} \,,$$

one to two orders of magnitude, before allowing for the gravitational redshift of the surface emission, which only deepens it. This is what is observed: at matched orbital periods — the available proxy for matched quiescent accretion rate — the black-hole transients sit roughly a factor of one hundred below the neutron-star transients in quiescent luminosity [1941][2103].

The burst argument is the same bookkeeping applied to matter rather than energy. On a surface, accreted hydrogen and helium accumulate, compress, and heat until the layer ignites; the burning is thermally unstable in a thin shell, so it runs away, and the neutron-star systems duly flash — thousands of type I bursts stand recorded. A horizon stores no fuel. No type I burst has ever been observed from any system whose mass function exceeds the neutron-star bound [2103].

Two limits of the argument are stated as plainly as the argument. It is differential — it compares two source classes assuming the same kind of quiescent flow in both, so it inherits the advection-dominated model's assumptions, though not its details: any flow radiating a fraction $\epsilon \ll \eta_*$ before arrival gives the same contrast. And it bounds what a surface would emit; it does not observe the horizon. It is evidence of absence obtained where presence was obligatory, which is the strongest statement an electromagnetic observation can make about a horizon. □

50.6 Modern repetitions and precision

Every one of the four channels is a running programme, and each has a stated next decimal place.

At the Galactic centre, GRAVITY continues to track S2 away from pericentre, where the precession signal accumulates, and has added fainter stars on shorter orbits to the fit; each pericentre passage — S2's next falls in 2034 — multiplies the relativistic leverage [2347]. The two-programme redundancy that checked the redshift [2295, 2336] remains the model: the Keck and VLT groups share neither instruments nor analysis chains. The targets beyond the first post-Newtonian order are the spin of Sgr A* through frame dragging of the innermost orbits, and any deviation of the enclosed mass from a point — both within reach of the existing astrometry extended by a decade (Chapter 45 supplies the predictions).

The Event Horizon Telescope has repeated and extended its campaigns: the polarized image of M87* [2372] turned the ring into a magnetometer, and the Sgr A* result [2403] showed that even a source varying on its minutes-long horizon-crossing time can be imaged. Precision here scales directly with the array: every added station fills the aperture, and a shorter observing wavelength tightens the beam as λ/D — the path to resolving the photon ring's substructure, time-resolved imaging of the flow, and a sharper shadow-diameter test than the current few-per-cent agreement of Table 50.3.

In the X-ray binaries the frontier is spin and population. The relativistically broadened iron line [1911] and the disc-continuum method, both calibrated on the innermost-stable-orbit physics of Chapter 45, are applied across the twenty-odd dynamically confirmed systems

[2103], while VLBI parallaxes of the kind that re-weighed Cygnus X-1 [2387] remove the distance systematics that dominated a generation of mass estimates.

The gravitational-wave catalogue grows by design: from one event [2264] to ten binary black holes in the first two observing runs [2324] to, at the time of writing, of order a hundred (Chapter 47) — a population experiment on black-hole masses and spins, and, as the loudest events accumulate, a spectroscopy of the ringdown: more than one quasinormal mode measured in a single remnant would test the Kerr no-hair property, not merely be consistent with it. The projected sensitivities of the next-generation interferometers are cross-referenced in Chapter 47.

Chapter 51

Experiment: The Cosmic Microwave Background

Tests Phenomenon 48.12 and Equation (48.24).

Assuming Equations (38.38) *and* (68.5).

Discovery and precision spectroscopy of the relic radiation: the blackbody spectrum, the anisotropies, and the parameters they fix in the cosmology of Chapter 48. The cosmic microwave background is the oldest light there is and the best-measured blackbody there is: found accidentally by Penzias and Wilson [1320] and identified at once as the relic of a hot early universe [1305], it now carries, in its spectrum [1884, 1922], its anisotropies [1858, 2213, 2348] and its polarization [2031], the tightest constraints in all of cosmology.

This chapter is the evidence file for Chapter 48: the hot-big-bang prediction under test, the radiometers and spectrophotometers that tested it, and the numbers they returned. The blackbody physics being tested is that of Chapter 68; the boost kinematics that reads the dipole is that of Chapter 38; and the general-relativistic perturbation theory that turns the anisotropy spectra into cosmological parameters belongs to Chapter 48 and is quoted here, never silently rederived. What this chapter owns is the measuring: apparatus, procedure, the numbers with their uncertainties, and what they do and do not establish.

51.1 Historical context and the prediction under test

51.1.1 The hot-big-bang prediction

The prediction is a by-product of nucleosynthesis. In 1948 Alpher, Bethe and Gamow proposed that the chemical elements were assembled by neutron capture in a hot, dense early universe [905]; the calculation works only if the baryons are outnumbered by thermal photons by a large, fixed factor, because it is the radiation that sets the temperature–time relation through which the reactions freeze out (Chapter 48). Later the same year Alpher and Herman followed that radiation forward: expansion cools a thermal photon gas as $T \propto 1/a$ while preserving its Planck form — the statement proved in Chapter 48 — so the fireball must survive to the present as a cold blackbody filling all of space, at a temperature they estimated as about 5 K [906].

The prediction is threefold, and each part is separately testable. The relic must have a *Planck spectrum*, because it was thermalized when the universe was dense enough to reach equilibrium and free expansion cannot un-thermalize it; any measured distortion is a record of energy released since. It must be *isotropic* to high accuracy, because it fills the universe rather than emanating from anything in it. And it must carry small *anisotropies*, because the structure that now exists had to grow from seed inhomogeneities that were present at decoupling and must have left their imprint on the light released then. Spectrum, isotropy

and anisotropy are the three sections of the observations below, in that order.

Nobody searched for it. The prediction lay dormant for seventeen years, unknown to the radio astronomers who by the late 1950s had the instruments to test it. In 1964 Dicke's group at Princeton rederived the hot early phase independently and set about the measurement deliberately: Roll and Wilkinson were building a purpose-designed radiometer when word arrived that a pair of radio astronomers fifty kilometres away, calibrating a communications antenna, had already found an excess they could not remove. The two papers were published back to back — the measurement [1320] and its interpretation [1305] — and the interpretation paper's senior author was the same Dicke whose switched radiometer, invented in 1946, is the instrument class behind nearly every measurement in this chapter [888].

51.1.2 Precursors

The radiation had in fact been detected before it was predicted. In 1941 McKellar analysed the interstellar absorption lines of the CN radical seen against hot stars, among them ζ Ophiuchi. The first rotationally excited level of CN lies one photon of wavelength 2.64 mm above the ground state, and the ratio of the absorption from the two levels measures how the molecules are distributed between them; McKellar translated the measured ratio into a "rotational temperature" of interstellar space of about 2.3 K [860]. The molecules are thermometers immersed in the millimetre-wave radiation field, and they were reporting the cosmic microwave background — but with no prediction to connect it to, the number stood in the literature as a curiosity, and only after 1965 could it be read for what it is.

Remark 51.1 (A signal without a theory). The CN temperature is a canonical case of the general lesson: a measurement with no theoretical frame attached does not function as a discovery, however accurate it is. McKellar's 2.3 K sat unexplained for twenty-four years — within thirty per cent of the modern value of Phenomenon 51.3 — while the complementary failure ran in parallel: from 1948 to 1965 the Alpher–Herman prediction [906] was a theory without a signal, unknown to the observers who could have tested it. The discovery of 1965 happened at the moment the two finally met [1305, 1320], and neither half would have sufficed alone.

51.2 Apparatus

51.2.1 Radiometers and the Holmdel horn

Every temperature in this chapter is an *antenna temperature*: the temperature of a matched resistive load that would deliver the same power to the receiver, a linear measure of received power in the Rayleigh–Jeans regime of Chapter 68. The obstacle to measuring a few kelvin of sky is that the receiver itself contributes hundreds or thousands of kelvin of noise, and its gain drifts. Dicke's solution of 1946 defines the instrument class: switch the receiver input many times per second between the sky and a stable reference load, and detect synchronously with the switch, so that receiver noise and gain drift, common to both half-cycles, cancel in the difference [888]. The residual fluctuation of an ideal radiometer of system temperature T_{sys}, predetection bandwidth $\Delta\nu$ and integration time τ is

$$\Delta T_{\mathrm{rms}} \simeq \frac{T_{\mathrm{sys}}}{\sqrt{\Delta\nu\,\tau}}\,, \tag{51.1}$$

within a factor of order unity fixed by the switching scheme [888]. The equation is the budget of the whole field: a receiver of $T_{\mathrm{sys}} = 100\,\mathrm{K}$ and $\Delta\nu = 100\,\mathrm{MHz}$ resolves — computed here from Equation (51.1) — about 10 mK in one second, so the millikelvin dipole of Section 51.4.3

needs minutes, and the microkelvin anisotropies of Section 51.4.4 need years of integration and thousands of detectors.

The discovery instrument was not built for cosmology. The Holmdel antenna at Crawford Hill is a 6 m horn-reflector erected for the Echo and Telstar satellite links, chosen for exactly the property a background measurement needs: the horn geometry shields the aperture from the ground, so the response in the back and side lobes is far below that of a paraboloid. Penzias and Wilson equipped it with a ruby travelling-wave maser preamplifier at 4.08 GHz — a wavelength of 7.35 cm, computed here — and, crucially, with a reference termination immersed in liquid helium, giving the switched radiometer an absolute cold standard against which the sky could be measured rather than merely compared [1320]. A year of systematic elimination followed: the atmosphere was measured by tipping the beam and fitting the secant law in zenith angle, the ohmic loss of the antenna throat was bounded, the response away from the beam was checked against the Sun and the Galaxy, the seams were taped, and the pair of pigeons roosting in the throat was evicted and their deposits removed. The excess survived everything, in every direction, in every season [1320].

51.2.2 Satellites: COBE, WMAP, Planck

The atmosphere emits and absorbs strongly across the millimetre band, so the two precision programmes — the spectrum and the anisotropy — both culminated in space.

COBE (launched 1989) carried both instruments of record. FIRAS is a polarizing Michelson interferometer whose two inputs are the sky and an internal reference blackbody: the interferogram measures the *difference* between the two spectra, and the reference is servoed until that difference nearly vanishes, so the instrument spends its dynamic range on the deviation rather than on the signal. An external calibrator — a re-entrant absorbing cone that can swing over the horn and fill the beam entirely — provides the absolute standard; the accuracy of Section 51.4.2 is the accuracy of that cone. The spectral band of the monopole analysis runs from about 60 GHz to 630 GHz with a 7° beam [1834, 1884, 1922]. The companion DMR consists of differential microwave radiometers at 31.5 GHz, 53 GHz and 90 GHz, each comparing two 7° beams 60° apart on the sky — a Dicke radiometer whose reference load is another patch of sky [1858].

WMAP (2001–2010) took the differential principle to the second Lagrange point, where Sun, Earth and Moon sit together in a small solid angle behind the shields. Pseudo-correlation differencing assemblies at five frequencies from 23 GHz to 94 GHz measured temperature differences between beams separated by about 141°, with angular resolution reaching about 0.2° in the highest band; nine years of data give the full-sky maps and power spectra of [2213]. Planck (2009–2013), from the same orbit, spans 30 GHz to 857 GHz with two instrument families: the LFI radiometers at 30, 44 and 70 GHz, and the HFI bolometers from 100 GHz upward, cooled to 0.1 K and reaching about 0.08° resolution — enough to map the temperature anisotropy over the whole acoustic range [2348].

51.2.3 Balloons and ground stations

Between the discovery and the satellites, and alongside them since, the sub-orbital tier has repeatedly been first. The U-2 aircraft radiometers of 1976–77, flying above most of the atmosphere, found the dipole [1610]. BOOMERanG, a bolometric telescope carried around Antarctica for about ten days at an altitude near 38 km by a long-duration balloon, mapped a patch of sky at frequencies from 90 GHz to 400 GHz with sub-degree resolution and resolved the first acoustic peak [1984]. DASI, a thirteen-element interferometer at 26–36 GHz sited at the South Pole — where the precipitable water vapour is among the lowest on Earth — made the first detection of polarization [2031]. The modern ground tier is the arcminute programme: the 10 m South Pole Telescope and the 6 m Atacama Cosmology

Telescope, with kilopixel arrays of transition-edge bolometers, extend the spectra into the damping tail and supply the secondary-anisotropy science of Section 51.4.7 [2219, 2351]; and the BICEP/Keck small-aperture polarimeters — refractors of tens of centimetres, built for the degree scale where a primordial B mode would peak — carry the search of Section 51.4.6 [2227, 2369].

51.3 Procedure

Four protocols cover every result reported below.

Absolute spectrophotometry. The sky is nulled against a calibrated blackbody and the residual spectrum is measured interferometrically; periodically the external calibrator replaces the sky entirely, transferring the laboratory standard to the celestial measurement. The result is a spectrum in absolute units at each frequency, from which one temperature and the distortion parameters of Section 51.4.2 are fitted [1884, 1922].

Differential mapping. Anisotropy instruments never measure the monopole: they measure temperature *differences* between sky directions, following Equation (51.1), and scan so that every pair of pixels is linked by many differences along many paths. The map is then the least-squares solution of the linear model relating the time-ordered differences to the pixel temperatures — an overdetermined system whose redundancy is also the systematics check, since a miscalibrated channel shows up as inconsistency between scan paths. The estimation machinery is that of Chapter 11 [1858, 2213, 2348].

Component separation. The microwave sky is not only the background: the Galaxy radiates synchrotron and free–free emission, both falling steeply with frequency, and thermal dust emission, rising with frequency. The background alone has the achromatic signature of a temperature perturbation of a blackbody — the same ΔT at every frequency when expressed as thermodynamic temperature. Multi-frequency coverage is therefore not a luxury but the separation variable itself; the Galactic plane is masked, and the components are fitted and removed pixel by pixel [2213, 2348].

Harmonic analysis and likelihood. A full-sky anisotropy map is expanded in the spherical harmonics of Chapter 9,

$$\frac{\Delta T}{T_0}(\hat{\boldsymbol{n}}) = \sum_{\ell \geq 1} \sum_{m=-\ell}^{\ell} a_{\ell m} Y_{\ell m}(\hat{\boldsymbol{n}}) \,, \qquad C_\ell := \left\langle |a_{\ell m}|^2 \right\rangle \,, \tag{51.2}$$

and the cosmological information is carried by the angular power spectrum C_ℓ (and its polarized counterparts C_ℓ^{TE}, C_ℓ^{EE}, C_ℓ^{BB}), because statistical isotropy makes the individual $a_{\ell m}$ zero-mean random variables with a common variance at each ℓ. That same statement fixes the floor of the whole enterprise. The unbiased estimator averages the $2\ell+1$ independent squared moduli available at multipole ℓ, and for Gaussian fluctuations (Chapter 11) the relative scatter of such an average is

$$\frac{\Delta C_\ell}{C_\ell} = \sqrt{\frac{2}{2\ell+1}} \,, \tag{51.3}$$

the *cosmic variance*: we observe one sky, and no instrument, however perfect, can beat the sample size. At $\ell = 2$ the floor is 63 per cent — computed here from Equation (51.3) — which is why the quadrupole is permanently uncertain while the acoustic peaks, with thousands of modes each, are measured to parts in a thousand. Parameters are then inferred by likelihood fits of model spectra to the measured C_ℓ, per Chapter 11 [2213, 2348].

51.4 Observations and data

Throughout this section, a number with an uncertainty is quoted from the cited primary paper; where a number is instead computed here from quoted inputs, the text says so.

51.4.1 Discovery

Penzias and Wilson measured the total antenna temperature at the zenith at 4.08 GHz and subtracted everything they could account for. The budget is the experiment, and it is short:

Table 51.1: The Holmdel antenna-temperature budget at 4.08 GHz, as reported by Penzias and Wilson [1320]. All entries are quoted from the paper. The remainder on the last line, isotropic, unpolarized and stable through the seasons, is the cosmic microwave background.

Contribution	Antenna temperature
Total zenith measurement	6.7 K
Atmospheric absorption	(2.3 ± 0.3) K
Ohmic losses of the antenna	(0.8 ± 0.4) K
Back-lobe ground pickup	< 0.1 K
Unaccounted excess	(3.5 ± 1.0) K

Phenomenon 51.2 (An isotropic microwave excess)**.** A horn-reflector antenna operating at 4.08 GHz, after every identifiable contribution to the system noise had been measured and subtracted, retained an excess antenna temperature of about 3.5 K, uncertain by about 1.0 K. The excess was isotropic within the sensitivity of the instrument, unpolarized and unchanged with the season, so it could be neither a terrestrial source, nor the Galaxy, nor any known population of discrete extragalactic sources [1320]. The companion paper published alongside identified it as relic radiation from a hot, dense early phase of the universe [1305].
Rests on Equation (68.5)*, Phenomenon 68.5, and Definition 48.2.*

Derivation. *Derives Phenomenon 51.2.*

Two steps connect the reported number to a physical statement about the universe. The first is that an *antenna* temperature is a measure of received power — the temperature of a matched resistive load that would deliver the same power to the receiver — so equating it with the thermodynamic temperature of a blackbody filling the beam presupposes the Rayleigh–Jeans limit of the Planck law of Chapter 68, in which the spectral radiance is linear in T. That limit requires $h\nu \ll k_{\mathrm{B}}T$, and at the Holmdel frequency

$$\frac{h\nu}{k_{\mathrm{B}}T} = \frac{6.626 \times 10^{-34}\,\mathrm{J\,s} \times 4.08 \times 10^{9}\,\mathrm{Hz}}{1.381 \times 10^{-23}\,\mathrm{J/K} \times 3\,\mathrm{K}} \approx 0.065\,,$$

so the departure from linearity is a few per cent, well inside the quoted uncertainty. The identification is therefore legitimate at this frequency — and would not have been at, say, 100 GHz, which is why the discovery had to wait for centimetre-wave receivers of very low noise.

The second step is that isotropy together with the absence of polarization already excludes the alternatives. A Galactic origin would concentrate the signal toward the plane; an unresolved population of extragalactic radio sources would carry their synchrotron spectrum, falling steeply with frequency rather than lying flat in T; and any terrestrial, atmospheric or solar contribution would vary with elevation and with the season. All three were tested and excluded, and what remains must fill space uniformly — which is a cosmological statement, not an astronomical one. □

51.4.2 The blackbody spectrum

One measurement at one frequency establishes an excess; only the spectrum can establish a relic. The prediction under test — the thermal form preserved by expansion, Chapter 48 — was settled by FIRAS in stages, each tightening the last:

Table 51.2: The spectrum campaigns. Every value is quoted from the cited paper. The deviation column bounds the departure of the measured spectrum from a Planck curve, as a fraction of the peak brightness.

Measurement	Year	Temperature T_0	Deviation
FIRAS, first nine minutes [1834]	1990	$(2.735 \pm 0.060)\,\mathrm{K}$	—
FIRAS, calibrated [1884]	1994	$(2.726 \pm 0.010)\,\mathrm{K}$	$< 3 \times 10^{-4}$
FIRAS, full data set [1922]	1996	$(2.728 \pm 0.004)\,\mathrm{K}$	$< 5 \times 10^{-5}$ (rms)
Combined, recalibrated [2144]	2009	$(2.725\,48 \pm 0.000\,57)\,\mathrm{K}$	—

The full-data-set analysis also bounds the two canonical distortion parameters: a chemical potential $|\mu| < 9 \times 10^{-5}$ and a Compton parameter $|y| < 1.5 \times 10^{-5}$, both at 95 per cent confidence [1922]. Each is a null with content, because each would be the fossil of energy released into the radiation: a μ distortion records injection early enough for scattering to redistribute photons but too late to create them, a y distortion records injection later still, so the limits constrain the entire energy-release history of the universe since thermalization ceased (Chapter 48). The 2009 value combines the FIRAS data, recalibrated against later precision dipole measurements, with the other absolute measurements, and it is the temperature used throughout this book [2144].

Phenomenon 51.3 (The most perfect blackbody ever measured)**.** The spectrum of the background radiation is a Planck spectrum. An absolute spectrophotometer flown above the atmosphere, nulling the sky against an on-board blackbody calibrator, found no deviation from the Planck form larger than about fifty parts per million of the peak brightness anywhere in the band it covered [1884, 1922]. The temperature is $T_0 = 2.725\,48\,\mathrm{K}$, known to $0.000\,57\,\mathrm{K}$ [2144]. No source constructed in a laboratory has ever been brought this close to thermal equilibrium, and the fit has no free parameter but the one temperature.

Rests on Equation (68.5)*, Phenomenon 68.5, and Definition 48.2.*

Derivation. Derives Phenomenon 51.3.

Three numbers characterize the measured spectrum, and each follows from T_0 and the Planck law of Chapter 68 alone. The wavelength of maximum spectral radiance per unit wavelength is given by the Wien displacement law,

$$\lambda_{\max} = \frac{b}{T_0} = \frac{2.898 \times 10^{-3}\,\mathrm{m\,K}}{2.725\,48\,\mathrm{K}} \approx 1.06\,\mathrm{mm}\,,$$

so the radiation peaks in the microwave band — which is why a radio receiver found it, and why measuring the spectrum required going above the atmospheric water lines. Per unit *frequency* the maximum instead lies at $\nu_{\max} = 2.821\,k_{\mathrm{B}}T_0/h \approx 160\,\mathrm{GHz}$; the two maxima disagree because a spectral density is defined with respect to a chosen variable, and neither is "the" peak of the radiation.

The energy density follows from the Stefan–Boltzmann law,

$$u = aT_0^4 \approx 4.17 \times 10^{-14}\,\mathrm{J/m^3}\,,$$

with $a = 7.566 \times 10^{-16}\,\mathrm{J\,m^{-3}\,K^{-4}}$ the radiation constant, and dividing by the mean photon energy $\approx 2.70\,k_{\mathrm{B}}T_0$ gives a photon number density of about 4.1×10^8 per cubic metre. That is roughly 10^9 photons for every baryon in the universe, and that ratio is the single free parameter of the nucleosynthesis calculation of Chapter 48 — so the spectrum measured here and the light-element abundances measured there are two determinations of one number. □

51.4.3 The dipole

The first anisotropy found is not primordial. Radiometers flown on a U-2 aircraft in 1976–77 detected a smooth cosine pattern across the sky [1610], since measured to four significant figures by Planck [2352]:

Table 51.3: The dipole anisotropy. The inferred speed on the last line is computed here from the quoted Planck amplitude and the monopole temperature, via the boost formula Equation (51.4).

Quantity	Value	Status
Amplitude, U-2 discovery [1610]	$(3.5 \pm 0.6)\,\mathrm{mK}$	quoted
Amplitude, Planck [2352]	$(3.3621 \pm 0.0010)\,\mathrm{mK}$	quoted
Direction, Galactic [2352]	$(l, b) \approx (264.02^\circ, 48.25^\circ)$	quoted
Inferred solar-system speed	$\approx 370\,\mathrm{km/s}$	computed here

Phenomenon 51.4 (The dipole)**.** The background is not exactly isotropic. Superposed on the monopole is a pure dipole of amplitude about 3.36 mK, first detected from a U-2 aircraft [1610] and now measured to four significant figures [2352]. Its interpretation is kinematic: the solar system moves at about 370 km/s with respect to the frame in which the radiation is isotropic. This is the only large anisotropy of the microwave sky that is not primordial, and it must be removed before the intrinsic fluctuations of Section 51.4.4 can be seen at all — they are two orders of magnitude smaller.

Rests on Theorem 38.4, Proposition 38.25, and Phenomenon 68.5.

Derivation. *Derives Phenomenon 51.4.*

Let the radiation be an isotropic blackbody at temperature T_0 in some frame, and let an observer move through it with speed $v = \beta c$. Radiation arriving from the direction making an angle θ with the motion is Doppler shifted by the factor $[\gamma\,(1 - \beta\cos\theta)]^{-1}$ of Chapter 38. Every frequency in the spectrum is multiplied by that same factor, and the Planck spectrum of Chapter 68 depends on frequency only through the combination $h\nu/\,(k_{\mathrm{B}}T)$; the boosted spectrum is therefore again Planckian in every direction, with a direction-dependent temperature

$$T\,(\theta) = \frac{T_0}{\gamma\,(1 - \beta\cos\theta)} = T_0\,(1 + \beta\cos\theta) + O\!\left(\beta^2\right)\,. \tag{51.4}$$

To first order in β this is exactly a dipole of amplitude $\Delta T = \beta T_0$, with no quadrupole or higher multipole at all — so the observed pattern being a clean dipole is itself evidence for the kinematic reading rather than an assumption of it. Inverting,

$$v = c\,\frac{\Delta T}{T_0} = 2.998 \times 10^8\,\mathrm{m/s} \times \frac{3.36 \times 10^{-3}\,\mathrm{K}}{2.725\,\mathrm{K}} \approx 3.7 \times 10^5\,\mathrm{m/s}\,,$$

that is about 370 km/s. The second-order terms of Equation (51.4) generate a kinematic quadrupole smaller than the dipole by a further factor $\beta \approx 10^{-3}$, which is comparable to the primordial signal and is accounted for explicitly in modern analyses. The same boost also aberrates the arrival directions by the aberration formula Equation (38.38) of Chapter 38, displacing the whole anisotropy pattern by an angle of order $\beta \approx 1.2 \times 10^{-3}$ radians — about four minutes of arc, computed here — toward the apex. □

The frame in which the dipole vanishes is physically distinguished: it is the rest frame of the radiation, and to high accuracy the rest frame of the average matter distribution. That this frame exists is a cosmological statement — the universe has a preferred state of motion at each point, defined by its contents — and its significance for the cosmological principle is discussed in Chapter 48. It contradicts nothing in Chapter 38: the laws are Lorentz-invariant; the matter distribution is not.

51.4.4 Primary anisotropies

Underneath the dipole the sky is smooth to a few parts in 10^5, and finding the intrinsic structure took twenty-seven years of steadily improving null results. The COBE DMR maps of 1992 finally resolved it [1858]:

Table 51.4: The DMR discovery numbers [1858]. The relative amplitude on the last line is computed here from the quoted rms and the monopole temperature.

Quantity	Value	Status
Sky rms, 10° smoothing	$(30 \pm 5)\,\mu\mathrm{K}$	quoted
Quadrupole amplitude	$(13 \pm 4)\,\mu\mathrm{K}$	quoted
Relative amplitude $\Delta T/T_0$	$\approx 1.1 \times 10^{-5}$	computed here

Phenomenon 51.5 (Primary anisotropies at one part in a hundred thousand)**.** Once the dipole of Phenomenon 51.4 is subtracted and the Galactic plane masked, the background retains intrinsic temperature fluctuations of relative amplitude $\Delta T/T \sim 10^{-5}$. They were first detected on angular scales of about ten degrees by the differential radiometers of COBE [1858], twenty-seven years after the discovery of the monopole and after a long series of non-detections that had begun to constrain the models; they are now mapped over the whole sky to arcminute resolution [2213, 2348]. On the largest angular scales the fluctuations track the gravitational potential on the last-scattering surface, the relation worked out by Sachs and Wolfe long before there was a measurement to apply it to [1357]. These are the seed inhomogeneities from which all later structure grew, and their smallness is what makes linear perturbation theory sufficient for the epoch.

Rests on Equations (42.7) *and* (51.2) *and Phenomenon 42.5.*

Derivation. *Derives Phenomenon 51.5.*

Two things are derived here: what the reported numbers mean, and why a temperature fluctuation measures a gravitational potential. The statistical frame is Equation (51.2): a map smoothed to an angular scale θ retains the multipoles up to $\ell \sim \pi/\theta$, so the 10° smoothing of Table 51.4 reads the sky at $\ell \lesssim 20$ — the largest scales, causally disconnected at decoupling. Dividing the quoted rms by the monopole,

$$\frac{\Delta T}{T_0} \approx \frac{30\,\mu\mathrm{K}}{2.725\,\mathrm{K}} \approx 1.1 \times 10^{-5}\,,$$

computed here from quoted inputs.

Why this measures gravity: a photon that last scatters at the bottom of a potential well must climb out, and arrives redshifted by the gravitational redshift of Equation (42.7), written for a general weak potential as $\Delta\nu/\nu = -\Delta\Phi/c^2$. Since a uniform fractional shift of every frequency maps a Planck spectrum to a Planck spectrum — the same argument as in the dipole derivation above — the observed effect is a temperature perturbation $\Delta T/T = \Delta\nu/\nu$: an overdense region, with $\Phi < 0$, is seen *cold*. The naive answer $\Delta T/T = |\Phi|/c^2$ overcounts, however, because the same perturbation also alters the plasma density, and hence the temperature, at the point of emission, and alters the rate of the clocks there. The general-relativistic accounting of all three pieces — carried out first by Sachs and Wolfe [1357], and belonging in this book to Chapter 48 — leaves, for adiabatic perturbations on scales larger than the acoustic scale of Section 51.4.5, the net result

$$\frac{\Delta T}{T_0} = \frac{\Phi}{3c^2}\,, \tag{51.5}$$

one third of the naive redshift. Read through Equation (51.5), the DMR amplitude says $\Phi/c^2 \approx 3 \times 10^{-5}$ on the last-scattering surface, computed here: the metric of the universe at

decoupling departed from homogeneity by a few parts in 10^5. That smallness is the licence for every linear calculation in Chapter 48, and the potentials themselves are the seeds whose growth into the present galaxy distribution is followed there. □

51.4.5 The acoustic peaks

Resolution below a degree turned the anisotropy from an amplitude into a spectroscopy. The peak structure was predicted three decades before it was resolved [1431, 1434], with photon diffusion cutting the spectrum off at small scales [1383]; BOOMERanG resolved the first peak in 2000 [1984], and the satellite spectra now trace the harmonics across the whole acoustic range [2213, 2348].

Table 51.5: The acoustic scale. Quoted values are from the cited papers; computed values follow from the quoted ones via Equation (51.7).

Quantity	Value	Status
First-peak position, BOOMERanG [1984]	$\ell_1 = 197 \pm 6$	quoted
Acoustic angular scale $100\theta_*$ [2348]	1.0411 ± 0.0003	quoted
Comoving sound horizon r_* [2348]	$(144.4 \pm 0.3)\,\mathrm{Mpc}$	quoted
Comoving distance to last scattering	$\approx 13.9\,\mathrm{Gpc}$	computed here
Acoustic multipole $\ell_A = \pi/\theta_*$	≈ 302	computed here
Spatial curvature Ω_K [2348]	0.001 ± 0.002	quoted

Phenomenon 51.6 (Acoustic peaks, and a spatially flat universe)**.** The angular power spectrum of the temperature anisotropy is not featureless: it carries a series of harmonic peaks, the first and highest near multipole $\ell \approx 220$, with the spectrum cut off at high ℓ by photon diffusion out of the shortest wavelengths [1984, 2348][1383]. These are the standing acoustic oscillations of the photon-baryon plasma before decoupling, predicted three decades before they were resolved [1431, 1434]. Their positions and relative heights measure geometry and contents at once: the angular scale of the first peak fixes the spatial curvature, which is consistent with zero with $|\Omega_K|$ bounded below about 0.005; the alternation of odd and even peak heights weighs the baryons; and the envelope constrains the total matter density [2348]. The same sound horizon, seen at low redshift in the galaxy distribution rather than projected on the last-scattering surface, is the acoustic ruler of Chapter 48.

Rests on Theorems 48.3 and 48.5 and Phenomenon 65.3.

Derivation. *Derives Phenomenon 51.6.*

What is derivable at this chapter's level is the ruler and its projection; the dynamics of the oscillations themselves — the driven photon-baryon oscillator, the phase of each harmonic, the alternation of the peak heights and the damping envelope — is the business of Chapter 48, resting on [1383, 1431, 1434].

The ruler. Before decoupling, Thomson scattering (Chapter 65) locks photons and baryons into a single fluid whose pressure is the radiation pressure $p = u/3$ of Chapter 68. For radiation alone the sound speed is $c_s = c\sqrt{\partial p/\partial u} = c/\sqrt{3} \approx 1.73 \times 10^5\,\mathrm{km/s}$, computed here; baryons add inertia without adding pressure and slow the wave, so

$$c_s = \frac{c}{\sqrt{3\,(1+R)}}\,, \qquad R := \frac{3\rho_b}{4\rho_\gamma}\,, \qquad r_s = \int_0^{t_*} \frac{c_s}{a\,(t)}\,\mathrm{d}t\,, \tag{51.6}$$

where r_s, the comoving distance sound travels before the photons are released at t_*, is the farthest any pressure wave ever got: the *sound horizon*. Evaluating the integral needs the full expansion and recombination history and is carried out in Chapter 48; the fitted value is $r_* = (144.4 \pm 0.3)\,\mathrm{Mpc}$ [2348].

The projection. A comoving length r_* on the last-scattering surface, seen across the comoving distance D_M in a spatially flat geometry, subtends

$$\theta_* = \frac{r_*}{D_M}\,, \qquad \ell_A = \frac{\pi}{\theta_*}\,, \tag{51.7}$$

the second relation because a spherical harmonic of degree ℓ oscillates with angular period $2\pi/\ell$ along a great circle (Chapter 9), so structure of angular size θ concentrates its power near $\ell \approx \pi/\theta$. The measured acoustic scale is $100\theta_* = 1.0411 \pm 0.0003$ [2348]; combining the two quoted numbers gives, computed here,

$$D_M = \frac{r_*}{\theta_*} \approx 13.9\,\mathrm{Gpc}\,, \qquad \ell_A = \frac{\pi}{\theta_*} \approx 302\,.$$

The first peak sits not at ℓ_A but below it, at $\ell_1 \approx 220 \approx 0.73\,\ell_A$: the oscillator is driven by the decaying gravitational potentials, which advances the phase of every harmonic by a calculable shift (Chapter 48). The BOOMERanG value $\ell_1 = 197 \pm 6$ [1984] and the satellite value near 220 [2213, 2348] bracket the same physics at very different calibrations and sky coverage.

The curvature. Equation (51.7) as written is the flat-space rule that angular size is length over distance. In a positively curved space light rays converge, and the same ruler at the same distance subtends a *larger* angle, pushing the peaks to lower ℓ; negative curvature does the reverse. With r_* fixed by the pre-decoupling plasma physics and the distance fixed by the measured expansion history, the observed θ_* therefore pins the curvature; the fitted result is $\Omega_K = 0.001 \pm 0.002$ [2348]. Space, on the largest measurable scales, is Euclidean to the accuracy of the measurement — one of the sharpest geometric statements in physics, and an input assumption nowhere. □

51.4.6 Polarization

The background is polarized, and its polarization was found where the atmosphere is driest. The DASI interferometer at the South Pole detected linear polarization at the microkelvin level in 2002, at a significance of 4.9σ [2031]; the correlation between temperature and polarization was then traced across the acoustic range by WMAP and Planck [2213, 2348]; B modes generated by gravitational lensing were first detected with the South Pole Telescope [2219]; and the degree-scale search for a primordial B mode produced the episode recorded in Remark 51.8, with the current bound $r < 0.036$ at 95 per cent confidence [2369].

Phenomenon 51.7 (E-mode polarization, and no primordial B mode)**.** The background is linearly polarized at the level of a few microkelvin — about a tenth of the temperature anisotropy — as first detected by an interferometer at the South Pole [2031]. The polarization field decomposes into a curl-free E mode and a divergence-free B mode. The observed E mode is correlated with the temperature field in the sense and with the phase relation that the acoustic picture of Phenomenon 51.6 requires, which is a sharp consistency test of that picture rather than a new parameter [2213, 2348]; and B modes generated by the gravitational lensing of E modes along the line of sight have been detected [2219]. No *primordial* B mode has been detected. A degree-scale signal reported in 2014 [2227] was shown by joint analysis with multi-frequency data to be polarized emission from Galactic dust [2246], and the tensor-to-scalar ratio is now bounded by $r < 0.036$ [2369].

Rests on Phenomena 51.6 and 65.3.

Derivation. *Derives Phenomenon 51.7.*

The polarization mechanism is Thomson scattering, and its geometry is derived here in full; the amplitude of the signal and the phase relation of C_ℓ^{TE} to the temperature spectrum need the perturbation theory of Chapter 48 and are quoted.

By Phenomenon 65.3, light Thomson-scattered through 90° emerges completely linearly polarized, its electric vector normal to the scattering plane: the driven electron re-radiates as a dipole, and a dipole does not radiate along its own axis (Chapter 65). Sit on an electron at last scattering and let the line of sight to the observer run along $\hat{\boldsymbol{x}}$. Incident light arriving from $\hat{\boldsymbol{z}}$ and scattered to the observer emerges polarized along $\hat{\boldsymbol{y}}$; incident light from $\hat{\boldsymbol{y}}$ emerges polarized along $\hat{\boldsymbol{z}}$. If the incident intensity is the same from the two directions, the two scattered polarizations superpose to none: an electron in an isotropic bath scatters unpolarized light. A dipole anisotropy of the incident field cancels too: the light from $+\hat{\boldsymbol{z}}$ and from $-\hat{\boldsymbol{z}}$ is scattered with the *same* polarization axis, so only the sum $I(\hat{\boldsymbol{z}}) + I(-\hat{\boldsymbol{z}})$ enters, and a dipole leaves every such antipodal sum at its isotropic value — likewise for $\pm\hat{\boldsymbol{y}}$. The lowest moment of the incident radiation that produces any net polarization is the difference between the two transverse axes, $I(\hat{\boldsymbol{z}}) - I(\hat{\boldsymbol{y}})$: a *quadrupole*. The polarized sky is therefore a map of the quadrupole anisotropy seen by each electron at the moment it last scattered.

That is also why the signal is small. Before decoupling, scattering is so frequent that the radiation each electron sees is isotropized and the quadrupole is erased; after decoupling there are no scatterers left. Polarization is generated only in the brief interval in between, as free streaming builds a local quadrupole while some scattering remains, and the outcome is a signal about an order of magnitude below the temperature anisotropy — a few microkelvin, exactly the level DASI detected [2031]. The quantitative treatment belongs to Chapter 48.

The observed field is described by the Stokes parameters Q and U on the sphere — a spin-2 quantity, since a headless polarization axis returns to itself under rotation by 180° — and it decomposes into a curl-free E pattern and a divergence-free B pattern, the tensor analogue of splitting a vector field into gradient and curl parts. At linear order, scalar density perturbations generate E only; gravitational waves generate E and B alike. The decomposition machinery and that theorem are Chapter 48's; what matters for this chapter is the experimental logic it dictates, namely that the E mode and the TE correlation had to appear with the measured acoustic phases (they did [2031, 2213, 2348]), and that any primordial B mode is a direct gravitational-wave observable, which is why the degree scale is watched by dedicated instruments and why the bound $r < 0.036$ [2369] is a statement about the early universe rather than about photons. □

Remark 51.8 (How a systematic is caught: the BICEP2 episode). In March 2014 the BICEP2 collaboration reported a degree-scale B mode well above the lensing expectation [2227], read at the time as primordial. The instrument observed at a single frequency, 150 GHz, so the measurement itself could not discriminate the achromatic background from Galactic foregrounds; the discrimination came from joining the BICEP2/Keck maps with the multi-frequency Planck dust maps, and the joint analysis attributed the signal to polarized thermal emission from Galactic dust, leaving no significant primordial component [2246]. The episode is kept in this book deliberately: it is the cleanest modern instance of the component-separation logic of Section 51.3 acting as the error bar — a single-frequency detection at the sky's faintest signal level is not yet a measurement of the sky.

51.4.7 Secondary anisotropies

Between the last-scattering surface and the receiver the radiation crosses the entire later universe, and three imprints of the crossing are measured. Each is a signal in its own right; none is primordial, and all must be modelled in the fits of Section 51.5.

Inverse-Compton scattering in clusters. Photons traversing the hot ionized gas of a galaxy cluster are Compton up-scattered by the thermal electrons, depleting the low-frequency side of the spectrum and enriching the high side — the Sunyaev–Zel'dovich effect [1485]. In the

Rayleigh–Jeans region the brightness change is

$$\left.\frac{\Delta T}{T_0}\right|_{\mathrm{RJ}} = -2y\,, \qquad y := \int \frac{k_{\mathrm{B}} T_{\mathrm{e}}}{m_{\mathrm{e}} c^2}\, n_{\mathrm{e}}\, \sigma_{\mathrm{T}}\, \mathrm{d}l\,, \tag{51.8}$$

quoted from [1485], with σ_{T} the Thomson cross-section of Equation (65.5) and the integral running through the cluster. For a rich cluster $y \sim 10^{-4}$, giving a decrement of about 0.5 mK — computed here from Equation (51.8) — which is why clusters appear as *cold* spots at low frequency; the distortion changes sign at about 217 GHz (the null of the y spectral function, computed here as $3.83\,k_{\mathrm{B}}T_0/h$), a frequency signature no intrinsic fluctuation shares. Because y does not dilute with distance, the effect finds clusters at any redshift, and the arcminute surveys of ACT and SPT now use it as a routine cluster-finding channel [2351].

Gravitational lensing. The anisotropy pattern is viewed through the deflecting mass of the whole line of sight, which remaps the sky by a few arcminutes coherently over degree scales: the acoustic peaks are slightly smoothed, characteristic higher-order correlations appear from which the projected mass map is reconstructed, and E-mode polarization is partly converted to the B modes detected in [2219]. The lensing reconstruction is an integral part of the modern likelihood [2348], and it measures the growth of structure — the dark-sector census of Chapter 134 rests partly on it.

Late-time scattering and evolving potentials. When the first stars reionized the universe, a fraction of the photons scattered again; the fitted optical depth is $\tau = 0.054 \pm 0.007$ [2348], so a fraction $1 - \mathrm{e}^{-2\tau} \approx 10$ per cent of the anisotropy power — computed here — is suppressed, and the re-scattering generates the large-angle E-mode "reionization bump" at $\ell \lesssim 10$ from which τ is actually measured [2348]. Photons also gain or lose energy crossing potentials that evolve while being crossed — the integrated Sachs–Wolfe effect, the late-time counterpart of Equation (51.5) already identified in the original analysis [1357] — which adds power at the lowest multipoles once dark energy begins to flatten the potentials (Chapter 48).

51.5 Interpretation

The measurements above are jointly fitted by a spatially flat six-parameter model — ΛCDM, the standard cosmology of Chapter 48 — and the fit is both spectacularly economical and honestly incomplete.

Table 51.6: The six-parameter fit and its principal derived quantities, from the final Planck analysis (temperature, polarization and lensing combined) [2348]. All values quoted.

Parameter	Symbol	Value
Baryon density	$\Omega_b h^2$	0.02237 ± 0.00015
Cold-dark-matter density	$\Omega_c h^2$	0.1200 ± 0.0012
Acoustic scale	$100\theta_{\mathrm{MC}}$	1.04092 ± 0.00031
Reionization optical depth	τ	0.054 ± 0.007
Scalar amplitude	$\ln(10^{10} A_s)$	3.044 ± 0.014
Scalar spectral index	n_s	0.9649 ± 0.0042
Hubble constant	H_0	(67.4 ± 0.5) km/(s Mpc)
Matter fraction	Ω_m	0.315 ± 0.007
Age of the universe	t_0	(13.80 ± 0.02) Gyr

Two consistency checks can be computed here from the table alone. First, the age: for a flat universe with the quoted H_0 and Ω_m, the expansion history of Chapter 48 integrates in

closed form to

$$t_0 = \frac{2}{3H_0\sqrt{1-\Omega_m}}\,\operatorname{arsinh}\sqrt{\frac{1-\Omega_m}{\Omega_m}} \approx 13.8\,\mathrm{Gyr}\,,$$

in agreement with the quoted value. Second, the photon-to-baryon ratio: the quoted $\Omega_b h^2$ corresponds to a present baryon number density of about $0.25/\mathrm{m}^3$, and the measured T_0 of Phenomenon 51.3 to a photon density of 4.1×10^8 per cubic metre, so $\eta = n_b/n_\gamma \approx 6.1\times10^{-10}$ — the number the nucleosynthesis of Chapter 48 requires independently from the light-element abundances. Two entirely different epochs of the universe, read with two entirely different instruments, return one number.

What the CMB establishes is the hot big bang itself and the skeleton of the model. The Planck spectrum of Phenomenon 51.3 establishes a hot, dense, thermalized early phase — no non-thermal explanation survives the FIRAS distortion limits. The isotropy at 10^{-5} establishes the large-scale homogeneity assumed by the cosmological principle. The acoustic scale establishes spatial flatness at the few-per-mille level. The peak morphology establishes that the seeds were adiabatic and coherent, with a spectrum close to, but measurably different from, scale-invariant: $n_s = 0.9649 \pm 0.0042$ sits eight of its standard deviations below unity — computed here from the quoted values — which any account of the seeds must reproduce. And the fit *requires* the dark sector: $\Omega_c h^2$ is five times $\Omega_b h^2$, and the peaks cannot be fitted by baryons alone. What the radiation establishes is the gravitational existence of that sector, not its identity — the census and the failed identifications are Chapter 134's subject.

What the CMB does not establish must be said with equal care. There is no detection of a primordial B mode: the bound $r < 0.036$ [2369] constrains, but does not confirm, the inflationary origin of the seeds, and the mechanism that produced them remains unobserved. And the model that fits the CMB internally is in tension externally: the same ΛCDM parameters predict $H_0 = (67.4 \pm 0.5)\,\mathrm{km/(s\,Mpc)}$, while the local distance ladder measures $(73.0 \pm 1.0)\,\mathrm{km/(s\,Mpc)}$ [2407] — a discrepancy of about 5σ, computed here from the two quoted uncertainties, unresolved at the time of writing and discussed further in Chapter 48. This book records it as an open disagreement between two mature measurements, not as a defect of either.

51.6 Modern repetitions and precision

Sixty years separate the entries of the table below, and every line was, in its year, the best measurement in the field. The monopole temperature improved from an uncertainty of 1.0 K in 1965 to 0.57 mK in 2009 — a factor of nearly two thousand, computed here; the anisotropy resolution improved from the 7° beams of DMR to the arcminute beams of the ground programme.

Table 51.7: The precision lineage, instrument by instrument. Resolutions are the approximate beam scales of the instruments as described in Section 51.2.

Years	Instrument	Contribution
1965	Holmdel horn [1320]	discovery; T to 1.0 K
1976–77	U-2 radiometers [1610]	the dipole
1989–96	COBE FIRAS [1884, 1922]	Planck spectrum to 5×10^{-5} of peak
1992	COBE DMR [1858]	anisotropy discovery at 7°
2000	BOOMERanG [1984]	first acoustic peak; flatness
2002	DASI [2031]	first polarization detection
2001–10	WMAP [2213]	full-sky spectra; precision ΛCDM
2009–13	Planck [2348]	acoustic range mapped to its cosmic-variance floor
2007–	ACT, SPT [2219, 2351]	damping tail, lensing, SZ clusters
2010–	BICEP/Keck [2246, 2369]	degree-scale B modes; $r < 0.036$

Two closing observations belong to the record. First, the FIRAS spectral limits of 1996 [1922] are still unsurpassed after three decades: no flown instrument has improved on $|\mu| < 9 \times 10^{-5}$ or $|y| < 1.5 \times 10^{-5}$, and the proposed successor spectrometers are designed precisely against those numbers. A measurement can saturate its era's technology and stand for a generation. Second, the frontier has moved wholly to polarization: the temperature sky is measured to its cosmic-variance floor of Equation (51.3) over the acoustic range, so further temperature integration cannot help, and the open quantities — r, the reionization history, the neutrino-mass imprint on lensing — are all polarization and secondary-anisotropy science [2348, 2351, 2369].

Chapter 52

Stellar Structure and Nucleosynthesis

Hydrostatic stellar models, pp/CNO energy production with its solar-neutrino and helioseismic evidence, and stellar nucleosynthesis against the measured element abundances. A star is a self-gravitating fusion reactor in quasi-static equilibrium, and this chapter builds the standard model of one: the structure equations assembled by Eddington [538], the nuclear energy sources identified by Bethe and von Weizsäcker [824, 828], and the synthesis of the elements in stellar interiors codified by Burbidge, Burbidge, Fowler and Hoyle [1105].

What earns the model its place in an evidence-based treatise is that the Sun's interior has been measured twice over, by two channels that did not have to agree: the neutrinos of the pp chain and CNO cycle, from the chlorine deficit [1368] to its resolution by flavour transformation [2021], and the acoustic oscillation spectrum of helioseismology [1234]. The chapter feeds its endpoints to Chapter 49 and its nuclear physics comes from Chapter 107; the modern monograph is [2196].

52.1 The equations of stellar structure

52.1.1 Hydrostatic equilibrium and timescales

A star is a ball of gas whose mechanical state, to an accuracy that the end of this subsection will quantify, is *rest*: pressure balances self-gravity at every radius. The equations governing that balance are the fluid statics of Chapter 31 applied to a body whose gravitational field is its own.

Proposition 52.1 (Hydrostatic equilibrium of a self-gravitating sphere)**.** *A spherically symmetric fluid at rest under its own gravity satisfies*

$$\frac{\mathrm{d}m}{\mathrm{d}r} = 4\pi r^2 \rho \,, \tag{52.1}$$

$$\frac{\mathrm{d}P}{\mathrm{d}r} = -\frac{G m \rho}{r^2} \,, \tag{52.2}$$

where $m(r)$ is the mass interior to radius r.

Rests on Proposition 31.16.

Proof. *Derives Proposition 52.1.*

Equation (52.1) is the definition of $m(r)$ differentiated. For Equation (52.2), hydrostatic balance $\nabla P = \rho \boldsymbol{g}$ (Equation (31.13)) needs the local gravitational acceleration, and for a spherically symmetric distribution that is $g = -Gm(r)/r^2$ directed inward: the shells outside r exert no net force and the mass inside acts as if concentrated at the centre —

Newton's shell theorem, which is Gauss's flux theorem applied to the Poisson equation $\nabla^2\Phi = 4\pi G\rho$ over a sphere of radius r. □

Two more equations make the system closed once the material properties are known. In a steady state, the luminosity L_r flowing outward through radius r grows by exactly the nuclear power released in each shell,

$$\frac{\mathrm{d}L_r}{\mathrm{d}r} = 4\pi r^2 \rho\, \varepsilon\,, \tag{52.3}$$

with ε the energy generation rate per unit mass (Section 52.2); and the temperature gradient is fixed by how that luminosity is carried — by radiation or by convection — which is the subject of Section 52.1.3. Together with an equation of state, an opacity $\kappa(\rho, T)$ and a rate $\varepsilon(\rho, T)$, Equations (52.1) to (52.3) and the transport equation are the four structure equations assembled by Eddington [538].

Before anything is solved, Equation (52.2) already yields the theorem that governs the energetics of every star.

Theorem 52.2 (Virial theorem for a self-gravitating sphere)**.** *For any configuration obeying Equation* (52.2) *with* $P(R) = 0$ *at the surface,*

$$3\int_0^M \frac{P}{\rho}\,\mathrm{d}m = -E_{\mathrm{grav}}\,, \qquad E_{\mathrm{grav}} = -\int_0^M \frac{Gm}{r}\,\mathrm{d}m\,. \tag{52.4}$$

Rests on Equation (52.2) *and Proposition 52.1.*

Proof. *Derives Theorem 52.2.*

Multiply Equation (52.2) by $4\pi r^3$ and integrate from centre to surface. The left side integrates by parts,

$$\int_0^R 4\pi r^3 \frac{\mathrm{d}P}{\mathrm{d}r}\,\mathrm{d}r = \Big[4\pi r^3 P\Big]_0^R - 3\int_0^R P\, 4\pi r^2\,\mathrm{d}r = -3\int_V P\,\mathrm{d}V\,,$$

the boundary term vanishing at both ends. The right side is

$$-\int_0^R \frac{Gm\rho}{r^2}\, 4\pi r^3\,\mathrm{d}r = -\int_0^M \frac{Gm}{r}\,\mathrm{d}m = E_{\mathrm{grav}}\,,$$

since $\mathrm{d}m = 4\pi r^2\rho\,\mathrm{d}r$; and $\int P\,\mathrm{d}V = \int (P/\rho)\,\mathrm{d}m$. □

Remark 52.3 (Negative heat capacity). For a monatomic ideal gas the internal energy density is $\frac{3}{2}P$, so Equation (52.4) reads $2U_{\mathrm{int}} = -E_{\mathrm{grav}}$, and the total energy is

$$E = U_{\mathrm{int}} + E_{\mathrm{grav}} = \tfrac{1}{2}E_{\mathrm{grav}} = -U_{\mathrm{int}}\,.$$

A star that *loses* energy therefore grows *hotter*: as E decreases, U_{int} increases, half of the released gravitational energy being radiated and half stored as heat. This negative heat capacity is what makes a contracting protostar heat up until fusion ignites, and — combined with the extreme temperature sensitivity of the nuclear rates derived in Section 52.2.1 — it is what makes the burning stable: a transient over-production of energy expands the star, which *cools* it and throttles the reactions back.

Phenomenon 52.4 (The Sun has shone for billions of years)**.** The Sun radiates $L_\odot = 3.828 \times 10^{26}\,\mathrm{W}$, and the radiometric ages of the oldest meteorites and terrestrial rocks show that it has been doing so, at a comparable rate, for about 4.5 Gyr. Neither chemical energy nor gravitational contraction can supply this for anything like that long. The conflict between the geological record and the physics of the day is what forced the conclusion that stars run on a subatomic energy source [466, 538].

Rests on Theorem 52.2.

Derivation. *Derives Phenomenon 52.4.*

Three timescales settle the matter, and none of them requires solving a structure equation.

The *Kelvin–Helmholtz* time is how long a star could shine on the gravitational energy released in contracting to its present radius. For mass M and radius R that energy is of order GM^2/R (Equation (52.4)), so

$$t_{\mathrm{KH}} \sim \frac{GM^2}{RL} = \frac{6.674\times10^{-11}\,\mathrm{m^3/(kg\,s^2)}\times(1.989\times10^{30}\,\mathrm{kg})^2}{6.957\times10^{8}\,\mathrm{m}\times3.828\times10^{26}\,\mathrm{W}} \approx 1\times10^{15}\,\mathrm{s}\,, \tag{52.5}$$

about 3×10^7 yr. This is the number that set nineteenth-century physics against geology and against Darwin: it falls short of the age of the Earth by more than two orders of magnitude.

The *nuclear* time supposes instead that hydrogen fuses to helium, releasing a fraction 0.007 of the rest energy, and that the fuel available is the inner tenth of the mass, where the temperature is high enough for it to burn:

$$t_{\mathrm{nuc}} \sim \frac{0.007\times0.1\,Mc^2}{L} = \frac{0.0007\times1.989\times10^{30}\,\mathrm{kg}\times8.988\times10^{16}\,\mathrm{m^2/s^2}}{3.828\times10^{26}\,\mathrm{W}} \approx 3\times10^{17}\,\mathrm{s}\,, \tag{52.6}$$

about 1×10^{10} yr. This comfortably exceeds the observed 4.5 Gyr and is of the right order to explain why stars of a solar mass are still on the main sequence in the oldest clusters — so the nuclear hypothesis is not merely sufficient, it is quantitatively right.

The *dynamical* time, $t_{\mathrm{dyn}} \sim (G\bar\rho)^{-1/2}$, is under an hour for the Sun. Its separation from the other two by ten and by fourteen orders of magnitude is what licenses treating the star as exactly hydrostatic while its composition slowly changes, which is the assumption every model in this chapter rests on. □

52.1.2 Polytropes and the Lane–Emden equation

The four structure equations couple mechanics to thermodynamics through the run of temperature. There is one family of models in which the mechanics closes on its own: assume a power-law relation between pressure and density. The classical treatment is [831].

Definition 52.5 (Polytrope)**.** A *polytrope of index* n is a self-gravitating sphere obeying Equations (52.1) and (52.2) with the equation of state

$$P = K\rho^{1+1/n}\,, \tag{52.7}$$

K and n constants.

Real stars realize particular indices exactly: a fully convective star is isentropic, and for a monatomic ideal gas constant entropy means $P\propto\rho^{5/3}$, that is $n=3/2$; a non-relativistic degenerate electron gas has the same exponent, and its relativistic limit $P\propto\rho^{4/3}$ is $n=3$ (Chapter 120, taken up for white dwarfs in Chapter 49); and a star in which the ratio of gas to total pressure is uniform is an $n=3$ polytrope, as shown at the end of this subsection.

Theorem 52.6 (Lane–Emden equation)**.** *Write* $\rho=\rho_{\mathrm c}\theta^n$ *with* $\rho_{\mathrm c}$ *the central density, and* $r=\alpha\xi$ *with*

$$\alpha^2 = \frac{(n+1)K}{4\pi G}\,\rho_{\mathrm c}^{\,\frac{1-n}{n}}\,. \tag{52.8}$$

Then Equations (52.1) *and* (52.2) *with Equation* (52.7) *are equivalent to*

$$\frac{1}{\xi^2}\frac{\mathrm d}{\mathrm d\xi}\left(\xi^2\frac{\mathrm d\theta}{\mathrm d\xi}\right) = -\theta^n\,, \qquad \theta(0)=1\,,\quad \theta'(0)=0\,. \tag{52.9}$$

The surface is the first zero ξ_1 *of* θ*, so* $R=\alpha\xi_1$*.*

Rests on Equations (52.1)*,* (52.2) *and* (52.7)*.*

Proof. *Derives Theorem 52.6.*

Divide Equation (52.2) by ρ, multiply by r^2, differentiate, and use Equation (52.1):

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(\frac{r^2}{\rho}\frac{\mathrm{d}P}{\mathrm{d}r}\right) = -G\frac{\mathrm{d}m}{\mathrm{d}r} = -4\pi G\rho r^2 \,. \tag{52.10}$$

For Equation (52.7),

$$\frac{1}{\rho}\frac{\mathrm{d}P}{\mathrm{d}r} = K\left(1+\frac{1}{n}\right)\rho^{\frac{1}{n}-1}\frac{\mathrm{d}\rho}{\mathrm{d}r} = (n+1)K\,\frac{\mathrm{d}}{\mathrm{d}r}\left(\rho^{1/n}\right) = (n+1)K\rho_{\mathrm{c}}^{1/n}\frac{\mathrm{d}\theta}{\mathrm{d}r}\,,$$

using $\rho^{1/n} = \rho_{\mathrm{c}}^{1/n}\theta$. Substituting into Equation (52.10) and setting $r = \alpha\xi$,

$$\frac{(n+1)K\rho_{\mathrm{c}}^{1/n}}{\alpha^2}\,\frac{1}{\xi^2}\frac{\mathrm{d}}{\mathrm{d}\xi}\left(\xi^2\frac{\mathrm{d}\theta}{\mathrm{d}\xi}\right) = -4\pi G\rho_{\mathrm{c}}\theta^n\,,$$

which is Equation (52.9) exactly when α is chosen as Equation (52.8). The boundary conditions state that the density is ρ_{c} at the centre and that the pressure gradient vanishes there, as Equation (52.2) requires since $m \sim r^3$. □

Proposition 52.7 (Exact solutions)**.** *Equation (52.9) has closed-form solutions for exactly three indices:*

$$n=0:\ \theta = 1-\frac{\xi^2}{6}\,,\qquad n=1:\ \theta=\frac{\sin\xi}{\xi}\,,\qquad n=5:\ \theta=\left(1+\frac{\xi^2}{3}\right)^{-1/2}\,,$$

with $\xi_1 = \sqrt{6}$, π and ∞ respectively; the $n=5$ sphere has infinite radius but finite mass.

Proof. For $n=1$ substitute $u=\xi\theta$: Equation (52.9) becomes $u''=-u$, so $u=\sin\xi$ selects the solution regular at the origin with $\theta(0)=1$. The $n=0$ and $n=5$ cases are verified by direct differentiation in the same way; for $n=5$, $\theta^5\xi^2\to 0$ fast enough that the mass integral below converges even though θ has no zero. □

For every other index the equation is integrated numerically, which is elementary: it is a regular initial-value problem away from $\xi=0$, started with the series $\theta = 1-\xi^2/6+n\xi^4/120-\cdots$. The two indices this chapter and Chapter 49 need are (computed here, by that integration)

$$\begin{aligned} n=\tfrac{3}{2}:&\quad \xi_1 = 3.654\,,\quad \xi_1^2\,|\theta'(\xi_1)| = 2.714\,,\quad \rho_{\mathrm{c}}/\bar\rho = 5.99\,,\\ n=3:&\quad \xi_1 = 6.897\,,\quad \xi_1^2\,|\theta'(\xi_1)| = 2.018\,,\quad \rho_{\mathrm{c}}/\bar\rho = 54.2\,. \end{aligned} \tag{52.11}$$

The mass follows from Equation (52.9) itself, with no further integration:

$$M = \int_0^R 4\pi r^2\rho\,\mathrm{d}r = 4\pi\alpha^3\rho_{\mathrm{c}}\int_0^{\xi_1}\theta^n\xi^2\,\mathrm{d}\xi = 4\pi\alpha^3\rho_{\mathrm{c}}\,\xi_1^2\,|\theta'(\xi_1)|\,, \tag{52.12}$$

since the integrand is $-\mathrm{d}\left(\xi^2\theta'\right)/\mathrm{d}\xi$. The ratio of central to mean density in Equation (52.11) is $\xi_1/\left(3\,|\theta'(\xi_1)|\right)$, a pure number fixed by n alone.

Eliminating ρ_{c} between Equation (52.12) ($M\propto\rho_{\mathrm{c}}^{(3-n)/2n}$ at fixed K) and $R=\alpha\xi_1\propto\rho_{\mathrm{c}}^{(1-n)/2n}$ gives the polytropic mass–radius relation

$$M \propto R^{\frac{3-n}{1-n}}\,. \tag{52.13}$$

Two cases carry physics. For $n=3/2$, $M\propto R^{-3}$: a non-relativistic degenerate star *shrinks* as mass is added, the inverted mass–radius relation of white dwarfs (Chapter 49). For

$n = 3$ the exponent diverges: the mass is independent of the radius, fixed by K alone — the degenerate ultra-relativistic case, where that unique mass is the Chandrasekhar limit (Equation (49.9)).

Eliminating K and ρ_{c} instead in favour of M and R gives the central pressure,

$$P_{\mathrm{c}} = W_n \frac{GM^2}{R^4}, \qquad W_n = \frac{1}{4\pi(n+1)\theta'(\xi_1)^2}, \tag{52.14}$$

with $W_{3/2} = 0.770$ and $W_3 = 11.05$ (computed here from Equation (52.11)).

Remark 52.8 (The Eddington standard model). Eddington's model of a star [538] is the assumption that the ratio $\beta \equiv P_{\mathrm{gas}}/P$ of gas pressure to total pressure is uniform, the remainder $P_{\mathrm{rad}} = (1-\beta)P = aT^4/3$ being radiation pressure (Equation (68.2); $a = 4\sigma/c$). Eliminating T between $P_{\mathrm{rad}} = aT^4/3 = (1-\beta)P$ and $P_{\mathrm{gas}} = \rho k_{\mathrm{B}} T/(\mu m_{\mathrm{u}}) = \beta P$ gives

$$P = \left[\frac{3(1-\beta)}{a}\right]^{1/3} \left[\frac{k_{\mathrm{B}}}{\beta \mu m_{\mathrm{u}}}\right]^{4/3} \rho^{4/3}, \tag{52.15}$$

a polytrope of index exactly 3, with K a known function of β and the mean molecular weight μ. Because the $n = 3$ mass Equation (52.12) depends on K alone, M determines β: substituting gives *Eddington's quartic equation*, $1-\beta \propto \beta^4 \mu^4 M^2$, which for the Sun ($\mu = 0.61$) evaluates to $1-\beta = 4.1 \times 10^{-4}$ (computed here): radiation pressure is negligible in the Sun. At $100\,M_\odot$ the same equation gives $1-\beta \approx 0.12$ — massive stars are increasingly radiation-supported, the structural face of the Eddington limit derived in Section 52.1.4.

The model's payoff is the solar centre with no nuclear physics and no transport theory at all. From Equations (52.11) and (52.14), computed here,

$$P_{\mathrm{c}} = 11.05 \frac{GM_\odot^2}{R_\odot^4} = 1.2 \times 10^{16}\,\mathrm{Pa}, \qquad \rho_{\mathrm{c}} = 54.2\,\bar{\rho}_\odot = 7.6 \times 10^4\,\mathrm{kg/m^3},$$

and, from the ideal-gas law with $\mu = 0.61$,

$$T_{\mathrm{c}} = \frac{P_{\mathrm{c}}\,\mu m_{\mathrm{u}}}{k_{\mathrm{B}}\,\rho_{\mathrm{c}}} \approx 1.2 \times 10^7\,\mathrm{K}.$$

The detailed standard solar model, with its opacity tables, composition gradient and helioseismic calibration, gives $T_{\mathrm{c}} = 1.57 \times 10^7\,\mathrm{K}$, $\rho_{\mathrm{c}} \approx 1.5 \times 10^5\,\mathrm{kg/m^3}$ and $P_{\mathrm{c}} \approx 2.3 \times 10^{16}\,\mathrm{Pa}$ [2072] (quoted): a one-parameter-family polytrope lands within a factor of two of all three, and the temperature within twenty-five per cent. That $T_{\mathrm{c}} \sim 10^7\,\mathrm{K}$, secure already at this level, is what Section 52.2 needs.

52.1.3 Energy transport: radiation and convection

Deep inside a star, photons are absorbed and re-emitted after mean free paths of millimetres. Energy therefore leaks outward as a diffusive trickle, and the machinery is the transport theory of Chapter 55 with the photon gas of Chapter 120 as the carrier.

Proposition 52.9 (Radiative diffusion)**.** *Where the photon mean free path $\ell = 1/(\kappa\rho)$ is small compared with the temperature scale height, the radiative energy flux is*

$$F = -\frac{c}{3\kappa\rho}\frac{\mathrm{d}}{\mathrm{d}r}\left(aT^4\right) = -\frac{4acT^3}{3\kappa\rho}\frac{\mathrm{d}T}{\mathrm{d}r}, \tag{52.16}$$

equivalently, with $L_r = 4\pi r^2 F$,

$$\frac{\mathrm{d}T}{\mathrm{d}r} = -\frac{3\kappa\rho L_r}{16\pi a c\, r^2 T^3}, \tag{52.17}$$

where κ is the Rosseland mean opacity (below).

Rests on Equation (68.2).

Proof. *Derives Proposition 52.9.*

Carriers of speed c and mean free path ℓ random-walking down a gradient of their energy density u transport the net flux $F = -(c\ell/3)\,\mathrm{d}u/\mathrm{d}r$ — the elementary mean-free-path transport argument of Chapter 55, the factor $\frac{1}{3}$ being the angular average. With matter and radiation locally equilibrated the photon energy density is that of a blackbody at the local temperature, $u = aT^4$ (Equation (68.2)), and $\ell = 1/(\kappa\rho)$ defines the opacity κ as an absorption cross-section per unit mass. Substituting gives Equation (52.16).

Both hypotheses are extravagantly satisfied. In the solar interior $\kappa\rho \sim 10^2/\mathrm{m}$, so $\ell \sim 10^{-2}\,\mathrm{m}$ against a scale height of $\sim 10^8\,\mathrm{m}$: the anisotropy the flux represents, $F/(cu)$, is of order 10^{-11} (computed here with $F \approx 2.5\times10^8\,\mathrm{W/m^2}$ and $T \approx 5\times10^6\,\mathrm{K}$ at mid-radius) — the radiation field is isotropic and Planckian to that accuracy, and the diffusion approximation is among the best in physics. Because real opacity depends on frequency, the κ appearing here must be the *Rosseland mean*: the transport-weighted *harmonic* mean, $1/\kappa = \langle \kappa_\nu^{-1} \rangle$ weighted by $\partial B_\nu/\partial T$, since the flux flows preferentially through the transparent frequency windows (the frequency-by-frequency statement is quoted; see [2196]). □

Two opacity regimes recur. At high temperature the electrons are free and Thomson scattering dominates (Chapter 65): $\kappa_{\mathrm{es}} = \sigma_{\mathrm{T}}(1+X)/2m_{\mathrm{u}} = 0.034\,\mathrm{m^2/kg}$ for hydrogen mass fraction $X = 0.7$ (computed here), independent of ρ and T. At lower temperatures bound–free and free–free absorption dominate, with the law Kramers derived from his X-ray absorption theory, $\kappa \propto \rho T^{-7/2}$ [503]. In cool stellar envelopes the opacity is instead governed by the $\mathrm{H^-}$ ion and *rises* steeply with temperature, which is what Section 52.3.3 will need.

Equation (52.16) also prices the journey: a photon random-walks $N \sim (R/\ell)^2$ steps, taking $t \sim R^2/(\ell c)$, which with the mean solar values above is of order $10^4\,\mathrm{yr}$ (computed here), lengthening to order $10^5\,\mathrm{yr}$ when the centrally concentrated run of $\kappa\rho$ is used (quoted [2196]). Energy generated in the core today emerges from the photosphere in the far future; only the neutrinos of Section 52.5 leave in real time.

Radiative diffusion fails, and convection takes over, when the gradient it demands is too steep to be mechanically stable.

Theorem 52.10 (Schwarzschild criterion)**.** *A chemically homogeneous stratification obeying Equation (52.2) is unstable to convection if and only if*

$$\nabla \equiv \frac{\mathrm{d}\ln T}{\mathrm{d}\ln P} > \nabla_{\mathrm{ad}} \equiv \left(\frac{\partial \ln T}{\partial \ln P}\right)_s , \tag{52.18}$$

where $\nabla_{\mathrm{ad}} = 1 - 1/\Gamma_1 = 2/5$ *for a monatomic ideal gas [330]. Radiative equilibrium is therefore stable exactly where*

$$\nabla_{\mathrm{rad}} \equiv \frac{3\kappa L_r P}{16\pi a c G\, m T^4} \le \nabla_{\mathrm{ad}} , \tag{52.19}$$

∇_{rad} *being the gradient Equation (52.17) written per unit of* $\ln P$ *using Equation (52.2).*
Rests on Equations (52.2) and (52.17).

Proof. *Derives Theorem 52.10.*

Displace a fluid parcel upward by δr, slowly enough to stay in pressure balance with its surroundings (the sound-crossing time of a parcel is far shorter than any transport time) yet fast enough to exchange no heat (the radiative diffusion time across it is far longer); both inequalities hold by margins of many orders of magnitude, which is what makes the adiabatic parcel an accurate idealization. Moving adiabatically at equal pressure, its density becomes

$$\rho_{\mathrm{p}} = \rho + \frac{\rho}{\Gamma_1 P}\frac{\mathrm{d}P}{\mathrm{d}r}\,\delta r ,$$

with $\Gamma_1 = (\partial \ln P/\partial \ln \rho)_s$, while the ambient density at the new position is $\rho + (\mathrm{d}\rho/\mathrm{d}r)\delta r$. The parcel keeps rising — instability — precisely when it arrives lighter than its surroundings:

$$\frac{\rho}{\Gamma_1 P}\frac{\mathrm{d}P}{\mathrm{d}r} < \frac{\mathrm{d}\rho}{\mathrm{d}r}\,.$$

For an ideal gas of uniform composition, $\ln\rho = \ln P - \ln T + \text{const}$, and dividing by $\mathrm{d}\ln P/\mathrm{d}r < 0$ reverses the inequality, turning it into $\nabla > 1 - 1/\Gamma_1 = \nabla_{\mathrm{ad}}$, which is Equation (52.18). In the stable case the restoring buoyancy makes the parcel oscillate at the Brunt–Väisälä frequency

$$N^2 = g\left(\frac{1}{\Gamma_1}\frac{\mathrm{d}\ln P}{\mathrm{d}r} - \frac{\mathrm{d}\ln\rho}{\mathrm{d}r}\right), \tag{52.20}$$

positive exactly when Equation (52.18) fails; these are the buoyancy (g-)modes of a stellar interior, the acoustic counterpart being Section 52.6. In the unstable case the same expression is a growth rate, of order the dynamical time — so a superadiabatic stratification overturns essentially instantly on stellar timescales, and a convection zone sits pinned at ∇ only infinitesimally above ∇_{ad} except in its outermost, tenuous layers. □

Equation (52.19) locates the convection zones. ∇_{rad} is large where the opacity is large or where L_r/m is large. Cool envelopes satisfy the first condition — in the Sun, hydrogen's partial ionization both raises κ enormously (H^-) and depresses ∇_{ad} below 2/5 (energy fed into ionization rather than temperature), so the outer envelope convects, from $0.71\,R_\odot$ to the surface as helioseismology locates it (Section 52.6.2). Stars burning on the CNO cycle satisfy the second: Section 52.2.3 concentrates ε so sharply that L_r saturates near the centre, and such stars have *convective cores* instead. The two configurations exchange roles across the mass scale, and the difference propagates into everything from surface abundances to main-sequence lifetimes.

Remark 52.11 (Mixing-length theory). What convection actually carries, once running, is modelled — not derived. Böhm-Vitense's mixing-length theory [1136] posits parcels that rise a distance $\ell_{\mathrm{m}} = \alpha_{\mathrm{MLT}} H_P$ (H_P the pressure scale height) before dissolving, and carries the flux implied by the buoyancy work over that distance. The single free parameter $\alpha_{\mathrm{MLT}} \approx 1.5$–$2$ is calibrated on the Sun, and this honest phenomenological confession sits inside every stellar evolution code. Deep convection is so efficient that the result barely matters there ($\nabla \to \nabla_{\mathrm{ad}}$, an isentrope, whatever α_{MLT}); it matters within the superadiabatic surface layers, and through them the stellar radius. The turbulence being modelled belongs to Chapter 31.

52.1.4 The mass–luminosity relation and the Eddington limit

With hydrostatics and radiative transport in hand, the structure equations yield their most consequential scaling law before any of them is solved.

Phenomenon 52.12 (The mass–luminosity relation)**.** Among main-sequence stars whose masses are measured directly, from the orbits of eclipsing and visual binaries, the luminosity rises as a steep power of the mass,

$$L \propto M^{\alpha}\,, \qquad \alpha \approx 3 \text{ to } 4\,, \tag{52.21}$$

across the bulk of the main sequence [511]. A star of ten solar masses is some thousands of times the more luminous. Set beside the fuel supply of Phenomenon 52.4, which grows only in proportion to the mass, this makes massive stars enormously short-lived, and it is what turns the main-sequence turnoff of a star cluster into a clock.

Rests on Equations (52.2) *and* (52.17) *and Propositions 52.1 and 52.9.*

Derivation. *Derives Phenomenon 52.12.*

The exponent follows from three of the structure equations without any of them being solved, by comparing the scalings of their terms — a *homology* argument. Write M and R for the mass and radius and P, $\rho \sim M/R^3$, T for characteristic interior values.

Hydrostatic equilibrium (Equation (52.2)) scales as

$$\frac{P}{R} \sim \frac{GM}{R^2} \cdot \frac{M}{R^3}\,, \qquad \text{so} \qquad P \sim \frac{GM^2}{R^4}\,.$$

For an ideal gas of mean molecular weight μ, that is $P = \rho k_{\mathrm{B}} T/(\mu m_{\mathrm{u}})$, and eliminating P and ρ leaves

$$T \sim \frac{G\mu m_{\mathrm{u}}}{k_{\mathrm{B}}} \cdot \frac{M}{R}\,. \tag{52.22}$$

Radiative diffusion carries the energy out (Equation (52.17)), which scales as

$$L \sim \frac{acR^2T^3}{\kappa\rho} \cdot \frac{T}{R} = \frac{acRT^4}{\kappa\rho} \sim \frac{acR^4T^4}{\kappa M}\,.$$

Substituting Equation (52.22), every factor of R cancels:

$$L \sim \frac{ac}{\kappa}\left(\frac{G\mu m_{\mathrm{u}}}{k_{\mathrm{B}}}\right)^4 M^3\,. \tag{52.23}$$

For an opacity independent of the local conditions — electron scattering, which dominates in hot interiors — this is $L \propto M^3$, with no free parameter and no dependence on the radius at all. The observed exponent runs somewhat above three because at lower masses the opacity instead follows Kramers' law $\kappa \propto \rho T^{-7/2}$ [503], which steepens the dependence.

The content of Equation (52.23) is worth stating plainly, because it is counter-intuitive: the luminosity of a main-sequence star is fixed by its mass and composition and does not refer to the energy source at all. A star shines as brightly as its own weight compels it to, and the nuclear reaction rate adjusts, by way of the central temperature, to supply exactly that. □

The same radiation that carries the luminosity pushes on the matter carrying it, and there is a luminosity at which the push wins.

Proposition 52.13 (Eddington luminosity)**.** *For fully ionized hydrogen, hydrostatic equilibrium is impossible above*

$$L_{\mathrm{Edd}} = \frac{4\pi GMm_{\mathrm{p}}c}{\sigma_{\mathrm{T}}} = 1.26\times10^{31}\,\mathrm{W}\times\frac{M}{M_\odot} = 3.3\times10^{4}\,L_\odot\times\frac{M}{M_\odot} \tag{52.24}$$

(computed here) [538].

Rests on Equation (52.16).

Proof. *Derives Proposition 52.13.*

A radiation flux F carries momentum flux F/c, and an electron intercepts it with cross-section σ_{T}, feeling an outward force $\sigma_{\mathrm{T}}F/c$; the protons, electrostatically tied to the electrons, supply almost all the weight, $Gm_{\mathrm{p}}M/r^2$ per electron. With $F = L/4\pi r^2$, both forces fall as $1/r^2$, so their ratio is one number for the whole star:

$$\frac{f_{\mathrm{rad}}}{f_{\mathrm{grav}}} = \frac{\sigma_{\mathrm{T}}L}{4\pi GMm_{\mathrm{p}}c} \equiv \frac{L}{L_{\mathrm{Edd}}}\,.$$

At $L > L_{\mathrm{Edd}}$ the effective gravity is outward at every radius and no hydrostatic atmosphere exists: the star sheds mass instead. Evaluating with the constants of Appendix B gives Equation (52.24). □

Setting Equation (52.23) against Equation (52.24): L grows as M^3 but L_{Edd} only as M, and the two meet near $180\,M_\odot$ (computed here from the calibration $L = L_\odot(M/M_\odot)^3$). Stars approaching that mass are radiation-pressure-dominated (Remark 52.8), loosely bound and violently unstable to mass loss, which is why the observed main sequence ends at masses of order $10^2\,M_\odot$. The same limit, applied to accretion instead of fusion, caps the luminosity of matter falling onto compact objects and calibrates the brightest X-ray sources and quasars (Chapter 50).

52.2 Nuclear energy generation

52.2.1 Tunnelling and the Gamow peak

The temperature that hydrostatics dictates (Remark 52.8) is, by the standards of nuclear physics, absurdly cold. Two protons must approach to a few femtometres to fuse, against a Coulomb barrier of 720 keV (Equation (107.99)), while $k_{\mathrm{B}}T_{\mathrm{c}} = 1.35\,\mathrm{keV}$: the barrier stands five hundred times above the mean thermal energy, and the Boltzmann factor for surmounting it classically, $\mathrm{e}^{-530} \sim 10^{-230}$, forbids fusion in any classical gas of any astrophysical size. The resolution is quantum tunnelling through the barrier [600], applied to stellar interiors by Atkinson and Houtermans within a year [622]. The machinery — the Gamow factor, the astrophysical S factor, and the thermal average over the Maxwell–Boltzmann tail — is built in Chapter 107, whose central result, Theorem 107.85, this section uses as is: the reaction rate is dominated by a narrow window of collision energies (the *Gamow peak*) centred on $E_0 = \left(E_G(k_{\mathrm{B}}T)^2/4\right)^{1/3}$ (Equation (107.101)), of width $\Delta E = 4\sqrt{E_0 k_{\mathrm{B}}T/3}$ (Equation (107.102)), where E_G is the Gamow energy of the colliding pair. For the Sun the worked numbers are Example 107.86: protons fuse at $E_0 \approx 6\,\mathrm{keV}$, from far out on the thermal tail.

What this chapter must add is the *temperature sensitivity*, because everything structural — the segregation of burning stages, the pp/CNO divide, the existence of convective cores, the stability of the whole configuration — hangs on it.

Proposition 52.14 (Temperature exponent of a nonresonant rate)**.** *With $S(E)$ slowly varying, the thermally averaged rate per pair behaves as*

$$\langle \sigma v \rangle \propto T^{-2/3} \exp\left(-\frac{3E_0}{k_{\mathrm{B}}T}\right), \tag{52.25}$$

so its local logarithmic slope is

$$\nu \equiv \frac{\partial \ln \langle \sigma v \rangle}{\partial \ln T} = \frac{\tau - 2}{3}, \qquad \tau \equiv \frac{3E_0}{k_{\mathrm{B}}T}. \tag{52.26}$$

Rests on Equations (107.101) *and* (107.102).

Proof. *Derives Proposition 52.14.*

The thermal average is $\langle \sigma v \rangle \propto (k_{\mathrm{B}}T)^{-3/2} \int S(E)\, \mathrm{e}^{-E/k_{\mathrm{B}}T - \sqrt{E_G/E}}\, \mathrm{d}E$, and the saddle-point evaluation performed in the proof of Theorem 107.85 gives for the integral a Gaussian of height $S(E_0)\,\mathrm{e}^{-3E_0/k_{\mathrm{B}}T}$ (the exponent at the peak is $E_0/k_{\mathrm{B}}T + \sqrt{E_G/E_0} = 3E_0/k_{\mathrm{B}}T$, using $\sqrt{E_G/E_0} = 2E_0/k_{\mathrm{B}}T$ from Equation (107.101)) and of width $\Delta E \propto \sqrt{E_0 k_{\mathrm{B}}T}$ (Equation (107.102)). Since $E_0 \propto T^{2/3}$, the width scales as $T^{5/6}$, and the prefactors assemble to $T^{-3/2} \times T^{5/6} = T^{-2/3}$, which is Equation (52.25). Differentiating: $\tau = 3E_0/k_{\mathrm{B}}T \propto T^{-1/3}$, so $\mathrm{d}\tau/\mathrm{d}\ln T = -\tau/3$ and

$$\frac{\partial \ln \langle \sigma v \rangle}{\partial \ln T} = -\frac{2}{3} + \frac{\tau}{3} = \frac{\tau - 2}{3}.$$

□

Table 52.1: Gamow-peak parameters of the hydrogen-burning reactions at the solar central temperature $T_{\mathrm{c}} = 1.57 \times 10^7\,\mathrm{K}$, that is $k_{\mathrm{B}}T = 1.353\,\mathrm{keV}$: Gamow energy E_G, peak energy E_0 and width ΔE (Equations (107.101) and (107.102)), and the temperature exponent ν of Equation (52.26). All entries computed here.

Reaction	E_G (MeV)	E_0 (keV)	ΔE (keV)	τ	ν
$p + p$	0.493	6.1	6.6	13.5	3.8
$^3\mathrm{He} + {}^4\mathrm{He}$	26.9	23.1	12.9	51.2	16.4
$p + {}^7\mathrm{Be}$	13.8	18.5	11.5	41.0	13.0
$p + {}^{14}\mathrm{N}$	45.1	27.4	14.1	60.8	19.6

Table 52.1 turns Equation (52.26) into the architecture of stellar burning. The pp reaction runs as T^4; the CNO bottleneck as T^{20}; and higher-Z fuels, with their larger E_G, switch on only at successively higher temperatures — which is why burning proceeds in *discrete, well-separated stages* (Section 52.2.4) rather than as a continuous smoulder. The steepness also closes the loop opened in Remark 52.3: a star that momentarily over-burns expands and cools, and a rate falling as the twentieth power of a falling temperature is a thermostat of extraordinary stiffness. A star is stable not despite the violence of its energy source but because of how sharply that source responds to the star's own mechanical state.

52.2.2 The pp chains

In the Sun, hydrogen burns predominantly by the proton–proton chains. The first step,

$$p + p \longrightarrow d + e^+ + \nu_e\,,$$

is a *weak* interaction — two protons form no bound state (Chapter 107), so one must convert to a neutron during the fleeting collision — first computed by Bethe and Critchfield from Fermi's theory [810] (Chapter 101). Its cross-section is some twenty orders of magnitude below direct measurement and is known only from theory; that a weak process gates the whole chain is why the Sun burns for 10^{10} years instead of detonating, and the derivation of the total release $Q = 26.73\,\mathrm{MeV}$ per helium nucleus is Phenomenon 107.87 (Equation (107.104)). The deuteron is consumed within seconds, and the chain then completes along three branches.

Table 52.2: The three pp branches. Q-values are computed here from the measured atomic mass excesses (Chapter 107), positron annihilation included, so each branch totals 26.73 MeV per ^{4}He (Equation (107.104)); neutrino energies are quoted from [2072]. Branch shares of chain terminations in the present Sun (quoted, BS05 [2072]): pp I about 85 %, pp II about 15 %, pp III about 0.02 %.

Branch	Reaction	Q (MeV)	E_ν (MeV)
pp I	$p + p \to d + e^+ + \nu_e$	1.442	≤ 0.420, $\langle E_\nu \rangle = 0.267$
	$d + p \to {}^3\mathrm{He} + \gamma$	5.493	—
	$^3\mathrm{He} + {}^3\mathrm{He} \to {}^4\mathrm{He} + 2p$	12.860	—
pp II	$^3\mathrm{He} + {}^4\mathrm{He} \to {}^7\mathrm{Be} + \gamma$	1.587	—
	$^7\mathrm{Be} + e^- \to {}^7\mathrm{Li} + \nu_e$	0.862	0.862 (90%), 0.384
	$^7\mathrm{Li} + p \to 2\,{}^4\mathrm{He}$	17.346	—
pp III	$^7\mathrm{Be} + p \to {}^8\mathrm{B} + \gamma$	0.137	—
	$^8\mathrm{B} \to 2\,{}^4\mathrm{He} + e^+ + \nu_e$	18.07	$\langle E_\nu \rangle \approx 6.7$

The neutrinos are not detail: they are the audit trail. Each branch loses a different fraction of Q to neutrinos, which never thermalize (computed here from Table 52.2): pp I loses $2 \times 0.267 = 0.53\,\mathrm{MeV}$, or 2.0 %; pp II loses 1.08 MeV, 4.0 %; pp III loses 7.0 MeV, fully 26 % of its Q. Weighted by the branch shares, the Sun's neutrino loss is about 2.3 % (computed here): the photon luminosity corresponds to an effective 26.1 MeV of heat per helium nucleus assembled. Two rare variants complete the bookkeeping: the *pep* reaction $p + e^- + p \to d + \nu_e$, a monochromatic 1.44 MeV line, and the *hep* reaction on ^{3}He, the highest-energy solar neutrinos. Branch by branch, this entire table has now been read out of the Sun in real time by neutrino spectroscopy (Section 52.5.3; [2297]), including the tiny pp III branch whose ^{8}B neutrinos carried the solar-neutrino problem for thirty years (Section 52.5.1).

52.2.3 The CNO cycle

Where carbon, nitrogen and oxygen are present, hydrogen can also burn catalytically, in the cycle proposed independently by von Weizsäcker [824] and worked out quantitatively by Bethe [828]:

Table 52.3: The CN cycle. Q-values computed here from the measured atomic mass excesses, positron annihilation included; they sum to 26.73 MeV, as they must, the C, N and O nuclei being returned unchanged. Neutrino mean energies quoted from [2072].

Reaction	Q (MeV)	E_ν (MeV)
$^{12}\mathrm{C} + p \to {}^{13}\mathrm{N} + \gamma$	1.943	—
$^{13}\mathrm{N} \to {}^{13}\mathrm{C} + e^+ + \nu_e$	2.220	$\langle E_\nu \rangle = 0.707$
$^{13}\mathrm{C} + p \to {}^{14}\mathrm{N} + \gamma$	7.551	—
$^{14}\mathrm{N} + p \to {}^{15}\mathrm{O} + \gamma$	7.297	—
$^{15}\mathrm{O} \to {}^{15}\mathrm{N} + e^+ + \nu_e$	2.754	$\langle E_\nu \rangle = 0.997$
$^{15}\mathrm{N} + p \to {}^{12}\mathrm{C} + {}^4\mathrm{He}$	4.965	—

The cycle's properties follow from Table 52.1. Its slowest link at stellar temperatures is $^{14}\mathrm{N}(p,\gamma)^{15}\mathrm{O}$ — the largest Gamow energy among the captures, compounded by a small S factor — so in equilibrium the catalysts pile up as ^{14}N: the CNO cycle is itself a nucleosynthesis process, and the cosmic abundance of nitrogen is largely its fossil [1105]. The same link sets the temperature exponent, $\nu \approx 20$ (Table 52.1), against $\nu \approx 4$ for pp. Two consequences:

First, the crossover. The pp rate, with its shallow slope, wins at low temperature; the CNO rate, at solar metallicity, overtakes it near $T \approx 1.7 \times 10^7\,\mathrm{K}$ — just above the solar centre — corresponding to main-sequence masses above about $1.3\,M_\odot$ (modern values, quoted [2196]). Bethe's own comparison, using the higher solar central temperature then accepted, placed the Sun itself on the CNO side [828]; improved solar models moved the divide just above it. The Sun sits below the divide: Borexino's direct detection of CNO neutrinos measures the cycle's contribution at about one per cent of the solar luminosity [2349], exactly the subordinate role the crossover predicts (Section 52.5.3).

Second, the core convection of Section 52.1.3. A T^{20} rate concentrates the burning into the innermost few per cent of the mass; L_r there saturates, ∇_{rad} of Equation (52.19) exceeds ∇_{ad}, and every CNO-burning star carries a convective core — continuously refuelled and chemically homogenized, which lengthens its life and reshapes its track in Section 52.3.

52.2.4 Helium burning and beyond

Past helium the chart of nuclides has a double gap: no stable mass 5, no stable mass 8. Salpeter identified the two-step route through the unbound ^{8}Be [1010], and Hoyle turned the observed abundance of carbon into the prediction of a nuclear excited state — the argument, stated from the nuclear-physics side in Remark 107.88, that this chapter records as a phenomenon because its input was astronomical.

Phenomenon 52.15 (Carbon exists, and so does the resonance that makes it)**.** Carbon is among the most abundant elements in the universe, yet the route to it is blocked twice: there is no stable nucleus of mass number 5 or 8, so helium burning must pass through the unstable ^{8}Be, whose lifetime is of order 10^{-16} s [1010]. From the bare fact of carbon's abundance, Hoyle argued that the triple-alpha rate must be resonantly enhanced and therefore that ^{12}C must possess a hitherto unknown excited state of spin-parity 0^{+} lying just above the three-alpha threshold, near 7.65 MeV of excitation. The state was then looked for, and found at that energy [1044]. It remains the clearest case in physics of a nuclear property predicted from an astronomical abundance.

Rests on Definition 107.31 and Proposition 52.16.

Derivation. *Derives Phenomenon 52.15.*

The threshold energy is fixed by the masses alone, and it is what makes the prediction quantitative. Three ^{4}He nuclei have a combined atomic mass of $3 \times 4.002602 = 12.007806$ in unified atomic mass units, while ^{12}C has, by the definition of that unit, a mass of exactly 12. The excess is 0.007806 mass units, and with $1\,\mathrm{u} = 931.494\,\mathrm{MeV}/c^{2}$,

$$Q_{3\alpha} = 0.007806 \times 931.494\,\mathrm{MeV} \approx 7.27\,\mathrm{MeV}\,. \tag{52.27}$$

The three-alpha system therefore enters ^{12}C at 7.27 MeV of excitation, so the state Hoyle required at 7.65 MeV sits 0.38 MeV *above* the threshold.

That placement is the whole of the argument. Below the threshold the state could not act as a resonance for three free alpha particles at all. A few hundred keV higher and the Boltzmann factor at helium-burning temperatures would have suppressed the rate, leaving a universe with very little carbon in it. The window is narrow, the abundance is large, and the state is where the abundance requires it to be — which is why the laboratory confirmation was taken as decisive rather than as a coincidence. □

The resonance also fixes how helium burning *responds* to temperature, which is qualitatively unlike the nonresonant rates of Section 52.2.1.

Proposition 52.16 (Temperature sensitivity of the triple-alpha rate)**.** *With the capture fully resonant through the Hoyle state at $E_{\mathrm{r}} = 380\,\mathrm{keV}$ above the three-alpha threshold, the rate per unit volume behaves as*

$$r_{3\alpha} \propto n_{\alpha}^{3}\, T^{-3} \exp\left(-\frac{E_{\mathrm{r}}}{k_{\mathrm{B}}T}\right)\,, \tag{52.28}$$

so its temperature exponent is $\nu = E_{\mathrm{r}}/k_{\mathrm{B}}T - 3 \approx 41$ at $T = 1 \times 10^{8}\,\mathrm{K}$ (computed here).

Rests on Equation (52.27).

Proof. *Derives Proposition 52.16.*

For a resonance narrow on the thermal scale, the thermally averaged rate per pair follows from inserting a sharply peaked cross-section into the Maxwell–Boltzmann average (Chapter 55): the distribution contributes its value at the resonance, $\propto (k_{\mathrm{B}}T)^{-3/2}\mathrm{e}^{-E/k_{\mathrm{B}}T}$, and the energy integral over the resonance profile contributes a temperature-independent strength, so $\langle \sigma v \rangle \propto T^{-3/2}\mathrm{e}^{-E/k_{\mathrm{B}}T}$ with E the resonance energy in the collision frame.

The triple-alpha route applies this twice. First, $\alpha + \alpha \rightleftharpoons {}^{8}\mathrm{Be}$: the ^{8}Be ground state sits $\Delta E_1 = 92\,\mathrm{keV}$ above two alphas, and because its formation and decay proceed through the same channel, the equilibrium population cancels the resonance strength entirely, leaving the Saha-like factor

$$\frac{n_8}{n_\alpha^2} \propto T^{-3/2} \exp\left(-\frac{\Delta E_1}{k_\mathrm{B} T}\right) .$$

Second, ${}^{8}\mathrm{Be} + \alpha \to {}^{12}\mathrm{C}^{*}$ through the Hoyle state, which lies $\Delta E_2 = 288\,\mathrm{keV}$ above the ${}^{8}\mathrm{Be} + \alpha$ threshold: another factor $T^{-3/2}\mathrm{e}^{-\Delta E_2/k_\mathrm{B}T}$. The product is Equation (52.28) with $E_\mathrm{r} = \Delta E_1 + \Delta E_2 = 380\,\mathrm{keV}$ — necessarily the Hoyle state's height above *three* free alphas, Equation (52.27) subtracted from 7.65 MeV. Differentiating logarithmically: $\nu = E_\mathrm{r}/k_\mathrm{B}T - 3$, and at $T = 1 \times 10^{8}\,\mathrm{K}$, where $k_\mathrm{B}T = 8.62\,\mathrm{keV}$, this is $44 - 3 = 41$. □

A rate scaling as T^{41} (and as the *cube* of the density) is effectively a switch: helium ignites abruptly near $1 \times 10^{8}\,\mathrm{K}$ and nowhere cooler. In stars below about $2\,M_\odot$ the helium core reaches that temperature only after becoming electron-degenerate, and ignition under degeneracy is explosive — pressure barely responds to temperature, the thermostat of Remark 52.3 is disconnected, and the burning runs away as the *helium flash* until degeneracy is lifted (Chapters 49 and 120).

Beyond the triple-alpha reaction, successive α captures climb the ladder ${}^{12}\mathrm{C}(\alpha,\gamma){}^{16}\mathrm{O}$ and onward. The carbon-to-oxygen ratio of the universe is set by the competition between the triple-alpha rate and the ${}^{12}\mathrm{C}(\alpha,\gamma)$ rate, whose S factor at stellar energies remains among the least certain numbers in nuclear astrophysics — an honest caveat carried by every model of white dwarf composition. The later stages then follow in the sequence Table 52.4, each ignited by the next Coulomb barrier per Proposition 52.14, each faster than the last: partly because less energy remains per reaction (Phenomenon 107.32), and mainly because from carbon burning onward the core's thermal neutrino emission, not photon diffusion, carries away the power, decoupling the burning from the surface luminosity entirely.

Table 52.4: Advanced burning stages of a massive star ($\sim 20\,M_\odot$): approximate ignition temperatures and durations, quoted as orders of magnitude from [2196]. The collapse of the timescales from millions of years to a day is driven by neutrino losses.

Stage	Principal products	T (K)	Duration
Hydrogen	${}^{4}\mathrm{He}$, ${}^{14}\mathrm{N}$	$\sim 4 \times 10^{7}$	$\sim 10^{7}\,\mathrm{yr}$
Helium	${}^{12}\mathrm{C}$, ${}^{16}\mathrm{O}$	$\sim 2 \times 10^{8}$	$\sim 10^{6}\,\mathrm{yr}$
Carbon	${}^{20}\mathrm{Ne}$, ${}^{23}\mathrm{Na}$, ${}^{24}\mathrm{Mg}$	$\sim 8 \times 10^{8}$	$\sim 10^{3}\,\mathrm{yr}$
Neon	${}^{16}\mathrm{O}$, ${}^{24}\mathrm{Mg}$	$\sim 1.5 \times 10^{9}$	$\sim 1\,\mathrm{yr}$
Oxygen	${}^{28}\mathrm{Si}$, ${}^{32}\mathrm{S}$	$\sim 2 \times 10^{9}$	$\sim 0.3\,\mathrm{yr}$
Silicon	iron-peak nuclei	$\sim 3.5 \times 10^{9}$	$\sim 10^{-2}\,\mathrm{yr}$

Silicon burning is not a fusion of two silicon nuclei — that barrier is out of reach — but a photodisintegration rearrangement: at $3.5 \times 10^{9}\,\mathrm{K}$ the thermal photons strip nucleons and alphas off nuclei and the ensemble relaxes toward nuclear statistical equilibrium, which populates the binding-energy maximum (Proposition 107.41). There the energy release stops, by Phenomenon 107.32: an iron core can only absorb energy, by photodisintegration and electron capture, and its collapse — with everything that follows, neutron stars, supernovae and stellar black holes — is where this chapter hands the star to Chapter 49.

52.3 The Hertzsprung–Russell diagram and stellar evolution

52.3.1 The diagram

Everything observable about the surface of a distant star reduces, to first approximation, to two numbers: a luminosity and a surface temperature (measured as a colour or a spectral type). Plotting stars in that plane is due to Hertzsprung [373] and, independently, Russell [420], and the result is the single observable summary against which every stellar model is judged.

Phenomenon 52.17 (The Hertzsprung–Russell diagram)**.** Stars do not fill the luminosity–temperature plane. About ninety per cent of them lie on one narrow band — the *main sequence* — running diagonally from hot and luminous to cool and faint; a separate population of *giants* sits cool yet luminous; *white dwarfs* sit hot yet faint, thousands of times below the main sequence [373, 420]. The bands are loci, not scatter: a star's position determines its other properties, and clusters of common age populate the diagram in sharply truncated patterns.

Rests on Equations (52.23) *and* (68.2) *and Phenomenon 52.12.*

Derivation. Derives Phenomenon 52.17.

The plane has a hidden third coordinate. A star radiates approximately as a blackbody, so (Equation (68.2))

$$L = 4\pi R^2 \sigma T_{\text{eff}}^4 \,, \tag{52.29}$$

and lines of constant radius are diagonals of slope four in $\log L$ against $\log T_{\text{eff}}$. Every feature of the diagram is a statement about radii.

The main sequence is the locus of hydrogen burners, traced by mass. Homology fixes both of its coordinates as functions of M alone. The luminosity is Equation (52.23), $L \propto M^3$. The radius follows from energy balance: the nuclear power $L \propto M\bar{\rho}T^\nu \propto M^{2+\nu}R^{-3-\nu}$ must equal the transported $L \propto M^3$, so

$$R \propto M^{\frac{\nu-1}{\nu+3}} \,, \tag{52.30}$$

which for pp burning ($\nu \approx 4$, Table 52.1) is $R \propto M^{0.43}$. Then Equation (52.29) gives $T_{\text{eff}}^4 \propto M^3/R^2 \propto M^{2.14}$, and eliminating M,

$$L \propto T_{\text{eff}}^{5.6} \tag{52.31}$$

(computed here): a single steep curve, parametrized by mass, with essentially no width — because homologous stars of one composition have no free parameter left. The main sequence is a mass sequence, not an age sequence.

The other bands are radius excursions. Giants are stars of ordinary mass at 10–$10^2\,R_\odot$ (Section 52.3.3); white dwarfs are stars of ordinary mass at $\sim 10^{-2}\,R_\odot$, the degenerate configurations of Chapter 49. Their separation from the main sequence by orders of magnitude in L at fixed T_{eff} is just Equation (52.29) read along a vertical line. And a cluster — a population of one age and composition — fills the main sequence only up to the mass whose lifetime (Section 52.3.2) equals the cluster's age, which is the truncation observed. □

52.3.2 Main-sequence lifetimes

The fuel scales as M; the burn rate as M^3 to M^4 (Phenomenon 52.12). So the main-sequence lifetime,

$$t_{\text{MS}} \approx \frac{0.007 \times 0.1\, Mc^2}{L} \propto M^{1-\alpha} \,, \tag{52.32}$$

falls as roughly $M^{-2.5}$: $1 \times 10^{10}\,\text{yr}$ for the Sun (Equation (52.6)), but only about $3 \times 10^7\,\text{yr}$ at $10\,M_\odot$ (computed here with $\alpha = 3.5$). The most massive stars live for astronomically

negligible times, which is why O stars are found only in regions of active star formation, and why the main-sequence *turnoff* of a cluster (Phenomenon 52.17) is a clock: reading the turnoff mass and applying Equation (52.32) dates the cluster. The oldest globular clusters date this way to about thirteen thousand million years (quoted; [2196]) — a lower bound on the age of the universe that cosmology must and does clear (Chapter 48).

What ends the main-sequence phase is not the exhaustion of hydrogen everywhere but the mechanics of the helium ash at the centre.

Proposition 52.18 (Schönberg–Chandrasekhar limit)**.** *An isothermal, non-degenerate helium core of mass M_{c} and molecular weight μ_{c}, at temperature T_{c} set by the surrounding envelope, can support that envelope only if its surface pressure does not exceed*

$$P_{\max} = \frac{c_1}{G^3 M_{\mathrm{c}}^2}\left(\frac{k_{\mathrm{B}} T_{\mathrm{c}}}{\mu_{\mathrm{c}} m_{\mathrm{u}}}\right)^4 , \tag{52.33}$$

c_1 a constant of order unity; matching to the envelope demand caps the core mass fraction at

$$q \equiv \frac{M_{\mathrm{c}}}{M} \;\le\; q_{\mathrm{SC}} \approx 0.37\left(\frac{\mu_{\mathrm{env}}}{\mu_{\mathrm{c}}}\right)^2 , \tag{52.34}$$

about ten per cent for a helium core beneath a hydrogen envelope (coefficient quoted from [868, 2196]).

Rests on Theorem 52.2.

Proof. *Derives Proposition 52.18.*

Repeat the integration by parts of Theorem 52.2 over the core alone: the boundary term no longer vanishes, leaving the virial theorem with a surface term,

$$3P_{\mathrm{s}}V_{\mathrm{c}} = 3\int_0^{M_{\mathrm{c}}} \frac{P}{\rho}\,\mathrm{d}m + E_{\mathrm{grav}} = \frac{3M_{\mathrm{c}}k_{\mathrm{B}}T_{\mathrm{c}}}{\mu_{\mathrm{c}}m_{\mathrm{u}}} - c_0\frac{GM_{\mathrm{c}}^2}{R_{\mathrm{c}}} ,$$

the first equality for an isothermal ideal gas, c_0 of order unity encoding the core's density profile. As a function of the core radius this is $P_{\mathrm{s}} = A/R_{\mathrm{c}}^3 - B/R_{\mathrm{c}}^4$ with $A \propto M_{\mathrm{c}}T_{\mathrm{c}}/\mu_{\mathrm{c}}$ and $B \propto GM_{\mathrm{c}}^2$: zero for a large diffuse core, zero again for a compressed one (gravity wins), with a maximum in between at $R_{\mathrm{c}}^{*} = 4B/3A$ of height $P_{\max} = 27A^4/256B^3$, which is Equation (52.33). The remarkable feature is the *denominator*: the more massive the core, the *less* pressure it can exert.

The envelope, meanwhile, demands of the core's surface a pressure of the star's own interior order, $P_{\mathrm{env}} \sim GM^2/R^4$, at a temperature it also dictates, $k_{\mathrm{B}}T_{\mathrm{c}} \sim G\mu_{\mathrm{env}}m_{\mathrm{u}}M/R$ (Equation (52.22)). Substituting both into $P_{\max} \ge P_{\mathrm{env}}$, all factors of R cancel:

$$\frac{(\mu_{\mathrm{env}}/\mu_{\mathrm{c}})^4\,GM^4}{M_{\mathrm{c}}^2\,R^4} \gtrsim \frac{GM^2}{R^4} \quad\Longrightarrow\quad q^2 \lesssim \left(\frac{\mu_{\mathrm{env}}}{\mu_{\mathrm{c}}}\right)^4 ,$$

which is Equation (52.34) up to the coefficient, obtained by integrating the isothermal core structure exactly [868]. With $\mu_{\mathrm{env}} \approx 0.6$ and $\mu_{\mathrm{c}} \approx 1.3$, $q_{\mathrm{SC}} \approx 0.08$ (computed here from Equation (52.34)). □

When shell burning pushes the helium core past q_{SC}, no isothermal equilibrium remains: the core contracts on its own Kelvin–Helmholtz timescale, and the star leaves the main sequence. (Below about $2\,M_\odot$ the core evades the limit by going degenerate — degeneracy pressure needs no temperature — which is why low-mass stars linger as subgiants while more massive stars cross the gap quickly.) The envelope's response to core contraction is expansion — the "mirror" behaviour every detailed calculation shows [2196] — and the star moves right in the diagram, toward the giant region and the track derived next.

52.3.3 Before and after the main sequence

A star arriving at or leaving the main sequence spends its time fully or largely convective, and for such stars there is a wall in the HR diagram.

Proposition 52.19 (The Hayashi track is nearly vertical)**.** *A fully convective star whose photospheric opacity follows the H^- law $\kappa = \kappa_0 \rho^{1/2} T^9$ (quoted fit, valid near $4 \times 10^3\,\mathrm{K}$ [2196]) satisfies*

$$T_{\mathrm{eff}} \propto M^{7/51}\, L^{1/102}\,, \tag{52.35}$$

so its effective temperature is nearly independent of its luminosity: fully convective stars of given mass form an almost vertical line in the HR diagram, and the region cooler than that line is forbidden [1209].

Rests on Theorems 52.6 and 52.10.

Proof. *Derives Proposition 52.19.*

Four ingredients, each one line.

(i) The interior is an $n = 3/2$ polytrope. Efficient convection enforces $\nabla = \nabla_{\mathrm{ad}}$ (Theorem 52.10 and Remark 52.11): the star is isentropic, $P = K\rho^{5/3}$, and the Lane–Emden mass relation Equation (52.12) with the scale Equation (52.8) fixes the adiabat's constant in terms of the bulk parameters: eliminating ρ_{c} between $M \propto K^{3/2}\rho_{\mathrm{c}}^{1/2}$ and $R \propto K^{1/2}\rho_{\mathrm{c}}^{-1/6}$ leaves $K \propto GM^{1/3}R$.

(ii) The adiabat in (P,T). With the ideal-gas law $\rho = \mu m_{\mathrm{u}} P/k_{\mathrm{B}}T$ substituted into $P = K\rho^{5/3}$,

$$P \propto K^{-3/2}\,T^{5/2} \propto M^{-1/2}R^{-3/2}\,T^{5/2}\,.$$

(iii) The photosphere. Hydrostatic equilibrium in the atmosphere, $\mathrm{d}P = (g/\kappa)\,\mathrm{d}\tau$ per unit optical depth, integrates to $P_{\mathrm{ph}}\,\kappa_{\mathrm{ph}} \simeq \frac{2}{3}\,g = \frac{2}{3}\,GM/R^2$ at the photosphere $\tau = \frac{2}{3}$. Writing the opacity law in (P,T) via the ideal-gas law, $\kappa \propto \rho^{1/2}T^9 \propto P^{1/2}T^{17/2}$, this is $P_{\mathrm{ph}}^{3/2}\,T_{\mathrm{eff}}^{17/2} \propto M/R^2$.

(iv) Match. The photosphere lies on the interior adiabat, so substituting (ii) into (iii):

$$M^{-3/4}R^{-9/4}\,T_{\mathrm{eff}}^{15/4}\cdot T_{\mathrm{eff}}^{17/2} \propto \frac{M}{R^2} \quad\Longrightarrow\quad T_{\mathrm{eff}}^{49} \propto M^7 R\,.$$

Eliminating $R \propto L^{1/2}T_{\mathrm{eff}}^{-2}$ (Equation (52.29)) gives $T_{\mathrm{eff}}^{51} \propto M^7 L^{1/2}$, which is Equation (52.35) (algebra verified numerically, computed here).

The exponent $1/102$ is the result: as L changes a thousandfold, T_{eff} moves by $1000^{1/102} \approx 7$ per cent (computed here). The forbidden region follows because a star pushed cooler than this track would have to be superadiabatic throughout its convective envelope, which convection erases on a dynamical timescale (Theorem 52.10). The extreme steepness of the H^- opacity in T is what pins the wall in place. □

Proposition 52.19 organizes both ends of a star's life. A collapsing protostar becomes fully convective and *descends* the Hayashi line at nearly constant T_{eff} (the Hayashi phase), then, as its interior heats and turns radiative, peels off toward the main sequence — reaching it on the Kelvin–Helmholtz timescale Equation (52.5), which is why 3×10^7 yr is the right answer to a question Kelvin asked about the wrong energy source. After the main sequence, the sequence of Proposition 52.18 runs: the helium core contracts, hydrogen burns in a shell, the envelope expands and cools until it *meets* the Hayashi line, and the star, unable to cross it, is deflected upward along it — the red giant branch, at ever-growing radius and luminosity. Helium ignition follows (Proposition 52.16; as a flash below $\sim 2\,M_\odot$), then core helium burning, and then the double-shell asymptotic giant branch, whose thermal pulses alternately ignite the two shells and drive the dredge-up episodes that carry freshly synthesized material to the surface — the fact that Phenomenon 52.21 turns into proof of

nucleosynthesis in situ. Mass loss then strips the envelope (planetary nebula), leaving the carbon–oxygen white dwarf; stars above about $8\,M_\odot$ instead burn through Table 52.4 to core collapse. Both endpoints, and the remnants they leave, are Chapter 49; the detailed evolutionary calculations behind this narrative are [2196].

52.4 Stellar nucleosynthesis

52.4.1 The abundance record

Nucleosynthesis theory has one empirical target: the measured abundances of the elements, compiled from the solar photosphere, primitive meteorites and stellar spectra into a single curve by Suess and Urey [1098], with the modern solar photospheric revision by Asplund and collaborators [2140]. The light-element floor — hydrogen, helium, and the lithium plateau — is set earlier, by big-bang nucleosynthesis, and belongs to Chapter 48; everything above it is made in stars.

Phenomenon 52.20 (The cosmic abundance curve)**.** Element abundances measured in the solar photosphere, in primitive meteorites and in stellar spectra are not arbitrary: plotted against mass number they trace one reproducible curve with definite features [1098, 2140]. Abundance falls by some ten orders of magnitude from hydrogen to the heaviest nuclei, but the fall is interrupted by a pronounced maximum at the iron group near mass number 56; nuclei that are whole multiples of the alpha particle stand systematically above their neighbours; and beyond iron there are two distinct pairs of peaks, offset from one another. This curve is the empirical target of every theory of the origin of the elements, and it is against it that the processes of [1105] were defined.

Rests on Phenomenon 107.32 and Equation (107.66)*.*

Derivation. *Derives Phenomenon 52.20.*

The iron peak, the most conspicuous feature, follows from the binding energies alone. The binding energy per nucleon B/A rises steeply among the lightest nuclei, where surface effects and nucleon pairing dominate; reaches a broad maximum of about 8.8 MeV in the iron-nickel region, near $A = 56$ to 62; and then declines slowly as the Coulomb repulsion of the growing proton number takes over (Chapter 107). Fusing two nuclei releases energy exactly when it raises B/A, so a self-gravitating fusion reactor liberates energy while it burns toward the iron group and would have to absorb energy to proceed past it.

Two consequences follow, and both are visible in the curve. Material processed through successive burning stages piles up where the energy release stops, which is the iron peak. And elements beyond iron cannot be made by fusion in a star at all: they require neutron capture, which faces no Coulomb barrier and so proceeds at any temperature, followed by beta decay [1105]. Whether capture is slow or fast compared with the intervening beta decays selects a different path across the chart of nuclides, and the two paths stall at different closed neutron shells — which is why the peaks beyond iron come in offset pairs rather than singly. □

52.4.2 B^{2}FH and the eight processes

Burbidge, Burbidge, Fowler and Hoyle organized the synthesis of every nuclide into eight processes, each defined by the feature of Phenomenon 52.20 it exists to explain [1105]; Cameron's independent contemporaneous framework reached essentially the same taxonomy [1106]. Table 52.5 lists them with their modern identifications.

The neutron-capture split deserves its derivation, because the abundance curve records it directly. A nucleus exposed to a neutron flux captures at a rate $1/\tau_n$ set by the flux, and

Table 52.5: The processes of [1105], with the sites and products as identified today. The first four are the burning stages of Sections 52.2 and 52.2.4; the last four are the origin of everything beyond the iron peak and of the light elements.

Process	Mechanism and site	Principal products
H burning	pp chains and CNO cycle (Sections 52.2.2 and 52.2.3)	^{4}He, ^{14}N
He burning	triple-alpha and α captures (Section 52.2.4)	^{12}C, ^{16}O
α	advanced burning stages (Table 52.4)	^{20}Ne to ^{40}Ca
e	nuclear statistical equilibrium in silicon burning and supernovae	iron peak
s	slow neutron capture in AGB stars (Section 52.3.3)	heavy nuclides along the valley; peaks at $A \approx 88$, 138, 208
r	rapid neutron capture in explosive, neutron-rich events (Section 52.4.3)	neutron-rich heavies; peaks at $A \approx 80$, 130, 195; actinides
p	photodisintegration of heavy seeds in supernovae	rare proton-rich isotopes
x	light-element synthesis, left open in 1957; now cosmic-ray spallation (Phenomenon 115.16) and big-bang nucleosynthesis (Chapter 48)	Li, Be, B

beta-decays toward stability at a rate $1/\tau_\beta$. The two limits draw different paths across the chart of nuclides:

Slow ($\tau_n \gg \tau_\beta$): every unstable capture product decays before the next capture, so the path hugs the valley of beta stability. At the magic neutron numbers $N = 50$, 82, 126 (Theorem 107.52) the capture cross-sections drop sharply — a closed shell holds the next neutron only weakly — so material accumulates just *at* the magic nuclides of the valley: abundance peaks at $A \approx 88$, 138, 208. The site is the He-burning shells of AGB stars, where (α, n) reactions on ^{13}C and ^{22}Ne release the neutrons; Phenomenon 52.21 is the proof that this runs where the theory puts it.

Rapid ($\tau_n \ll \tau_\beta$): captures outrun decay and drive the material far to the neutron-rich side, until binding is so weak that photodisintegration balances capture. The path then climbs along *waiting points* at the same magic N — but on the neutron-rich side, where a given N is reached at *lower* A. When the flux ceases, the nuclei decay back to the valley at roughly constant A, leaving peaks shifted below the s-process peaks: $A \approx 80$, 130, 195. The twin offset peaks of Phenomenon 52.20 are therefore a direct spectrogram of the magic numbers, read twice at two neutron excesses — and the offset measures how far from stability the r-process ran.

The r-process demands an environment of extreme neutron density on a timescale of seconds. Burbidge, Burbidge, Fowler and Hoyle assigned it to supernovae; the one site now *observed* is the neutron-star merger of Section 52.4.3, with core-collapse supernovae remaining a possible contributor — an honest open fraction.

52.4.3 Direct evidence

The theory above is constrained by the abundance curve it reproduces, but two observations catch nucleosynthesis in the act.

Phenomenon 52.21 (Technetium in stellar atmospheres)**.** The absorption spectra of certain cool giants of spectral class S contain the lines of technetium [1006]. Technetium has no stable isotope, and the longest-lived of them has a half-life of about 4×10^6 years — three orders of magnitude shorter than the lifetime of the star, and four shorter than the age of the Galaxy. The element cannot have been present when the star formed, and there is no mechanism by which it could have been acquired from outside. It is therefore being manufactured in the interior now and carried to the surface: direct observational proof that nucleosynthesis happens inside stars, published five years before the systematic theory [1105].

Rests on Phenomenon 107.2 and Proposition 52.19.

Derivation. *Derives Phenomenon 52.21.*

Radioactive decay is exponential, $N(t) = N_0 2^{-t/t_{1/2}}$, so with $t_{1/2} = 4 \times 10^6$ years any technetium present when a star of age $t = 10^9$ years formed would by now have been reduced by the factor

$$2^{-t/t_{1/2}} = 2^{-250} \approx 10^{-75}\,.$$

This is not merely a small number: a solar mass holds about 10^{57} nucleons, so the surviving population would be less than one atom in the entire star. The observed lines cannot be a relic of the star's formation under any assumption about its initial composition.

Since the atmosphere is far too cool for nuclear reactions to run there, the technetium must be produced in the deep interior and transported outward on a timescale short compared with $t_{1/2}$. That requirement — a dredge-up operating within a few million years — is itself a constraint on the convective structure of evolved giants, and it is met by the thermal pulses of the asymptotic giant branch (Section 52.3.3). The observation therefore does double duty: it establishes in-situ synthesis and it dates the mixing. □

The r-process has its own caught-in-the-act moment, sixty-five years later. The binary neutron-star merger GW170817 (Section 47.4) was followed by a kilonova whose optical and infrared light curve decayed on the timescales of freshly synthesized radioactive heavy nuclei — the thermal glow of an r-process event of about 10^{-2} solar masses of ejecta, observed while it happened [2278]. Technetium in a giant's atmosphere and radioactive heavy elements in merger debris bracket the two neutron-capture processes of Table 52.5: both have now been watched running. On the longest timescales the same processes write galactic history — each stellar generation enriches the gas that forms the next, which is why the ancient halo stars are metal-poor while the young disc is metal-rich, the abundance–age correlation already read as evolutionary in [1105].

52.5 Solar neutrinos

52.5.1 The chlorine experiment and the solar-neutrino problem

Everything in Sections 52.1 and 52.2 rests on physics happening at the centre of a star, under 2×10^{16} Pa of overburden that no photon crosses in less than millennia (Section 52.1.3). The neutrinos of Table 52.2 are the one probe that leaves the core at the speed of light, and Davis built the detector: six hundred tonnes of perchloroethylene deep underground, counting individual argon atoms produced by $\nu_e + {}^{37}\mathrm{Cl} \to e^- + {}^{37}\mathrm{Ar}$ [1368]. The apparatus — installed 1478 m below ground in the Homestake mine — with its procedure and data is registered with the other oscillation experiments in Section 114.2.2; here the Sun's side of the story is told. The chlorine threshold of 0.814 MeV puts the dominant pp neutrinos out of reach: the measured rate is carried mainly by the rare ^{8}B branch of Table 52.2, with a minority from ^{7}Be — precisely the branches most sensitive to the model. Against Bahcall's contemporaneous standard-solar-model prediction [1365], Davis's first result was already low; twenty-five years of running settled the measured rate at 2.56 ± 0.23 SNU, one SNU being 10^{-36} captures per target atom per second, against a predicted 8.1 ± 1.2 (Table 114.4; [1950, 2072]) — a ratio of 0.32 ± 0.05, quoted.

Phenomenon 52.22 (The solar-neutrino deficit, and its resolution)**.** A radiochemical detector deep underground, counting the argon atoms produced by neutrino capture on chlorine, measured a solar electron-neutrino rate about one third of the standard solar model's prediction [1365, 1368]. Every later experiment confirmed a deficit, and it stood for three decades: either the Sun, or the model of it, or the neutrino was misunderstood. The resolution came from a detector sensitive to both the electron-flavour flux and the flavour-blind total. The total agreed with the solar model, while the electron-flavour fraction was depleted by just the observed factor [2021]. The Sun was right and the stellar model was right; the neutrinos change flavour in flight. What had looked for thirty years like a failure of astrophysics became a precision confirmation of it — and, incidentally, the discovery that neutrinos have mass (Chapter 103).

Rests on Equations (107.101) *and* (114.6)*, Proposition 52.14, and Phenomenon 52.25.*

Derivation. *Derives Phenomenon 52.22.*

Two quantitative points carried the thirty-year argument: why the deficit *could* be blamed on astrophysics for so long, and what measurement could not be so blamed.

The ^8B flux is a thermometer of vicious sensitivity. The branch is fed through $^3\mathrm{He} + {}^4\mathrm{He}$ (temperature exponent $\nu = 16.4$, Table 52.1), which builds the ^{7}Be supply, and drained through $p + {}^7\mathrm{Be}$ ($\nu = 13.0$); the competing destruction of ^{7}Be by electron capture is a weak process with almost no temperature dependence. At fixed density and composition the flux therefore responds with the *sum* of the two Gamow exponents, $\Phi({}^8\mathrm{B}) \propto T_\mathrm{c}^{29}$ or so (computed here; detailed solar-model perturbation studies, which let the structure readjust self-consistently, soften the exponent somewhat without changing what follows).

The lever is enormous: with that exponent, a central temperature just four per cent below the model's gives $0.96^{29} \approx 0.31$ (computed here) — the measured ratio. An error of one part in twenty-five in a fifteen-million-kelvin prediction was the entire "astrophysical solution", and no chlorine measurement could exclude it. It was excluded from two independent directions: the gallium detectors reached the pp neutrinos, whose flux is pinned by the solar luminosity itself (Equation (114.6), the bound of Phenomenon 114.3), and still saw a deficit; and helioseismology (Section 52.6.2) measured the sound speed — $c_s^2 \propto T/\mu$ — through the core to a few parts in a thousand, excluding a temperature error of that size by more than an order of magnitude.

The charged-current to neutral-current ratio is flavour-blind astrophysics-proof. On deuterium two channels are open (Section 114.4.4): the charged-current breakup $\nu_e + d \to p + p + e^-$, which only ν_e can drive at these energies, and the neutral-current breakup $\nu + d \to p + n + \nu$, whose amplitude is identical for ν_e, ν_μ and ν_τ because the Z couples to the three lepton doublets with one strength (Chapter 101). The neutral-current rate therefore measures the *total* active flux whatever the Sun does, the charged-current rate measures its electron-flavour part, and their ratio measures the surviving ν_e fraction with every solar uncertainty cancelling. SNO measured the ratio near one third while the neutral-current total matched the solar-model prediction within its uncertainty (Phenomenon 114.5, Table 114.6; [2021]): the missing electron neutrinos were arriving with the wrong flavour, not missing. The oscillation mechanism, the matter effect that shapes the energy dependence, and the parameter determinations belong to Chapters 103 and 114. □

52.5.2 Resolution: flavour transformation

What SNO delivered in 2002 was the comparison the derivation above calls for: in one target, during one exposure, the electron-flavour flux from the charged-current channel and the flavour-blind total from the neutral-current channel (Section 114.4.4). The electron fraction came out near one third; the total ^{8}B flux agreed with the standard solar model within the model's own sixteen per cent uncertainty (Table 114.2) [2021]. Read as stellar physics, that is a *precision confirmation* delivered by the most temperature-sensitive observable the Sun emits: the $T_c^{\sim 20}$ thermometer of Phenomenon 52.22 returned the model's central temperature to within a fraction of a per cent. The Sun was right; the neutrinos oscillate, with all that follows for particle physics developed in Chapter 103 and measured across Chapter 114.

52.5.3 Complete spectroscopy of solar fusion

The modern standard solar model — updated opacities, equation of state, and helioseismic calibration — is that of Bahcall, Serenelli and Basu [2072], whose predicted fluxes are Table 114.2. Borexino measured them: the pp, pep, ^{7}Be and ^{8}B branches separately and in real time [2297], and in 2020 the CNO neutrinos [2349] (Section 114.6.1, Table 114.11).

Phenomenon 52.23 (The Sun's energy budget audited reaction by reaction)**.** Real-time spectroscopy in an ultra-pure liquid scintillator has measured the neutrino fluxes of the individual branches of the pp chain separately [2297], and detected the neutrinos of the CNO cycle, which supplies about one per cent of the Sun's power [2349]. The nuclear energy generation rate reconstructed from those neutrinos agrees with the luminosity the Sun is observed to radiate in photons. The two are not measurements of the same thing at the same time: neutrinos leave the core immediately while photons diffuse out over some 10^5 years, so their agreement also says that the solar output has been steady across that interval.

Rests on Equation (107.104) *and Phenomenon 52.4.*

Derivation. *Derives Phenomenon 52.23.*

The total neutrino flux is fixed by the luminosity with essentially no model dependence, and that is the quantity these measurements check. The net effect of the pp chain, and equally of the CNO cycle, is

$$4\,{}^{1}\mathrm{H} \longrightarrow {}^{4}\mathrm{He} + 2e^{+} + 2\nu_{\mathrm{e}}\,,$$

releasing $Q = 26.73\,\mathrm{MeV}$ per helium nucleus formed (Equation (107.104)) and producing exactly two neutrinos. Each such reaction therefore contributes Q to the luminosity and two neutrinos to the flux, so at the Earth's distance d

$$\Phi_{\nu} = \frac{2L_{\odot}}{Q\,4\pi d^{2}}\,. \tag{52.36}$$

Numerically, with $Q = 26.73\,\mathrm{MeV} = 4.283 \times 10^{-12}\,\mathrm{J}$ and $d = 1.496 \times 10^{11}\,\mathrm{m}$,

$$\Phi_{\nu} = \frac{2 \times 3.828 \times 10^{26}\,\mathrm{W}}{4.283 \times 10^{-12}\,\mathrm{J} \times 4\pi\,(1.496 \times 10^{11}\,\mathrm{m})^{2}} \approx 6.4 \times 10^{14}/(\mathrm{m^{2}\,s})\,,$$

that is some 6×10^{10} per square centimetre per second — the statement made from the nuclear-physics side as Equation (107.105), and deployed as the luminosity constraint on every oscillation analysis in Equation (114.6).

Observe what went into this: the observed luminosity, the energy release of the net reaction, and the Earth–Sun distance. No opacity, no equation of state, no reaction rate, no central temperature. It is a slight overestimate, by a few per cent, because the neutrinos themselves carry away a small part of Q that never becomes light (the loss budget computed in Section 52.2.2). That the measured pp flux matches it is a check on the entire picture of hydrogen burning; the value of the branch-by-branch spectroscopy lies in what it adds beyond this bound — the *distribution* of the fusion rate among the branches, which does depend on the central temperature and the composition, and which is compared with the model term by term in Table 114.11. □

52.6 Helioseismology

52.6.1 The five-minute oscillations

In 1962 Leighton, Noyes and Simon, Doppler-imaging the photosphere, found its surface heaving: patches thousands of kilometres across oscillating vertically with periods clustered around five minutes [1234]. Ulrich proposed that these are not a surface phenomenon but standing *acoustic waves* — sound, trapped in a resonant cavity inside the Sun [1437] — and the proposal carried a sharp signature: trapped modes exist only on discrete ridges in the wavenumber–frequency plane. Deubner's observations resolved exactly those ridges [1543]. The mechanics is the acoustics of Chapters 28 and 31 on a stratified sphere, and the cavity can be exhibited with WKB tools (Chapter 9).

Proposition 52.24 (The p-mode cavity)**.** *Linear adiabatic acoustic waves of angular frequency ω and spherical-harmonic degree ℓ in a stratified star propagate where*

$$k_{r}^{2} = \frac{\omega^{2} - \omega_{\mathrm{ac}}^{2}}{c_{\mathrm{s}}^{2}} - \frac{\ell(\ell+1)}{r^{2}} > 0 \qquad (\omega \gg N)\,, \tag{52.37}$$

with c_{s} the sound speed (Section 31.10.1), N the buoyancy frequency Equation (52.20), and

$$\omega_{\mathrm{ac}} = \frac{c_{\mathrm{s}}}{2H} \tag{52.38}$$

the acoustic cutoff of the near-isothermal atmosphere, H its pressure scale height. A mode is trapped between the inner turning radius r_{t}, where $c_{\mathrm{s}}(r_{\mathrm{t}})/r_{\mathrm{t}} = \omega/\sqrt{\ell(\ell+1)}$, and the surface layer where $\omega < \omega_{\mathrm{ac}}$; the trapped frequencies satisfy

$$\int_{r_{\mathrm{t}}}^{R} k_r \,\mathrm{d}r = (n+\alpha)\pi\,, \tag{52.39}$$

n the radial order and α a slowly varying surface phase.

Rests on Equation (52.20) and Theorems 9.78, 31.12 and 31.22.

Proof. *Derives Proposition 52.24.*

The cutoff. In an isothermal atmosphere, $\rho_0 \propto \mathrm{e}^{-z/H}$ with constant c_{s} and H. Linearize continuity, momentum and the adiabatic condition about this background for vertical motion, neglect buoyancy ($\omega \gg N$), and eliminate all variables in favour of $\chi \equiv \delta p/\sqrt{\rho_0}$: the exponential factors cancel and the three equations collapse to

$$\frac{\mathrm{d}^2\chi}{\mathrm{d}z^2} + \frac{\omega^2 - \omega_{\mathrm{ac}}^2}{c_{\mathrm{s}}^2}\,\chi = 0\,, \qquad \omega_{\mathrm{ac}} = \frac{c_{\mathrm{s}}}{2H}\,,$$

the $\frac{1}{4H^2}$ arising as the square of the $\rho_0^{-1/2}$ gradient. Below ω_{ac} the wave is evanescent: the thinning atmosphere reflects it back down. With photospheric values $T_{\mathrm{eff}} = 5772\,\mathrm{K}$, $\mu \approx 1.25$, $g = 274\,\mathrm{m/s^2}$: $c_{\mathrm{s}} \approx 8.0\,\mathrm{km/s}$, $H = k_{\mathrm{B}}T/\mu m_{\mathrm{u}} g \approx 140\,\mathrm{km}$, so $\omega_{\mathrm{ac}}/2\pi \approx 5\,\mathrm{mHz}$ — a period near three and a half minutes (computed here). Waves of longer period, the five-minute band included, cannot escape: the photosphere is a mirror.

The turning point. In the interior, WKB with $\nabla_{\mathrm{h}}^2 Y_{\ell m} = -\ell(\ell+1)Y_{\ell m}/r^2$ gives the local dispersion relation $\omega^2 = c_{\mathrm{s}}^2(k_r^2 + k_{\mathrm{h}}^2)$ with $k_{\mathrm{h}}^2 = \ell(\ell+1)/r^2$, i.e. Equation (52.37) (the cutoff term matters only near the surface). Descending, c_{s} rises, refracting the ray horizontal: k_r vanishes where $c_{\mathrm{s}}/r = \omega/\sqrt{\ell(\ell+1)}$ and the wave turns back up. High-ℓ modes skim the envelope; low-ℓ modes plunge nearly to the centre — which is what makes the spectrum an interior probe at every depth.

Quantization. A wave trapped between two turning surfaces interferes constructively when its radial phase integral is an integer-plus-phase multiple of π (Theorem 9.78), which is Equation (52.39): at each n, a discrete curve $\omega_n(\ell)$ — precisely the observed ridges of [1543]. The observed power peaks near 3.3 mHz because the modes are driven stochastically by the granulation of the convection zone (Remark 52.11), which shakes hardest at those frequencies (quoted [2024]). □

52.6.2 The seismic Sun

Millions of mode frequencies $\omega_{n\ell}$ have been measured, many to relative accuracies of 10^{-5}. Through Equation (52.39) each is an integral of $1/c_{\mathrm{s}}$ along a different chord of the interior, and a sufficiently rich set of chords can be *inverted*.

Phenomenon 52.25 (The Sun rings, and its interior can be inverted)**.** The solar surface oscillates, with a velocity field whose power is concentrated near a period of five minutes [1234]. The oscillations are not a surface phenomenon but the superposition of millions of trapped acoustic eigenmodes of the whole star [1437], as the discrete ridges observed in the wavenumber–frequency plane confirmed [1543]. Inverting the measured mode frequencies yields the sound speed as a function of radius; it agrees with the standard solar model to a few parts in 10^3 throughout the radiative interior and locates the base of the convection zone [2024]. One discrepancy remains and is recorded here as unresolved: the inversions prefer the older, higher photospheric abundances to the downward-revised ones [2072, 2140].

Rests on Equation (52.39) and Proposition 52.24.

Derivation. *Derives Phenomenon 52.25.*

Away from the surface layers the cutoff term in Equation (52.37) is negligible, and Equation (52.39) becomes

$$\frac{(n+\alpha)\pi}{\omega} = \int_{r_t}^{R} \sqrt{\frac{1}{c_s^2} - \frac{1}{w^2 r^2}}\, \mathrm{d}r \equiv F(w)\,, \qquad w \equiv \frac{\omega}{\sqrt{\ell(\ell+1)}}\,. \tag{52.40}$$

The left side is data; the right side depends on (n, ℓ, ω) only through the single combination w. That millions of measured frequencies, spanning hundreds of ℓ values, collapse onto *one* function $F(w)$ is itself a sharp, parameter-free test of the acoustic-cavity picture, and the solar spectrum passes it (the collapse is known as the Duvall law; quoted [2024]).

The inversion is then classical. Let $a(r) = c_s/r$, monotonic in the region of interest, so that $1/c_s^2 = 1/(a^2 r^2)$ and the turning point is $a(r_t) = w$. Changing variable from r to a,

$$F(w) = \int_{a_s}^{w} \sqrt{\frac{1}{a^2} - \frac{1}{w^2}}\, G(a)\, \mathrm{d}a\,, \qquad G(a) = -\frac{\mathrm{d}\ln r}{\mathrm{d}a}\,,$$

with a_s the surface value. In the variables $x = w^{-2}$, $y = a^{-2}$ this is $\tilde{F}(x) = \int_x^{y_s} \sqrt{y-x}\, g(y)\, \mathrm{d}y$ with $g \geq 0$, and differentiating once,

$$\tilde{F}'(x) = -\frac{1}{2}\int_x^{y_s} \frac{g(y)}{\sqrt{y-x}}\, \mathrm{d}y\,,$$

an integral equation of Abel type. Its classical solution is

$$g(y) = \frac{2}{\pi}\frac{\mathrm{d}}{\mathrm{d}y}\int_y^{y_s} \frac{-\tilde{F}'(x)}{\sqrt{x-y}}\, \mathrm{d}x\,, \tag{52.41}$$

verified by substituting back, exchanging the order of integration, and using $\int_y^x \mathrm{d}u/\sqrt{(x-u)(u-y)} = \pi$. Integrating G recovers $r(a)$ by a quadrature, hence $a(r)$, hence $c_s(r)$: *the sound speed at every radius, from the mode frequencies alone*, the surface phase $\alpha(\omega)$ being fitted along the way — the honest caveat of the method, confined to the layers every mode shares.

What the inversion returns [2024] (quoted): a sound-speed profile agreeing with the standard solar model to a few parts in a thousand at every radius outside the innermost few per cent; the base of the convection zone — visible as the kink where the stratification leaves the adiabat of Theorem 52.10 — at $r = 0.713\,R_\odot$; the envelope helium abundance, read from the Γ_1 depression in the helium ionization zone; and, from the rotational splitting of the modes, the internal rotation — differential through the convection zone, near-rigid beneath, with the shear concentrated in a thin tachocline at the interface, the presumptive seat of the solar dynamo (Chapter 66). Since $c_s^2 \propto T/\mu$, the profile pins the central temperature at the sub-per-cent level, which is what closed the astrophysical escape route in Phenomenon 52.22: the Sun's interior has been measured twice — acoustically and in neutrinos — and the two channels agree with each other and with the model. The one standing tension, between the seismic profile and the revised photospheric abundances [2072, 2140], is recorded in the phenomenon above as unresolved. □

Chapter 53

Experiment: The Classical Tests of General Relativity

Chapter 42 states the classical tests of general relativity as phenomena, and Chapter 44 supplies the field equations from which they follow. Neither shows the measuring. That is the gap this chapter closes: the book has been asserting for five chapters that Mercury's perihelion advances by some 43 seconds of arc per century, that starlight grazing the Sun bends by 1.75 seconds of arc, that a clock at the top of a tower runs fast, and that a radar echo is delayed by passing the Sun — without once exhibiting the apparatus, the raw numbers or the error budget that make those statements evidence rather than doctrine.

Six experiments are reported. They are not six tests of one prediction: they probe logically separable pieces of the theory, and the separation is the point. The redshift measurement and the free-fall null tests constrain the equivalence principle alone, and would be passed by any metric theory of gravity whatever; the light deflection and the radar delay measure the curvature of space, which is where a metric theory first parts company with Newtonian gravity dressed in geometry; the perihelion advance is the first quantity that tests the field equations themselves; and the gyroscope precessions test the behaviour of a locally inertial frame carried through a curved and rotating spacetime. The experiments also span an unusually wide range of evidential quality, from a single photographic campaign of 1919 whose plate selection is still argued over, to a satellite null test at parts in 10^{15}. Both are reported here at their true weight.

53.1 Le Verrier and the perihelion of Mercury (1859)

Tests Phenomenon 53.1.

This is the oldest of the classical tests and the only one whose anomaly was established before the theory that explains it. Its apparatus is not an instrument but an archive: a century and a half of positional astronomy, reduced by the perturbation theory of Chapter 27 until nothing but a residue remained.

53.1.1 Apparatus

Meridian circles and transit instruments of the great European observatories, and above all the record of the transits of Mercury across the solar disc. A transit fixes the instant at which the planet crosses the limb of the Sun to within seconds of time, and therefore constrains the longitude of Mercury's node and perihelion far more sharply than a meridian observation of a small object seen in twilight close to the Sun. Le Verrier's material was the accumulated series of such transits from the end of the seventeenth century to his own day, together with the ordinary meridian observations of the planet [151]. The analytical half

of the apparatus was the theory of secular perturbations: Lagrange's planetary equations integrated for the perturbations of Mercury by Venus, the Earth, Mars, Jupiter and Saturn.

53.1.2 Procedure

An osculating Keplerian ellipse is fitted to the observations; the computed gravitational perturbations of the other planets are applied; and the observed motion of the perihelion is then compared with the computed one. The comparison must be made in a well-defined reference direction, and the conventional one — the equinox — is itself moving, so the largest term in the budget is not gravitational at all but the general precession of the equinoxes. The procedure is thus a subtraction of three large and well-understood quantities from one large observed quantity, in the hope that the remainder is either zero or interesting. Le Verrier found it was not zero.

53.1.3 Observations and data

The perihelion budget, in the modern determination, stands as follows. All entries are rates in seconds of arc per Julian century, referred to the moving equinox.

Table 53.1: The perihelion budget of Mercury, in seconds of arc per Julian century. The first three lines are observation and Newtonian celestial mechanics; the residual on the fourth line is what Le Verrier isolated in 1859, and the fifth is what general relativity supplies with no adjustable parameter.

Contribution	Rate
Observed advance of the perihelion	5600
General precession of the equinoxes	−5025
Perturbations by the other planets	−531
Unexplained residual	43
General relativity, Equation (53.1)	42.98

Le Verrier's own residual was smaller, near 38 seconds of arc per century; the value settled near 43 only after Newcomb's re-reduction of the observations and the improved planetary masses of the later nineteenth century [267]. Nothing in this chapter turns on the difference: the two agree that a residual exists, of the order of tens of seconds of arc per century, and that it is many times the uncertainty of the observations.

Phenomenon 53.1 (Measured anomalous advance of Mercury's perihelion)**.** After the precession of the equinoxes and every Newtonian planetary perturbation have been computed and subtracted, the perihelion of Mercury still advances in the direction of the orbital motion at a rate of about 43 seconds of arc per century. The residual was isolated by Le Verrier in 1859 and no distribution of matter consistent with the rest of solar-system astronomy was ever found to account for it [151]. General relativity predicts, for a bound orbit of semi-major axis a and eccentricity e about a mass M, an advance of

$$\Delta\varphi = \frac{6\pi GM}{c^2 a\,(1-e^2)} \tag{53.1}$$

per revolution, with no adjustable parameter [428]; for Mercury this is 42.98 seconds of arc per century.

Rests on Postulate 43.1 and Proposition 45.8.

Derivation. *Derives Phenomenon 53.1.*

Take from Chapter 45 the orbit equation of a timelike geodesic of the Schwarzschild field in the equatorial plane, written for the inverse radius $u = 1/r$ with $h = r^2\,\mathrm{d}\varphi/\mathrm{d}\tau$ the conserved specific angular momentum:

$$\frac{\mathrm{d}^2u}{\mathrm{d}\varphi^2} + u = \frac{GM}{h^2} + \frac{3GM}{c^2}\,u^2 \,. \tag{53.2}$$

The final term is the whole of the relativistic correction. Its ratio to the term on the left is $3h^2u^2/c^2$, of order v^2/c^2 and so of order 10^{-7} for Mercury; it may therefore be treated as a perturbation.

Dropping it leaves the Newtonian conic of Chapter 27,

$$u_0 = \frac{GM}{h^2}\left(1 + e\cos\varphi\right) ,$$

a closed ellipse whose perihelion does not move. Substituting u_0 into the perturbing term gives

$$\frac{3GM}{c^2}u_0^2 = \frac{3G^3M^3}{c^2h^4}\left(1 + 2e\cos\varphi + e^2\cos^2\varphi\right) .$$

The constant piece and the piece in $\cos 2\varphi$ hidden in $\cos^2\varphi$ drive the oscillator off resonance and produce only bounded corrections to the shape of the orbit. The piece in $\cos\varphi$ drives it *at* its own frequency, and it is this term alone that accumulates. Solving

$$\frac{\mathrm{d}^2u_1}{\mathrm{d}\varphi^2} + u_1 = \frac{6G^3M^3e}{c^2h^4}\cos\varphi \qquad \text{gives} \qquad u_1 = \frac{3G^3M^3e}{c^2h^4}\,\varphi\sin\varphi \,,$$

so that to first order

$$u \simeq \frac{GM}{h^2}\left[1 + e\cos\varphi + e\,\delta\,\varphi\sin\varphi\right] \simeq \frac{GM}{h^2}\left[1 + e\cos((1-\delta)\,\varphi)\right] , \qquad \delta := \frac{3G^2M^2}{c^2h^2} ,$$

the last step using $\cos\left((1-\delta)\,\varphi\right) \simeq \cos\varphi + \delta\varphi\sin\varphi$, valid because $\delta\varphi \ll 1$ over a single revolution. The radius therefore returns to its minimum not after 2π but after $\varphi = 2\pi/\left(1-\delta\right) \simeq 2\pi\left(1+\delta\right)$, and the perihelion advances by

$$\Delta\varphi = 2\pi\delta = \frac{6\pi G^2M^2}{c^2h^2}$$

per revolution. Eliminating h with the Newtonian relation $h^2 = GMa\left(1-e^2\right)$ yields Equation (53.1).

Inserting $GM_\odot = 1.327\,12 \times 10^{20}\,\mathrm{m^3/s^2}$, $a = 5.7909 \times 10^{10}\,\mathrm{m}$ and $e = 0.205\,63$ gives $\Delta\varphi = 5.02 \times 10^{-7}$ in radian measure per revolution. Mercury's period is 87.969 days, so it completes 415.2 revolutions in a Julian century, and the accumulated advance is 2.084×10^{-4} radian, that is 42.98 seconds of arc per century — the fifth line of Table 53.1. □

53.1.4 Interpretation

Two things must be said plainly. The first is that this is a *postdiction*: the number was known for fifty-six years before the theory that produced it, and Einstein computed it in November 1915 knowing what he had to match [428]. The second is that this costs the result almost nothing, for the reason set out in Chapter 1: Equation (53.1) contains no free parameter that could have been tuned. The theory was not built to fit 43 seconds of arc; the field equations were fixed by general covariance and the Newtonian limit, and the orbit followed. A postdiction with no adjustable parameter carries the evidential weight of a prediction, and it is a fair test precisely because the alternatives on offer were all parametric

— an intramercurial planet of adjustable mass, a solar oblateness of adjustable size, a force law $r^{-(2+\epsilon)}$ with adjustable ϵ — and each of them, tuned to fit Mercury, then contradicted the other planets or the observed shape of the Sun.

The same effect has since been measured far outside the solar system. The star S2 orbiting the compact object at the Galactic centre shows a Schwarzschild precession of its orbit, detected by near-infrared interferometry and consistent with Equation (53.1) at a gravitational potential some four orders of magnitude deeper than Mercury's [2347]; that measurement and its instrument belong to Chapter 50.

53.1.5 Primary references

[151] for the anomaly, [428] for the computation that accounts for it, and [2347] for the Galactic-centre analogue. The modern budget of Table 53.1 is the standard one summarized by [2240]; the numbers on its first three lines are quoted at second hand and rounded, and only the last line is computed here.

53.2 Dyson, Eddington and Davidson: the eclipse of 1919

Tests Phenomenon 53.2.

Light deflection is the first of the classical tests in which the prediction preceded the measurement, and the first that distinguishes general relativity from a theory in which gravity acts on light through the equivalence principle alone. The factor separating them is exactly two, which is what makes a photographic measurement of moderate precision decisive.

53.2.1 Apparatus

Two expeditions of the Greenwich Observatory, to Sobral in northern Brazil and to the island of Príncipe in the Gulf of Guinea [465]. Both used photographic refractors fed by coelostat mirrors, since the instruments had to be shipped and set up in the field and could not be pointed at the Sun directly:

- at Sobral, an astrographic objective of 33 cm aperture and 3.4 m focal length, and beside it a smaller lens of 10 cm aperture and 5.8 m focal length;
- at Príncipe, a second astrographic objective of the same 33 cm pattern.

The original report quotes apertures in inches and focal lengths in feet; they are converted here per the unit axiom of Chapter 2. Detection is photographic, on glass plates measured afterwards on a screw micrometer at Greenwich.

53.2.2 Procedure

During totality the star field surrounding the eclipsed Sun is photographed. The same field is photographed again from the same instrument at another epoch — months earlier or later, at night, when the Sun is elsewhere in the sky — to give an undeflected reference. The two plates are then compared star by star. What is sought is a systematic *radial* displacement of each star away from the centre of the Sun, falling off as the reciprocal of the angular distance from it.

The difficulty is that a plate scale which changed between the two epochs would mimic exactly that pattern for a field of limited extent. The reduction therefore solves simultaneously for the scale, the orientation, the plate centre and the deflection constant, and it is the availability of stars at a range of distances from the limb, whose predicted

deflections differ, that separates the deflection from the scale. The eclipse of 29 May 1919 was chosen years in advance for two reasons: its totality was among the longest of the century, and the Sun stood in front of the Hyades, so that an unusually rich field of bright stars surrounded it.

53.2.3 Observations and data

The competing predictions for a ray grazing the solar limb are 1.75 seconds of arc from the full theory and 0.87 from the equivalence principle alone; zero is the third possibility, if light does not fall. The measured deflections, reduced to the value at the limb, were

Table 53.2: Deflection at the solar limb from the two 1919 stations, in seconds of arc, with the uncertainties as quoted by the authors. The Sobral astrographic plates were set aside in the original reduction; see the text.

Instrument	Deflection at the limb
Sobral, 10 cm lens	1.98 ± 0.12
Príncipe, astrographic	1.61 ± 0.30
Sobral, astrographic (set aside)	0.93
General relativity	1.75
Equivalence principle alone	0.87

The Sobral astrographic plates were rejected in the original reduction on an instrumental ground stated at the time: the coelostat mirror serving that telescope had changed figure in the heat of the day, and the star images on the eclipse plates were visibly out of focus, so that the plate scale could not be transferred reliably from the comparison epoch [465].

Phenomenon 53.2 (Measured deflection of starlight at the solar limb)**.** Starlight passing close to the Sun is deflected toward it, so that stars seen near the eclipsed limb are displaced radially outward. The two accepted 1919 determinations bracket the general-relativistic value of 1.75 seconds of arc and both exclude the value 0.87 obtained from the equivalence principle alone [465]. For an impact parameter b with $b \gg GM/c^2$ the theory gives

$$\Delta\vartheta = \frac{4GM}{c^2 b}\,. \tag{53.3}$$

Very-long-baseline radio interferometry on quasars now confirms Equation (53.3) at the level of one part in 10^4 [1903, 2145][2240], and the same bending on galactic and cluster scales produces the multiple images of gravitational lenses, of which the twin quasar 0957+561 was the first identified [1645].

Rests on Postulate 43.1 and Proposition 45.8.

Derivation. *Derives Phenomenon 53.2.*

For a null geodesic the constant term on the right of Equation (53.2) is absent — it came from the rest mass — and the orbit equation of Chapter 45 reduces to

$$\frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2} + u = \frac{3GM}{c^2}\,u^2\,.$$

With the right-hand side dropped the solution is a straight line passing at perpendicular distance b from the centre,

$$u_0 = \frac{\sin\varphi}{b}\,,$$

which indeed gives $r\sin\varphi = b$. Substituting u_0 into the right-hand side,

$$\frac{\mathrm{d}^2 u_1}{\mathrm{d}\varphi^2} + u_1 = \frac{3GM}{c^2 b^2}\sin^2\varphi = \frac{3GM}{2c^2 b^2}\,(1 - \cos 2\varphi)\,,$$

whose particular solution is

$$u_1 = \frac{3GM}{2c^2b^2}\left(1 + \tfrac{1}{3}\cos 2\varphi\right) .$$

Nothing here is resonant, and the correction stays bounded; what it does is move the asymptotes. The ray comes from infinity and returns to it where $u = 0$. Near $\varphi = 0$ the equation $u = 0$ reads

$$\frac{\varphi}{b} + \frac{3GM}{2c^2b^2}\cdot\frac{4}{3} = 0 \qquad \Longrightarrow \qquad \varphi = -\frac{2GM}{c^2b} ,$$

and near $\varphi = \pi$, writing $\varphi = \pi + \epsilon$ and using $\sin(\pi + \epsilon) \simeq -\epsilon$, it reads $\epsilon = +2GM/(c^2b)$. The total angle swept between the two asymptotes therefore exceeds π by

$$\Delta\vartheta = \frac{4GM}{c^2b} ,$$

which is Equation (53.3). Half of this comes from the Newtonian-like attraction that the equivalence principle already supplies; the other half comes from the term in u^2, that is from the curvature of space, and it is the half that the 1919 plates were looking for. Numerically, with $GM_\odot = 1.327\,12 \times 10^{20}\,\mathrm{m^3/s^2}$ and $b = R_\odot = 6.957 \times 10^8\,\mathrm{m}$, one finds $\Delta\vartheta = 8.49 \times 10^{-6}$ in radian measure, or 1.751 seconds of arc. □

53.2.4 Interpretation

The logic of the result is not that either station measured 1.75 accurately — neither did, and the quoted uncertainties are large — but that the two accepted determinations lie on opposite sides of 1.75 and that both lie many quoted uncertainties above 0.87. The experiment was designed to separate two hypotheses differing by a factor of two, and it separated them.

The rejection of the Sobral astrographic plates has been argued over ever since, and honesty requires that the argument be reported rather than settled here. The case against the rejection is that a value of 0.93 is close to the half-deflection, that the rejection was decided by people who expected the full value, and that the surviving Príncipe result rests on two usable plates. The case for it is that the defocusing of those plates was an instrumental fact recorded at the time and independent of what they showed, and that later re-measurements of the same Sobral astrographic plates with modern machines returned values consistent with the full deflection [1640] — which is the decisive point, because it means the rejection, whatever its statistical propriety, did not bias the conclusion. What settles the matter beyond argument is not the 1919 plates at all but the radio interferometry of the past four decades, which measures the same deflection with a precision four orders of magnitude better and finds Equation (53.3) [1903, 2145][2240].

53.2.5 Primary references

[465] for the expeditions and their reduction; [371] for the half-deflection and [428] for the full value; [1645] for the first gravitational lens; [2240] for the modern radio limits, quoted at second hand.

53.3 Pound, Rebka and Snider: redshift in a tower (1960–1965)

Tests Phenomenon 53.3.

The gravitational redshift is the one classical test that can be done indoors. It is also the one that tests the least: it follows from the equivalence principle and energy conservation alone, as the derivation in Chapter 42 shows, and no field equation enters. That is precisely why it is worth doing — it isolates the assumption on which everything geometric rests.

53.3.1 Apparatus

The tower of the Jefferson Physical Laboratory at Harvard, giving a height difference of 22.5 m between source and absorber. The clock is a nucleus. A source of ^{57}Co decays to ^{57}Fe, which emits a gamma ray of 14.4 keV; the same transition in a foil of iron enriched in ^{57}Fe absorbs it resonantly. Both source and absorber are bound in a crystal lattice, so that a large fraction of the emissions and absorptions are recoil-free in the sense of Mössbauer [1154] and the line retains its natural width: the excited state of ^{57}Fe has a mean life of about 141 ns, corresponding to a fractional linewidth of about 3×10^{-13}. A proportional counter behind the absorber records the transmitted intensity. The gamma path runs inside a mylar tube filled with helium, to keep absorption in air from destroying the count rate over 22.5 m, and the source is mounted on a magnetic transducer — in effect a loudspeaker cone — which moves it sinusoidally so as to impose a known first-order Doppler shift [1189, 1321].

53.3.2 Procedure

The quantity to be detected is a fractional frequency shift of gH/c^2, which for 22.5 m is 2.46×10^{-15}: some two orders of magnitude smaller than the natural width of the line being used to measure it. It is detected as a small asymmetry in the transmitted intensity between the two halves of the transducer cycle, and calibrated by the transducer velocity itself: the velocity needed to cancel the gravitational shift is $v = c\,\Delta\nu/\nu \simeq 0.74\,\mu\text{m/s}$.

The essential trick is a reversal. The whole measurement is performed once with the source at the bottom and the absorber at the top, and once the other way round. The gravitational shift changes sign; almost every systematic error does not. Differencing the two configurations therefore doubles the signal and cancels, to first order, every constant difference between the two nuclear environments — lattice chemistry, hyperfine fields, sample impurities, counter drift. What survives the reversal is a genuine dependence on the direction of propagation in the gravitational field.

One systematic error is not cancelled by the reversal, because it depends on the temperatures of the two samples rather than on their positions: the second-order Doppler shift produced by the thermal vibration of the emitting and absorbing nuclei in their lattices. Its size is derived below. It is comparable to the entire effect for a temperature difference of one kelvin, and the control of source and absorber temperatures is in practice the limiting art of the experiment.

53.3.3 Observations and data

Phenomenon 53.3 (Gravitational shift of gamma rays over a tower)**.** A 14.4 keV gamma ray propagating upward through a height $H = 22.5$ m in the Earth's field is received with its frequency lowered by the fraction $gH/c^2 = 2.46 \times 10^{-15}$, and a downward ray is received with its frequency raised by the same fraction. The 1960 measurement gave a ratio of observed to predicted shift of 1.05 ± 0.10 [1189], and the 1965 repetition with longer integration and improved control of the sample temperatures gave 0.9990 ± 0.0076 [1321].

Rests on Definition 42.2 and Phenomena 38.13 and 42.5.

The derivation of gH/c^2 itself is given in Chapter 42 and is not repeated here. What is derived instead is the systematic that limits the measurement, because it is what decides

whether the number above can be believed.

Derivation. *Derives Phenomenon 53.3.*

A nucleus bound in a lattice at temperature T is not at rest: it vibrates, and although its mean velocity vanishes its mean square velocity does not. A moving emitter is seen, to second order in v/c, with its frequency lowered by the time-dilation factor of Chapter 38,

$$\frac{\Delta\nu}{\nu} = -\frac{\langle v^2 \rangle}{2c^2} \,.$$

The sign is independent of the direction of the motion, which is why this shift does not average away over a vibration cycle and why it does not reverse when the apparatus is turned upside down. In the classical regime, equipartition over the three vibrational degrees of freedom of a nucleus of mass M gives $\frac{1}{2}M\langle v^2 \rangle = \frac{3}{2}k_{\mathrm{B}}T$, hence

$$\frac{\Delta\nu}{\nu} = -\frac{3k_{\mathrm{B}}T}{2Mc^2} \,, \qquad \frac{\mathrm{d}}{\mathrm{d}T}\left(\frac{\Delta\nu}{\nu}\right) = -\frac{3k_{\mathrm{B}}}{2Mc^2} \,. \tag{53.4}$$

For ^{57}Fe, $M = 9.46 \times 10^{-26}\,\mathrm{kg}$, and the coefficient is $-2.4 \times 10^{-15}/\mathrm{K}$.

That number is the point of the derivation. It is essentially equal to the entire gravitational effect of Phenomenon 53.3, so a systematic temperature difference of one kelvin between source and absorber would mimic or cancel the shift completely. Holding the error from this source below the one per cent finally quoted therefore requires the two samples to agree in temperature to about 10 mK, since $0.01 \times 2.46 \times 10^{-15}$ divided by the coefficient above is 1.0×10^{-2} kelvin. It is also why the effect survives the reversal test: heating one end of the tower does not care which way the gamma ray is travelling. The measurement is in this sense a thermometry experiment as much as a gravitational one. □

53.3.4 Interpretation

The redshift exists, has the predicted sign, and has the predicted size to one per cent. Because the derivation of gH/c^2 uses only the equivalence principle, kinematics and energy conservation, this result does not test the field equations at all; it tests the assumption that a local laboratory in free fall is indistinguishable from an inertial one, which is the assumption that licenses describing gravity as geometry in the first place. A theory that failed here would not need repairing but abandoning.

The measurement has been superseded many times over and always in the same direction. A hydrogen maser flown on a suborbital rocket verified the shift at the level of 7×10^{-5} [1660]; optical clocks now resolve it over height differences of less than a metre [2154] and, more recently, across a millimetre-scale atomic sample [2401]; and the same shift has been detected in the spectrum of the star S2 as it passes its closest approach to the Galactic-centre black hole [2295]. The satellite-navigation clock budget of Chapter 42 is the same effect run continuously as an engineering necessity, and the flown caesium clocks of Chapter 41 measure it summed with the kinematic dilation.

53.3.5 Primary references

[1189, 1321]; the recoil-free emission that makes the measurement possible is [1154]. The later and more precise measurements quoted in the interpretation are [1660, 2154, 2295, 2401].

53.4 Shapiro: the radar time delay (1964–2003)

Tests Phenomenon 53.4.

The fourth classical test was not available to Einstein: it requires a transmitter powerful enough to get an echo back from another planet. Shapiro pointed out in 1964 that a radar pulse whose path passes close to the Sun takes measurably longer to return than the same geometric path taken far from it [1296], and the experiment became possible within four years.

53.4.1 Apparatus

For the first measurements, planetary radar: the Haystack antenna, a steerable dish of about 37 m aperture working in the centimetre band, and the 305 m fixed reflector at Arecibo at metre wavelength, transmitting coded pulse trains at Mercury and Venus and receiving the echo some minutes later [1382]. The timing reference is an atomic frequency standard; the range model is a numerical ephemeris of the solar system.

Later measurements replace the passive planet with a spacecraft transponder, which returns a far stronger and better-defined signal: the Viking landers on Mars, ranged to over several superior conjunctions [1644], and finally the Cassini spacecraft on its cruise to Saturn, whose radio link was operated simultaneously at two uplink and three downlink frequencies [2046].

53.4.2 Procedure

Range to the target as a function of time through a superior conjunction, when the line of sight passes close to the Sun, and compare the observed round-trip delay with the delay computed from the ephemeris in flat spacetime. The excess grows logarithmically as the ray approaches the limb, peaking at conjunction, and this characteristic shape is what identifies it: it is not degenerate with an error in the planetary distance, which varies on the orbital timescale rather than with the impact parameter.

Two systematics dominate. The first is the solar corona, whose plasma delays a radio signal by an amount proportional to the inverse square of the frequency, and which is both large and variable precisely where the relativistic effect is largest. The first-generation experiments had to model it; the Cassini experiment instead cancelled it, by running the link at several widely separated frequencies and using the known dispersion of a plasma to solve the plasma delay away — which is why Cassini improved on Viking by two orders of magnitude. The second is the topography and rotation of a planetary target, which the spacecraft transponder experiments remove by construction.

53.4.3 Observations and data

Phenomenon 53.4 (Excess delay of a radar echo passing the Sun)**.** A signal travelling between two points at radii r_1 and r_2 from the Sun, past a closest approach b with $b \ll r_1, r_2$, takes longer than the same path in flat spacetime by

$$\Delta t = \frac{4GM}{c^3} \ln\!\left(\frac{4r_1 r_2}{b^2}\right) \tag{53.5}$$

for the round trip. For an Earth–Venus circuit grazing the solar limb this is of order 200 µs. The effect was proposed as a fourth test in 1964 [1296] and detected in radar echoes from Mercury and Venus within a few years, in agreement with the prediction at the level of tens of per cent [1382]; ranging to the Viking landers confirmed it to about one part in 10^3 [1644]; and the Cassini radio link, which measures the post-Newtonian parameter γ entering Equation (53.5) through an overall factor $(1+\gamma)/2$, gave $\gamma - 1 = (2.1 \pm 2.3) \times 10^{-5}$ [2046].

Rests on Postulate 43.1 and Proposition 45.14.

Derivation. *Derives Phenomenon 53.4.*

Write the Schwarzschild metric of Chapter 45 in isotropic coordinates and keep only first order in $GM/\left(c^2 r\right)$:

$$\mathrm{d}s^2 = -\left(1 - \frac{2GM}{c^2 r}\right) c^2\,\mathrm{d}t^2 + \left(1 + \frac{2GM}{c^2 r}\right)\left(\mathrm{d}x^2 + \mathrm{d}y^2 + \mathrm{d}z^2\right) .$$

Isotropic coordinates are the right choice here because their spatial part is conformally flat, so that a coordinate straight line is the unperturbed ray and the whole effect appears in one place. Setting $\mathrm{d}s^2 = 0$ for a light ray and writing $\mathrm{d}l$ for the Euclidean coordinate length element,

$$c\,\mathrm{d}t = \mathrm{d}l\,\frac{\left(1 + GM/c^2 r\right)}{\left(1 - GM/c^2 r\right)} \simeq \mathrm{d}l\left(1 + \frac{2GM}{c^2 r}\right) .$$

The coordinate speed of light is less than c in the presence of the mass, and equally so in every direction; the factor two is one part time dilation and one part spatial curvature, exactly as in Equation (53.3).

Integrate along the unperturbed straight line, measuring l from the point of closest approach, so that $r = \sqrt{b^2 + l^2}$. The excess over the flat-space time $\mathrm{d}l/c$ is, one way,

$$\Delta t_1 = \frac{2GM}{c^3}\int_{-l_1}^{l_2} \frac{\mathrm{d}l}{\sqrt{b^2 + l^2}} = \frac{2GM}{c^3}\left[\operatorname{arcsinh}\frac{l_1}{b} + \operatorname{arcsinh}\frac{l_2}{b}\right] .$$

For $b \ll l_i$ one has $\operatorname{arcsinh}\left(l/b\right) \simeq \ln\left(2l/b\right)$ and $l_i \simeq r_i$, so the bracket is $\ln\left(4r_1 r_2/b^2\right)$; doubling for the return trip gives Equation (53.5).

Numerically, $4GM_\odot/c^3 = 1.97\times10^{-5}\,\mathrm{s}$. For a circuit from the Earth at $r_1 = 1.496\times10^{11}\,\mathrm{m}$ to Venus at $r_2 = 1.082\times10^{11}\,\mathrm{m}$ grazing the limb at $b = 6.96\times10^{8}\,\mathrm{m}$, the logarithm is 11.8 and $\Delta t = 2.3\times10^{-4}\,\mathrm{s}$. Note how weakly the answer depends on the geometry: halving the impact parameter adds only $2.7\times10^{-5}\,\mathrm{s}$, which is why the measurement needs a well-sampled conjunction rather than a single well-placed shot. □

53.4.4 Interpretation

The radar delay is the sharpest of the classical tests, and it is sharp for an unglamorous reason: it measures a time, and time is the quantity physics measures best. The Cassini bound $\gamma - 1 = (2.1 \pm 2.3)\times10^{-5}$ [2046] is the tightest constraint in the solar system on any metric theory of gravity, and every proposed alternative to general relativity must survive it before anything else is discussed. It is worth noticing what the delay and the deflection have in common: both are governed by the same coefficient γ, and both would be exactly half their observed size if space were flat and only time were curved. The two experiments are, at post-Newtonian order, measurements of the same number by entirely different means — one photographic and angular, one electronic and temporal — agreeing to the precision of the weaker.

The same delay appears wherever a signal passes a mass, and it has become a workaday astrophysical tool rather than a test: the Shapiro delay in the timing of a pulsar whose companion passes in front of it is now one of the standard ways of weighing a neutron star, as Chapter 49 describes [2155].

53.5 The Eötvös lineage and MICROSCOPE (1922–2022)

Tests Phenomenon 53.5.

The universality of free fall is the foundation the whole geometric description rests on, and it is the only one of these tests that is a *null* experiment: what is measured is the absence of a differential acceleration, and the result is a bound. The bound has been driven down by six orders of magnitude in a century, by instruments that have almost nothing in common except the quantity they report.

53.5.1 Apparatus

Two families of instrument, both comparing the free fall of two bodies of different composition.

The torsion balance, in the lineage that descends from the Cavendish instrument of Chapter 33. A horizontal beam is suspended by a fine wire with test bodies of different materials at its ends; a composition-dependent horizontal force appears as a torque about the fibre and is read by an optical lever or autocollimator. In the Eötvös–Pekár–Fekete instrument, operated from 1906 to 1909 and published only in 1922, a beam some tens of centimetres long hung from a platinum-iridium wire inside a triple thermal enclosure, and platinum was compared against copper, water, asbestos, tallow and a magnesium-aluminium alloy among others [486]. In the modern Eöt-Wash instrument the whole balance sits on a slowly and continuously rotating turntable, and the test bodies are beryllium and titanium [2135].

The orbiting differential accelerometer. The MICROSCOPE satellite carried two differential electrostatic accelerometers in a sun-synchronous orbit at about 710 km. Each held two coaxial hollow cylindrical test masses whose centres were made to coincide; electrodes around each mass sensed its displacement and applied the electrostatic force needed to hold it centred, and that force is the measurement. One accelerometer held masses of two different alloys — a platinum-rhodium alloy against a titanium alloy — and the other held two masses of the same platinum-rhodium alloy, serving as a null reference that should show no signal whatever [2289, 2409].

53.5.2 Procedure

In both families the measured quantity is the Eötvös parameter

$$\eta_{AB} := \frac{2\,(a_A - a_B)}{a_A + a_B}\,, \tag{53.6}$$

and in both the art is to modulate it. A null experiment cannot be done by measuring once, because everything that is not the signal is also a constant: the signal must be made to vary in a known way while the instrument does not.

In the terrestrial torsion balance the modulation is geometric. The attractor is the Earth, or the Sun, or the Galaxy; the source direction rotates with respect to the instrument as the Earth turns, so a violation appears as a torque varying with a diurnal or annual period. Eötvös modulated by hand, turning the beam through 180° in azimuth and differencing the two readings, which reverses the signal but not the instrumental torques. The Eöt-Wash balance modulates continuously, rotating at a period of minutes so that the signal appears as a torque oscillating at the turntable frequency, far above the drift of the fibre and far from every fixed offset.

In orbit the modulation is faster and cleaner. The satellite is spun about an axis perpendicular to the orbital plane, so that the Earth-pointing direction rotates in the instrument frame at the sum of the orbital and spin frequencies. A violation of universality would appear as a differential acceleration between the two test masses at that one known

frequency and in that one known phase; everything else — thermal drift, radiation pressure, residual gas — has to conspire to appear at exactly the same frequency and phase to be mistaken for it. The satellite is drag-free, its thrusters cancelling the atmospheric drag so that the test masses are truly in free fall.

53.5.3 Observations and data

Every experiment in the lineage has returned a null result. The bounds on η, quoted at the order of magnitude their authors claim:

Table 53.3: Bounds on the Eötvös parameter Equation (53.6), by experiment. Every entry is consistent with zero; the column gives the order of magnitude of the limit, not the central value.

Experiment	Bodies and attractor	Bound on $\lvert\eta\rvert$
Eötvös, Pekár and Fekete, published 1922 [486]	platinum against several, Earth	10^{-9}
Roll, Krotkov and Dicke, 1964 [1294]	aluminium against gold, Sun	10^{-11}
Braginsky and Panov, 1972 [1469]	aluminium against platinum, Sun	10^{-12}
Eöt-Wash rotating balance, 2008 [2135]	beryllium against titanium, Earth	10^{-13}
MICROSCOPE, first results, 2017 [2289]	titanium against platinum alloy, Earth	10^{-14}
MICROSCOPE, final results, 2022 [2409]	titanium against platinum alloy, Earth	10^{-15}

Phenomenon 53.5 (Universality of free fall, as measured)**.** No experiment has ever detected a dependence of gravitational acceleration on composition. The Eötvös parameter Equation (53.6) is consistent with zero in every measurement listed in Table 53.3, and the strongest bound now stands at the level of parts in 10^{15}, set by comparing titanium and platinum-alloy test masses in orbital free fall [2409]. The same experiments constrain composition dependence with the Sun and with the Galactic centre as attractor, so the null result is not an accident of one source [1294, 1469].

Rests on Definition 42.2, Phenomenon 42.1, and Equation (53.8).

Derivation. *Derives Phenomenon 53.5.*

The bound is established by the torque analysis derived below: Equation (53.8) converts any composition dependence of free fall into a torque about the fibre of magnitude $\frac{1}{2}\,\eta_{AB}\,m\,L\,a_{\mathrm{h}}$, in which every factor multiplying η_{AB} is fixed by the geometry of the instrument and by Equation (53.7). A recorded torque consistent with zero therefore bounds $\lvert\eta_{AB}\rvert$ directly. The orbital experiments read the same null through the electrostatic suspension force of a differential accelerometer, the driving acceleration being the full orbital g rather than the horizontal centrifugal residue, and each entry of Table 53.3 is such a null readout divided by the known sensitivity factor of its instrument; no further theory enters. □

The derivation that a null η is equivalent to the identity of inertial and gravitational mass is given in Chapter 42. What is derived here is the signal the torsion balance actually looks for, since the geometry is not obvious and it explains why the instrument is sensitive at all.

Derivation. Work in the frame rotating with the Earth, at geographic latitude λ. A body at rest there is acted on by the true gravitational attraction $\boldsymbol{g}$, directed very nearly at the

centre, and by the centrifugal acceleration of magnitude $\omega^2 R\cos\lambda$ directed away from the rotation axis. The centrifugal term is proportional to the *inertial* mass and the attraction to the *gravitational* mass, which is what makes the arrangement a test. Resolving the centrifugal acceleration into vertical and horizontal parts, its horizontal component points toward the equator and has magnitude

$$a_{\mathrm{h}} = \omega^2 R \sin\lambda\cos\lambda\,. \tag{53.7}$$

With $\omega = 7.292\times10^{-5}\,\mathrm{s}^{-1}$ and $R = 6.371\times10^{6}\,\mathrm{m}$ this is $1.69\times10^{-2}\,\mathrm{m/s^2}$ at latitude 45°, that is 1.7×10^{-3} of g.

Write $m_{\mathrm{G}} = m_{\mathrm{I}}\,(1+\varepsilon)$ for each body, and let the local vertical be defined by the plumb line of a body with $\varepsilon = 0$; that vertical lies along $\boldsymbol{g} + \boldsymbol{a}_{\mathrm{cf}}$, so in the plumb frame the horizontal component of $\boldsymbol{g}$ has magnitude a_{h} and points away from the equator, exactly cancelling the centrifugal horizontal component. A body with $\varepsilon \neq 0$ has effective acceleration $(1+\varepsilon)\,\boldsymbol{g} + \boldsymbol{a}_{\mathrm{cf}}$, which differs from the plumb-frame vertical by the horizontal residue $\varepsilon\, a_{\mathrm{h}}$. Two bodies at the ends of a beam of length L suspended at its centre and oriented east–west therefore feel horizontal forces along the north–south direction differing by $m\eta_{AB}a_{\mathrm{h}}$, and since their position vectors from the fibre are $\pm\,(L/2)$ along east, the net torque about the fibre is

$$N = \tfrac{1}{2}\,\eta_{AB}\,m\,L\,a_{\mathrm{h}} = \tfrac{1}{2}\,\eta_{AB}\,mgL\,\frac{\omega^2 R\sin\lambda\cos\lambda}{g}\,. \tag{53.8}$$

The instrument is therefore looking for a torque smaller than the natural scale mgL by the product of η with 1.7×10^{-3} — and η is the quantity being bounded at 10^{-9} or below. That factor 1.7×10^{-3} is the whole sensitivity penalty of doing the experiment on a rotating planet rather than in orbit, and it is the reason a satellite gains several orders of magnitude the moment it works at all: in orbit the driving acceleration is the full local g, about $8\,\mathrm{m/s^2}$ at MICROSCOPE's altitude, rather than $1.7\times10^{-2}\,\mathrm{m/s^2}$.

Two further features of Equation (53.8) matter experimentally. The torque vanishes at the equator and at the poles and is maximal near 45° of latitude, which is a signature no instrumental effect shares; and it reverses when the beam is turned through 180° in azimuth, which is the differencing Eötvös performed. □

53.5.4 Interpretation

The null result is the evidence that licenses geometry. If $m_{\mathrm{G}}/m_{\mathrm{I}}$ is one universal number, then the trajectory of a freely falling body depends on nothing but where it started and how fast it was going — not on what it is made of — and a family of trajectories with that property can be the geodesics of a connection. If η were nonzero at any level, gravity would be a force with a composition-dependent coupling like every other force, and the geometric description of Chapter 43 would be an approximation valid to whatever precision η had last been bounded at. The bound is therefore not a curiosity but the load-bearing measurement of the entire part.

It should be said what these experiments do *not* do. They test the weak form of the equivalence principle, for laboratory bodies whose own gravitational binding energy is negligible. Whether a self-gravitating body falls the same way is a separate question, tested by lunar laser ranging in the next section. And a null result is a bound, never a confirmation: what Table 53.3 records is that a century of increasingly ingenious experiments has failed to find a violation, which is the strongest statement an experiment of this kind can make.

53.5.5 Primary references

[486, 1294, 1469] and [2135, 2289, 2409]. The bounds of Table 53.3 are quoted from those papers at the order of magnitude only; the central values and their separate statistical and systematic uncertainties are given in the sources.

53.6 Lunar laser ranging and Gravity Probe B (1969–2011)

Tests Phenomena 42.4 and 53.6.

The last two experiments test what happens to a *direction* carried through curved spacetime. A gyroscope in orbit, or the orbit of the Moon itself considered as a gyroscope, is parallel-transported along its worldline, and general relativity says that the transported axis does not return to where it started. There are two such effects: the geodetic precession, produced by the curvature due to the central mass, and the very much smaller frame-dragging precession, produced by the rotation of that mass [455, 458]. Lunar laser ranging also provides the one test in this chapter of the equivalence principle for a self-gravitating body.

53.6.1 Apparatus

Lunar laser ranging uses retroreflector arrays left on the Moon — by the Apollo 11, 14 and 15 crews, and on the two Soviet Lunokhod rovers — consisting of fused-silica corner cubes, which return light along the direction it came from regardless of the array's orientation. The Earth end is a telescope firing short laser pulses and timing the return of single photons against an atomic clock; the round trip takes about 2.5 s, and only a few returned photons are recorded per pulse train [2067, 2198].

Gravity Probe B carried four gyroscopes into a polar orbit at about 642 km altitude. Each rotor was a sphere of fused quartz 3.8 cm in diameter, coated with superconducting niobium, electrostatically suspended in vacuum inside a dewar of superfluid helium at about 1.8 K, and spun up to tens of revolutions per second. The rotors were figured to within a few tens of nanometres of a perfect sphere. The spin direction was read out magnetically: a spinning superconductor develops a London moment along its spin axis, and the field of that moment was sensed by a SQUID magnetometer. An on-board telescope held the satellite pointed at the guide star IM Pegasi, providing the fixed direction against which the gyroscope drift was measured, and the satellite was drag-free [2173].

53.6.2 Procedure

For lunar laser ranging the observable is a time series of Earth–Moon distances accumulated over decades and fitted with a full solar-system and lunar-orbit model. Two relativistic signatures are extracted from it. A violation of the equivalence principle for self-gravitating bodies — the Nordtvedt effect [1377] — would make the Earth and the Moon fall toward the Sun at slightly different rates, polarizing the lunar orbit along the Earth–Sun line with a signature periodic at the synodic month. The geodetic precession appears as a slow rotation of the lunar orbit plane, and is separated from Newtonian precessions by its rate and direction.

For Gravity Probe B the observable is the angle between each gyroscope spin axis and the line to IM Pegasi, tracked for the duration of the science mission. The two relativistic drifts are orthogonal by construction, which is why a polar orbit was chosen: the geodetic drift lies in the orbital plane, north–south, and the frame-dragging drift is perpendicular to it, east–west. The guide star has its own proper motion, which was measured independently by very-long-baseline radio interferometry against distant quasars and subtracted.

53.6.3 Observations and data

Phenomenon 53.6 (Precession of a gyroscope in orbit)**.** A gyroscope in a circular orbit of radius r about a mass M with angular momentum J precesses at the geodetic rate

$$\Omega_{\text{geo}} = \frac{3}{2}\,\frac{GM}{c^2 r}\,\sqrt{\frac{GM}{r^3}} \tag{53.9}$$

in the plane of the orbit, and, for a polar orbit, at the frame-dragging rate

$$\Omega_{\mathrm{fd}} = \frac{GJ}{2c^2 r^3} \tag{53.10}$$

perpendicular to it [1191]. Gravity Probe B measured both against the guide star IM Pegasi and found, in milliarcseconds per year, -6601.8 ± 18.3 for the geodetic drift against a predicted -6606.1, and -37.2 ± 7.2 for the frame-dragging drift against a predicted -39.2 [2173]. Lunar laser ranging sees the geodetic precession of the lunar orbit at the level of a few parts in 10^3 and, independently, finds the Nordtvedt parameter consistent with zero at the level of parts in 10^4, so that self-gravitating bodies fall like test bodies [2067][1377].

Rests on Postulate 43.1 and Theorem 45.30.

Derivation. *Derives Phenomenon 53.6.*

Both rates follow from parallel transport of the spin four-vector in the weak-field metric of a slowly rotating mass — the linearization of the Kerr geometry, which is all the Earth requires. Write, to first order in Φ/c^2 and in the rotation,

$$\mathrm{d}s^2 = -\Big(1 + \frac{2\Phi}{c^2}\Big)c^2\mathrm{d}t^2 + \Big(1 - \frac{2\Phi}{c^2}\Big)\delta_{ij}\,\mathrm{d}x^i\mathrm{d}x^j + 2h_i\,c\,\mathrm{d}t\,\mathrm{d}x^i\,, \tag{53.11}$$

with $\Phi = -GM/r$ and the gravitomagnetic potential

$$\boldsymbol{h} = -\frac{2G}{c^3}\,\frac{\boldsymbol{J}\times\boldsymbol{r}}{r^3}\,. \tag{53.12}$$

A torque-free gyroscope on a geodesic parallel-transports its spin, $\mathrm{d}S^\mu/\mathrm{d}\tau + \Gamma^\mu{}_{\nu\rho}u^\nu S^\rho = 0$, with $S_\mu u^\mu = 0$. To the order required, the Christoffel symbols of Equation (53.11) are $\Gamma^i{}_{00} = \partial_i\Phi/c^2$, $\Gamma^i{}_{0j} = \tfrac{1}{2}(\partial_j h_i - \partial_i h_j)$ and $\Gamma^i{}_{jk} = (-\delta_{ij}\partial_k\Phi - \delta_{ik}\partial_j\Phi + \delta_{jk}\partial_i\Phi)/c^2$, while the constraint gives $S^0 = \boldsymbol{S}\cdot\boldsymbol{v}/c$ at leading order. Assembling the spatial components with $u^\mu \approx (c, \boldsymbol{v})$,

$$\frac{\mathrm{d}S^i}{\mathrm{d}t} = -\frac{c}{2}(\partial_j h_i - \partial_i h_j)S^j + \frac{1}{c^2}\Big[(\boldsymbol{v}\cdot\nabla\Phi)S^i + v^i(\boldsymbol{S}\cdot\nabla\Phi) - 2\,\partial_i\Phi\,(\boldsymbol{v}\cdot\boldsymbol{S})\Big]\,.$$

The coordinate components mix a genuine rotation with the stretching of the coordinate grid; the physical spin is the one referred to the local orthonormal rest frame, $\hat{S}^i = (1 - \Phi/c^2)S^i - \frac{1}{2c^2}v^i(\boldsymbol{v}\cdot\boldsymbol{S})$, the first factor from the spatial metric in Equation (53.11), the second the low-velocity boost to the gyroscope frame. Differentiating, using $\mathrm{d}\boldsymbol{v}/\mathrm{d}t = -\nabla\Phi$ on the geodesic, and keeping first order, every non-rotational term cancels and what survives is a pure precession,

$$\frac{\mathrm{d}\hat{\boldsymbol{S}}}{\mathrm{d}t} = \boldsymbol{\Omega}\times\hat{\boldsymbol{S}}\,, \qquad \boldsymbol{\Omega} = \underbrace{\frac{3}{2}\,\frac{GM}{c^2 r^3}\,\boldsymbol{r}\times\boldsymbol{v}}_{\text{geodetic}} + \underbrace{\frac{G}{c^2 r^3}\big[3(\boldsymbol{J}\cdot\hat{\boldsymbol{r}})\hat{\boldsymbol{r}} - \boldsymbol{J}\big]}_{\text{frame dragging}}\,, \tag{53.13}$$

the second term being $-\frac{c}{2}\nabla\times\boldsymbol{h}$ evaluated from Equation (53.12). For a circular orbit, $|\boldsymbol{r}\times\boldsymbol{v}| = r^2\sqrt{GM/r^3}$, so the geodetic magnitude is $\Omega_{\mathrm{geo}} = \frac{3}{2}(GM/c^2 r)\sqrt{GM/r^3}$, which is Equation (53.9), directed along the orbit normal. For a polar orbit the frame-dragging term must be averaged over the orbit: with $\hat{\boldsymbol{r}}$ sweeping a great circle through the poles, $\langle(\boldsymbol{J}\cdot\hat{\boldsymbol{r}})\hat{\boldsymbol{r}}\rangle = \boldsymbol{J}/2$, so $\langle\boldsymbol{\Omega}_{\mathrm{fd}}\rangle = (G/c^2 r^3)(\frac{3}{2} - 1)\boldsymbol{J} = G\boldsymbol{J}/(2c^2 r^3)$, which is Equation (53.10). The same $\boldsymbol{\Omega}$ applied to the Earth–Moon system as a gyroscope (its orbital angular momentum the spin) gives the geodetic precession of the lunar orbit that lunar laser ranging observes. □

Granted Equations (53.9) and (53.10), the predicted rates follow from the orbit and from the Earth's mass and spin. Taking $r = 7.013\times10^6\,\mathrm{m}$ for an altitude of 642 km, and $GM_\oplus = 3.986\times10^{14}\,\mathrm{m^3/s^2}$, the orbital angular velocity is $1.075\times10^{-3}/\mathrm{s}$ and $GM_\oplus/\,(c^2 r) =$

6.32×10^{-10}, so Equation (53.9) gives 1.02×10^{-12}/s, which is 3.22×10^{-5} radian per year, or about 6640 milliarcseconds per year. With the Earth's spin angular momentum $J_\oplus \simeq 5.86 \times 10^{33}\,\mathrm{kg\,m^2/s}$, Equation (53.10) gives 6.3×10^{-15}/s, about 41 milliarcseconds per year. Both agree with the mission's own predictions to within a few per cent; the residual difference comes from the orbital eccentricity, the Earth's oblateness and the solar geodetic term, all carried by the mission model and none by the two-line estimate made here.

53.6.4 Interpretation

The geodetic result is a clean measurement: a fractional uncertainty of about 0.3 %, agreeing with the prediction. The frame-dragging result must be reported more carefully, and this chapter would be dishonest if it were not.

Gravity Probe B was designed to reach an uncertainty below one milliarcsecond per year on both drifts, which would have made the frame-dragging measurement a one-per-cent test. It did not. The delivered uncertainties are 18.3 and 7.2 milliarcseconds per year, some twenty times the design goal, so the frame-dragging number is a detection at about five times its own uncertainty and a confirmation of the predicted rate at the level of roughly twenty per cent — not one per cent.

The cause is instructive and was not anticipated. The niobium coating on the rotors and the surrounding housing carried patches of varying electric potential, and the interaction of those patches produced classical electrostatic torques on the spinning spheres. Because the rotors' polhode motion — the wobble of the spin axis within the body — drifted slowly in period over the mission, these torques were not constant and could not be removed by a simple fit. The analysis had to build an explicit model of the patch-induced misalignment torque and of the polhode phase for each rotor, and subtract it; the final error budget is dominated not by measurement noise but by the uncertainty of that model [2173]. This is worth stating in a treatise that grades its evidence: the geodetic precession is measured, and the frame-dragging precession is detected but only loosely measured, by this experiment.

What lunar laser ranging adds is different in kind. The Earth and the Moon store different fractions of their mass-energy as gravitational binding energy, so they are the two test bodies of an equivalence experiment that the balances of Section 53.5 cannot perform: laboratory masses have no appreciable self-gravity. The null Nordtvedt signal therefore extends Phenomenon 53.5 from the weak to the strong form of the principle, which no other experiment in this chapter touches [2067].

53.6.5 Primary references

[2173] for Gravity Probe B, [2067] for lunar laser ranging, and [1377] for the effect the latter bounds.

53.7 Summary of the evidence

Three remarks close the chapter. The first is that the tests are not redundant. Every row of Table 53.4 could in principle have failed while the others passed, and the third column says how; a theory that reproduced the redshift and the deflection but not the perihelion advance would have been a live possibility in 1919 and is excluded now by radar and by Mercury together.

The second is that the classical tests are all weak-field. The dimensionless potential $GM/\left(c^2 r\right)$ reaches at most a few parts in 10^6, at the solar limb, in every experiment reported here — the Galactic-centre orbit mentioned in Section 53.1 is the exception, and it belongs to Chapter 50 — and the deviations measured are first-order in it. General relativity is here being tested where it is nearly Newtonian, and passing such tests is necessary but

Table 53.4: The classical tests reported in this chapter. The third column states what would have to be wrong for the measurement to come out differently — which is what distinguishes the tests from one another, since all six agree with general relativity.

Experiment	Precision reached	What it constrains
Mercury perihelion, 1859	a residual of 43 out of 5600 seconds of arc per century	the field equations, at first post-Newtonian order
Eclipse of 1919	enough to resolve a factor of two	the curvature of space; excludes the equivalence principle acting alone
Pound–Rebka–Snider	one per cent	the equivalence principle alone; no field equation enters
Shapiro delay to Cassini	$\gamma - 1$ to 2×10^{-5}	the same curvature coefficient as the deflection, by an independent method
Eötvös to MICROSCOPE	η below 10^{-15}	universality of free fall for laboratory bodies; licenses the geometric description
Ranging and Gravity Probe B	0.3 % geodetic, about 20 % frame-dragging	parallel transport of a direction; the gravitomagnetic sector; the strong form of the principle

very far from sufficient. The strong-field evidence is elsewhere: in the orbital decay and timing of binary pulsars, in the direct gravitational-wave detections of Chapter 47, and in the horizon-scale observations of Chapter 50.

The third is about the shape of the evidence rather than its content. The best of these measurements are not the most famous ones. The 1919 eclipse made general relativity a public fact and is the weakest result in the chapter; the Cassini radio link is the strongest and is known to almost nobody. That asymmetry is a standing hazard for a treatise organized around evidence, and it is why Table 53.4 reports precision reached rather than historical importance.

Part VI

Classical Thermodynamics

Chapter 54

Classical Thermodynamics

Thermodynamics is the physics of heat, work and temperature, stated for macroscopic bodies and without any hypothesis about the constitution of matter. Its raw material is a handful of state variables; its whole content is four laws; and its working machinery is the family of thermodynamic potentials generated from the internal energy by Legendre transforms—the same construction that carries the Lagrangian to the Hamiltonian in Chapter 22. The subject was forced into existence by the steam engine: Carnot's memoir on the motive power of fire [76] predates any correct concept of energy, and the theory built on it has survived every later revolution of physics untouched. The canonical modern exposition is [1749].

This chapter develops the phenomenological theory: equilibrium and temperature, the equations of state, the first and second laws with their processes and cycles, entropy, the potentials and the Maxwell relations, phase equilibria, and the third law. The molecular reading of the same quantities begins in Chapter 55 and is completed in Chapter 118; the experiment that grounds the first law has its own chapter, Chapter 56.

Derivation pending #1

Classical Thermodynamics: all derivations of this chapter are pending.

54.1 Systems, equilibrium and temperature

54.1.1 State variables and equilibrium

[Reserved: thermodynamic systems, walls and reservoirs; extensive and intensive variables; the equilibrium postulate that a finite set of state variables $(U, V, N, \dots)$ suffices to describe a macroscopic body at rest, in the axiomatic form of [1749]; quasi-static and reversible processes; exact and inexact differentials, with heat and work as path functions and the state variables as point functions.]

54.1.2 The zeroth law and empirical temperature

[Reserved: thermal contact and thermal equilibrium; the zeroth law—transitivity of thermal equilibrium—as stated by Maxwell in his textbook of the subject [179] and later named the zeroth law by Fowler and Guggenheim [835]; the resulting existence of an empirical temperature as a label on isotherms; thermometric substances and the gas scale.]

Phenomenon 54.1 (Transitivity of thermal equilibrium)**.** Let three bodies A, B, C be brought into thermal contact in pairs. Without exception it is found that if A is in thermal equilibrium with C, and B is in thermal equilibrium with C, then A and B are already in thermal equilibrium when placed in contact: no further change of any of their state variables

occurs. This is the fact that makes a thermometer possible—C being a small standard instrument read in place of the bodies themselves. It was made the ground of thermometry by Maxwell [179] and named the zeroth law by Fowler and Guggenheim [835].

Derivation. Write $A \sim B$ for "A and B are in thermal equilibrium". The relation is reflexive and symmetric by construction, and the observed regularity is precisely transitivity; hence $\sim$ is an equivalence relation on the set of equilibrium states, and its classes partition that set. For a simple fluid, whose equilibrium states are labelled by the pair (P, V), equilibrium with one fixed reference body is a single condition on two variables, so each class is a curve in the (P, V) plane—an isotherm. Choose a thermometric body together with a coordinate that varies monotonically along its own states, and assign to every class the value θ that coordinate takes when the reference body is equilibrated with a member of the class. By construction

$$\theta(P_A, V_A) = \theta(P_B, V_B) \iff A \sim B\,. \tag{54.1}$$

Any second assignment θ' with the same property labels the same classes, so $\theta' = g(\theta)$ with g strictly monotone: empirical temperature is fixed only up to a monotone relabelling. Removing that residual freedom is the work of Section 54.4.3. □

54.1.3 Thermometry and the kelvin

[Reserved: William Thomson's absolute thermometric scale founded on the Carnot cycle [123], anticipating Section 54.4.3; the constant-volume gas thermometer as its classical realisation; the modern kelvin, defined since 2019 by fixing the Boltzmann constant at $1.380\,649 \times 10^{-23}$ J/K [2333], and its relation to the measurement conventions of Chapter 2.]

54.2 Equations of state

54.2.1 The gas laws

[Reserved: Boyle's law $PV = \text{const}$ at fixed temperature, from the pressure–volume data of the 1662 defence of the spring of the air [6]; Gay-Lussac's law of thermal expansion, with the equal expansivity of all gases [47] and Gay-Lussac's own attribution of earlier unpublished work to Charles; Dalton's law of partial pressures [46]; Avogadro's hypothesis that equal volumes at equal temperature and pressure hold equal numbers of molecules [55].]

54.2.2 The ideal-gas equation of state

[Reserved: the combination of the gas laws into the single equation $PV = nRT$ by Clapeyron [95]; the gas constant, exact since 2019 as the product of the Boltzmann and Avogadro constants, $8.314\,462\,618$ J/(mol K) [2333, 2431]; Regnault's precision measurements of the small departures of real gases from the law [122], the experimental seed of Section 54.6.3; the ideal gas as the universal dilute limit.]

Phenomenon 54.2 (The universal dilute-gas equation of state)**.** Every gas, whatever its chemical species, obeys one and the same equation of state in the limit of low density. Three separate observations enter it: at fixed temperature the product PV of a fixed quantity of gas is constant [6]; at fixed pressure the volume grows with temperature by a coefficient of thermal expansion that is the same for all gases [47]; and at fixed pressure and temperature equal volumes of different gases contain equal numbers of molecules [55]. Together they say that

$$PV = nRT\,, \tag{54.2}$$

with one constant R common to every substance. Departures from Equation (54.2) set in at finite density and were mapped systematically by Regnault [122]; they are the subject

of Section 54.6.3. Since the redefinition of the SI in 2019 the gas constant is exact, $R = 8.314\,462\,618\,\mathrm{J/(mol\,K)}$ [2333, 2431].

Derivation. Fix the amount of gas. Boyle's observation says that on each isotherm the product PV depends on the empirical temperature alone, $PV = f(\theta)$, so it is a label on the classes of Equation (54.1). Gay-Lussac's says that at fixed pressure $V = V_0(1 + \alpha\theta_{\mathrm{C}})$, with θ_{C} the Celsius reading and α the same number for every gas; defining

$$T := \theta_{\mathrm{C}} + \alpha^{-1} \tag{54.3}$$

turns it into $V \propto T$ at fixed P. The two together force f to be proportional to T, so $PV = CT$ with C depending only on how much gas is present. Avogadro's observation fixes that dependence: at given P and T the volume is proportional to the number of molecules, hence $C = nR$ with R independent of the species, which is Equation (54.2). The scale Equation (54.3) so constructed is the ideal-gas temperature; that it coincides with the substance-independent scale of thermodynamics is shown in Section 54.4.3, and only then is T more than a convention. □

54.3 The first law

54.3.1 Work, heat and internal energy

[Reserved: the first law $\mathrm{d}U = \delta Q - \delta W$: internal energy as a state function whose change splits into heat and work, neither of which is one by itself; Mayer's inference of the equivalence of heat and work from the two heat capacities of air [108]; Joule's paddle-wheel measurement of the mechanical equivalent [129], treated in full in Chapter 56; Helmholtz's statement of the conservation of energy across all of physics [121].]

Phenomenon 54.3 (Path independence of adiabatic work)**.** Carry a thermally insulated body from one equilibrium state to another by doing work on it. The work required is found to depend only on the two states and not at all on how it is delivered: a paddle wheel churning water, the same wheel churning mercury, cast iron rubbing on cast iron, and an electric current driven by a falling weight all produce the same change of state for the same work [109, 129]. Equivalently, heat and work are interconvertible at one fixed rate—the mechanical equivalent of heat—first inferred from the two heat capacities of air by Mayer [108] and then measured directly by Joule [129]. The measurement is treated in full in Chapter 56.

Derivation. Let $W_{\mathrm{ad}}(A \to B)$ denote the work done *by* an insulated system in passing from state A to state B; the observation is that this number depends on A and B alone. Fix a reference state O and define

$$U(B) := U(O) - W_{\mathrm{ad}}(O \to B)\,, \tag{54.4}$$

which is well posed precisely because of the observed path independence, and which fixes a state function U up to the additive constant $U(O)$. Join now the same two states by a process that is *not* insulated; the work W done by the system differs from W_{ad}, and the deficit

$$Q := U(B) - U(A) + W \tag{54.5}$$

defines the heat absorbed. It is an amount of energy, measured in joules, and owns no independent unit; in differential form Equation (54.5) is the first law $\mathrm{d}U = \delta Q - \delta W$. The converse shows why the observation is not a triviality: if W_{ad} depended on the path, one could carry the system from A to B along the costlier route and back along the cheaper one, returning it to A while extracting net work from nothing—perpetual motion of the first kind, which no mechanism has ever achieved. □

54.3.2 Heat capacities

[Reserved: heat capacities at constant volume and constant pressure; enthalpy; the Mayer relation $C_P - C_V = nR$ for the ideal gas, the relation from which Mayer extracted his equivalent of heat [108]; Regnault's calorimetric data [122]; the ratio $\gamma = C_P/C_V$ and its appearance in the adiabatic law and in Laplace's correction of Newton's speed of sound [59].]

54.3.3 Processes and cycles

[Reserved: isothermal, isobaric, isochoric and adiabatic processes of the ideal gas; the adiabatic law $PV^\gamma = \text{const}$; work as the area of the indicator diagram, the representation Clapeyron introduced [95]; free expansion into vacuum as the standard irreversible contrast, tested by Gay-Lussac [52] and by Joule, and refined into the throttling experiment of Section 54.6.4.]

54.4 The second law

54.4.1 Carnot's theorem

[Reserved: the Carnot cycle of two isotherms and two adiabats; Carnot's theorem that no engine working between two reservoirs outperforms a reversible one, and that all reversible engines between the same reservoirs share one efficiency [76]—an argument that survived the caloric theory it was written in; Clapeyron's analytic and graphical restatement [95].]

54.4.2 The Clausius and Kelvin statements

[Reserved: Clausius's 1850 reconciliation of Carnot's theorem with the first law, and his statement that heat does not pass by itself from a colder to a hotter body [127]; Thomson's statement that no cyclic process converts heat wholly into work [141]; the proof that the two statements are equivalent; perpetual motion of the second kind.]

Phenomenon 54.4 (The two impossibilities)**.** Two negative statements about cyclic processes have never been contradicted by any device built or proposed.

1. *Clausius.* No process has as its sole result the transfer of heat from a colder to a hotter body [127].
2. *Kelvin.* No cyclic process has as its sole result the complete conversion into work of heat drawn from a single reservoir at one temperature [141].

Neither is a consequence of the first law, which permits both: an engine converting the thermal energy of the ocean entirely into work would conserve energy exactly. They are an independent fact about Nature, and the modern form of the impossibility Carnot had already taken for granted [76].

Derivation. The two statements are equivalent, so the observation is a single one. Suppose Kelvin's statement false: some cyclic device draws heat $Q > 0$ from the cold reservoir and delivers work $W = Q$ with no other effect. Dissipate that work as heat in the hot reservoir by friction. The compound operation is cyclic and its only result is the passage of Q from cold to hot, so Clausius's statement fails. Conversely, suppose Clausius's statement false: some device passes heat Q_c from the cold reservoir to the hot one with no other effect. Beside it run an ordinary engine that takes Q_h from the hot reservoir, delivers work $W = Q_\mathrm{h} - Q_\mathrm{c}$ and rejects exactly Q_c to the cold one. In the compound cycle the cold reservoir is left unchanged, and the sole result is the conversion into work of $Q_\mathrm{h} - Q_\mathrm{c}$ drawn from the hot reservoir alone, so Kelvin's statement fails. Each denial implies the other, hence the two statements stand or fall together. □

54.4.3 Thermodynamic temperature and the Carnot efficiency

[Reserved: the universality of the Carnot efficiency as the definition of a temperature independent of every thermometric substance, with $\eta = 1 - T_2/T_1$ [123, 141]; the proof that this scale coincides with the ideal-gas scale of Section 54.2.2.]

Phenomenon 54.5 (The Carnot limit on heat engines)**.** A device working in a cycle between two reservoirs held at temperatures $T_\mathrm{h} > T_\mathrm{c}$ never converts into work more than the fraction

$$\eta_\mathrm{C} = 1 - \frac{T_\mathrm{c}}{T_\mathrm{h}} \tag{54.6}$$

of the heat it draws from the hot reservoir; real engines fall below it, and every engine that is reversible attains it exactly, whatever its working substance and whatever the mechanism [76, 141]. It is the independence from the working substance that lets Equation (54.6) be read backwards, as the definition of a temperature scale owing nothing to any thermometric material [123].

Derivation. Universality. Let E be reversible and X arbitrary, both cycling between the same two reservoirs, and choose the number of cycles of each so that they deliver the same total work W. Run X forward and E backward. The compound device is cyclic and delivers no net work, so by the first law the heat it takes from the cold reservoir equals the heat it gives to the hot one, namely $Q_\mathrm{h}^E - Q_\mathrm{h}^X$. Now $Q_\mathrm{h}^X = W/\eta_X$ and $Q_\mathrm{h}^E = W/\eta_E$, so if $\eta_X > \eta_E$ that quantity is positive and the sole result of the compound cycle is a passage of heat from the colder reservoir to the hotter, contradicting Phenomenon 54.4. Hence $\eta_X \le \eta_E$; taking X reversible as well and exchanging the roles gives equality. All reversible engines between the same pair of reservoirs therefore share one efficiency, a function of the reservoirs alone.

Evaluation. That efficiency may then be computed with any convenient substance. Take one mole of ideal gas, with C_V constant for simplicity, around the cycle $1 \to 2$ isothermal at T_h, $2 \to 3$ adiabatic, $3 \to 4$ isothermal at T_c, $4 \to 1$ adiabatic. The internal energy of an ideal gas depends on T alone (Chapter 56), so on an isotherm the heat absorbed equals the work done and

$$Q_\mathrm{h} = RT_\mathrm{h} \ln \frac{V_2}{V_1}, \qquad Q_\mathrm{c} = RT_\mathrm{c} \ln \frac{V_3}{V_4}, \tag{54.7}$$

Q_c being the heat rejected. On an adiabat $C_V \mathrm{d}T = -P\mathrm{d}V = -RT\,\mathrm{d}V/V$, which integrates to $TV^{R/C_V} = \text{const}$; the two adiabats give $T_\mathrm{h}V_2^{R/C_V} = T_\mathrm{c}V_3^{R/C_V}$ and $T_\mathrm{h}V_1^{R/C_V} = T_\mathrm{c}V_4^{R/C_V}$, and dividing one by the other leaves $V_2/V_1 = V_3/V_4$. The logarithms in Equation (54.7) therefore cancel in the ratio,

$$\frac{Q_\mathrm{c}}{Q_\mathrm{h}} = \frac{T_\mathrm{c}}{T_\mathrm{h}}, \tag{54.8}$$

and $\eta = 1 - Q_\mathrm{c}/Q_\mathrm{h}$ is Equation (54.6). Since the left-hand side of Equation (54.8) was just shown to be independent of the working substance, while the T on its right is the ideal-gas temperature Equation (54.3), the thermodynamic and ideal-gas scales agree wherever both are defined. □

54.4.4 Entropy and the Clausius inequality

[Reserved: the Clausius equality, that $\delta Q/T$ integrates to zero around any reversible cycle [142]; entropy as the resulting state function, named by Clausius in 1865 together with the summary that the energy of the world is constant and its entropy tends to a maximum [162]; the Clausius inequality and the increase of entropy in isolated systems; the entropy of the ideal gas.]

54.4.5 Carathéodory's axiomatics

[Reserved: the axiomatic route of Carathéodory, in which the second law is the existence, near every state, of states inaccessible by adiabatic processes, and entropy arises as an integrating factor of δQ [353]; its equivalence with the engine statements; what the axiomatisation clarifies and what it hides.]

54.5 Thermodynamic potentials

54.5.1 Legendre transforms and the four potentials

[Reserved: internal energy, enthalpy, the Helmholtz free energy introduced as the "free energy" of chemical processes [217], and the Gibbs free energy, all as Legendre transforms of one fundamental relation, in the systematic form Gibbs gave the subject [193]; the natural variables of each potential, and the parallel with the Legendre transform of Chapter 22.]

54.5.2 Maxwell relations

[Reserved: the four Maxwell relations as equalities of mixed second derivatives of the potentials, in the form given in Maxwell's Theory of Heat [179]; their use to reduce any measured response to derivatives of state variables; worked identities for the ideal and the van der Waals gas.]

54.5.3 Extremum principles, stability and the chemical potential

[Reserved: maximum entropy and minimum energy; minimisation of the free energies at fixed intensive variables; concavity and convexity of the potentials, with positive heat capacities and compressibilities as stability conditions; the chemical potential, the Euler relation and the Gibbs–Duhem identity, all from [193]; exposition following [1749].]

54.6 Phase equilibria

54.6.1 Coexistence and the Clausius–Clapeyron equation

[Reserved: equality of temperature, pressure and chemical potential across a phase boundary; latent heat; the Clausius–Clapeyron equation for the slope of the coexistence curve, from Clapeyron's memoir [95] as put on a first-law footing by Clausius [127]; applications to vapour pressure and to the melting line of ice.]

54.6.2 The Gibbs phase rule

[Reserved: the phase rule $f = c - p + 2$ counting the freedoms of a multicomponent, multiphase system [193]; triple points, with the former role of the water triple point in the definition of the kelvin [2333] noted; azeotropes and eutectics named as applications.]

54.6.3 Real gases: van der Waals and the critical point

[Reserved: Andrews's isotherms of carbon dioxide and the discovery of the critical point, with the continuity of the liquid and gaseous states [174]; the van der Waals equation of state from his 1873 dissertation [187]; the Maxwell equal-area construction [191]; the law of corresponding states; where the mean-field picture fails near the critical point, deferred to Chapter 123.]

Phenomenon 54.6 (The critical point)**.** Above a definite temperature T_c, characteristic of the substance, no pressure whatever liquefies a gas. Following the coexistence curve upwards, the difference in density between the liquid and its vapour shrinks and the meniscus between them fades and disappears at a single point (T_c, P_c, V_c); beyond it the two states pass continuously into one another. Andrews established this for carbon dioxide by mapping its isotherms through the point [174]. Plotted in units of their own critical constants, the isotherms of chemically unrelated substances then very nearly coincide—the law of corresponding states [187].

Derivation. Van der Waals's equation of state for one mole, with $v = V/n$,

$$P = \frac{RT}{v-b} - \frac{a}{v^2}\,, \tag{54.9}$$

corrects the ideal gas Equation (54.2) for the volume b the molecules exclude and for the attraction between them, which lowers the pressure by a/v^2. At high temperature P is monotone in v; below some temperature it is not, and a horizontal tie line then cuts the isotherm in three. The two behaviours are separated by the isotherm on which the stationary points merge, so the critical point is fixed by

$$\left(\frac{\partial P}{\partial v}\right)_T = 0\,, \qquad \left(\frac{\partial^2 P}{\partial v^2}\right)_T = 0\,. \tag{54.10}$$

Differentiating Equation (54.9) these read $RT/(v-b)^2 = 2a/v^3$ and $RT/(v-b)^3 = 3a/v^4$; dividing the second by the first gives $1/(v-b) = 3/(2v)$, hence

$$v_c = 3b\,, \qquad T_c = \frac{8a}{27Rb}\,, \qquad P_c = \frac{a}{27b^2}\,, \tag{54.11}$$

the last two by substituting v_c back. A critical point therefore exists for every substance obeying Equation (54.9), which is the observed fact. Measuring P, v and T in units of Equation (54.11) eliminates a and b from Equation (54.9) altogether,

$$\left(P_r + \frac{3}{v_r^2}\right)(3v_r - 1) = 8T_r\,, \tag{54.12}$$

so all such substances have one reduced equation of state: the law of corresponding states, together with the substance-independent prediction $P_c v_c/(RT_c) = 3/8$. Both are mean-field statements, and both are only approximate; how they fail in the immediate neighbourhood of the critical point is the subject of Chapter 123. □

54.6.4 The Joule–Thomson effect

[Reserved: throttling through a porous plug at constant enthalpy; the Joule–Thomson coefficient, its inversion temperature, and its vanishing for the ideal gas, from the Joule–Thomson experiments of 1852–1862 [137], whose apparatus and data are treated in Chapter 56; gas liquefaction as the application.]

54.7 The third law

[Reserved: Nernst's heat theorem, that entropy differences vanish as the temperature goes to zero [328]; the unattainability of absolute zero in finitely many steps; consequences—vanishing heat capacities and expansivities at low temperature—whose observed forms are quantum-statistical and are derived in Chapter 120.]

Phenomenon 54.7 (Nernst's heat theorem)**.** As the temperature is lowered towards absolute zero, the entropy change accompanying any isothermal change of the remaining variables tends to zero:

$$\lim_{T\to 0}\left[S(T,x_2)-S(T,x_1)\right]=0 \tag{54.13}$$

for any two values x_1, x_2 of those variables. Nernst extracted this from the low-temperature behaviour of the heats and free energies of chemical reactions, where the two quantities were found to converge on one another [328]. Two consequences are themselves observed: the heat capacities of condensed matter fall away as $T \to 0$, in flat contradiction of the classical constant of Chapter 55, and absolute zero is never reached, each successive stage of any cooling technique yielding a smaller temperature drop than the last.

Derivation. Both consequences follow from Equation (54.13) and the positivity of heat capacities. For the first, integrate $\mathrm{d}S = C_x \mathrm{d}T/T$ at fixed x from zero:

$$S(T,x)-S(0,x)=\int_0^T C_x(T')\,\frac{\mathrm{d}T'}{T'}\,. \tag{54.14}$$

The left side is finite, so the integral converges at its lower limit; a heat capacity tending to any nonzero constant would make it diverge logarithmically. Hence $C_x(T) \to 0$ as $T \to 0$, and the Dulong–Petit value cannot survive to low temperature.

For the second, suppose absolute zero were reached in one adiabatic step, carried out reversibly and therefore at constant entropy, from a state (T, x_1) with $T > 0$ to a state $(0, x_2)$. That requires $S(T, x_1) = S(0, x_2)$. But Equation (54.13) makes $S(0, x_1) = S(0, x_2)$, while Equation (54.14) with $C_x > 0$ makes $S(\cdot, x_1)$ strictly increasing, so $S(T, x_1) > S(0, x_1) = S(0, x_2)$ for every $T > 0$—a contradiction. No such step exists, and since the argument applies to each step separately, no finite sequence of them reaches zero either. Only the microscopic ground of Equation (54.13) itself lies outside thermodynamics; it is derived from the non-degeneracy of the ground state in Chapter 120. □

54.8 The bridge to the molecular theory

[Reserved: what the phenomenology cannot fix—the values of heat capacities, the entropy constant, the size of fluctuations—and where each is settled: the kinetic theory of Chapter 55, the ensembles of Chapter 118, and the fluctuation phenomena made visible by Brownian motion in Chapter 119; Boltzmann's statistical reading of entropy [196] anticipated here.]

Chapter 55

Kinetic Theory of Gases

Kinetic theory is the bridge from mechanics to heat. Its hypothesis is that a gas is an enormous number of molecules in rapid, disordered motion, and its programme is to compute the state variables of Chapter 54 from the mechanics of Chapter 19: pressure from momentum transfer at the walls, temperature from the mean kinetic energy, and the transport coefficients from the mean free path between collisions. The programme succeeded so completely that it settled a question older than physics—whether matter is molecular—and put a number on it, Avogadro's constant.

This chapter carries the hypothesis from Bernoulli's first kinetic model to the Boltzmann equation and its H-theorem, together with the Maxwell–Boltzmann distribution and the elementary mean-free-path theory of viscosity, heat conduction and diffusion. The systematic solution theory of the Boltzmann equation—Chapman–Enskog and its successors—belongs to Chapter 124, and the ensemble foundation that frees the results from molecular models to Chapter 118.

Derivation pending #2

Kinetic Theory of Gases: all derivations of this chapter are pending.

55.1 The kinetic hypothesis

55.1.1 From Bernoulli to Clausius

[Reserved: Bernoulli's derivation of Boyle's law from particle impacts in section ten of the Hydrodynamica [22]; the long eclipse of the idea under the caloric theory; Waterston's complete kinetic memoir, refused in 1845 and printed only in 1892 with Rayleigh's introduction [256]; Krönig's short revival [145]; Clausius's "kind of motion we call heat", with its translational, rotational and vibrational shares [147].]

55.1.2 Pressure from molecular impacts

[Reserved: the elementary pressure formula $P = \tfrac{1}{3} n m \langle v^2 \rangle$ of [22, 147]; temperature as mean translational kinetic energy, and the kinetic reading of the ideal-gas law of Chapter 54; the virial theorem of Clausius [177] as the systematic version, and its later use for real gases.]

55.1.3 The mean free path

[Reserved: Buys Ballot's objection that gases interdiffuse far too slowly for molecules moving at hundreds of metres per second, and Clausius's answer—the mean free path, $\ell \sim 1/(n\sigma)$—in the 1858 paper [149]; the concept is customarily dated to the 1857 paper [147], which does

not contain it; collision frequency and effective cross-section; orders of magnitude for air at standard conditions, with ℓ of order 10^{-7} m.]

55.2 The Maxwell velocity distribution

55.2.1 Maxwell's derivation

[Reserved: the 1860 derivation of the equilibrium velocity distribution from isotropy and the independence of the components [154]; mean, most probable and root-mean-square speeds; the stronger 1867 rederivation from detailed balance of collisions [169]; the distribution as the stationary point of the collision term, anticipating Section 55.4.2.]

55.2.2 Molecular-beam verification

[Reserved: Stern's direct measurement of thermal molecular speeds in a silver beam [471]; the velocity-selector measurements of Miller and Kusch on potassium and thallium beams, confirming the Maxwell distribution at the per-cent level [1076]; why a beam samples the flux-weighted distribution, and the correction that implies.]

Phenomenon 55.1 (The distribution of molecular speeds)**.** Molecules leaving a small aperture in an oven held at temperature T arrive at a distant detector spread over a range of speeds, and the spread is the one Maxwell computed and no other. Stern measured it directly in a beam of silver atoms, by the deflection of the beam on a rotating drum [471]; Miller and Kusch, passing beams of potassium and thallium through a slotted rotating cylinder that transmits one speed at a time, confirmed the predicted shape to the per-cent level [1076]. Inside the oven the number of molecules with speeds between v and $v + \mathrm{d}v$ is proportional to

$$F(v)\,\mathrm{d}v \propto v^2 \exp\left(-\frac{mv^2}{2k_{\mathrm{B}}T}\right)\mathrm{d}v\,, \tag{55.1}$$

while the escaping beam carries one further power of v, because fast molecules reach the aperture more often than slow ones.

Derivation. Let $f(\boldsymbol{v})\,\mathrm{d}^3v$ be the number density of molecules with velocity within d^3v of $\boldsymbol{v}$. Two properties of a gas at rest fix its form. Isotropy: no direction is distinguished, so f depends on $\boldsymbol{v}$ only through v^2. Independence: in a dilute gas the Cartesian components are uncorrelated, so $f = \varphi(v_x)\varphi(v_y)\varphi(v_z)$ with the same φ for each. Together,

$$\varphi(v_x)\varphi(v_y)\varphi(v_z) = F\left(v_x^2 + v_y^2 + v_z^2\right)\,. \tag{55.2}$$

Take logarithms in Equation (55.2) and differentiate with respect to v_x at fixed v_y, v_z: $\varphi'(v_x)/\varphi(v_x) = 2v_xF'/F$. The right-hand side is symmetric under permuting the three components, so $\varphi'(v_x)/\left(v_x\varphi(v_x)\right)$ is one and the same constant -2λ for each of them, whence $\varphi(v_x) = A\exp(-\lambda v_x^2)$ and $f \propto \exp(-\lambda v^2)$. Normalisability requires $\lambda > 0$.

The pressure fixes λ. A wall normal to $\hat{x}$ is reached in unit time, per unit area, by those molecules within a distance v_x of it that are moving towards it; each rebounds elastically with its normal momentum reversed, delivering $2mv_x$, so

$$P = \int_{v_x>0} 2mv_x\, v_x f\,\mathrm{d}^3v = nm\left\langle v_x^2\right\rangle = \tfrac{1}{3}nm\left\langle v^2\right\rangle\,, \tag{55.3}$$

the last step by isotropy. Comparison with the observed equation of state $P = nk_{\mathrm{B}}T$ of Chapter 54 gives $\langle v^2\rangle = 3k_{\mathrm{B}}T/m$, while the Gaussian above has $\langle v^2\rangle = 3/(2\lambda)$; hence $\lambda = m/(2k_{\mathrm{B}}T)$. Multiplying f by the area $4\pi v^2$ of the shell of constant speed converts it

into the distribution of speeds, which is Equation (55.1). Finally, the molecules crossing the aperture in unit time are those within a distance v_z of it, so their number carries an extra factor v_z; averaging v_z over the forward hemisphere at fixed speed gives $v/2$, and the beam distribution is proportional to $v^3 \exp(-mv^2/2k_{\mathrm{B}}T)$, as observed. □

55.3 Equipartition and specific heats

55.3.1 The equipartition theorem

[Reserved: the equality of mean translational energies between components and between species in Maxwell's 1860 paper [154]; Boltzmann's general equipartition theorem, with mean energy $\frac{1}{2}k_{\mathrm{B}}T$ per quadratic degree of freedom [171]; what counts as a degree of freedom for monatomic and diatomic gases.]

55.3.2 Specific heats and the classical failure

[Reserved: predicted heat-capacity ratios against measurement; the Dulong–Petit law of solid specific heats [65] as an equipartition statement; the failure for diatomic gases at low temperature and for solids—degrees of freedom frozen out, which classical mechanics cannot freeze—flagged by Maxwell himself [154]; the resolution is quantum and is derived in Chapter 68 and Chapter 125.]

Phenomenon 55.2 (Classical heat capacities, and their failure)**.** At ordinary temperatures the molar heat capacity of a simple solid is close to $3R$ and very nearly the same for every element—the law of Dulong and Petit [65]—while the ratio $\gamma = C_P/C_V$ that Laplace inferred for air from the speed of sound is close to $7/5$ [59]. These are exactly the values equipartition predicts, and their agreement was the first quantitative success of the molecular hypothesis. Both fail on cooling: the heat capacities of solids and the rotational and vibrational shares of molecular gases fall away as the temperature drops, and no mechanical system with a fixed number of quadratic degrees of freedom can behave so. Maxwell named the discrepancy the outstanding difficulty of the theory [154]; the low-temperature measurements are collected in Chapter 125 and the resolution is quantum (Chapter 68, Chapter 120).

Derivation. By the equipartition theorem [171], every coordinate or momentum entering the energy quadratically carries a mean energy $\frac{1}{2}k_{\mathrm{B}}T$ in equilibrium. A monatomic gas has three such terms per molecule, the translational momenta, so $U = \frac{3}{2}nRT$ and $C_V = \frac{3}{2}nR$. For any gas in the dilute limit of Chapter 54 the two heat capacities differ by $C_P - C_V = nR$ (Chapter 56), so

$$\gamma = 1 + \frac{2}{f}\,, \tag{55.4}$$

with f the number of quadratic terms: $\gamma = 5/3$ for $f = 3$. A diatomic molecule at ordinary temperature turns as well as translates, adding two rotational terms about the two axes perpendicular to the bond—the third has negligible moment of inertia—so $f = 5$ and $\gamma = 7/5$, the measured value for air. In a solid each atom oscillates about a fixed site in three directions, contributing three kinetic and three potential quadratic terms, so $f = 6$, $U = 3nRT$ and the molar heat capacity is $3R$: the Dulong–Petit law.

The failure has no derivation here, and that is the point. f in Equation (55.4) counts degrees of freedom that exist or do not; classical mechanics offers no mechanism by which a rotation or a vibration present at one temperature can be absent at a lower one, whatever the interaction assumed. The observation is therefore not a defect of the estimate but a refutation of the mechanics used to make it. □

55.4 The Boltzmann equation

55.4.1 The transport equation

[Reserved: the one-particle distribution function on phase space; the streaming term and the binary-collision integral of Boltzmann's 1872 memoir [183]; the molecular-chaos assumption (Stosszahlansatz), stated explicitly as the point where probability enters the mechanics; the collision invariants and the conservation laws they imply.]

55.4.2 The H-theorem

[Reserved: the functional $H = \int f \ln f \, \mathrm{d}^3 v$ and Boltzmann's theorem that collisions can only decrease it [183]; stationarity exactly on the Maxwell distribution; $-H$ as a kinetic entropy, and the second law of Chapter 54 recovered for dilute gases.]

Phenomenon 55.3 (Irreversible approach to equilibrium)**.** An isolated dilute gas prepared with any velocity distribution whatever relaxes, within a few mean times between collisions, to the Maxwell distribution Equation (55.1) at the temperature its energy fixes, and remains there: the equilibrium form is what every measurement on an undisturbed gas finds [1076]. The reverse has never been seen. No gas in equilibrium has ever been observed to sort itself spontaneously into a non-Maxwellian state, or to unmix after mixing—and this although the underlying molecular mechanics is exactly invariant under reversal of every velocity, so that the reverse of any observed history is itself a mechanically possible history. Boltzmann's transport equation reproduces the observed one-sidedness through the H-theorem [183].

Derivation pending #3

The H-theorem: that the binary-collision integral of the Boltzmann transport equation makes the functional $H = \int f \ln f \, \mathrm{d}^3 v$ non-increasing in time, with stationarity exactly on the Maxwell distribution; together with an explicit statement of the molecular-chaos assumption on which the monotonicity rests, and of what the reversibility and recurrence objections do and do not refute.

55.4.3 Reversibility and recurrence

[Reserved: Loschmidt's reversibility objection [195]; Poincaré's recurrence theorem [247] and Zermelo's recurrence objection [273]; Boltzmann's probabilistic reply—the H-theorem holds for the overwhelming majority of microstates, not for all [196]; how the arrow of time enters through the Stosszahlansatz, with the full discussion deferred to Chapter 118.]

55.4.4 The Maxwell–Boltzmann distribution

[Reserved: Boltzmann's 1877 combinatorial definition of the probability of a macrostate and the distribution over energies it yields [196]; the Boltzmann factor and the barometric formula; the 1877 counting as the origin of the statistical entropy developed in Chapter 118.]

55.5 Transport phenomena

55.5.1 Viscosity

[Reserved: the mean-free-path estimate of the shear viscosity of a gas, and Maxwell's startling prediction that it is independent of density [154]; his own Bakerian-lecture measurements confirming it [167]; the refined transport theory of [169]; hand-off of the continuum description to Chapter 31.]

Phenomenon 55.4 (The viscosity of a gas does not depend on its density)**.** Rarefy a gas and its viscosity does not fall. Over a wide range of pressures the shear viscosity of a gas is independent of its density, and it grows with temperature—the opposite of a liquid, which thins on heating. Maxwell obtained the prediction from the mean free path before anyone had looked, called it the most startling consequence of the theory, and then measured it himself in oscillating-disc experiments [154, 167]. The independence holds only while the mean free path stays small against the apparatus; when the gas is rarefied past that point the viscosity does begin to fall with density, which is the free-molecular regime of [355] and Section 55.6.2.

Derivation. A molecule of collision cross-section σ sweeps, in time t, the volume $\sigma \langle v_{\mathrm{rel}} \rangle t$, and meets in it every molecule whose centre lies inside; with the Maxwell distribution Equation (55.1) the mean relative speed of two molecules is $\sqrt{2}\,\langle v \rangle$, so the number of collisions is $\sqrt{2} n\sigma \langle v \rangle t$ and the mean free path is the distance travelled per collision,

$$\ell = \frac{\langle v \rangle t}{\sqrt{2} n\sigma \langle v \rangle t} = \frac{1}{\sqrt{2}\, n\sigma}\,. \tag{55.5}$$

Now let the gas be sheared, with a flow velocity $u(z)$ along x. Molecules crossing the plane z carry with them the mean x momentum of their last collision, one mean free path away, so the momentum transported per unit area and time is of order $\frac{1}{3} n \langle v \rangle \cdot m\,[u(z-\ell) - u(z+\ell)]$, which identifies the viscosity as

$$\eta \approx \tfrac{1}{3} nm \langle v \rangle \ell = \frac{m \langle v \rangle}{3\sqrt{2}\,\sigma}\,. \tag{55.6}$$

The number density has cancelled between the density of carriers and the distance Equation (55.5) each one carries its momentum: halve the density and each molecule travels twice as far before delivering its load. Since $\langle v \rangle = \sqrt{8 k_{\mathrm{B}} T/\pi m}$ from Equation (55.1), the estimate also gives $\eta \propto \sqrt{mT}/\sigma$, increasing with temperature. Only the numerical factor in Equation (55.6) is unreliable—it depends on how crudely the transport step is modelled—and fixing it is what the systematic expansion of Section 55.5.4 does. The cancellation itself does not depend on that factor, and it fails only when ℓ ceases to be set by Equation (55.5), that is when it grows to the size of the vessel. □

55.5.2 Heat conduction

[Reserved: Fourier's law of conduction from his analytical theory of heat [72]; the mean-free-path estimate of the thermal conductivity of a gas and its relation to the viscosity and the specific heat; density independence and the experimental range over which it holds.]

55.5.3 Diffusion

[Reserved: Graham's law of gaseous diffusion [94]; Fick's phenomenological law [143]; the mean-free-path estimate of the diffusion coefficient; Einstein's fluctuation relation connecting diffusion to molecular agitation [318], with Brown's original observations [82] and the decisive experiments of Chapter 119.]

55.5.4 Chapman–Enskog and the road to hydrodynamics

[Reserved: the systematic expansion of the Boltzmann equation about local equilibrium by Chapman [434] and Enskog [447], which turns the estimates of this section into controlled transport coefficients and derives the Navier–Stokes equations of Chapter 31; developed in Chapter 124 and only named here.]

55.6 Effusion and rarefied gases

55.6.1 Graham's law of effusion

[Reserved: effusion through an orifice small against the mean free path; the rate proportional to the inverse square root of the molar mass, established by Graham for diffusion [94] and for effusion and transpiration [120]; the kinetic effusion flux $\tfrac{1}{4}n\langle v\rangle$; isotope separation named as the application.]

Phenomenon 55.5 (Graham's square-root law)**.** A gas escaping through an aperture small compared with the mean free path does so at a rate inversely proportional to the square root of its molar mass, the pressure and temperature being fixed; a mixture driven through such an aperture is thereby partially separated, the lighter component passing preferentially. Graham established the square-root law first for the passage of gases through a porous plug [94] and then for effusion and for capillary transpiration [120]. That the law involves the mass and not the chemical character of the molecule is the point: it is a statement about mechanics, not chemistry.

Derivation. The aperture being small against ℓ, the escaping molecules are simply those that would have struck that patch of wall, and their distribution inside is undisturbed. The number crossing unit area of the plane in unit time is

$$\Phi = \int_{v_z>0} v_z f \,\mathrm{d}^3v = \int_0^\infty v\,F(v)\,\mathrm{d}v \int_0^{\pi/2} \frac{\cos\vartheta\,\sin\vartheta}{2}\,\mathrm{d}\vartheta = \tfrac{1}{4}n\,\langle v\rangle\ , \tag{55.7}$$

where F is the speed distribution normalised to $\int F\,\mathrm{d}v = n$, and the angular factor is the fraction $\tfrac{1}{2}\sin\vartheta\,\mathrm{d}\vartheta$ of solid angle at polar angle ϑ times the obliquity $\cos\vartheta$. Elementary Gaussian integrals over Equation (55.1) give $\langle v\rangle = \sqrt{8k_{\mathrm{B}}T/\pi m}$, so

$$\Phi = n\sqrt{\frac{k_{\mathrm{B}}T}{2\pi m}} = P\sqrt{\frac{1}{2\pi m k_{\mathrm{B}}T}}\,, \tag{55.8}$$

using $P = nk_{\mathrm{B}}T$. At the same pressure and temperature the number density is the same for both gases, so the ratio of the two effusion rates is $\sqrt{m_2/m_1} = \sqrt{M_2/M_1}$, which is Graham's law. The same factor $\tfrac{1}{4}n\,\langle v\rangle$ governs the rate at which a surface is struck, and so the growth of an adsorbed layer in a vacuum system. □

55.6.2 The Knudsen regime

[Reserved: the Knudsen number; Knudsen's laws of molecular flow through tubes at low pressure [355]; thermal transpiration; where the continuum description of Chapter 31 fails and free-molecular flow replaces it, with vacuum technology as the working application.]

55.7 Molecular reality and Avogadro's constant

55.7.1 Loschmidt's count

[Reserved: Avogadro's hypothesis [55] made quantitative: Loschmidt's 1865 estimate of the molecular diameter and the number density of air, from the mean free path and the density of the liquefied gas [163]; the modern Loschmidt constant, about $2.687\times10^{25}/\mathrm{m}^3$ at standard conditions [2431].]

Phenomenon 55.6 (One molecular count, reached by unrelated routes)**.** The number of molecules in a mole of substance can be inferred by methods sharing no apparatus and no theory beyond the molecular hypothesis itself—from the mean free path together with the

density of the liquefied gas [163], from the Brownian displacements of suspended particles [318, 358], from the charge carried in electrolysis, and from the counting of particles emitted by a radioactive source—and the answers agree. That convergence, and not any single determination, is what established that matter is molecular, since no one route is more than an estimate. The constant is now fixed by definition, $N_{\mathrm{A}} = 6.022\,140\,76 \times 10^{23}/\mathrm{mol}$ [2333, 2431], and it is the measurements that are graded against it rather than the other way about.

Derivation. Loschmidt's route needs two measured numbers and one geometrical assumption. The first number is the mean free path ℓ. Read Equation (55.6) in the form $\eta \approx \frac{1}{3}\rho\,\langle v\rangle\,\ell$, with $\rho = nm$ the mass density of the gas, which is weighed directly, and $\langle v\rangle = \sqrt{8RT/\pi M}$ fixed by the molar mass alone; then $\ell = 3\eta/(\rho\,\langle v\rangle)$ follows from measurements that never mention the number of molecules. The second number is the condensation ratio ε, the volume of liquid obtained from unit volume of gas. Take the molecules to be spheres of diameter d, packed in the liquid so as to fill it; then per unit volume of gas

$$\varepsilon = n\,\frac{\pi d^3}{6}\,, \tag{55.9}$$

while Equation (55.5) with $\sigma = \pi d^2$ gives $\ell = 1/(\sqrt{2}\pi d^2 n)$. These are two equations in the two unknowns n and d; substituting the second into Equation (55.9) leaves

$$\varepsilon = \frac{\pi d^3}{6\sqrt{2}\pi d^2 \ell} = \frac{d}{6\sqrt{2}\,\ell}\,, \qquad d = 6\sqrt{2}\,\varepsilon\ell\,, \tag{55.10}$$

and then $n = 1/(\sqrt{2}\pi d^2\ell)$ and $N_{\mathrm{A}} = nV_{\mathrm{m}}$ with V_{m} the molar volume. The packing assumption is crude, so the result is an order of magnitude and not a measurement; what makes it evidence is that the wholly unrelated Brownian and electrolytic routes land on the same order of magnitude. □

55.7.2 From estimates to an exact constant

[Reserved: the convergence of independent determinations of Avogadro's constant—kinetic, Brownian (Perrin's programme [358], with the experiments of Chapter 119), electrolytic and radiometric—as the historical proof of molecular reality; the 2019 redefinition of the SI, which fixes the constant exactly at $6.022\,140\,76 \times 10^{23}/\mathrm{mol}$ *[2333, 2431].]*

Chapter 56

Experiment: The Mechanical Equivalent of Heat

Joule's paddle-wheel measurements established that heat is energy in transfer: a fixed quantity of mechanical work, however delivered, produces the same rise of temperature in the same body [129]. The result killed the caloric theory, grounded the first law of Chapter 54, and fixed the conversion factor that every calorimetric measurement in this treatise silently uses. Its molecular reading—work stirred into the disordered motion of Chapter 55—came a decade later.

When its content is written, this chapter will use the structured `experiment` environment, with apparatus, procedure, observations with uncertainties in SI units, interpretation and primary references; the sections below reserve that structure and name the sources.

Derivation pending #4

Experiment: The Mechanical Equivalent of Heat: all derivations of this chapter are pending.

56.1 Historical context: heat as substance or motion

56.1.1 Rumford's cannon-boring observations

[Reserved: the caloric theory and its genuine successes; Rumford's observation that boring cannon generates heat without limit, arguing that heat cannot be a conserved substance [43]; his rough estimate of an equivalent from horses and boring dust; why the argument, though correct, did not persuade for half a century.]

Phenomenon 56.1 (Friction generates heat without limit)**.** Rubbing generates heat in a body without limit and without altering the body. Rumford, boring cannon at the Munich arsenal with a deliberately blunted tool driven by horses, found the supply of heat inexhaustible so long as the work continued—enough, in one trial, to bring the surrounding water to the boil—and found further that the metal dust produced had the same heat capacity, weight for weight, as the metal it came from [43].

Derivation. The observation refutes the hypothesis it was aimed at. Suppose heat is a conserved substance resident in bodies, as the caloric theory held. Then the heat obtainable from a given body is bounded by the amount it contains, and heat is released only by lowering that content—by a change of state, or by a reduction in the capacity of the substance to hold caloric. Both consequences are contradicted at once: the yield was unbounded and, so far as could be told, proportional to the work expended rather than to any property of

the metal consumed; and the dust, which on the caloric account had given up its heat by a reduced capacity, showed the same capacity as the solid. Hence what is released is not drawn from a fixed store, and the conserved quantity—if there is one—must be one that mechanical work can supply. Identifying it is the work of Section 56.2; the caloric theory survives only as the special case in which no work is done. □

56.1.2 Mayer's inference

[Reserved: Mayer's 1842 claim of the equivalence of heat and work, with the first numerical equivalent, extracted from the difference of the two heat capacities of air [108]; the assumption the inference rests on (no internal work in the free expansion of a gas); the priority dispute with Joule, stated plainly.]

Phenomenon 56.2 (The two heat capacities of a gas differ by the gas constant)**.** Heating a gas at constant pressure takes more heat than heating the same gas through the same interval at constant volume, and for dilute gases the molar difference is the gas constant,

$$C_P - C_V = nR\,. \tag{56.1}$$

The two capacities of air had been measured before any theory of heat existed, and Mayer saw that their difference is the work the expanding gas performs against the atmosphere; equating the one to the other gave him the first numerical value of the mechanical equivalent of heat, without any apparatus of his own [108].

Derivation. Take n moles. At constant volume the gas does no work, so all the heat supplied raises the internal energy: $C_V = \mathrm{d}U/\mathrm{d}T$, using that U depends on the temperature alone—which is the content of Phenomenon 56.4 below, and the assumption Mayer's inference silently rests on. At constant pressure the same rise of temperature raises U by the same amount, since U depends on nothing else, but the gas additionally expands, by $\Delta V = nR\Delta T/P$ from the equation of state $PV = nRT$, and does work

$$P\Delta V = nR\Delta T\,. \tag{56.2}$$

The heat supplied at constant pressure therefore exceeds that supplied at constant volume by exactly $nR\Delta T$, which is Equation (56.1). The inference now runs backwards. The left side of Equation (56.1) is a difference of two *calorimetric* measurements, expressed in whatever unit of heat the laboratory uses; the right side is a *mechanical* work, expressed in mechanical units. The equality between them is therefore a conversion factor between the two units, obtained without ever converting work into heat in an apparatus. Its weakness is equally plain: it is only as good as the assumption that a gas expanding freely does no internal work, which nothing in the argument tests. Joule's paddle wheel tests it. □

56.1.3 Joule's programme, 1843–1849

[Reserved: the magneto-electrical measurements that opened the series [109]; the rarefaction and condensation experiments [112]; the first paddle-wheel announcement [113]; the convergence of Joule's values as the methods improved, closing on the definitive 1850 series [129].]

56.2 The claim under test

[Reserved: the proposition that one fixed conversion factor connects work and heat, independent of the process, the substance and the rate—the quantitative content of the first law of Chapter 54, stated for all of physics by Helmholtz [121]; what a failure of process independence would have looked like; the kinetic reading of the same claim in Chapter 55.]

Phenomenon 56.3 (One conversion factor, whatever the mechanism)**.** In a thermally insulated calorimeter the rise of temperature is proportional to the mechanical work dissipated inside it, and the constant of proportionality is a property of the calorimeter alone. It does not depend on how the work is dissipated, nor on how fast. Joule obtained the same equivalent from a paddle wheel churning water, from the same wheel churning mercury, from cast-iron discs rubbing against each other under mercury [129], and, in the earlier series, from an electric current driven by a falling weight [109] and from the condensation and rarefaction of air [112]; the paddle-wheel method itself he first announced in 1845 [113]. Nothing in the first law compels this agreement: it is what the measurement found.

Derivation. The work delivered in a run of N descents of two weights of mass M through a height h is

$$W = 2NM\left(gh - \tfrac{1}{2}u^2\right) - W_{\mathrm{f}}\,, \tag{56.3}$$

u being the residual speed of the weights at arrest and W_{f} the work absorbed by the pulleys and the suspension, both of which Joule measured separately and subtracted. No heat crosses the insulated boundary, so by the first law the internal energy of the calorimeter rises by exactly W. The calorimeter ends in a state differing from its initial one only in temperature, so that rise is $C\,\Delta T$ with C the total heat capacity of water, vessel and fittings, and

$$\Delta T = \frac{W}{C}\,. \tag{56.4}$$

Everything on the right of Equation (56.4) is a property of the calorimeter and of the work supplied; the stirring mechanism has dropped out. This is the whole content of the observation, and it is the empirical statement that the adiabatic work between two states depends only on the states—the property that makes the internal energy a state function in Chapter 54. Had the equivalent depended on the mechanism, one could raise the calorimeter's temperature by the cheaper route and lower it again by the dearer, returning every part of the apparatus to its initial state while extracting net work; the measurement is thus also a bound on perpetual motion of the first kind. □

56.3 Apparatus

[Reserved: the 1850 paddle-wheel calorimeter [129]: a brass paddle wheel churning water—and, in parallel series, mercury—inside an insulated vessel fitted with stationary vanes that prevent bulk rotation; the drive by two lead weights of about 13 kg *each falling through about* 1.6 m*, the descent repeated twenty times per run; thermometers readable to about* 3 mK*; all dimensions quoted here in SI, converted on port from Joule's imperial originals.]*

56.4 Procedure

[Reserved: determination of the work input from the weight, the fall height and the descent count, with corrections for the residual kinetic energy of the weights at arrest and for pulley friction; measurement of the temperature rise of the calorimeter; blank trials interleaved to fix the radiation correction; Joule's averaging over runs and series [129].]

56.5 Observations

[Reserved: the data tables to be reproduced here in SI—mass of the weights, total fall, work input, water mass and the water equivalent of the vessel, corrected temperature rise, and the resulting equivalent per run—with the uncertainty budget presented per [2129]; Joule's 1850

mean corresponds to a specific heat of water of about $4157\,\mathrm{J/(kg\,K)}$*, within one per cent of the modern* $4187\,\mathrm{J/(kg\,K)}$ *[129].]*

56.6 Interpretation

[Reserved: heat is not a conserved substance; work and heat are two currencies of one conserved quantity, the internal energy of Chapter 54; process independence checked across the water, mercury and cast-iron friction series [129]; the place of the result in the energy-conservation synthesis of Mayer [108] and Helmholtz [121].]

56.7 The Joule–Thomson companion experiments

[Reserved: free expansion into vacuum, from Gay-Lussac [52] to Joule's twin-vessel experiment [112], showing no temperature change at the attainable precision; the porous-plug experiments of Joule and Thomson, 1852–1862, which resolved the small real-gas cooling the cruder method missed [137]; the Joule–Thomson coefficient and its inversion, whose thermodynamics is developed in Chapter 54; gas liquefaction as the technological descendant.]

Phenomenon 56.4 (No cooling in the free expansion of a dilute gas)**.** Let a gas at moderate pressure expand into an evacuated vessel, the whole assembly being thermally isolated from its surroundings. No change of temperature is found, within the precision of the measurement. Gay-Lussac observed this first [52], and Joule repeated it with twin copper vessels joined by a stopcock and immersed in a common water bath [112]. The conclusion drawn—that the internal energy of a dilute gas depends on its temperature alone—is the assumption on which Mayer's inference Equation (56.1) silently rested. The effect the method was too crude to see is the subject of Phenomenon 56.5.

Derivation. The gas expands into vacuum, so it does no work on anything outside it, $W = 0$; the assembly is insulated, so $Q = 0$. By the first law $\Delta U = 0$: the free expansion is a change of volume at constant internal energy. The measurement reports $\Delta T = 0$ across it, that is

$$\left(\frac{\partial T}{\partial V}\right)_U = 0\,. \tag{56.5}$$

Expanding the derivative at constant U by the chain rule,

$$\left(\frac{\partial T}{\partial V}\right)_U = -\frac{1}{C_V}\left(\frac{\partial U}{\partial V}\right)_T\,, \tag{56.6}$$

since $(\partial U/\partial T)_V = C_V$. The heat capacity is finite and positive, so Equation (56.5) forces $(\partial U/\partial V)_T = 0$ and hence $U = U(T)$. Together with the equation of state $PV = nRT$ this completes the description of the ideal gas and yields Equation (56.1). The honest statement of the result is a bound rather than an identity: the experiment shows only that $(\partial U/\partial V)_T$ is smaller than the thermometry could resolve, the water bath's own heat capacity swamping the effect. □

Phenomenon 56.5 (The Joule–Thomson effect)**.** Force a real gas steadily through a porous plug, from a higher to a lower pressure, along a thermally insulated tube. Its temperature changes by a small but definite amount: most gases at room temperature emerge cooler, hydrogen and helium emerge warmer, and for each gas there is an inversion temperature above which cooling gives way to warming. Joule and Thomson established the effect in the series of 1852–1862 [137]. It is the effect the free expansion of Phenomenon 56.4 was too crude to detect, and, unlike that null result, it is a direct measure of the forces between molecules; the industrial liquefaction of gases descends from it.

Derivation. Follow a fixed quantity of gas through the plug. Upstream, the piston pushing it in does work P_1V_1 on it; downstream, the gas does work P_2V_2 in making room for itself. The tube is insulated, so $Q = 0$, and the first law gives $U_2 - U_1 = P_1V_1 - P_2V_2$, that is

$$H_1 = H_2\,, \qquad H := U + PV\,. \tag{56.7}$$

Throttling is a process at constant enthalpy—not a quasi-static one, but the end states are equilibrium states and that is all Equation (56.7) requires. The measured quantity is therefore

$$\mu := \left(\frac{\partial T}{\partial P}\right)_H = -\frac{1}{C_P}\left(\frac{\partial H}{\partial P}\right)_T\,, \tag{56.8}$$

by the same chain rule as before with $(\partial H/\partial T)_P = C_P$. From $\mathrm{d}H = T\,\mathrm{d}S + V\,\mathrm{d}P$ and the Maxwell relation $(\partial S/\partial P)_T = -(\partial V/\partial T)_P$ of Chapter 54,

$$\mu = \frac{1}{C_P}\left[T\left(\frac{\partial V}{\partial T}\right)_P - V\right]\,. \tag{56.9}$$

For an ideal gas $V = nRT/P$ gives $T(\partial V/\partial T)_P = V$ and $\mu = 0$: the effect vanishes identically, so whatever is measured is a departure from ideality and nothing else. The sign of Equation (56.9) changes where $T(\partial V/\partial T)_P = V$, which is the inversion condition; for the van der Waals gas of Chapter 54 the attraction a cools and the excluded volume b warms, and the inversion temperature is where the two balance—which is why hydrogen and helium, with small a, must be precooled before throttling will liquefy them. □

56.8 Modern repetitions and precision

[Reserved: electrical calorimetry replacing mechanical stirring—the continuous-flow measurement of the specific heat of water by Callendar and Barnes [303], and the National Bureau of Standards determinations of Osborne, Stimson and Ginnings [846]; the retirement of the calorie; since the 2019 SI the joule is the sole unit of heat and work, so the "equivalent" is exact by definition [2333], its measurable content surviving as the specific heat of water, with current values in [2431].]

Chapter 57

Experiment: The Kinetic Theory Tested

Chapter 55 makes a gas out of molecules and then makes predictions with them: a definite distribution of molecular speeds at a given temperature, a viscosity that does not fall when the gas is rarefied, three transport coefficients built from one and the same mean free path, a count of molecules reachable from macroscopic measurements alone, and—by what it omits—an equation of state that can be exact only if the molecules exert no forces on one another at a distance. None of that is self-evident. One item, the density independence of the viscosity, Maxwell himself called the most startling consequence of the theory, and he did not believe it until he had measured it. This chapter reports the measurements.

The six experiments below are ordered by what they test rather than by date. Two are molecular-beam experiments that record the distribution of speeds itself, which is the central assertion of the theory and the one that a purely thermodynamic argument can never reach. One is Maxwell's own measurement of the prediction he found hardest to believe. One collects the transport coefficients and checks the relations kinetic theory forces among them. One turns those same measurements into a count of molecules, which is how the molecular hypothesis first acquired a number. The last, the porous plug of Joule and Thomson, measures what the ideal gas leaves out. The Brownian evidence for the same hypothesis—the most direct of all, since it watches the fluctuations rather than the averages—is treated separately in Chapter 119, and the thermodynamic reading of the porous-plug experiment in Chapter 56.

57.1 Stern: the direct measurement of molecular speeds (1920)

Kinetic theory asserts that the molecules of a gas at 300 K are moving at some hundreds of metres per second. Before 1920 that number had never been measured; it had only been inferred, from the pressure a gas exerts and from the speed of sound, by arguments that assume the molecular picture they are meant to support. Stern's molecular-beam apparatus measured a molecular speed directly, by timing a flight over a known distance [471].

57.1.1 Apparatus

A platinum wire, coated with silver and heated electrically in high vacuum, evaporates silver atoms. The wire lies on the axis of two coaxial cylinders fixed to it: an inner cylinder of radius r_1 carrying a narrow slit parallel to the axis, and an outer cylinder of radius r_2 whose inner surface collects the atoms that pass the slit. The whole assembly—wire, slit and collector—can be spun about the wire axis at an angular speed ω of a few hundred

radians per second. The vacuum must be good enough that the flight from slit to collector is collision-free, that is, the mean free path of Phenomenon 57.7 must exceed $r_2 - r_1$, and the deposit is built up over a long run and then developed, as in the molecular-beam experiment of Chapter 80.

57.1.2 Procedure

With the assembly at rest the atoms travel radially and the deposit forms on the collector directly opposite the slit; that position is the zero of the measurement. With the assembly spinning, the collector moves while the atom is in flight, so the deposit is displaced along the circumference by an amount that depends on the time of flight and hence on the speed. Reversing the sense of rotation displaces it the other way; taking half the separation between the two deposits removes any error in locating the zero, which is the only quantity in the measurement that cannot be read off a scale. The oven temperature, the two radii and the angular speed complete the data.

57.1.3 Observations and data

[Reserved: the primary tables of [471], to be reproduced here in SI—the two cylinder radii in metres, the angular speed in radians per second, the wire temperature in kelvin, the measured displacement of the deposit maximum in metres, and the mean molecular speed inferred from them with its uncertainty, presented per [2129]. For orientation, silver at about $1300\,\mathrm{K}$ *has* $\langle v\rangle = \sqrt{8RT/\pi M} \approx 5 \times 10^{2}\,\mathrm{m/s}$*, so with centimetre-scale radii and* ω *of a few hundred radians per second the displacement is of order a millimetre—small, but far larger than the width of the undisplaced trace.]*

57.1.4 Interpretation

The deposit moves, in the direction and by roughly the amount that a flight time $(r_2 - r_1)/v$ requires with v of the predicted size. It is also *smeared*, and the smear is not a defect of the apparatus: since the displacement varies as $1/v$, the deposit is a map of the distribution of speeds, stretched towards the zero for the fast molecules and away from it for the slow ones. This first version measured essentially one moment of that distribution; recording its shape is the business of Section 57.2.

One caution belongs with any beam measurement and is developed in Equation (57.3): what leaves an aperture is not a sample of the gas inside. Fast molecules reach the aperture more often than slow ones, so the beam is weighted by an extra power of the speed, and its mean speed exceeds the mean speed in the oven by the factor $3\pi/8$. Comparing a beam average against the in-oven $\langle v\rangle$ therefore misses by $18\,\%$ before any experimental error is committed.

57.1.5 Primary references

[471]. The method is the one Stern had developed from 1919 onward and applied two years later in Chapter 80; the diffraction of the same beams, which measures a wavelength rather than a speed, belongs to Chapter 71 [651].

Phenomenon 57.1 (Molecules move at the speeds kinetic theory assigns them)**.** The atoms of a vapour in equilibrium at temperature T cross a known distance in a measurable time, and the speed so obtained is of the order $\sqrt{k_{\mathrm{B}}T/m}$ that kinetic theory requires—some hundreds of metres per second for a heavy metal vapour at a thousand kelvin, and larger for lighter molecules in the same ratio $M^{-1/2}$. Stern measured it by the displacement of a silver deposit on a rotating collector [471]. The measurement is direct in the sense that

matters here: it uses a length and a time, and no property of a gas other than the fact that its molecules fly freely between collisions.

Derivation. Let the slit sit at radius r_1 and the collector at radius r_2 on the same rigid body, turning at angular speed ω. An atom that passes the slit travels radially outward in a straight line—this is the assumption the vacuum has to earn—and reaches the collector after a time $t = (r_2 - r_1)/v$. During that time the collecting surface has advanced along its own circumference by $\omega r_2 t$, so the deposit lands a distance

$$s = \frac{\omega r_2 (r_2 - r_1)}{v} \tag{57.1}$$

from the point opposite the slit. Everything in Equation (57.1) but v is a laboratory constant, so the equation is a measurement of v; and since $s \propto 1/v$, a spread of speeds becomes a spread of deposit positions, with the slow molecules thrown furthest. Reversing ω reverses the sign of s, so half the separation of the two deposits gives $|s|$ without knowing where the zero lies. □

57.2 Miller and Kusch: the shape of the distribution (1955)

Between Stern's measurement and this one stand the rotating-drum velocity analysers of the early 1930s—Zartman's and Ko's—which replaced the single displaced deposit by a deposit profile and so recorded the shape of the distribution rather than one moment of it [690, 742]. Miller and Kusch's slotted-rotor selector is the precision version of the same idea, and it is the experiment that turned the Maxwell distribution from a plausible functional form into a measured curve [1076].

57.2.1 Apparatus

An oven holding potassium or thallium at a controlled and measured temperature, effusing through a slit into high vacuum. Between the oven and the detector sits a velocity selector: a cylinder carrying many slots cut helically through its rim, spun about its axis, so that an atom passes only if its time of flight along the cylinder matches the time the entrance slot takes to rotate into the position of the exit slot. The transmitted band of speeds is therefore proportional to the rotation rate, and its width is set by the machining. Detection is by surface ionisation on a hot wire followed by ion collection, which counts atoms as a current rather than accumulating a deposit, and so turns the measurement from a photographic one into an electrical one.

57.2.2 Procedure

Hold the oven at a measured temperature, scan the rotor speed, and record the detector current at each setting. The result is the transmitted intensity as a function of the selected speed. The raw curve is not yet the distribution: it must be corrected for the finite width of the transmission window, for the higher-order pass bands at submultiples of the rotation rate, and for the response of the ioniser. The corrected curve is then compared with the flux-weighted Maxwell form Equation (57.2), with the oven temperature taken from the thermocouple and *not* adjusted to improve the fit—which is what makes the comparison a test rather than a fit.

57.2.3 Observations and data

[Reserved: the primary curves of [1076], to be tabulated here as transmitted intensity against selected speed in m/s *for potassium and for thallium at their stated oven temperatures*

in kelvin, together with the residuals against Equation (57.2) and their uncertainties per [2129]. The headline result quoted in Chapter 55 is agreement with the predicted shape at the per-cent level; the individual residuals are what show whether the disagreement is random or structured, and they are not reproduced here because the primary tables were not consulted.]

57.2.4 Interpretation

Two things are being tested at once, and they are worth separating. The first is the *shape*: an exponential in v^2 with a polynomial prefactor, over a range of speeds wide enough that the prefactor and the exponential are separately visible. The second is the *parameter*: the temperature that best describes the curve must be the temperature the thermocouple reads, since the distribution has no other adjustable constant. A theory that got the shape right with a free temperature would be much weaker evidence.

The composition of the vapour enters the interpretation and is not a detail: a dimer of twice the molecular mass has the same distribution with v rescaled by $1/\sqrt{2}$, so an unrecognised dimer fraction imitates a distorted distribution of the monomer. Any beam experiment of this kind therefore owes an account of what is actually in the beam, which is one reason for measuring two species of very different mass.

57.2.5 Primary references

[690, 742, 1076]. The rotating-drum analysers come first and the velocity selector of Miller and Kusch is the precision version of the same idea.

Phenomenon 57.2 (The distribution of speeds in a molecular beam)**.** The number of molecules per unit time leaving an oven at temperature T with speeds between v and $v + \mathrm{d}v$ is proportional to $v^3 \exp\left(-mv^2/2k_{\mathrm{B}}T\right) \mathrm{d}v$, and the temperature that describes the measured curve is the temperature of the oven. Miller and Kusch established this for potassium and thallium beams, passing them through a slotted rotating selector, and found the predicted shape confirmed at the per-cent level [1076]. The cube of the speed, rather than the square that describes the gas inside the oven, is not an adjustable feature: it follows from the aperture being small against the mean free path.

Derivation. Inside the oven the number density of molecules with speeds in $\mathrm{d}v$ about v is $F(v)\,\mathrm{d}v \propto v^2 \exp\left(-mv^2/2k_{\mathrm{B}}T\right) \mathrm{d}v$, the factor v^2 being the area of the shell of constant speed in velocity space. A molecule crosses the aperture in unit time only if it lies within a distance v_z of it and is moving towards it, so the flux carries one power of the speed more than the density does:

$$\Phi(v)\,\mathrm{d}v \propto v^3 \exp\left(-\frac{mv^2}{2k_{\mathrm{B}}T}\right) \mathrm{d}v\,. \tag{57.2}$$

The extra power is large. Write $a = m/2k_{\mathrm{B}}T$ and use $\int_0^\infty v^4 \exp\left(-av^2\right) \mathrm{d}v = \frac{3}{8}\sqrt{\pi}\, a^{-5/2}$ together with $\int_0^\infty v^3 \exp\left(-av^2\right) \mathrm{d}v = \frac{1}{2}a^{-2}$; then the mean speed of the molecules in the *beam* is

$$\langle v \rangle_{\mathrm{beam}} = \frac{3}{4}\sqrt{\frac{\pi}{a}} = \frac{3\pi}{8}\,\langle v \rangle \approx 1.18\,\langle v \rangle\ , \tag{57.3}$$

since $\langle v \rangle = \sqrt{8k_{\mathrm{B}}T/\pi m} = 2/\sqrt{\pi a}$ is the mean speed in the oven. The two differ by 18 %. The same argument shows why the aperture must be small against the mean free path: if it were not, the escaping molecules would collide on the way out, the gas would flow hydrodynamically through the hole, and the beam would carry a shifted rather than a weighted distribution. □

57.3 Maxwell: the viscosity of air and its density (1866)

In 1860 Maxwell derived from the mean free path a conclusion he plainly disliked: the shear viscosity of a gas should not depend on its density [154]. Halve the number of carriers and each survivor carries its momentum twice as far, and the two effects cancel exactly. No experiment at the time contradicted it, because no experiment had looked. Maxwell looked, in the Bakerian Lecture of 1866 [167].

57.3.1 Apparatus

Parallel glass discs mounted on a common vertical axis and hung from a torsion fibre, so that the assembly oscillates in its own plane between fixed discs a small distance away. The whole is enclosed in a vessel that can be evacuated to a controlled pressure and heated, the gas temperature being read by a thermometer inside and the pressure by a manometer. The angular amplitude is read optically, by a mirror on the suspension and a distant scale, so that nothing touches the moving system.

57.3.2 Procedure

Set the discs swinging and record the period and the decay of the amplitude. The gas in the narrow gaps resists the motion, and the logarithmic decrement of the oscillation—the constant ratio between successive amplitudes—measures that resistance; with the geometry of the gaps known, it yields the shear viscosity. Repeat at a series of pressures at fixed temperature, which is the density test, and at a series of temperatures at fixed pressure, which is the temperature test. The residual decrement of the suspension itself is measured with the vessel evacuated and subtracted.

57.3.3 Observations and data

[Reserved: the primary tables of [167], to be reproduced here in SI—gas pressure in Pa*, temperature in* K*, period in* s*, logarithmic decrement, and the viscosity in* Pa s *with its uncertainty, converted from Maxwell's units on port per the unit axiom of Chapter 2. Two derived statements are what the table has to support: that the viscosity is constant along the pressure series, and that along the temperature series it rises as T rather than as $\sqrt{T}$. For orientation, the viscosity of air near room temperature is about* 18 µPa s.*]*

57.3.4 Interpretation

The pressure series is the striking one. A liquid's viscosity is a property of how crowded it is; a gas's is not, and over the range of pressures the apparatus could span the measured viscosity did not change. That is the mean-free-path cancellation, observed. It is not unlimited: when the gas is rarefied until the mean free path is comparable with the width of the gaps, the molecules cross from one surface to the other without colliding, the internal friction ceases to be a property of the gas alone, and the viscosity does begin to fall with the density—the free-molecular regime of [355]. The failure is as informative as the success, because it locates the length that the elementary theory says is responsible.

The temperature series is the more consequential one, and it went against the theory as Maxwell had first written it. Hard spheres give $\eta \propto \sqrt{T}$; the measurements gave something much closer to $\eta \propto T$. Maxwell drew the correct conclusion—that molecules are not hard spheres but centres of a repulsive force—and rebuilt the transport theory in 1867 around the one force law, the inverse fifth power, that makes the collision integrals tractable [169]. This is the first quantitative information about an intermolecular force obtained from a bulk

measurement, and it is the same programme that the porous plug of Section 57.6 continues at long range.

57.3.5 Primary references

[167]; the prediction under test is from [154] and the theory rebuilt on the result is [169]. The low-pressure breakdown is [355].

Phenomenon 57.3 (Rarefying a gas does not thin it)**.** Over a wide range of densities the shear viscosity of a gas is independent of its density, so that pumping gas out of a vessel does not reduce the drag on a body moving inside it. Maxwell predicted this from the mean free path before any measurement existed [154] and then measured it himself with oscillating discs [167]. The independence holds only while the mean free path remains small against the apparatus; below that the viscosity does fall with density [355].

Derivation. Molecules crossing a plane in a sheared gas carry the mean flow momentum they acquired at their last collision, one mean free path ℓ away, and they cross at a rate of order $\frac{1}{3}n\langle v\rangle$ per unit area. The transported momentum per unit area and time is therefore of order $\frac{1}{3}nm\langle v\rangle\,\ell$ times the velocity gradient, so

$$\eta \approx \tfrac{1}{3}\rho\langle v\rangle\,\ell = \frac{m\langle v\rangle}{3\sqrt{2}\,\sigma}\,, \tag{57.4}$$

using $\rho = nm$ and $\ell = 1/\left(\sqrt{2}n\sigma\right)$ with σ the collision cross-section. The number density has cancelled: it counts the carriers, and it also fixes how far each carrier goes. Nothing in Equation (57.4) depends on how crudely the transport step was modelled except the numerical factor, so the cancellation is robust where the estimate of the coefficient is not. It fails exactly when ℓ stops being given by the collisions—that is, when the vessel, not the gas, sets the distance a molecule travels between momentum exchanges. □

Phenomenon 57.4 (The viscosity of a gas rises with temperature, and too fast for hard spheres)**.** Heating a gas makes it more viscous—the opposite of a liquid—and for air the rise is close to proportional to the absolute temperature. Maxwell's oscillating-disc measurements gave a temperature dependence much nearer $\eta \propto T$ than the $\eta \propto \sqrt{T}$ that follows from treating molecules as hard spheres [167], and it was this discrepancy, not any theoretical preference, that led him to replace the spheres by point centres repelling as the inverse fifth power of the distance [169].

Derivation. Let the molecules repel along the line of centres with a force K/r^{ν}. Two molecules approaching with relative kinetic energy of order $k_{\mathrm{B}}T$ are deflected through an angle of order unity when the potential energy at closest approach is comparable with that energy, $K/b^{\nu-1} \sim k_{\mathrm{B}}T$, where b is the impact parameter. The effective collision radius therefore shrinks as the gas is heated,

$$b \sim \left(\frac{K}{k_{\mathrm{B}}T}\right)^{1/(\nu-1)}\,, \qquad \sigma \sim \pi b^2 \propto T^{-2/(\nu-1)}\,, \tag{57.5}$$

and substituting into Equation (57.4) with $\langle v\rangle \propto \sqrt{T}$ gives a pure power law,

$$\eta \propto T^{s}\,, \qquad s = \frac{1}{2} + \frac{2}{\nu-1}\,. \tag{57.6}$$

Hard spheres are the limit $\nu \to \infty$, for which $s = \frac{1}{2}$: the cross-section is a constant of the molecule and the whole temperature dependence comes from $\langle v\rangle$. The observed $s \approx 1$ requires $2/(\nu-1) = \frac{1}{2}$, that is $\nu = 5$. So the measurement does not merely disagree with hard spheres; it returns a number, the exponent of the force law, and it is a bulk measurement of a molecular interaction. □

57.4 Graham: diffusion, effusion and the transport coefficients (1833–1846)

The kinetic hypothesis nearly foundered on an objection of Buys Ballot: if the molecules of the air move at hundreds of metres per second, a smell released at one end of a room should reach the other end at once, and it does not. Clausius's answer was the mean free path [149]. The quantitative form of the objection and of its answer is the diffusion coefficient, and Graham had measured the relevant rates before either was written down [94, 120].

57.4.1 Apparatus

For diffusion: a graduated glass tube closed at one end by a plug of plaster of Paris—a septum whose pores are small but very numerous—and standing with its open end under water or mercury, so that the change of volume as the enclosed gas exchanges with the outside air is read directly on the graduations. For transpiration: long capillary tubes of known bore through which the gas is driven by a measured pressure difference. For effusion: a fine aperture in a thin plate, small compared with the mean free path, which is the case the kinetic theory treats exactly.

57.4.2 Procedure

Fill the tube with the test gas, note the initial volume, and let the gas interchange with the atmosphere through the septum until the level has moved by a measured amount; time the process. Repeat with a series of gases under identical conditions of temperature, pressure and apparatus, so that everything except the molecular mass is held fixed and the ratios of the rates carry the whole result. The same discipline governs the capillary and aperture versions.

57.4.3 Observations and data

[Reserved: Graham's rate tables from [94] and [120], to be reproduced here as diffusion rates relative to air for hydrogen, oxygen, nitrogen, carbon dioxide and the other gases he used, set against $M^{-1/2}$, with the residuals and their uncertainties. To be tabulated alongside them, for the comparison of Equation (57.9), are the modern transport coefficients of air near $300\,\mathrm{K}$ *and* $100\,\mathrm{kPa}$*: a viscosity of about* $18\,\mu\mathrm{Pa\,s}$*, a thermal conductivity of about* $26\,\mathrm{mW/(m\,K)}$*, and a self-diffusion coefficient of order* $2\times10^{-5}\,\mathrm{m^2/s}$*.]*

57.4.4 Interpretation

Graham's law—rate proportional to $M^{-1/2}$ at fixed temperature and pressure—is a statement about mass and not about chemistry, and that is its whole force: nothing in a chemical account of gases would predict that carbon dioxide and nitrous oxide, which behave quite differently in every reaction, should diffuse at the same rate because they happen to have the same molecular mass.

The coefficients are the sharper test. Kinetic theory does not merely predict that gases diffuse; it predicts a diffusion coefficient built from the same $\langle v\rangle$ and the same ℓ that appear in the viscosity, and therefore predicts relations *among* the three transport coefficients with no free parameter at all. Those relations hold in order of magnitude, which is the content of Phenomenon 57.6, and fail in their numerical coefficients—the elementary argument gives a heat-conduction to viscosity ratio of 1 where the monatomic gases give about $\tfrac{5}{2}$. The discrepancy is not a failure of the molecular picture but of the averaging: fast molecules carry more energy than slow ones but the same momentum, so the three transports do not sample the same molecules and cannot share one mean free path. Repairing that is the

systematic expansion of Chapman and Enskog [434, 447, 1416], developed in Chapter 124, whose continuum limit is the hydrodynamics of Chapter 31.

57.4.5 Primary references

[94, 120]; the phenomenological law of diffusion is [143] and that of heat conduction [72]. The mean free path that reconciles the rates with the speeds is [149].

Phenomenon 57.5 (Gases interdiffuse far more slowly than they move)**.** The molecules of air travel at some hundreds of metres per second, yet a gas released at one point of a still room takes hours to spread across it by diffusion alone. The measured interdiffusion coefficients of common gases at standard conditions are of order $2 \times 10^{-5}\,\mathrm{m^2/s}$ [94, 143], some ten orders of magnitude below the product of a molecular speed and a room. The discrepancy is not evidence against the kinetic hypothesis but a measurement of the mean free path [149].

Derivation. A molecule does not travel in a straight line but executes a random walk of step ℓ at speed $\langle v\rangle$, so the transport is diffusive with

$$D \approx \tfrac{1}{3}\,\langle v\rangle\,\ell\,, \tag{57.7}$$

by the same carrier argument that gave Equation (57.4), with the number density of a labelled species in place of the momentum density. With $\langle v\rangle \approx 470\,\mathrm{m/s}$ and $\ell \approx 1 \times 10^{-7}\,\mathrm{m}$ for air near 300 K and 100 kPa—the values established in Phenomenon 57.7—this gives $D \approx 1.6 \times 10^{-5}\,\mathrm{m^2/s}$, which is the observed order. The time to cross a distance L follows from $L^2 \approx 2Dt$: about a hundredth of a second for a millimetre, but some hours for a metre, since the time grows as the *square* of the distance. The suppression relative to free flight is the ratio ℓ/L, which is about 10^{-7} for a metre—and that, and not any slowness of the molecules, is the answer to Buys Ballot. □

Phenomenon 57.6 (The three transport coefficients of a gas are not independent)**.** Viscosity, thermal conductivity and diffusion in a dilute gas are carried by the same molecules over the same mean free path, so kinetic theory predicts that the dimensionless combinations $\rho D/\eta$ and $\kappa m/\left(\eta c_V^{(1)}\right)$ are pure numbers of order unity, independent of the gas, of its density and of its temperature. Measurement confirms that they are numbers of order unity, and shows that the elementary estimate of those numbers is wrong: for the monatomic gases the second ratio is close to $\frac{5}{2}$ rather than to 1 [167, 403, 434, 447].

Derivation. Each coefficient is the same transport step applied to a different carried quantity. A molecule crossing a plane carries the value its last collision gave it, one mean free path away, so for any transported density χ the flux is of order $-\frac{1}{3}\,\langle v\rangle\,\ell\,\mathrm{d}\chi/\mathrm{d}z$. Taking χ to be the momentum density, the energy density and the number density of a labelled species in turn,

$$\eta \approx \tfrac{1}{3}\rho\,\langle v\rangle\,\ell\,, \qquad \kappa \approx \tfrac{1}{3} n c_V^{(1)}\,\langle v\rangle\,\ell\,, \qquad D \approx \tfrac{1}{3}\,\langle v\rangle\,\ell\,, \tag{57.8}$$

with $c_V^{(1)}$ the heat capacity of a single molecule. The mean free path and the mean speed—the two quantities that are hard to measure and easy to get wrong—cancel between them, leaving

$$\frac{\rho D}{\eta} \approx 1\,, \qquad f := \frac{\kappa m}{\eta c_V^{(1)}} \approx 1\,. \tag{57.9}$$

That these are pure numbers is a prediction with no adjustable content whatever, and it is confirmed. That they are not equal to unity is equally informative. The elementary argument gave one ℓ to all three transports, but the molecules that dominate the energy

flux are faster than those that dominate the momentum flux, and a faster molecule has both a longer free path and a larger weight; the correct averages therefore differ, and by a factor of order unity that only a solution of the transport equation can supply. □

Derivation pending #5

The Chapman–Enskog transport coefficients: that the first-order solution of the Boltzmann transport equation about local equilibrium fixes the numerical coefficients left undetermined by the mean-free-path argument, and in particular gives the ratio of thermal conductivity to viscosity times specific heat as 5/2 for a monatomic gas, against the value 1 of the elementary estimate.

57.5 Loschmidt: the size of an air molecule (1865)

Every measurement so far in this chapter has been of a bulk property. Loschmidt's determination is the step that converts two of them into a molecular length and a molecular count, and it is the first time anyone put a number on the size of a molecule [163]. It is included among the experiments, although it built no apparatus of its own, because its inputs are measurements and its output is a number about the world; the honest description of it is a determination, not a theory.

57.5.1 Apparatus

None of its own. The determination consumes two independent laboratory results: the viscosity of the gas, from an experiment of the kind described in Section 57.3, and the density of the same substance in its condensed state, from weighing a known volume of the liquid. Both were available in 1865, and neither had been made with molecules in mind.

57.5.2 Procedure

From the measured viscosity and mass density obtain the mean free path, $\ell \approx 3\eta/(\rho\,\langle v\rangle)$, with $\langle v\rangle$ fixed by the molar mass and the temperature alone. From the volume of liquid obtained from unit volume of gas obtain the condensation ratio ε. Assume the molecules are spheres that fill the liquid when packed. Then ℓ and ε are two equations in the two unknowns—the molecular diameter d and the number density n—and both follow.

57.5.3 Observations and data

[Reserved: Loschmidt's own inputs and outputs from [163], converted to SI—the viscosity and condensation ratio he used, the diameter he obtained (about $1\,\mathrm{nm}$*), and the number density that follows. The comparison to record beside them: on modern inputs the same equations give a collision diameter near* $3\times10^{-10}\,\mathrm{m}$*, and the Loschmidt constant, the number density of an ideal gas at* $273.15\,\mathrm{K}$ *and* $101\,325\,\mathrm{Pa}$*, is* $2.6867\times10^{25}/\mathrm{m}^3$ *[2431], while the Avogadro constant has been exact since 2019 at* $6.022\,140\,76\times10^{23}/\mathrm{mol}$ *[2333].]*

57.5.4 Interpretation

The packing assumption is crude and the answer is correspondingly crude—Loschmidt's diameter is several times the modern collision diameter, and since n varies as d^{-2} his number density is low by about an order of magnitude. That is not the point, and treating it as a failed precision measurement misreads what happened. Before 1865 the molecular hypothesis had no scale at all: molecules could as well have been 10^{10} times smaller. Afterwards it had

one, obtained from two measurements that mention no molecules, and the scale was small enough to explain why molecules had never been seen and large enough to be consistent with the mean free path.

What made the number believable was not its accuracy but its corroboration by methods sharing neither apparatus nor theory: the Brownian determinations of Chapter 119 [358, 409], the electrolytic route through the elementary charge [407], and the counting of particles from a radioactive source. Agreement among routes with nothing in common but the hypothesis is what an inference of this kind can be worth, and it is why the molecular constitution of matter stopped being an opinion around 1910.

57.5.5 Primary references

[163]; the viscosity input is of the kind measured in [167] and the mean free path is [149]. The modern values are [2431] and [2333].

Phenomenon 57.7 (The mean free path is a measurable length)**.** The average distance a molecule travels between collisions is not a theoretical fiction: it is fixed by measurements that never mention molecules, since inverting the viscosity relation expresses it through the measured viscosity, the weighed mass density and the molar mass alone [149, 167]. For air near 300 K and 100 kPa it comes out of order 1×10^{-7} m: about three hundred times the molecular diameter, and seven orders of magnitude below the size of any vessel—which is why the gas behaves as a continuum in Chapter 31 and ceases to when it does not [355].

Derivation. Solve Equation (57.4) for the mean free path,

$$\ell \approx \frac{3\eta}{\rho \langle v \rangle}, \qquad \langle v \rangle = \sqrt{\frac{8RT}{\pi M}}, \tag{57.10}$$

and note what stands on the right: η from a viscometer, ρ from a balance, and $\langle v \rangle$ from the molar mass and the thermometer. With $\eta \approx 18\,\mu\text{Pa s}$, $\rho \approx 1.2\,\text{kg/m}^3$ and $M \approx 0.029\,\text{kg/mol}$ at 300 K, so that $\langle v \rangle \approx 470\,\text{m/s}$, this gives $\ell \approx 1 \times 10^{-7}\,\text{m}$. The cross-section follows from $\ell = 1/\left(\sqrt{2} n \sigma\right)$ with $n = P/k_\text{B}T \approx 2.4 \times 10^{25}/\text{m}^3$, giving $\sigma \approx 3 \times 10^{-19}\,\text{m}^2$ and a collision diameter $d = \sqrt{\sigma/\pi} \approx 3 \times 10^{-10}\,\text{m}$. Loschmidt's second equation then closes the system: taking the molecules to be spheres of diameter d packed so as to fill the liquid, the condensation ratio is $\varepsilon = n\pi d^3/6$, and eliminating n between it and $\ell = 1/\left(\sqrt{2}\pi d^2 n\right)$ leaves $d = 6\sqrt{2}\,\varepsilon\ell$—a molecular diameter from a condensation ratio and a viscosity. The Avogadro constant is then $N_\text{A} = nV_\text{m}$ with V_m the molar volume. Every step but the packing assumption is exact; that one step is what makes the result an order of magnitude rather than a measurement. □

57.6 Joule and Thomson: the porous plug and the forces between molecules (1852)

The ideal gas of Chapter 54 is the gas whose molecules do not interact except in the instant of collision. Kinetic theory needs to know whether that is true, and if not, by how much and with what sign. The porous-plug experiment answers all three questions with one thermometer, because the effect it measures vanishes identically for a gas of non-interacting molecules [137].

57.6.1 Apparatus

A long tube, thermally lagged and of low conductivity, with a plug of cotton wool or unspun silk packed tightly into the bore so as to present a large flow resistance without any moving

part. Compressed gas is supplied steadily from a pump through a coil immersed in a bath of known temperature, so that the gas arrives at the plug at a controlled temperature; thermometers sit in the stream immediately upstream and downstream of the plug, and pressure gauges read the pressure on each side.

57.6.2 Procedure

Establish a steady flow and hold it until the temperatures cease to drift, which is what makes the analysis a steady-flow one and lets the enthalpy balance of Chapter 56 apply. Read the upstream and downstream temperatures and pressures. The plug is essential and is not merely a convenient resistance: it destroys the kinetic energy of the stream, so that no part of the temperature change can be attributed to the gas being set in bulk motion. Repeat for different gases, different pressure drops and different bath temperatures, the last being what maps the change of sign.

57.6.3 Observations and data

[Reserved: the primary series of [137] and its sequels, to be reproduced here in SI—upstream and downstream pressures in Pa*, bath temperature in* K*, and the measured temperature drop in* K *with its uncertainty, for each gas and each pressure drop, together with the coefficient* $\mu = (\partial T/\partial P)_H$ *in* K/Pa *derived from them. The qualitative pattern the table must show: air at room temperature cools by a fraction of a kelvin per atmosphere of pressure drop, carbon dioxide cools by several times more, and hydrogen warms instead of cooling.]*

57.6.4 Interpretation

The kinetic reading of the result is the one that concerns this chapter. A gas of point molecules that never interact has an internal energy depending on temperature alone and an equation of state $PV = nRT$, and for such a gas the throttling coefficient is identically zero—not small, but exactly zero, as the derivation below shows. Every kelvin measured here is therefore a direct measurement of the interactions the ideal gas omits. Better, the *sign* separates them: cooling means that work has been done against attraction as the molecules were pulled apart, warming that the molecules were already so crowded that their own volume dominates. A gas that does both, at different temperatures, is telling the experimenter that both a long-range attraction and a short-range repulsion exist, and where they balance.

This complements Section 57.3 exactly. The viscosity measurement probes the repulsive core, because it is collisions that transport momentum, and returned an exponent for the repulsive force. The porous plug probes the attractive tail, because it is the work done against attraction on expansion that cools the gas. Between them they outline the intermolecular potential from a thermometer and a torsion fibre—a fact worth pausing over, since neither apparatus can resolve anything smaller than a millimetre.

57.6.5 Primary references

[137]. The cruder free expansion that failed to see the effect is [112]; the thermodynamic treatment of both, with the enthalpy argument and the inversion curve, is in Chapter 56 and Chapter 54.

Phenomenon 57.8 (Molecules exert forces on one another at a distance)**.** Forcing a real gas steadily through a porous plug from a higher to a lower pressure, along a thermally insulated tube, changes its temperature by a small but definite amount, and the sign of the change depends on the gas and on its temperature: most gases at room temperature emerge

cooler, hydrogen and helium emerge warmer, and each gas has an inversion temperature separating the two behaviours. Joule and Thomson established the effect in the series beginning in 1852 [137]. For a gas of molecules exerting no forces at a distance the effect would be exactly zero at every temperature and every pressure, so its magnitude and sign measure the intermolecular potential directly.

Derivation. The measured quantity is $\mu = (\partial T/\partial P)_H$, since throttling conserves enthalpy—the steady-flow first law of Chapter 56—and by the chain rule together with a Maxwell relation,

$$\mu = \frac{1}{C_P}\left[T\left(\frac{\partial V}{\partial T}\right)_P - V\right]. \tag{57.11}$$

For the ideal gas $V = nRT/P$ gives $T\,(\partial V/\partial T)_P = V$ identically, so $\mu \equiv 0$: nothing whatever is measured, at any pressure or temperature. This is what makes the experiment a clean test. Now let the molecules attract weakly at long range and exclude a volume b per mole at short range, so that to first order in the departures from ideality $V_{\mathrm{m}} \approx RT/P + b - a/RT$. Then $T\,(\partial V_{\mathrm{m}}/\partial T)_P = RT/P + a/RT$, and

$$\mu \approx \frac{1}{C_{P,\mathrm{m}}}\left(\frac{2a}{RT} - b\right). \tag{57.12}$$

The two molecular effects enter with opposite signs, exactly as the observation requires: the attraction a cools, the excluded volume b warms, and the attraction loses its advantage as the gas is heated because the molecules pass too quickly to be held. The coefficient vanishes at the inversion temperature

$$T_{\mathrm{inv}} = \frac{2a}{Rb}, \tag{57.13}$$

above which throttling warms the gas. Hydrogen and helium have small a and therefore inversion temperatures far below room temperature, which is why they warm on throttling and must be precooled before a Joule–Thomson stage will liquefy them—an inference from Equation (57.13) that the liquefaction industry has tested more thoroughly than any laboratory. Finally, b is the same excluded volume that appears as the collision cross-section in Phenomenon 57.7: two independent measurements of one molecular size, which is the consistency check that makes the whole scheme more than a fit. □

57.7 Summary of the evidence

No entry in Table 57.1 can be obtained from thermodynamics, and none of them contains an adjustable parameter beyond the one molecular size and one force law that the whole set shares. Taken together with the Brownian measurements of Chapter 119, which watch the fluctuations that these experiments only average over, they are the experimental case for the hypothesis of Chapter 55: that a gas is a very large number of small bodies in disordered motion, obeying the mechanics of Chapter 19. What they do not settle is the statistical foundation—why the equilibrium distribution is the one observed, independently of any model of the molecules—which is the work of Chapter 118, nor the failure of equipartition at low temperature, which no classical mechanics can repair and which Chapter 125 and Chapter 68 resolve.

57.8 Giauque: adiabatic demagnetization and the third law (1933)

This last section is an addendum to the six tests summarised in Table 57.1 and not a seventh of them: it puts no prediction of Chapter 55 at risk. It is placed here because

Table 57.1: Tests of the kinetic theory of gases reported in this chapter. The middle column names the prediction of Chapter 55 that the experiment puts at risk; in every case a purely thermodynamic account of gases predicts nothing at all for the quantity measured, which is what makes these experiments evidence for molecules rather than merely for heat.

Experiment	Prediction tested	Result
Stern 1920	thermal speeds	flight time over a known distance gives speeds of the predicted order, scaling as $\sqrt{T/M}$
Miller–Kusch 1955	shape of the distribution	beam intensity follows $v^3 \exp(-mv^2/2k_{\mathrm{B}}T)$ at the per-cent level, at the oven temperature
Maxwell 1866	viscosity independent of density	confirmed over the accessible pressure range; and $\eta \propto T$, not $\sqrt{T}$, giving the force exponent $\nu = 5$
Graham 1833–1846	transport from one mean free path	rates scale as $M^{-1/2}$; the coefficients obey the predicted relations in order of magnitude, with the numbers fixed only by Chapman–Enskog
Loschmidt 1865	a molecular scale exists	a diameter and a number density from viscosity plus a condensation ratio, correct to an order of magnitude
Joule–Thomson 1852	the ideal gas omits forces	a nonzero throttling coefficient of both signs, where non-interacting molecules give exactly zero

the paragraph above names the boundary at which the classical account of matter fails, and because crossing that boundary was itself an experiment. The third law is stated in Chapter 54 in the form Nernst gave it [328, 378], and the unattainability of absolute zero is deduced there as a theorem of thermodynamics. Both halves are also measurements, and the measurements came out of one programme: the cooling of paramagnetic salts by adiabatic demagnetization, proposed independently by Debye in 1926 and by Giauque in 1927, achieved by Giauque and MacDougall in 1933, and recognised by the Nobel Prize in Chemistry for 1949. What the technique opened was not merely a lower temperature but a region in which the entropy of matter can be watched approaching its limit.

57.8.1 Apparatus

A paramagnetic salt in which the magnetic ions are held far apart by water of crystallisation: Giauque and MacDougall used hydrated gadolinium sulfate, $\mathrm{Gd_2(SO_4)_3 \cdot 8H_2O}$, whose $\mathrm{Gd^{3+}}$ ion has a half-filled shell, and therefore no orbital moment to be quenched, and a ground multiplet of eight equally spaced states. The salt hangs in a vacuum space inside a bath of liquid helium—available at all only since [343]—pumped below its normal boiling point to reach somewhat under 1 K. An electromagnet supplies a flux density of order a tesla over the sample. The thermal switch between sample and bath is helium exchange gas, admitted to couple them and pumped away to isolate the sample; there is no mechanical link, because at these temperatures any solid support conducts far too well. Thermometry is the sample itself: two coaxial coils around the vacuum space read its magnetic susceptibility by mutual inductance, and the Curie law of Chapter 129 converts a susceptibility into a temperature.

That last step is the subtle one, and the apparatus has to answer for it. The Curie law is the high-temperature limit of the paramagnetic response [264, 323, 2011], and it fails exactly where the experiment is going; what the bridge reads is therefore a *magnetic* temperature T^{*} defined by $\chi = C/T^{*}$, which coincides with the thermodynamic temperature only while the ions remain independent. Converting one into the other needs a separate calorimetric measurement: feed the isolated salt a measured quantity of energy, follow the resulting change in T^{*}, and recover the thermodynamic temperature from $T^{-1} = (\partial S/\partial U)$. A magnetic temperature quoted as a thermodynamic one is the characteristic error of this field, and it is an error in the direction of claiming too much.

57.8.2 Procedure

Four steps, run as a cycle. First, with exchange gas in place and the salt anchored to the bath at T_{i}, raise the field to B_{i}: the moments align, the magnetic entropy falls, and the heat of magnetization passes into the helium, which is what makes this step isothermal. Second, pump the exchange gas away, isolating the salt. Third, lower the field to zero, as slowly as the eddy-current heating of the metal parts requires, and no more slowly than the heat leak allows; the salt cools. Fourth, read the susceptibility bridge repeatedly as the salt warms back up, which yields the final temperature, the heat capacity, and—from the slope of the warm-up—the size of the parasitic heat input that has to be subtracted from it. The whole is repeated over a series of initial fields and initial bath temperatures, because the prediction under test is a relation between a ratio of temperatures and a ratio of fields, not a single number.

57.8.3 Observations and data

[Reserved: the primary series of Giauque and MacDougall (1933) and of de Haas, Wiersma and Kramers in the same year, to be reproduced here in SI—initial bath temperature in K*, initial flux density in* T*, the susceptibility before and after, the magnetic temperature* T^{*}

derived from it, and the thermodynamic temperature with its uncertainty stated per [2129]; alongside them the calibration run, as energy input in J *against entropy in* $\mathrm{J/(mol\,K)}$*, from which the zero-field curve* $S(T)$ *is built. Three orientation figures, computed here from stated inputs rather than taken from the papers: the ground multiplet of* $\mathrm{Gd^{3+}}$ *carries a molar entropy* $R\ln 8 = 17.3\,\mathrm{J/(mol\,K)}$ *per mole of ions; the Bohr magneton divided by the Boltzmann constant is* $0.67\,\mathrm{K/T}$ *[2333, 2431], so at* $1\,\mathrm{T}$ *that multiplet is spread over about* $9\,\mathrm{K}$ *and a bath near* $1\,\mathrm{K}$ *is cold enough to order it; and the lattice entropy competing with it is smaller by orders of magnitude, by the Debye law used in Equation* (57.15)*. The first demagnetizations reached a few tenths of a kelvin, and the more dilute salts used later reach a few millikelvin, which is the regime Chapter 110 works in.]*

57.8.4 Interpretation

Two facts make the method work, and neither is incidental. The first is that at $1\,\mathrm{K}$ a solid has almost no entropy left in its lattice: by the Debye law [382] the vibrational entropy falls as T^3, so for a salt of Debye temperature of order $1\times10^2\,\mathrm{K}$ it stands four or more orders of magnitude below the magnetic entropy. Essentially all the disorder that remains is the orientation of the magnetic ions, and that is precisely the disorder a magnetic field can address. The second is that the ions are dilute: the water of crystallisation holds them far enough apart that they behave independently well below the temperature of the bath, which is what makes the magnetic entropy a function of B/T alone and gives the cooling the simple law of Equation (57.16).

The same dilution sets the limit, and it is there that the experiment stops being a refrigeration technique and becomes a statement about the third law. The ions are not perfectly independent: each sits in the dipolar field of its neighbours and in the electric field of the crystal, and the residual internal field that results cannot be switched off [659, 744]. Demagnetizing to zero *applied* field therefore leaves the moments in that residual field rather than in nothing, and the temperature falls only in the corresponding ratio. Stage a second cycle below the first and the same factor applies again, so the temperature after several stages is a geometric sequence with a positive ratio: it has zero as a limit and never as a value. That is the unattainability statement, and here it is not a postulate but the operating characteristic of a machine, measurable stage by stage.

It is worth pausing on the fact that the two halves of the third law are one fact seen from two sides. Were the ions exactly independent, the residual field would vanish, a single stage would reach absolute zero, and the entropy at zero temperature would be $R\ln(2J+1)$ per mole in zero field and zero in any field however small—so Nernst's theorem, which requires the limiting entropy to be independent of the other variables, would fail in the same breath in which unattainability failed. The interactions that put a floor under the refrigerator are the interactions that give the salt a non-degenerate ground state. A thermodynamic law that reads like a prohibition is, microscopically, the statement that matter has a ground state.

The approach of the entropy to a constant was established by a second route in the same programme, and the route matters because at the bottom it uses no thermodynamics at all. The entropy of a substance can be obtained calorimetrically, by integrating C_P/T upward from the lowest attainable temperature and closing the gap below it with the Debye law; and it can be computed, for a gas, from spectroscopic constants alone by way of the partition function of Chapter 118. These are independent determinations of the same quantity, and the calorimetric one is complete only if the entropy left below the integration limit is zero. For most substances the two agree. Where they do not, the discrepancy is not scatter but a number of a particular kind—close to $R\ln w$ for a small w, with w counting the arrangements a molecule can be frozen into—and that is a far stronger confirmation of the third law than agreement alone would be, because it says what the limiting entropy is and

not merely that there is one.

Finally, the technique outlived the question it was built for. Cooling a paramagnetic salt to a few millikelvin puts the hyperfine field of a nucleus embedded in it to work: once the nuclear Zeeman splitting is comparable with $k_{\mathrm{B}}T$, the nuclei align, and an ensemble of oriented nuclei is a laboratory sample with a definite direction in it. That is exactly how the cobalt-60 of Chapter 110 was polarized—the active layer grown on a cerium magnesium nitrate crystal, demagnetized, and left to warm through the useful window [1101, 1133]. A method devised to test a law of thermodynamics is what made a symmetry of the weak interaction measurable, which is the kind of debt between fields that a treatise organised by subject tends to hide.

57.8.5 Primary references

The primary sources of this section are named here in full because they are not yet in the bibliography of this treatise; the works cited by key below are the supporting ones. The proposal is P. Debye, "Einige Bemerkungen zur Magnetisierung bei tiefer Temperatur", *Annalen der Physik* **386** (1926) 1154–1160, and, independently, W. F. Giauque, "A Thermodynamic Treatment of Certain Magnetic Effects. A Proposed Method of Producing Temperatures Considerably Below 1° Absolute", *Journal of the American Chemical Society* **49** (1927) 1864–1870. The achievement is W. F. Giauque and D. P. MacDougall, "Attainment of Temperatures Below 1° Absolute by Demagnetization of $\mathrm{Gd_2(SO_4)_3 \cdot 8H_2O}$", *Physical Review* **43** (1933) 768, confirmed within months by W. J. de Haas, E. C. Wiersma and H. A. Kramers in *Physica* **1** (1933). The residual entropy of ice is measured in W. F. Giauque and J. W. Stout, *Journal of the American Chemical Society* **58** (1936), and counted in L. Pauling, "The Structure and Entropy of Ice and of Other Crystals with Some Randomness of Atomic Arrangement", *Journal of the American Chemical Society* **57** (1935) 2680–2684, whose argument is reproduced in [1188]. The nuclear extension is N. Kurti, F. N. H. Robinson, F. Simon and D. A. Spohr, "Nuclear Cooling", *Nature* **178** (1956) 450–453.

[Reserved: the eight references named in full above are to be entered in the bibliography and the prose replaced by citations. Until then the supporting keys are [328, 378] for the heat theorem, [382] for the lattice entropy, [264, 323, 2011] for the paramagnetism, [659, 744] for the interactions that set the floor, [343] for the helium that preceded the technique, and [1101, 1133] for the use later made of it.]

Phenomenon 57.9 (Demagnetizing an isolated paramagnetic salt cools it)**.** A paramagnetic salt magnetized isothermally in contact with a bath near 1 K, then thermally isolated and demagnetized, ends colder than the bath, and the drop is fixed by the ratio of the fields rather than by any property of the apparatus: the final temperature is the initial one multiplied by the ratio of the residual field to the applied field. Giauque and MacDougall reached a few tenths of a kelvin from hydrated gadolinium sulfate in 1933, and de Haas, Wiersma and Kramers did the same within months. With more dilute salts the method reaches a few millikelvin [1133] and, applied to nuclear rather than electronic moments, the microkelvin range. Before it, the lowest temperatures in existence were those of pumped liquid helium [343].

Derivation. Take N non-interacting ions of angular momentum J and Landé factor g in a flux density B. Each level of the multiplet has energy $E_m = g\mu_{\mathrm{B}}Bm$ with $m = -J, \dots, J$, so the single-ion partition function

$$Z = \sum_{m=-J}^{J} \exp\left(-\frac{g\mu_{\mathrm{B}}Bm}{k_{\mathrm{B}}T}\right) \tag{57.14}$$

depends on B and T only through their ratio: the field scales every energy in the same proportion, and the temperature is measured against energy. The magnetic entropy inherits

the property, since with $x = g\mu_{\mathrm{B}}B/k_{\mathrm{B}}T$ the free energy is $-Nk_{\mathrm{B}}T\ln Z(x)$ and

$$S_{\mathrm{m}} = Nk_{\mathrm{B}}\left(\ln Z - x\,\frac{\mathrm{d}\ln Z}{\mathrm{d}x}\right) = S_{\mathrm{m}}(B/T)\ . \tag{57.15}$$

A reversible demagnetization of a thermally isolated sample holds the total entropy fixed. The lattice carries almost none of it—by the Debye law the vibrational entropy per mole of atoms is $(4\pi^4/5)\,R\,(T/\Theta_{\mathrm{D}})^3$ [382], which near 1 K is smaller than $R\ln(2J+1)$ by orders of magnitude—so holding the total entropy fixed holds S_{m} fixed, and by Equation (57.15) it holds B/T fixed:

$$\frac{T_{\mathrm{f}}}{T_{\mathrm{i}}} = \frac{B_{\mathrm{f}}}{B_{\mathrm{i}}}\,. \tag{57.16}$$

Nothing in Equation (57.16) refers to the particular salt, which is what makes it a prediction rather than a fit; the salt enters only through how small B_{f} can be made and how much entropy $R\ln(2J+1)$ there was to remove. The two assumptions are equally visible: the ions must be independent, which fails once $k_{\mathrm{B}}T$ falls to their interaction energy, and the process must be slow enough to be reversible, which eddy currents in any metal near the sample threaten. □

Phenomenon 57.10 (The entropy of a substance tends to a constant, and the constant counts ground states)**.** The entropy of a substance measured calorimetrically—by integrating C_P/T upward from the lowest attainable temperature—agrees, for most substances, with the entropy computed from spectroscopic data through the partition function; and the agreement requires that the entropy remaining below the integration limit be zero. Where the two determinations disagree, the discrepancy is not scattered but close to $R\ln w$ with w a small number of arrangements per molecule frozen in as the substance is cooled. For ice it is near $R\ln(3/2) = 3.37\,\mathrm{J/(mol\,K)}$, which is the count of proton placements consistent with two protons per oxygen [1188]; for carbon monoxide, whose two ends are nearly indistinguishable, it is of the order of $R\ln 2 = 5.76\,\mathrm{J/(mol\,K)}$. The entropy therefore tends as $T \to 0$ to a constant fixed by the degeneracy of the ground state and not by the substance's chemistry, which is Equation (54.13) in its sharp form.

Derivation. The calorimetric statement is Equation (54.14): the integral $\int_0^T C_x\,\mathrm{d}T'/T'$ converges, so it defines $S(T) - S(0)$ and the calorimetric route measures entropy *differences* only. The absolute value it is compared against comes from Boltzmann's counting [196], $S = k_{\mathrm{B}}\ln W$, which at zero temperature counts ground states. If each molecule can be frozen into any of w arrangements independently of its neighbours then $W = w^N$ and

$$S(0) = Nk_{\mathrm{B}}\ln w = R\ln w \tag{57.17}$$

per mole: a discrete set of admissible values, which is why a discrepancy between the two routes is diagnostic rather than merely disappointing.

Pauling's count for ice is the worked case, and it needs only the two rules the hydrogen bonds impose. Each oxygen has four tetrahedral neighbours and keeps two protons close to it, which it may place on any two of the four bonds: $\binom{4}{2} = 6$ arrangements per molecule, hence 6^N if the molecules were free of one another. Each of the $2N$ bonds must carry exactly one proton; of the four ways the two molecules sharing a bond may independently place a proton on it or not, two satisfy that rule and two do not, so each bond costs a factor $\frac{1}{2}$. Treating the bonds as independent,

$$W \approx 6^N\left(\tfrac{1}{2}\right)^{2N} = \left(\tfrac{3}{2}\right)^N\,, \qquad S(0) = R\ln\tfrac{3}{2}\,. \tag{57.18}$$

The independence of the bonds is an approximation, and the exact counting on the ice lattice exceeds Equation (57.18) by well under a per cent—far less than the calorimetric uncertainty. The comparison therefore tests the physical claim, that the protons are disordered, rather than the combinatorics. □

Phenomenon 57.11 (Absolute zero is unattainable, and the unattainability is an operating characteristic)**.** Every stage of a demagnetization cycle multiplies the temperature by a ratio smaller than one but bounded away from zero, because the applied field cannot be reduced below the field the magnetic ions exert on one another. A finite number of stages therefore leaves a finite temperature, and the successive stages of every cooling technique are observed to yield diminishing returns, exactly as Phenomenon 54.7 requires. The statement is not a postulate of thermodynamics tested at one remove: the bounding ratio is a measurable property of the salt [659, 744], and the machine displays the prohibition in its own performance.

Derivation. Write the field at an ion as the applied flux density combined with an internal field of magnitude b, arising from the dipolar field of the neighbours and from the crystal-field splitting of the multiplet; b is a property of the lattice and does not respond to the magnet. The smallest field a demagnetization can leave is therefore b, and Equation (57.16) gives

$$T_{\mathrm{f}} \geq \frac{b}{B_{\mathrm{i}}}\, T_{\mathrm{i}}\,, \tag{57.19}$$

so that n identical stages reach $T_n \geq (b/B_{\mathrm{i}})^n\, T_{\mathrm{i}} > 0$ for every finite n. A geometric sequence of positive ratio has zero as a limit and never as a value, which is unattainability in the form the apparatus states it.

The two halves of the third law meet here. Suppose b were zero, so that the bound vanished and one stage sufficed. The ions would then be exactly independent at every temperature, the zero-temperature entropy would be $R \ln (2J+1)$ per mole in zero field and zero in any field however small, and Equation (54.13)—the requirement that the limiting entropy not depend on the other variables—would fail in the same breath. Conversely, an interaction strong enough to order the moments discharges $R \ln (2J+1)$ before absolute zero is reached and makes the limiting entropy independent of the field, at the price of a floor under the cooling. Unattainability and Nernst's theorem are one statement about the ground state, read once as a prohibition and once as a limit. □

Derivation pending #6

The residual internal field of a paramagnetic salt: that the dipolar sum over the lattice of magnetic ions, together with the crystal-field splitting of the ground multiplet, fixes the ordering temperature and hence the floor under a single demagnetization stage, so that the cooling ratio is a computable property of the salt rather than a fitted parameter.

Derivation pending #7

The spectroscopic entropy of a gas: that the translational, rotational, vibrational and electronic partition functions, evaluated from band-spectrum constants and molecular masses, give the absolute molar entropy against which the calorimetric integration is compared, together with the symmetry number and the nuclear-spin terms that cancel between the two routes.

Part VII

Classical Field Theory and Electrodynamics

Chapter 58

Electrostatics

Electrostatics is the theory of the fields produced by charges at rest. The chapter follows the order of the source: the Coulomb force is postulated, the electrostatic field and its potential are constructed by continuous superposition, the local field equations — Gauss's law and the vanishing of the curl — are derived, and the boundary-value methods for obtaining the potential are developed. The Coulomb constant is kept throughout as k_E, so that every formula remains valid in any system of units; the worked examples, ported from the companion problem collection, are written in SI units, where $k_E = 1/(4\pi\epsilon_0)$.

58.1 The electrostatic field

58.1.1 Fundamentals

Point charge

Definition 58.1 (Point charge)**.** A *point charge* is a point of space to which one assigns a constant real scalar quantity q called its *charge*.

The Coulomb force

We state as a fundamental principle:

Postulate 58.2 (Coulomb's law)**.** The force that a charge q' located at $\boldsymbol{x}'$ exerts on a charge q located at $\boldsymbol{x}$ is proportional to the product of the charges and inversely proportional to the square of the distance separating them. That is,

$$\boldsymbol{F} = k_E \, \frac{qq'}{|\boldsymbol{x} - \boldsymbol{x}'|^2} \, \frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|} \,, \tag{58.1}$$

where k_E is a positive real constant.

Remark 58.3 (Unit systems). The constant k_E selects the system of units: in Gaussian units $k_E = 1$, while in SI units $k_E = 1/(4\pi\epsilon_0)$, with ϵ_0 the vacuum permittivity [1976, 2333]. The worked examples of this chapter are written in SI units.

Continuous charge distributions

Definition 58.4 (Continuous charge distribution)**.** Consider a set of infinitesimal charges $\mathrm{d}q'$ located at points $\boldsymbol{x}'$ (with respect to a fixed coordinate origin) which together form a continuum occupying a volume V'. We call this continuum a *continuous charge distribution*.

Consider further a charge q at $\boldsymbol{x}$. The *force felt by q due to a continuous charge distribution* is the continuous sum of the forces that the individual charges $\mathrm{d}q'$ exert on it. By Coulomb's law,

$$\boldsymbol{F} = k_E\, q \int_{V'} \mathrm{d}q'\, \frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|^3}\,. \tag{58.2}$$

Charge densities

Definition 58.5 (Charge densities)**.** The *volume charge density* of a distribution is

$$\rho(\boldsymbol{x}') = \frac{\mathrm{d}q'}{\mathrm{d}V'}\,. \tag{58.3}$$

Equivalently one defines the *surface charge density*

$$\sigma(\boldsymbol{x}') = \frac{\mathrm{d}q'}{\mathrm{d}s'} \tag{58.4}$$

on a surface S', and the *line charge density*

$$\lambda(\boldsymbol{x}') = \frac{\mathrm{d}q'}{\mathrm{d}l'} \tag{58.5}$$

on a curve C'.

Substituting Equation (58.3) into Equation (58.2), the force felt by a charge q due to a continuous distribution of density ρ is

$$\boldsymbol{F} = k_E\, q \int_{V'} \rho(\boldsymbol{x}')\, \frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|^3}\, \mathrm{d}V'\,, \tag{58.6}$$

and analogously for the surface and line densities,

$$\boldsymbol{F} = k_E\, q \int_{S'} \sigma(\boldsymbol{x}')\, \frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|^3}\, \mathrm{d}s'\,, \qquad \boldsymbol{F} = k_E\, q \int_{C'} \lambda(\boldsymbol{x}')\, \frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|^3}\, \mathrm{d}l'\,. \tag{58.7}$$

Comparing Equation (58.6) with Equation (58.1), we see that a point charge q located at $\boldsymbol{x}'$ is the particular distribution whose density is

$$\rho(\boldsymbol{x}) = q\, \delta(\boldsymbol{x} - \boldsymbol{x}')\,. \tag{58.8}$$

The electrostatic field

Definition 58.6 (Electrostatic field)**.** The *electrostatic field due to a continuous charge distribution* is the vector field obtained from the force exerted on a test charge q at $\boldsymbol{x}$ in the limit in which q tends to zero — so that the field generated by the test charge itself does not interfere with the field generated by the distribution:

$$\boldsymbol{E}(\boldsymbol{x}) = \lim_{q \to 0} \frac{\boldsymbol{F}}{q}\,. \tag{58.9}$$

From this definition and Equation (58.6), the electrostatic field due to a continuous charge distribution is

$$\boldsymbol{E}(\boldsymbol{x}) = k_E \int_{V'} \rho(\boldsymbol{x}')\, \frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|^3}\, \mathrm{d}V'\,. \tag{58.10}$$

Conversely, consider a charge q at $\boldsymbol{x}$ subject to an external electrostatic field $\boldsymbol{E}$ produced by some distribution of density ρ: the field is given by Equation (58.10) and the force it exerts on q by Equation (58.6). Comparing the two expressions, the *force felt by a charge in an external electrostatic field* is

$$\boldsymbol{F} = q\, \boldsymbol{E}\,. \tag{58.11}$$

The electrostatic potential

Lemma 58.7. *For $\boldsymbol{x} \neq \boldsymbol{x}'$,*

$$\partial_i \left(\frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|} \right) = -\frac{x_i - x_i'}{|\boldsymbol{x} - \boldsymbol{x}'|^3} \,. \tag{58.12}$$

Derivation pending #8

Gradient identity Equation (58.12): direct differentiation of $|\boldsymbol{x} - \boldsymbol{x}'|^{-1}$ (asserted without proof in the source).

From Equation (58.10) we have, in components,

$$\begin{aligned} E_i(\boldsymbol{x}) &= k_E \int_{V'} \rho(\boldsymbol{x}') \, \frac{x_i - x_i'}{|\boldsymbol{x} - \boldsymbol{x}'|^3} \, \mathrm{d}V' \\ &= -k_E \int_{V'} \rho(\boldsymbol{x}') \, \partial_i \left(\frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|} \right) \mathrm{d}V' \qquad (58.13) \\ &= -\partial_i \left(k_E \int_{V'} \frac{\rho(\boldsymbol{x}')}{|\boldsymbol{x} - \boldsymbol{x}'|} \, \mathrm{d}V' \right) , \qquad (58.14) \end{aligned}$$

where Equation (58.12) was used in the second step and the derivative, which acts on $\boldsymbol{x}$ only, was taken outside the integral in the third.

Definition 58.8 (Electrostatic potential)**.** The *electrostatic potential* of a continuous charge distribution is

$$\phi(\boldsymbol{x}) = k_E \int_{V'} \frac{\rho(\boldsymbol{x}')}{|\boldsymbol{x} - \boldsymbol{x}'|} \, \mathrm{d}V' \,. \tag{58.15}$$

With this definition, Equation (58.14) reads

$$\boldsymbol{E}(\boldsymbol{x}) = -\boldsymbol{\nabla} \phi(\boldsymbol{x}) \,. \tag{58.16}$$

Gauss's law

Lemma 58.9. *In the sense of distributions,*

$$\partial_i \partial_i \left(\frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|} \right) = -4\pi \, \delta(\boldsymbol{x} - \boldsymbol{x}') \,. \tag{58.17}$$

Derivation pending #9

Distributional Laplacian of $|\boldsymbol{x} - \boldsymbol{x}'|^{-1}$, Equation (58.17) (asserted without proof in the source).

Theorem 58.10 (Gauss's law)**.** *The divergence of the electrostatic field due to a distribution of charge density ρ is*

$$\boldsymbol{\nabla} \cdot \boldsymbol{E}(\boldsymbol{x}) = 4\pi k_E \, \rho(\boldsymbol{x}) \,. \tag{58.18}$$

Derivation. Applying ∂_i to Equation (58.13),

$$\begin{aligned} \partial_i E_i(\boldsymbol{x}) &= -k_E \int_{V'} \rho(\boldsymbol{x}') \, \partial_i \partial_i \left(\frac{1}{|\boldsymbol{x} - \boldsymbol{x}'|} \right) \mathrm{d}V' \\ &= 4\pi k_E \int_{V'} \rho(\boldsymbol{x}') \, \delta(\boldsymbol{x} - \boldsymbol{x}') \, \mathrm{d}V' \\ &= 4\pi k_E \, \rho(\boldsymbol{x}) \,, \end{aligned}$$

where Equation (58.17) was used in the second step. □

Integrating Equation (58.18) over an arbitrary volume V enclosing a total charge q_V, and using that by Equation (58.3) the volume integral of the density is the enclosed charge,

$$\int_V \partial_i E_i \, \mathrm{d}V = 4\pi k_E \int_V \rho \, \mathrm{d}V = 4\pi k_E \, q_V \,,$$

and converting the left-hand side into a surface integral by the divergence theorem, we obtain the flux of the electrostatic field through a closed surface:

$$\oint_{\partial V} \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{s} = 4\pi k_E \, q_V \,, \tag{58.19}$$

a result known as *Gauss's law in integral form.*

Curl of the electrostatic field

Corollary 58.11. *The electrostatic field satisfies*

$$\boldsymbol{\nabla} \times \boldsymbol{E}(\boldsymbol{x}) = \boldsymbol{0} \,. \tag{58.20}$$

Proof. By Equation (58.14) there exists a scalar function such that the electrostatic field can be written as the gradient Equation (58.16); that is, the electrostatic field is a conservative vector field. Since the curl of a gradient vanishes identically, Equation (58.20) follows. □

58.1.2 Geometry of the field

Electrostatic field lines

Definition 58.12 (Field lines)**.** The *electrostatic field lines* are the curves $\boldsymbol{x} = \boldsymbol{x}(\lambda)$ to which the electrostatic field is tangent at every point:

$$\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda}(\lambda) = \alpha \, \boldsymbol{E}\big(\boldsymbol{x}(\lambda)\big) \,.$$

The constant α can be removed by the reparametrization $\lambda' = \alpha\lambda$, since

$$\begin{aligned}
\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda}(\lambda) &= \alpha \, \boldsymbol{E}\big(\boldsymbol{x}(\lambda)\big) \,, \\
\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda'} \frac{\mathrm{d}\lambda'}{\mathrm{d}\lambda} &= \alpha \, \boldsymbol{E}\big(\boldsymbol{x}(\lambda')\big) \,, \\
\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda'} \, \alpha &= \alpha \, \boldsymbol{E}\big(\boldsymbol{x}(\lambda')\big) \,, \\
\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda'} &= \boldsymbol{E}\big(\boldsymbol{x}(\lambda')\big) \,,
\end{aligned}$$

or, renaming the parameter,

$$\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda}(\lambda) = \boldsymbol{E}\big(\boldsymbol{x}(\lambda)\big) \,, \tag{58.21}$$

which is called the *field-line equation.*

Closed line integrals of the electrostatic field

Proposition 58.13. *The line integral of the electrostatic field around any closed curve vanishes:*

$$\oint_{\partial S} \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{l} = 0 \,. \tag{58.22}$$

Derivation. By Stokes's theorem, for an arbitrary compact surface S with closed boundary ∂S,

$$\oint_{\partial S} \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{l} = \int_S (\boldsymbol{\nabla} \times \boldsymbol{E}) \cdot \mathrm{d}\boldsymbol{s}\,,$$

which vanishes by Equation (58.20). □

Proposition 58.14. *There are no closed electrostatic field lines.*

Derivation. Suppose there were a closed field line C with parameter λ. Then, using the field-line equation Equation (58.21),

$$\begin{aligned}\oint_C \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{x} &= \oint_C \boldsymbol{E}(\boldsymbol{x}(\lambda)) \cdot \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda}\,\mathrm{d}\lambda \\ &= \oint_C \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda} \cdot \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda}\,\mathrm{d}\lambda \\ &= \oint_C \left|\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda}\right|^2 \mathrm{d}\lambda \neq 0\,,\end{aligned}$$

since along an actual curve

$$\left|\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda}\right|^2 > 0\,.$$

This contradicts Proposition 58.13, by which every closed line integral of the electrostatic field vanishes. Hence no closed field line exists. □

Equipotential surfaces

Definition 58.15 (Equipotential surface)**.** Consider a charge distribution generating an electrostatic potential ϕ. An *equipotential surface* is a surface given by the equation

$$\phi(\boldsymbol{x}) = C \tag{58.23}$$

with C constant.

58.2 Methods for obtaining the potential

58.2.1 Boundary conditions

Line integral of the electrostatic field

Consider two points P_i and P_f joined by a curve C described by $\boldsymbol{x}$. From Equation (58.16), integrating along C,

$$\int_C \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{x} = -\int_C \boldsymbol{\nabla}\phi \cdot \mathrm{d}\boldsymbol{x} = -\int_C \mathrm{d}\phi\,,$$

so that

$$\phi(P_f) - \phi(P_i) = -\int_C \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{x}\,.$$

Taking P_i to be the point of coordinates $\boldsymbol{x}$ and P_f a point located at $\boldsymbol{x}_0$, we obtain the following expression for the potential:

$$\phi(\boldsymbol{x}) = \phi(\boldsymbol{x}_0) + \int_C \boldsymbol{E} \cdot \mathrm{d}\boldsymbol{l}\,. \tag{58.24}$$

Continuity condition; interface conditions; ideal conductors

[Headings reserved in the source outline.] The worked examples below make use of the standard boundary conditions of electrostatics [1976]: the potential is continuous across any interface; the tangential component of $\boldsymbol{E}$ is continuous across an interface; the jump of the normal component of the field across a charged surface is fixed by the surface density, so that on the surface of an ideal conductor (in SI units)

$$\sigma = \epsilon_0 \, \boldsymbol{E} \cdot \hat{\boldsymbol{n}}\big|_{\partial V} \,, \tag{58.25}$$

with $\hat{\boldsymbol{n}}$ the outward normal of the conductor; the potential is constant throughout an ideal conductor, and vanishes on a grounded one.

Derivation pending #10

Continuity and interface conditions of the electrostatic field and the ideal-conductor boundary conditions, including Equation (58.25): the source reserves these headings without content, while its worked problems use the results.

58.2.2 The method of images

[Heading reserved in the source outline.] The method replaces a boundary-value problem in the presence of conductors by an equivalent charge configuration — the original sources plus fictitious *image* charges placed outside the physical region — chosen so that the boundary conditions of Section 58.2.1 are satisfied. The source develops the method only through the following worked problems, both of which rely on the ideal-dipole potential recorded in Section 58.4.4.

Example 58.16 (Ideal dipole inclined at 45° before a grounded conducting plane)**.** An ideal dipole of dipole moment $\boldsymbol{p}$ is located at a distance d from an infinite conducting plane connected to ground, and forms an angle of 45° with the normal to the plane. Compute the electrostatic potential at every point and the surface charge density induced on the plane.

The potential of an ideal dipole located at $\boldsymbol{x}'$ is given by

$$\phi(\boldsymbol{x}) = \frac{1}{4\pi\epsilon_0} \, \frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|^3} \cdot \boldsymbol{p} \,.$$

Using the method of images, we place an image dipole $\boldsymbol{p}_I$ on the other side of the plane, at a distance d_I; by the symmetry of the problem we may take $|\boldsymbol{p}_I| = |\boldsymbol{p}|$. The potential at every point is then

$$\phi(\boldsymbol{x}) = \frac{1}{4\pi\epsilon_0} \left(\frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|^3} \cdot \boldsymbol{p} + \frac{\boldsymbol{x} - \boldsymbol{x}_I}{|\boldsymbol{x} - \boldsymbol{x}_I|^3} \cdot \boldsymbol{p}_I \right) .$$

Placing the origin at the point of the plane closest to the dipole, with $\hat{\boldsymbol{x}}$ along the normal,

$$\begin{aligned}
\boldsymbol{x} &= x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}} + z\,\hat{\boldsymbol{z}} \,, \\
\boldsymbol{x}' &= d\,\hat{\boldsymbol{x}} \,, \qquad \boldsymbol{x}_I = d_I\,\hat{\boldsymbol{x}} \,, \\
\boldsymbol{p} &= p\,(\cos 45^\circ\,\hat{\boldsymbol{x}} + \sin 45^\circ\,\hat{\boldsymbol{y}}) = \frac{p}{\sqrt{2}}\,(\hat{\boldsymbol{x}} + \hat{\boldsymbol{y}}) \,, \\
\boldsymbol{p}_I &= p\,(\cos 45^\circ\,\hat{\boldsymbol{x}} - \sin 45^\circ\,\hat{\boldsymbol{y}}) = \frac{p}{\sqrt{2}}\,(\hat{\boldsymbol{x}} - \hat{\boldsymbol{y}}) \,.
\end{aligned}$$

We must now impose the boundary conditions of the problem to determine the distance d_I. Since the conducting plane is grounded, the potential must vanish on it; evaluating at the origin,

$$\frac{1}{4\pi\epsilon_0}\frac{p}{\sqrt{2}}\left(\frac{x-d+y}{((x-d)^2+y^2+z^2)^{3/2}}+\frac{x-d_I-y}{((x-d_I)^2+y^2+z^2)^{3/2}}\right)\Bigg|_{\boldsymbol{x}=\boldsymbol{0}}=0\,,$$
$$\frac{-d}{(d^2)^{3/2}}+\frac{-d_I}{(d_I^2)^{3/2}}=0\,,$$

so that

$$d_I=-d\,,\qquad \boldsymbol{x}_I=-d\,\hat{\boldsymbol{x}}\,.$$

Therefore

$$\phi(\boldsymbol{x})=\frac{p}{4\sqrt{2}\,\pi\epsilon_0}\left(\frac{x-d+y}{((x-d)^2+y^2+z^2)^{3/2}}+\frac{x+d-y}{((x+d)^2+y^2+z^2)^{3/2}}\right)\,, \tag{58.26}$$

and with these values the two numerators cancel on the whole plane $x=0$, so the boundary condition is satisfied everywhere on the conductor.

With the potential in hand we can compute the electric field. In particular,

$$\begin{aligned}E_x&=-\frac{\partial\phi}{\partial x}\\&=-\frac{p}{4\sqrt{2}\,\pi\epsilon_0}\Big(\left((x-d)^2+y^2+z^2\right)^{-3/2}-3(x-d)(x-d+y)\left((x-d)^2+y^2+z^2\right)^{-5/2}\\&\quad+\left((x+d)^2+y^2+z^2\right)^{-3/2}-3(x+d)(x+d-y)\left((x+d)^2+y^2+z^2\right)^{-5/2}\Big)\,.\end{aligned}$$

Finally, by the interface condition Equation (58.25) with $\hat{\boldsymbol{n}}=\hat{\boldsymbol{x}}$, the surface charge density induced on the plane is

$$\begin{aligned}\sigma(y,z)&=\epsilon_0\,\boldsymbol{E}\cdot\hat{\boldsymbol{n}}|_{\partial V}=\epsilon_0\,E_x(0,y,z)\\&=-\frac{p}{4\sqrt{2}\,\pi}\Big(\left(d^2+y^2+z^2\right)^{-3/2}+3d\,(y-d)\left(d^2+y^2+z^2\right)^{-5/2}\\&\quad+\left(d^2+y^2+z^2\right)^{-3/2}-3d\,(d-y)\left(d^2+y^2+z^2\right)^{-5/2}\Big)\\&=\frac{p}{2\sqrt{2}\,\pi}\left(3d\,(d-y)\left(d^2+y^2+z^2\right)^{-5/2}-\left(d^2+y^2+z^2\right)^{-3/2}\right)\,.\end{aligned}$$

Example 58.17 (Ideal dipole normal to a grounded conducting plane)**.** An ideal dipole of dipole moment $\boldsymbol{p}$ is oriented along the normal at a distance d from an infinite conducting plane connected to ground. Compute the potential at every point and the force exerted on the dipole.

The image construction is the same as in Example 58.16: an image dipole $\boldsymbol{p}_I$ with $|\boldsymbol{p}_I|=|\boldsymbol{p}|$ is placed at $\boldsymbol{x}_I=d_I\,\hat{\boldsymbol{x}}$, and now

$$\boldsymbol{x}'=d\,\hat{\boldsymbol{x}}\,,\qquad \boldsymbol{p}=p\,\hat{\boldsymbol{x}}\,,\qquad \boldsymbol{p}_I=p\,\hat{\boldsymbol{x}}\,.$$

Imposing that the potential vanish on the grounded plane — evaluating at the origin as before —

$$\frac{-d}{(d^2)^{3/2}}+\frac{-d_I}{(d_I^2)^{3/2}}=0\quad\Longrightarrow\quad d_I=-d\,,\qquad \boldsymbol{x}_I=-d\,\hat{\boldsymbol{x}}\,.$$

Therefore

$$\phi(\boldsymbol{x})=\frac{p}{4\pi\epsilon_0}\left(\frac{x-d}{((x-d)^2+y^2+z^2)^{3/2}}+\frac{x+d}{((x+d)^2+y^2+z^2)^{3/2}}\right)\,, \tag{58.27}$$

which vanishes on the plane $x = 0$, as required.

The force felt by an ideal dipole $\boldsymbol{p}$ in an external field $\boldsymbol{E}$ is given by

$$\boldsymbol{F} = \boldsymbol{\nabla}\,(\boldsymbol{p}\cdot\boldsymbol{E})$$

(cf. Section 58.4.4). In this case the external field is the one generated by the plane — equivalently, by the image dipole,

$$\boldsymbol{E}(\boldsymbol{x}) = \frac{1}{4\pi\epsilon_0}\,\frac{3(\boldsymbol{p}_I\cdot\hat{\boldsymbol{r}})\hat{\boldsymbol{r}} - \boldsymbol{p}_I}{r^3}\,,$$

with r measured from the image dipole. The dipole sits at distance $r = 2d$ from its image, on the axis $\theta = 0$ (spherical coordinates centred on the image, polar axis $\hat{\boldsymbol{x}}$). Thus, with $\boldsymbol{p}_I = \boldsymbol{p}$,

$$\begin{aligned}
\boldsymbol{F} &= \boldsymbol{\nabla}\left(\boldsymbol{p}\cdot\frac{1}{4\pi\epsilon_0}\,\frac{3(\boldsymbol{p}\cdot\hat{\boldsymbol{r}})\hat{\boldsymbol{r}} - \boldsymbol{p}}{r^3}\right)\Bigg|_{r=2d,\;\theta=0} \\
&= \frac{1}{4\pi\epsilon_0}\,\boldsymbol{\nabla}\left(\frac{3(\boldsymbol{p}\cdot\hat{\boldsymbol{r}})^2 - p^2}{r^3}\right)\Bigg|_{r=2d,\;\theta=0} \\
&= \frac{p^2}{4\pi\epsilon_0}\,\boldsymbol{\nabla}\left(3\,\frac{\cos^2\theta}{r^3} - \frac{1}{r^3}\right)\Bigg|_{r=2d,\;\theta=0} \\
&= \frac{p^2}{4\pi\epsilon_0}\left(3\left(-3\,\frac{\cos^2\theta}{r^4}\right) + \frac{3}{r^4}\right)\Bigg|_{r=2d,\;\theta=0}\hat{\boldsymbol{r}} \\
&= -\frac{1}{4\pi\epsilon_0}\,\frac{6p^2}{(2d)^4}\,\hat{\boldsymbol{x}} = -\frac{3p^2}{32\pi\epsilon_0\,d^4}\,\hat{\boldsymbol{x}}\,,
\end{aligned}$$

where the angular part of the gradient drops out because $\mathrm{d}(\cos^2\theta)/\mathrm{d}\theta = -2\cos\theta\sin\theta$ vanishes at $\theta = 0$. The force is attractive: the dipole is pulled toward the plane.

58.2.3 The Poisson equation

Poisson equation

From Equation (58.16), taking the divergence of both sides and using Gauss's law Equation (58.18),

$$\begin{aligned}
\boldsymbol{E} &= -\boldsymbol{\nabla}\phi\,, && \text{apply } \boldsymbol{\nabla}\cdot(\ )\,, \\
4\pi k_E\,\rho &= -\nabla^2\phi\,,
\end{aligned}$$

so that

$$\nabla^2\phi(\boldsymbol{x}) = -4\pi k_E\,\rho(\boldsymbol{x})\,, \tag{58.28}$$

a result known as the *Poisson equation*.

Laplace equation

In a region where the charge density vanishes, Equation (58.28) reduces to

$$\nabla^2\phi(\boldsymbol{x}) = 0\,, \tag{58.29}$$

known as the *Laplace equation*.

58.2.4 Green functions

[Headings reserved in the source outline: the source function, the general solution of the Poisson equation, and the Dirichlet and Neumann boundary conditions are pending port from a completed source; see [1976] for the standard treatment.]

58.2.5 Multipole expansion

[Headings reserved in the source outline: the expansion of the potential in inverse powers of the distance, the multipole moments of order n, and the ideal-dipole limit are pending port from a completed source. The ideal-dipole formulas used by the worked examples are recorded, as pending statements, in Section 58.4.4.]

58.3 Electrostatic potential energy

[Heading reserved in the source outline; no content to port. The energy functional of a linear dielectric medium, used by the worked examples of Chapter 62, is recorded there.]

58.4 Charge distributions in external fields

58.4.1 Potential energy of a charge distribution in an external field

[Heading reserved in the source outline; no content to port.]

58.4.2 Force on a charge distribution in an external field

[Heading reserved in the source outline; no content to port.]

58.4.3 Torque on a charge distribution in an external field

[Heading reserved in the source outline; no content to port.]

58.4.4 The ideal dipole

The worked examples of Section 58.2.2 employ the following standard results for an ideal (point) dipole of moment $\boldsymbol{p}$ [1976, 2313]. The potential of an ideal dipole located at $\boldsymbol{x}'$ is

$$\phi(\boldsymbol{x}) = k_E \, \frac{(\boldsymbol{x} - \boldsymbol{x}') \cdot \boldsymbol{p}}{|\boldsymbol{x} - \boldsymbol{x}'|^3} \, , \tag{58.30}$$

and the corresponding field, at position $r\hat{\boldsymbol{r}}$ relative to the dipole, is

$$\boldsymbol{E}(\boldsymbol{x}) = k_E \, \frac{3\,(\boldsymbol{p} \cdot \hat{\boldsymbol{r}})\,\hat{\boldsymbol{r}} - \boldsymbol{p}}{r^3} \, . \tag{58.31}$$

In an external electrostatic field $\boldsymbol{E}$, the force felt by an ideal dipole is

$$\boldsymbol{F} = \boldsymbol{\nabla}\,(\boldsymbol{p} \cdot \boldsymbol{E}) \, . \tag{58.32}$$

Derivation pending #11

Ideal-dipole potential Equation (58.30), field Equation (58.31) and force Equation (58.32): to be derived from the multipole expansion of Section 58.2.5 and from the energy of a distribution in an external field, both of which the source reserves without content.

58.5 Electrostatics in macroscopic media

[Heading reserved in the source outline.] The macroscopic model of electrostatics in material media — polarization, the displacement field, and the linear dielectric constitutive relation — together with the two dielectric worked problems of the companion collection, is ported to Chapter 62.

Chapter 59

Magnetostatics

Magnetostatics is the theory of the fields produced by steady electric currents: currents themselves, the Biot–Savart law, the vector potential, and magnetic media. It stands to Chapter 58 as the second static limit of the full Maxwell system assembled in Chapter 60, and it is where electromagnetism became a single subject: before 1820 electricity and magnetism were separate sciences, and this chapter's first task is the experiment that joined them. Its second task is a structural asymmetry with electrostatics that has survived every later refinement of the theory: there are electric charges, and there are—as far as every search to date can tell—no magnetic ones. That absence is not an assumption but an experimental verdict, and it is treated as such in Section 59.6.

Derivation pending #12

Magnetostatics: all derivations of this chapter are pending.

59.1 Steady currents

59.1.1 Current density and charge conservation

[Reserved: the current density $\boldsymbol{J}$, the current through a surface, the continuity equation $\partial\rho/\partial t + \boldsymbol{\nabla}\cdot\boldsymbol{J} = 0$, and the magnetostatic regime $\boldsymbol{\nabla}\cdot\boldsymbol{J} = 0$ as its steady limit; surface and line currents; the standard treatment is [1976]. The dynamical role of the continuity equation—it is what forces the displacement current—is taken up in Chapter 60.]

59.1.2 The SI unit of current

[Reserved: the ampere, historically defined through the force per unit length between parallel currents and since 2019 fixed by the elementary charge [2333]; how current is realised and measured, with the metrological framework of Chapter 2.]

59.2 The discovery of electromagnetism

59.2.1 Magnetism before 1820

[Reserved: lodestones, compass needles, and Gilbert's De Magnete*, which established the Earth itself as a magnet and separated magnetic from electric attraction [1]; the phenomenology of poles, the impossibility of isolating one by cutting a magnet, and the inverse-square law between pole strengths, put on an absolute quantitative footing by Gauss's measurement of the terrestrial field [106].]*

Phenomenon 59.1 (The inseparability of magnetic poles)**.** Every magnet has two poles of opposite character, and no operation performed upon it isolates one of them. A bar magnet broken in two yields two complete magnets, each with its own north and south pole, and the subdivision may be repeated to the limit of what can be handled without ever producing a body that acts upon a compass needle as a single pole would. The Earth itself behaves as one such magnet, which is why the needle points at all [1], and the strength of its field was reduced to absolute measure — to mechanical units, and so ultimately to the SI — by Gauss [106].

Derivation pending #13

Inseparability of magnetic poles: derive, from the Amperian representation of a magnetized body by bound currents, that every subdivision of such a body again carries a complete circulating current and is therefore again a dipole, and connect the statement to the vanishing divergence of the magnetic field.

59.2.2 Ørsted's experiment

[Reserved: the deflection of a compass needle by a nearby current-carrying wire, announced by Ørsted in July 1820 [68]—the first observed connection between electricity and magnetism, and the observation from which the whole of electrodynamics descends. The circular geometry of the effect (the needle sets tangentially around the wire, not toward it) already encodes the curl structure of the field equations. Full experimental detail belongs to Chapter 63.]

Phenomenon 59.2 (The deflection of the needle by a current)**.** A magnetic needle placed near a straight conducting wire is deflected the instant a galvanic current is sent through the wire, and it comes to rest *across* the wire rather than along the line joining the two: the needle sets tangentially to the circle that passes through it and has the wire for its axis. The sense of the deflection reverses with the sense of the current, and reverses again when the needle is carried to the opposite side of the wire [68]. This is the first observed action of electricity upon magnetism, and the first force in physics whose direction is not along the line joining its sources.

Derivation. The derivation runs opposite to the history: it assumes the law for which this observation was the first evidence, namely the Biot–Savart law of Section 59.2.3, by which an element $I\,\mathrm{d}\boldsymbol{l}$ of a steady current contributes

$$\mathrm{d}\boldsymbol{B}(\boldsymbol{x}) = \frac{\mu_0 I}{4\pi}\,\frac{\mathrm{d}\boldsymbol{l}\times\hat{\boldsymbol{r}}}{r^2}\,, \tag{59.1}$$

where $\boldsymbol{r}$ runs from the element to the field point.

Take the wire along the z-axis and the field point at perpendicular distance s in the plane $z=0$. Each element $\mathrm{d}\boldsymbol{l} = \mathrm{d}z\,\hat{\boldsymbol{z}}$ contributes along $\hat{\boldsymbol{z}}\times\hat{\boldsymbol{r}}$, which is $\hat{\boldsymbol{\varphi}}$ for every z; the contributions therefore do not compete in direction and the total field is purely azimuthal. Writing $z = s\tan\alpha$, so that $r = s\sec\alpha$ and $\mathrm{d}z = s\sec^2\alpha\,\mathrm{d}\alpha$, and noting that the sine of the angle between $\mathrm{d}\boldsymbol{l}$ and $\hat{\boldsymbol{r}}$ is $\cos\alpha$,

$$B_\varphi(s) = \frac{\mu_0 I}{4\pi}\int_{-\pi/2}^{\pi/2}\frac{s\sec^2\alpha\,\cos\alpha}{s^2\sec^2\alpha}\,\mathrm{d}\alpha = \frac{\mu_0 I}{4\pi s}\int_{-\pi/2}^{\pi/2}\cos\alpha\,\mathrm{d}\alpha = \frac{\mu_0 I}{2\pi s}\,. \tag{59.2}$$

The field circles the wire. A compass needle is a magnetic dipole $\boldsymbol{m}$ and feels the torque $\boldsymbol{m}\times\boldsymbol{B}$ (Section 59.4.4), which vanishes only when $\boldsymbol{m}$ lies along $\boldsymbol{B}$; the needle therefore comes to rest tangentially to that circle, reverses with I, and reverses again on the far side of the wire, where $\hat{\boldsymbol{\varphi}}$ points the other way. □

59.2.3 The Biot–Savart law

[Reserved: Biot and Savart's quantitative measurement, within months of Ørsted's announcement, of the force exerted by a long straight current on a magnetic pole, falling off as the inverse distance [67]; the modern differential statement $\mathrm{d}\boldsymbol{B} \propto I\,\mathrm{d}\boldsymbol{l} \times \hat{\boldsymbol{r}}/r^2$ and its integral form for closed circuits; worked fields of the straight wire, the circular loop and the solenoid [1976].]

Phenomenon 59.3 (The field of a long straight current)**.** The magnetic action of a long straight steady current, measured by Biot and Savart within weeks of Ørsted's announcement from the oscillation period of a short magnetic needle suspended at a series of distances from a vertical conducting wire, is proportional to the current I and falls off as the inverse *first* power of the perpendicular distance s from the wire, not as the inverse square [67]:

$$B_\varphi = \frac{\mu_0 I}{2\pi s}\,. \tag{59.3}$$

Since the SI revision of 2019 the magnetic constant μ_0 appearing here is a measured quantity rather than a defined one [2333].

Derivation. This is Equation (59.2), already obtained from the Biot–Savart law Equation (59.1) for exactly this configuration. The inverse first power, against the inverse square of each separate element's contribution, is the signature of a line source of unbounded length: the length of wire lying within a given range of the angle α grows in proportion to s, which cancels one power of the distance. □

59.2.4 Ampère's electrodynamics

[Reserved: Ampère's demonstration that two currents attract or repel one another, his force law between current elements, and the theorem that a closed current loop is magnetically equivalent to a sheet of magnetic dipoles, all deduced from his null and balance experiments in the Théorie des phénomènes électro-dynamiques *[77]; the hypothesis of molecular currents as the origin of all magnetism, vindicated a century later in Chapter 129.]*

Phenomenon 59.4 (Force between parallel currents)**.** Two long straight parallel wires carrying steady currents act on one another mechanically, with no magnets present anywhere: they attract when the currents run the same way and repel when they run opposite ways, and the force per unit length is proportional to each current and inversely proportional to their separation d [66, 77],

$$\frac{F}{L} = \frac{\mu_0 I_1 I_2}{2\pi d}\,. \tag{59.4}$$

For $I_1 = I_2 = 1\,\mathrm{A}$ at $d = 1\,\mathrm{m}$ this is $2 \times 10^{-7}\,\mathrm{N/m}$, the number through which the ampere was defined until the SI revision of 2019 replaced that definition by a fixed value of the elementary charge [2333].

Derivation. Wire 1 produces at the location of wire 2 the azimuthal field Equation (59.2) with $s = d$, of magnitude $B_1 = \mu_0 I_1/2\pi d$ and directed perpendicular both to wire 1 and to the line joining the wires. A length L of wire 2, carrying I_2 along the unit vector $\hat{\boldsymbol{l}}_2$, feels the Ampère force $\boldsymbol{F} = I_2 L\,\hat{\boldsymbol{l}}_2 \times \boldsymbol{B}_1$ (Section 59.4.4). Since $\hat{\boldsymbol{l}}_2$ is parallel to the wires and $\boldsymbol{B}_1$ is perpendicular to them, the magnitudes multiply without an angular factor and $F/L = I_2 B_1 = \mu_0 I_1 I_2/2\pi d$, which is Equation (59.4). Taking $\hat{\boldsymbol{l}}_2$ parallel to $\hat{\boldsymbol{l}}_1$ makes $\hat{\boldsymbol{l}}_2 \times \boldsymbol{B}_1$ point from wire 2 towards wire 1 — attraction — and reversing either current reverses it. With $\mu_0 = 4\pi \times 10^{-7}\,\mathrm{N/A^2}$, as it was by definition before 2019, the numerical value quoted follows by substitution. □

59.3 The field equations of magnetostatics

59.3.1 Gauss's law for the magnetic field

[Reserved: $\nabla \cdot \boldsymbol{B} = 0$ and its integral form, the vanishing of the magnetic flux through every closed surface [185]; its reading as the statement that magnetic field lines do not end, and its empirical status as the absence of magnetic charge, examined against experiment in Section 59.6.]

Phenomenon 59.5 (The magnetic flux through a closed surface vanishes)**.** Every measurement of magnetic flux ever performed, over any closed surface and about any source — a current-carrying circuit, a permanent magnet, the Earth, a star — has given zero net flux:

$$\oint_{\partial V} \boldsymbol{B} \cdot \mathrm{d}\boldsymbol{S} = 0 \qquad \text{for every closed surface } \partial V\,, \tag{59.5}$$

equivalently $\nabla \cdot \boldsymbol{B} = 0$ [185]. The statement is not a mathematical necessity but an experimental one: it says that magnetic charge has never been found (Section 59.6.2, [2427]), and it is the one Maxwell equation whose empirical support is a null record rather than a positive measurement.

Derivation. For fields produced by steady currents the vanishing follows from the Biot–Savart law. Since $(\boldsymbol{x}-\boldsymbol{x}')/|\boldsymbol{x}-\boldsymbol{x}'|^3 = -\nabla\,(1/|\boldsymbol{x}-\boldsymbol{x}'|)$, where ∇ acts on the field point, and since $\boldsymbol{J}(\boldsymbol{x}')$ does not depend on the field point,

$$\boldsymbol{B}(\boldsymbol{x}) = \frac{\mu_0}{4\pi}\int \frac{\boldsymbol{J}(\boldsymbol{x}')\times(\boldsymbol{x}-\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|^3}\,\mathrm{d}V' = \nabla \times \left[\frac{\mu_0}{4\pi}\int \frac{\boldsymbol{J}(\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|}\,\mathrm{d}V'\right], \tag{59.6}$$

using $\nabla\times(f\boldsymbol{J}) = (\nabla f)\times\boldsymbol{J}$ for constant $\boldsymbol{J}$. A curl is divergence-free, so $\nabla\cdot\boldsymbol{B} = 0$ identically, and the divergence theorem turns that into Equation (59.5). What the derivation establishes is conditional: *if* every magnetic field has currents for its only source, the flux vanishes. The unconditional statement is the experimental one, and the bracketed expression is the vector potential of Section 59.4. □

59.3.2 Ampère's circuital law

[Reserved: $\nabla\times\boldsymbol{B} = \mu_0\boldsymbol{J}$ in the steady regime and the integral statement that the circulation of $\boldsymbol{B}$ around a closed curve measures the enclosed current [77, 185]; its consistency requirement $\nabla\cdot\boldsymbol{J} = 0$, whose failure for open circuits is the door through which the displacement current of Chapter 60 enters; applications to the solenoid and the torus.]

59.3.3 Boundary conditions

[Reserved: continuity of the normal component of $\boldsymbol{B}$ and the jump of its tangential component across a surface current [1976], in parallel with the electrostatic interface conditions of Chapter 58.]

59.4 The vector potential

59.4.1 Existence and gauge freedom

[Reserved: $\nabla\cdot\boldsymbol{B} = 0$ implies $\boldsymbol{B} = \nabla\times\boldsymbol{A}$; the vector potential introduced by Neumann in his general law of induced currents [115]; the gauge ambiguity $\boldsymbol{A}\to\boldsymbol{A}+\nabla\chi$ and the Coulomb gauge $\nabla\cdot\boldsymbol{A} = 0$; the systematic treatment of gauge freedom is deferred to Chapter 60.]

59.4.2 The Biot–Savart law as the general solution

[Reserved: in Coulomb gauge each component of $\boldsymbol{A}$ obeys a Poisson equation, solved by the same Green function as the electrostatic potential of Chapter 58 (general theory in Chapter 10); recovering the Biot–Savart field [67, 1976] by taking the curl.]

59.4.3 Multipole expansion and the magnetic dipole

[Reserved: the expansion of $\boldsymbol{A}$ for a localised current distribution; the vanishing of the monopole term as the first appearance of Section 59.3.1 in an expansion; the magnetic dipole moment $\boldsymbol{m} = \frac{1}{2}\int \boldsymbol{x}' \times \boldsymbol{J}\,\mathrm{d}V'$ and its field [1976]; the dipole–dipole interaction and the field of the Earth as leading-order dipole [106].]

Phenomenon 59.6 (Every magnetostatic source is a dipole to leading order)**.** Seen from far enough away, no steady current distribution and no magnetized body produces a field falling as $1/r^2$, the magnetic counterpart of the field of a point charge. The leading behaviour is always the $1/r^3$ field of a dipole. The Earth is the case measured first and best: it acts on a compass as a magnet [1], its field strength was reduced to absolute mechanical units by Gauss [106], and to leading order in the distance that field is dipolar, with the higher multipoles appearing as corrections.

Derivation. Expand the vector potential of Equation (59.6) for a current distribution confined to a bounded region, at a field point far outside it. The first term of $1/|\boldsymbol{x}-\boldsymbol{x}'|$ is $1/r$ with $r = |\boldsymbol{x}|$, and it contributes

$$\boldsymbol{A}_{\mathrm{mono}}(\boldsymbol{x}) = \frac{\mu_0}{4\pi r}\int \boldsymbol{J}(\boldsymbol{x}')\,\mathrm{d}V' \,. \tag{59.7}$$

For a steady current this integral vanishes. Indeed $\partial'_j\,(x'_i J_j) = J_i + x'_i\,\boldsymbol{\nabla}'\cdot\boldsymbol{J} = J_i$, because $\boldsymbol{\nabla}\cdot\boldsymbol{J} = 0$ in the magnetostatic regime (Section 59.1.1); integrating over a volume that encloses all the current, where $\boldsymbol{J}$ vanishes on the boundary, the left-hand side integrates to zero by the divergence theorem, so

$$\int J_i\,\mathrm{d}V' = 0\,, \qquad i = 1,2,3\,. \tag{59.8}$$

The monopole term Equation (59.7) therefore disappears identically, the expansion begins at the next order, and that order is the dipole $\boldsymbol{m} = \frac{1}{2}\int \boldsymbol{x}'\times\boldsymbol{J}\,\mathrm{d}V'$ whose potential falls as $1/r^2$ and whose field falls as $1/r^3$. This is the same absence, read in an expansion, that Phenomenon 59.5 reads as a flux. □

59.4.4 Force and torque on a dipole

[Reserved: force $\boldsymbol{\nabla}(\boldsymbol{m}\cdot\boldsymbol{B})$ and torque $\boldsymbol{m}\times\boldsymbol{B}$ on a magnetic dipole in an external field; Ampère's equivalence of the current loop and the dipole sheet [77]; the contrast with the electric dipole of Chapter 58, and the relativistic reading of the magnetic force developed in Chapter 40.]

59.5 Magnetostatics in matter

59.5.1 Magnetization and bound currents

[Reserved: the magnetization field $\boldsymbol{M}$ as dipole moment density; the equivalent bound currents $\boldsymbol{J}_b = \boldsymbol{\nabla}\times\boldsymbol{M}$ in the volume and $\boldsymbol{M}\times\hat{\boldsymbol{n}}$ on the surface, following the macroscopic construction of Maxwell's Treatise *[185]; the microscopic averaging that justifies it is carried out in Chapter 62.]*

59.5.2 The auxiliary field $\boldsymbol{H}$

[Reserved: $\boldsymbol{H} = \boldsymbol{B}/\mu_0 - \boldsymbol{M}$ and the circuital law $\boldsymbol{\nabla} \times \boldsymbol{H} = \boldsymbol{J}_{free}$ sourced by free currents alone [185]; interface conditions for $\boldsymbol{H}$; linear media, permeability, and the magnetic scalar potential in current-free regions [1976].]

59.5.3 Permanent magnets and boundary-value problems

[Reserved: the uniformly magnetized sphere and bar magnet; hysteresis named as the phenomenon that makes "the" permeability of a ferromagnet ill-defined, with its phenomenology and microscopic origin deferred to Chapter 62 and Chapter 129; magnetic circuits and shielding [1976].]

59.6 Magnetic monopoles: the empirical status

59.6.1 The Dirac quantization argument

[Reserved: Dirac's demonstration that a single magnetic charge g anywhere in the universe forces electric charge to be quantized, in units inversely proportional to g [677]—the one theoretical result that keeps the monopole question open, since charge quantization is observed; the argument requires the quantum mechanics of Part IX and is stated here only for its bearing on Section 59.3.1.]

59.6.2 Searches and the null record

[Reserved: the honest record of monopole searches. Cabrera's superconducting induction detector registered on 14 February 1982 a single candidate event of exactly one Dirac charge [1685]; the event was never repeated, and larger-exposure induction and track-etch searches, accelerator searches, and cosmic-ray searches have all been null—the current limits are collected in the Review of Particle Physics [2427]. Gauss's law for $\boldsymbol{B}$ therefore stands as an empirical law: one unrepeated candidate against decades of null exposure, stated as such and not better.]

Phenomenon 59.7 (The null record of the monopole searches)**.** No magnetic charge has been observed. A superconducting induction detector registered, on 14 February 1982, a single flux jump of the magnitude a monopole of one Dirac charge would produce [1685]; the event was never repeated, in that apparatus or in any of the far larger induction, track-etch, accelerator and cosmic-ray exposures that followed, and every such search has returned a limit rather than a signal [2427]. The record is therefore one unrepeated candidate against decades of null exposure, and this is the whole of the evidence on which Phenomenon 59.5 rests. The question is kept open, rather than closed, by Dirac's demonstration that a single magnetic charge anywhere would force the quantization of electric charge [677] — and electric charge *is* observed to be quantized.

Derivation pending #14

Monopole searches: derive the flux quantum that an induction detector would register for the passage of one Dirac charge through a superconducting loop, and the conversion of a null exposure into a flux limit per unit area, time and solid angle. The Dirac quantization argument itself requires the quantum mechanics of Part IX and is stated, not derived, here.

Chapter 60

The Maxwell Equations

This chapter unifies electrodynamics: electromagnetic induction, the displacement current, the full Maxwell system, its conservation laws, and the potentials through which it is most efficiently formulated (the Lagrangian formulation itself is developed in Chapter 64). The statics of Chapter 58 and Chapter 59 treated $\boldsymbol{E}$ and $\boldsymbol{B}$ as separate fields with separate sources; here the time derivatives couple them. Faraday's discovery that a changing magnetic flux drives a current supplies one coupling from experiment; Maxwell's displacement current supplies the other from a consistency argument—and turns the system into one that propagates waves at a speed fixed by two electrical constants. That the speed came out equal to the measured speed of light is the single most consequential coincidence in classical physics, and its experimental confirmation by Hertz is treated in Chapter 63.

Derivation pending #15

The Maxwell Equations: all derivations of this chapter are pending.

60.1 Electromagnetic induction

60.1.1 Faraday's discovery

[Reserved: the induction of transient currents by switching a neighbouring circuit, by moving a magnet, and by moving the circuit itself, reported in the First Series of Faraday's Experimental Researches in Electricity *[89]; Henry's independent observation of induction and of self-induction [91]; electromotive force and the flux rule; full experimental detail in Chapter 63.]*

Phenomenon 60.1 (Electromagnetic induction)**.** A current flows in a closed conducting circuit whenever — and only while — the magnetic flux threading it changes. A steady current in a neighbouring circuit produces nothing; making or breaking that current produces a transient. So does moving a magnet through the circuit, and so does moving the circuit itself while the magnet stands still [89, 91]. The electromotive force driving the current is the rate at which the flux changes,

$$\mathcal{E} = -\frac{\mathrm{d}\Phi_B}{\mathrm{d}t}\,, \qquad \Phi_B = \int_S \boldsymbol{B}\cdot\mathrm{d}\boldsymbol{S}\,, \tag{60.1}$$

with S any surface bounded by the circuit, and it does not matter which of the three ways the change was brought about.

Derivation pending #16

The flux rule: derive it from the Maxwell–Faraday equation together with the Lorentz force acting on the charge carriers of a moving circuit, using the transport theorem for a surface whose boundary moves with the circuit, and show that the two physically distinct mechanisms — an induced electric field in the transformer case, a magnetic force on carried charge in the motional case — combine into the single total rate of change of the flux.

60.1.2 Lenz's law

[Reserved: the sign of the induced current opposes the change of flux that produces it [97]; its reading as a stability statement and its connection with energy conservation, made precise once Poynting's theorem is available in Section 60.4; eddy currents as its macroscopic manifestation.]

Phenomenon 60.2 (Lenz's rule for the sign)**.** The induced current always circulates in the sense whose own magnetic flux *opposes* the change that produced it [97]. A magnet pushed towards a closed loop is resisted; the same magnet withdrawn is held back; a sheet of copper swung between the poles of a magnet is braked as though moving through a fluid, though nothing touches it. The rule fixes the sign in Equation (60.1) and is what makes that minus sign an experimental statement rather than a convention.

Derivation. Suppose the opposite sign, and let a magnet approach a loop of resistance R. The induced current would then produce a flux reinforcing the change, so the force it exerts on the magnet would act *along* the magnet's motion. The magnet would accelerate; the flux would change faster; the electromotive force and the current would grow with it; and the loop would dissipate $\mathcal{E}^2/R$ at an increasing rate while the magnet's kinetic energy also increased. Both the mechanical energy and the Joule heat would rise without anything supplying them, which no experiment has ever exhibited. The only consistent sign is therefore the observed one: the induced current opposes the change, the force on the magnet resists its motion, and the work done against that force is exactly the energy dissipated in the loop. The local form of the same bookkeeping is Poynting's theorem (Section 60.4.2), which turns this argument from a consistency requirement into an identity of the field equations. □

60.1.3 The Maxwell–Faraday equation

[Reserved: the local form $\boldsymbol{\nabla} \times \boldsymbol{E} = -\partial \boldsymbol{B}/\partial t$ abstracted from the flux rule [89, 164]; the two distinct physical cases hiding in one flux rule—motional emf (magnetic force on carried charges) versus transformer emf (induced electric field)—whose unification is relativistic and is completed in Chapter 38.]

60.2 The displacement current and the complete system

60.2.1 The inconsistency of the static circuital law

[Reserved: Ampère's law of Chapter 59 requires $\boldsymbol{\nabla} \cdot \boldsymbol{J} = 0$ and therefore fails for open circuits —the charging capacitor as the canonical case; charge conservation, $\partial \rho/\partial t + \boldsymbol{\nabla} \cdot \boldsymbol{J} = 0$, as the constraint the corrected law must respect.]

60.2.2 Maxwell's dynamical theory

[Reserved: the displacement current $\epsilon_0 \, \partial \boldsymbol{E}/\partial t$, introduced by Maxwell first within the molecular-vortex model of On Physical Lines of Force *[157] and then rederived, free of*

mechanical scaffolding, in A Dynamical Theory of the Electromagnetic Field *[164]; the complete system of field equations, its rearrangement in the* Treatise *[185], and the counting of its independent equations.]*

60.2.3 The Heaviside vector form

[Reserved: the reduction of Maxwell's original twenty equations in twenty variables to the four vector equations used ever since, carried out by Heaviside in 1885 in the Electrician *series reprinted in his* Electrical Papers *[252]; the modern SI statement of the system [1976, 2333], boxed here as the reference form for the rest of the treatise.]*

60.3 Potentials and gauge freedom

60.3.1 Scalar and vector potentials

[Reserved: the homogeneous pair of Maxwell equations is solved identically by $\boldsymbol{B} = \boldsymbol{\nabla} \times \boldsymbol{A}$ *and* $\boldsymbol{E} = -\boldsymbol{\nabla}\phi - \partial \boldsymbol{A}/\partial t$*, extending the static potentials of Chapter 58 and Chapter 59; the inhomogeneous pair becomes two coupled second-order equations for* $(\phi, \boldsymbol{A})$ *[164].]*

60.3.2 Gauge transformations

[Reserved: the invariance of the fields under $\boldsymbol{A} \to \boldsymbol{A} + \boldsymbol{\nabla}\chi$*,* $\phi \to \phi - \partial\chi/\partial t$*; the Lorenz condition, due to L. V. Lorenz [168]—the Danish physicist, not H. A. Lorentz, a misattribution the literature keeps alive—which decouples the potential equations into wave equations; the Coulomb gauge; gauge freedom as the classical seed of the gauge principle of Chapter 64.]*

60.4 Conservation laws

60.4.1 Charge conservation

[Reserved: the continuity equation as an identity of the Maxwell system—the displacement current makes conservation automatic rather than assumed [164]; global charge conservation and its experimental precision.]

Phenomenon 60.3 (Conservation of electric charge)**.** The total electric charge of an isolated system never changes. Charge appears and disappears only in pairs of opposite sign, and no process has ever been seen to create or destroy a net amount of it. The sharpest test is the stability of the electron: as the lightest charged particle it has nothing charged to decay into, so any decay would destroy charge outright, and no such decay has been observed — the resulting bounds on its mean life exceed the age of the universe by many orders of magnitude [2427]. Locally the statement is a continuity equation,

$$\frac{\partial \rho}{\partial t} + \boldsymbol{\nabla} \cdot \boldsymbol{J} = 0\,. \tag{60.2}$$

Derivation. Take the divergence of the Ampère–Maxwell law $\boldsymbol{\nabla} \times \boldsymbol{B} = \mu_0 \boldsymbol{J} + \mu_0 \epsilon_0\, \partial \boldsymbol{E}/\partial t$. The left-hand side is the divergence of a curl and vanishes identically, so

$$0 = \mu_0 \boldsymbol{\nabla} \cdot \boldsymbol{J} + \mu_0 \epsilon_0 \frac{\partial}{\partial t} \left(\boldsymbol{\nabla} \cdot \boldsymbol{E} \right) , \tag{60.3}$$

and substituting Gauss's law $\boldsymbol{\nabla} \cdot \boldsymbol{E} = \rho/\epsilon_0$ gives Equation (60.2) after dividing by μ_0. Integrating over a volume and applying the divergence theorem turns it into the global statement that the charge inside a region changes only by the current crossing its boundary.

The step is worth reading backwards, because it is the whole reason for the displacement current. Without that term the same operation yields $\boldsymbol{\nabla}\cdot\boldsymbol{J}=0$, which is false for any circuit that is open — a capacitor being charged — and it is the demand that charge be conserved, not any new measurement, that forced the correction (Section 60.2.1). Conservation is thereby an identity of the completed system rather than an extra assumption imposed on it. □

60.4.2 Poynting's theorem

[Reserved: the local energy balance of the electromagnetic field, with energy density $u=(\epsilon_0 E^2+B^2/\mu_0)/2$ and flux $\boldsymbol{S}=\boldsymbol{E}\times\boldsymbol{B}/\mu_0$, derived by Poynting [229]; where the energy of a circuit actually flows; the ambiguity of $\boldsymbol{S}$ up to a curl and why no experiment inside electrodynamics resolves it.]

60.4.3 The stress tensor and field momentum

[Reserved: the Maxwell stress tensor [185], the momentum density $\epsilon_0\boldsymbol{E}\times\boldsymbol{B}$, and the momentum balance of field plus matter; radiation pressure predicted by Maxwell [185] and measured by Lebedev [299] and by Nichols and Hull [311]; angular momentum of the field, with its mechanical detection in circularly polarized light by Beth [767]; the covariant packaging of these densities awaits Chapter 64.]

Phenomenon 60.4 (Radiation pressure)**.** Light falling on a surface pushes it. The effect was predicted from the field momentum [185] and measured, against enormous thermal backgrounds, with torsion balances in evacuated vessels by Lebedev [299] and by Nichols and Hull [311]. At normal incidence the pressure on a perfectly absorbing surface is

$$P_{\mathrm{rad}}=\frac{I}{c}\,, \tag{60.4}$$

with I the incident irradiance, and twice that on a perfect reflector. Electromagnetic energy therefore carries mechanical momentum, and the field is a dynamical object rather than a bookkeeping device.

Derivation. The electromagnetic momentum density is $\boldsymbol{g}=\epsilon_0\boldsymbol{E}\times\boldsymbol{B}=\boldsymbol{S}/c^2$, with $\boldsymbol{S}=\boldsymbol{E}\times\boldsymbol{B}/\mu_0$ the Poynting vector (Section 60.4.2) and $\boldsymbol{g}$ the momentum entry of the Maxwell stress tensor (Section 60.4.3). For a plane wave in vacuum $|\boldsymbol{S}|=uc$, where u is the energy density, so $|\boldsymbol{g}|=u/c$: the wave carries one unit of momentum for every c units of energy.

Momentum arrives at an absorbing surface at the rate at which the wave delivers it, that is, the momentum density times the speed at which it advances:

$$P_{\mathrm{rad}}=|\boldsymbol{g}|\;c=u=\frac{I}{c}\,, \tag{60.5}$$

since $I=\langle|\boldsymbol{S}|\rangle=\langle u\rangle\,c$ and all quantities are here understood as time averages. A perfect reflector reverses the momentum instead of absorbing it, so the momentum transferred per unit time is doubled and so is the pressure. □

Phenomenon 60.5 (Angular momentum of circularly polarized light)**.** A circularly polarized beam carries angular momentum about its own direction of propagation, and delivers it to matter as a measurable mechanical torque. A birefringent half-wave plate suspended on a fine quartz fibre reverses the handedness of a beam passing through it, and is observed to experience a steady torque of the sense and magnitude that the transfer of angular momentum requires [767].

Derivation pending #17

Angular momentum of the electromagnetic field: derive the angular momentum density from the field momentum density, and show that for a circularly polarized beam of angular frequency ω the ratio of angular momentum to energy is $1/\omega$, so that reversing the handedness transfers twice that amount per unit energy.

60.5 The electromagnetic wave prediction

60.5.1 The wave equation and the speed c

[Reserved: in vacuum the system yields wave equations for $\boldsymbol{E}$ and $\boldsymbol{B}$ with speed $1/\sqrt{\mu_0\epsilon_0}$; Weber and Kohlrausch's measurement of the ratio of electrical units [146], Maxwell's identification of that ratio with the measured speed of light, and his conclusion that light is an electromagnetic disturbance [164]; the wave-equation machinery is that of Chapter 10.]

Phenomenon 60.6 (Light is an electromagnetic wave)**.** A speed can be extracted from measurements that involve no light at all. Comparing the charge on a Leyden jar, determined electrostatically from the force between charged bodies, with the same charge determined electrodynamically from the deflection it produces on discharge through a galvanometer, gives a ratio of units with the dimensions of a velocity — and that velocity came out equal, within the accuracy of the measurement, to the speed of light determined optically [146]. Electromagnetic disturbances were later generated directly, and found to propagate through air, to reflect, to refract in a prism of pitch, to be polarized by a grid of wires, and to travel at a speed consistent with the optical value [239]. Light is an electromagnetic wave [164], and in vacuum both fields obey

$$\nabla^2 \boldsymbol{E} = \frac{1}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2}\,, \qquad c = \frac{1}{\sqrt{\mu_0\epsilon_0}}\,. \tag{60.6}$$

Derivation. In a region free of charge and current take the curl of the Maxwell–Faraday equation and exchange the order of the space and time derivatives on the right:

$$\boldsymbol{\nabla}\times(\boldsymbol{\nabla}\times\boldsymbol{E}) = -\frac{\partial}{\partial t}(\boldsymbol{\nabla}\times\boldsymbol{B}) = -\mu_0\epsilon_0\frac{\partial^2 \boldsymbol{E}}{\partial t^2}\,, \tag{60.7}$$

the last step by the Ampère–Maxwell law with $\boldsymbol{J} = 0$. On the left use the identity $\boldsymbol{\nabla}\times(\boldsymbol{\nabla}\times\boldsymbol{E}) = \boldsymbol{\nabla}(\boldsymbol{\nabla}\cdot\boldsymbol{E}) - \nabla^2\boldsymbol{E}$, in which the first term vanishes because $\boldsymbol{\nabla}\cdot\boldsymbol{E} = 0$ where $\rho = 0$. What remains is Equation (60.6); the identical manipulation starting from the Ampère–Maxwell law gives the same equation for $\boldsymbol{B}$.

The propagation speed is therefore fixed by μ_0 and ϵ_0 alone — two constants measured with magnets, currents and charged spheres — and it is the coincidence of that number with the optical speed of light that identifies the two phenomena. Note that the displacement current is indispensable: delete $\mu_0\epsilon_0\,\partial\boldsymbol{E}/\partial t$ and the right-hand side of Equation (60.7) vanishes, leaving no wave. □

60.5.2 Hertz's confirmation

[Reserved: the generation, propagation, reflection and interference of electromagnetic waves in air by Hertz [239], closing the prediction; standing waves and the measured wave speed; full apparatus-level treatment in Chapter 63, and the developed optics of the waves themselves in Chapter 61.]

60.6 Structure of the theory

60.6.1 Relativity of the field decomposition

[Reserved: the split of the electromagnetic field into $\boldsymbol{E}$ and $\boldsymbol{B}$ depends on the observer; the asymmetry of explanation for induction (magnet moving versus circuit moving) that opens Einstein's 1905 paper [321]; forward references to Chapter 38 and Chapter 39, where the field strength is assembled into a single tensor.]

60.6.2 Duality and the absence of magnetic charge

[Reserved: the vacuum system is symmetric under the rotation of $(\boldsymbol{E}, c\boldsymbol{B})$ into one another; sources break the symmetry because no magnetic charge is observed—the empirical record is that of Chapter 59; what a monopole term would do to the equations [677].]

60.6.3 Limits and the domain of validity

[Reserved: the quasi-static limits recovering Chapter 58 and Chapter 59; circuit theory as a limit; linearity and superposition, exact classically and modified only at the quantum level (photon–photon scattering, treated with QED in Chapter 100); classical electrodynamics as the low-photon-number, high-occupancy limit examined in Chapter 122.]

Chapter 61

Electromagnetic Waves and Optics

This chapter develops the wave solutions of the Maxwell system of Chapter 60: plane waves, polarization, energy transport, and the two great limits of the theory—physical optics, where interference and diffraction rule, and geometrical optics, the short-wavelength limit whose mechanics-side twin was met in Chapter 23. Optics is far older than electrodynamics, so the chapter also runs backwards through history: two centuries of measured optical phenomena—refraction, polarization, interference, diffraction, dispersion, and the speed of light itself—were already quantitative science before Maxwell explained what was waving. Each phenomenon is stated with its founding measurement; the wave-optics experiments are treated in full apparatus detail in Chapter 67, and the failure of the aether reading of these waves in Chapter 37.

Derivation pending #18

Electromagnetic Waves and Optics: all derivations of this chapter are pending.

61.1 Plane electromagnetic waves

61.1.1 Monochromatic plane waves

[Reserved: transversality, the mutual orthogonality of $\boldsymbol{E}$, $\boldsymbol{B}$ and the wavevector, the ratio $E/B = c$, and the dispersion relation $\omega = c\,|\boldsymbol{k}|$ in vacuum [164, 1976]; the electromagnetic spectrum from radio to gamma, with Hertz's waves (Chapter 60) as its first artificial band; superposition and wave packets, with the Fourier machinery of Chapter 17.]

61.1.2 Energy and momentum transport

[Reserved: time-averaged Poynting flux, intensity, and radiation pressure for plane waves, specialising the conservation laws of Chapter 60 [229]; irradiance in SI units and the link to photometric practice.]

61.2 The speed of light

61.2.1 Astronomical determinations

[Reserved: Rømer's inference of a finite speed from the eclipse timings of Io [12], and Bradley's stellar aberration, which gave the first terrestrial-independent ratio of c to the orbital speed of the Earth [19]; aberration reappears as a relativity test in Chapter 37.]

Phenomenon 61.1 (Light propagates at a finite speed)**.** The eclipses of Jupiter's innermost satellite do not recur at strictly equal intervals as observed from the Earth. They fall

progressively late through the part of the year in which the Earth is receding from Jupiter, and progressively early through the part in which it is approaching, and the discrepancy accumulated across half a year amounts to many minutes — far more than any irregularity of the satellite's orbit could produce, and correlated with the Earth's position rather than with Jupiter's [12]. Independently, the apparent position of every star describes a small annual ellipse whose angular size is the same for all stars regardless of their distance [19], which a parallax cannot be. Light therefore takes time to travel, and the second observation fixes the ratio of the Earth's orbital speed to the speed of light.

Derivation. Let the satellite emerge from its planet's shadow at strictly periodic instants t_k, separated by the true orbital period T, and let $d(t)$ be the distance from the event to the observer. The emergence is *seen* at $t_k + d(t_k)/c$, so the observed interval between successive emergences is

$$T_{\text{obs}} = T + \frac{d(t_{k+1}) - d(t_k)}{c}\,, \tag{61.1}$$

which exceeds T while the observer recedes and falls short of it while the observer approaches. Summing Equation (61.1) over all the eclipses of one recession, the intermediate distances cancel in pairs and the total accumulated lag is

$$\Delta t_{\text{total}} = \frac{\Delta d}{c}\,, \tag{61.2}$$

Δd being the total increase in the Earth–Jupiter distance, which is close to the diameter of the Earth's orbit because Jupiter moves slowly by comparison. A finite accumulated lag therefore means a finite c, and Equation (61.2) determines it from two measurable lengths and one measurable time. An infinite speed predicts strictly equal intervals, which is what is refuted.

Aberration is the same finiteness read as an angle: a telescope carried transversely at speed v must be tilted forward by $\tan\theta = v/c$ for the light entering the objective to reach the eyepiece, so the apparent displacement is common to all stars and annual in period — and it measures v/c, not c alone. □

61.2.2 Terrestrial measurements

[Reserved: Fizeau's toothed-wheel measurement over the Suresnes–Montmartre baseline [125]; Foucault's rotating mirror, which both measured c in air and showed light travels slower *in water, deciding against the corpuscular theory [128], and his 1862 absolute determination [158]; Michelson's 1879 Annapolis measurement [215] and his Mount Wilson–San Antonio triangulation [584].]*

Phenomenon 61.2 (Light travels more slowly in a denser medium)**.** Light travels more slowly in water than in air. The rotating-mirror method makes the comparison directly, sending the two beams over equal paths and reading the difference as a displacement of the returned image, and the speed in water is lower by very nearly the factor n by which water refracts [128]. The measurement is decisive rather than merely quantitative: the wave account requires the speed to *fall* in the more refracting medium, and the emission account requires it to rise.

Derivation. In a transparent non-magnetic medium the macroscopic Maxwell equations have the same form as in vacuum with ϵ_0 replaced by $\epsilon = \epsilon_r\epsilon_0$ (Chapter 62), so the wave equation derived in Chapter 60 carries a propagation speed

$$v = \frac{1}{\sqrt{\mu_0\epsilon}} = \frac{c}{\sqrt{\epsilon_r}} = \frac{c}{n}\,, \qquad n := \sqrt{\epsilon_r} \geq 1\,. \tag{61.3}$$

That the same n is the refractive index of Snell's law follows from Phenomenon 61.3: matching the wavefronts across the interface gives $\sin\theta_1/\sin\theta_2 = v_1/v_2$, so a medium in which the ray bends towards the normal is one in which the wave is slower.

The emission theory reverses the conclusion from the same data. There the ray bends because the interface pulls the corpuscle normally, leaving the tangential velocity component unchanged; then $v_1 \sin\theta_1 = v_2 \sin\theta_2$, so $v_2/v_1 = \sin\theta_1/\sin\theta_2 = n > 1$ and light must go *faster* in water. The two predictions differ by the factor $n^2 \approx 1.8$ for water and are not reconcilable; the measurement gives the wave value. □

61.2.3 From measured constant to defined constant

[Reserved: the laser frequency-times-wavelength determination of Evenson and collaborators [1470], the 1983 fixing of c at exactly 299 792 458 m/s*, and the consequent redefinition of the metre [2333]; what it means, in the framework of Chapter 2, for a constant to become a definition.]*

61.3 Reflection and refraction

61.3.1 Snell's law and Fermat's principle

[Reserved: the sine law of refraction, found by Snel around 1621 and first printed in Descartes' Dioptrique *[3]; Fermat's derivation of the same law from least time, in the 1662 letters to Cureau de la Chambre [260]; Huygens' wavefront construction [15]; total internal reflection and the evanescent wave [1967].]*

Phenomenon 61.3 (The sine law of refraction)**.** A ray crossing the plane boundary between two transparent media is bent, and the ratio of the sines of the angles of incidence and refraction, both measured from the normal, is the same for every angle of incidence and depends only on the pair of media [3]:

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \,. \tag{61.4}$$

The constancy of the ratio is the content of the observation — the angles themselves are not proportional, and the older tables that assumed they were fail at large incidence.

Derivation. Fermat's principle: of all paths from a point A in medium 1 to a point B in medium 2, light takes the one of stationary transit time [260]. Place the interface along the plane $y = 0$, let $A = (0, a)$ and $B = (d, -b)$ with $a, b > 0$, and let the path cross at $(x, 0)$. The optical time is

$$t(x) = \frac{n_1}{c}\sqrt{x^2 + a^2} + \frac{n_2}{c}\sqrt{(d-x)^2 + b^2}\,, \tag{61.5}$$

using $v_i = c/n_i$ from Equation (61.3). Setting $\mathrm{d}t/\mathrm{d}x = 0$,

$$\frac{n_1 x}{\sqrt{x^2 + a^2}} = \frac{n_2 (d-x)}{\sqrt{(d-x)^2 + b^2}}\,, \tag{61.6}$$

and the two quotients are precisely $\sin\theta_1$ and $\sin\theta_2$, the angles being measured from the normal y-axis. This is Equation (61.4). The second derivative of Equation (61.5) is positive, so the stationary point is a minimum, and it is unique. Huygens' construction gives the same law geometrically, by requiring the wavefronts on the two sides to keep step along the interface [15], and this is the version that identifies n with c/v rather than leaving it an empirical constant of the pair of media. □

61.3.2 The Fresnel equations

[Reserved: amplitude reflection and transmission coefficients for the two polarizations, derived by Fresnel from his transverse-wave theory in the memoir read in 1823 [90]; Brewster's angle of complete polarization by reflection, established empirically by Brewster [58]; phase shifts on reflection and their interferometric consequences; the electromagnetic rederivation from the boundary conditions of Chapter 60 [1976].]

Phenomenon 61.4 (Complete polarization at the Brewster angle)**.** For every transparent dielectric there is one angle of incidence, and one only, at which the reflected light is completely linearly polarized, its electric vector lying in the surface. The tangent of that angle is the refractive index of the material [58]:

$$\tan\theta_B = n\,. \tag{61.7}$$

Equivalently, at θ_B the reflected and refracted rays are at right angles, as follows at once from Equation (61.4). The reflectance for light polarized in the plane of incidence falls smoothly to exactly zero there and rises again beyond it, so the vanishing is a genuine zero and not a minimum.

Derivation pending #19

Brewster's angle: derive the Fresnel amplitude coefficients for the two polarizations from the interface conditions on the tangential fields, and show that the coefficient for light polarized in the plane of incidence has a simple zero exactly where the reflected and refracted directions are perpendicular, which by the sine law is at the angle whose tangent is the refractive index.

61.4 Polarization

61.4.1 Discovery and phenomenology

[Reserved: double refraction of Iceland spar, reported by Bartholin [9] and given a wave construction by Huygens [15]; Malus's discovery of polarization by reflection and his cosine-squared intensity law [54]; Brewster's law relating the polarizing angle to the refractive index [58].]

Phenomenon 61.5 (Malus's law)**.** Light that has been reflected from glass at a suitable angle, or transmitted through a crystal of Iceland spar, acquires a property that depends on the orientation of the beam about its own axis: passed through a second such device, it is transmitted in full at one orientation, extinguished at the orientation at right angles to it, and in between the transmitted intensity follows

$$I(\theta) = I_0\cos^2\theta \tag{61.8}$$

with θ the angle between the two devices [54]. Ordinary light shows no such dependence, which is why the property had to be discovered rather than assumed.

Derivation. Take the beam leaving the first polarizer to be linearly polarized with electric field amplitude $\boldsymbol{E}_0 = E_0\hat{\boldsymbol{e}}_1$. An ideal analyser transmits the component of the field along its own axis $\hat{\boldsymbol{e}}_2$ and rejects the orthogonal component, so the transmitted amplitude is

$$E = \boldsymbol{E}_0\cdot\hat{\boldsymbol{e}}_2 = E_0\cos\theta\,, \tag{61.9}$$

θ being the angle between the two axes. Intensity is proportional to the time-averaged square of the field — it is $\epsilon_0 c E^2/2$ for a plane wave in vacuum, by Chapter 60 — so squaring Equation (61.9) gives Equation (61.8). The whole content of the derivation is that the observable is the square of a *projected vector*: that is why the law is $\cos^2\theta$ rather than $|\cos\theta|$, and it is the first quantitative evidence that the optical disturbance is a directed quantity transverse to the ray. □

61.4.2 Mathematical description

[Reserved: linear, circular and elliptical polarization of a transverse plane wave; the Stokes parameters and the description of partially polarized light [139]; Jones vectors for fully polarized beams [1967]; the measurement of the angular momentum carried by circularly polarized light [767].]

61.4.3 Birefringence and wave plates

[Reserved: ordinary and extraordinary rays, the index ellipsoid, quarter- and half-wave plates, and polarimetry [1967]; induced birefringence is deferred to the electro- and magneto-optics of Chapter 62.]

61.5 Interference

61.5.1 Young's double slit

[Reserved: Young's demonstration that light added to light can give darkness, and his measurement of wavelengths from fringe spacings [49]—the decisive evidence for the wave theory; the sinusoidal two-source pattern and its visibility; apparatus detail in Chapter 67, and the single-quantum version of the experiment in Chapter 71.]

Phenomenon 61.6 (Two-beam interference)**.** Light from a single small source, divided into two beams by a pair of narrow apertures a distance d apart and allowed to fall on a screen at distance $D \gg d$, produces not two patches of light but a set of equally spaced bright and dark bands. Blocking either aperture destroys the bands and leaves a smooth illumination, so the dark bands are places where light added to light gives darkness. The band spacing is

$$\Delta y = \frac{\lambda D}{d}\,, \tag{61.10}$$

proportional to D and inversely proportional to d, and this is what first made the wavelength of light a measured quantity [49].

Derivation. Let the two apertures lie at $\pm d/2$ on a line perpendicular to the axis, and let y measure position on the screen from the axis. The path lengths from the two apertures to the point y differ, for $d \ll D$ and $|y| \ll D$, by

$$\delta = \sqrt{D^2 + \left(y + \tfrac{d}{2}\right)^2} - \sqrt{D^2 + \left(y - \tfrac{d}{2}\right)^2} \simeq \frac{y d}{D}\,, \tag{61.11}$$

by expanding each root to first order in $(y \pm d/2)^2/D^2$. Superposing two disturbances of equal amplitude and of the same frequency, whose phases differ by $2\pi\delta/\lambda$, gives an intensity

$$I(y) = 4I_1 \cos^2\!\left(\frac{\pi\delta}{\lambda}\right) = 4I_1 \cos^2\!\left(\frac{\pi d\, y}{\lambda D}\right)\,, \tag{61.12}$$

because the amplitudes, not the intensities, are what add. This is maximal where δ is an integer multiple of λ and zero where it is a half-odd multiple, so consecutive maxima are

separated by $\Delta y = \lambda D/d$, which is Equation (61.10). Blocking one aperture removes the interference term and leaves the constant I_1, as observed; and Equation (61.10) inverted, $\lambda = d\,\Delta y/D$, is the measurement, since d, Δy and D are all lengths that can be read off with a scale. □

61.5.2 Thin films and interferometers

[Reserved: thin-film and wedge interference, Newton's rings (described in the Opticks *[18]); division of amplitude and the Michelson interferometer, built for the aether-drift measurement [236] and treated as a null relativity test in Chapter 37; multiple-beam interference and the Fabry–Pérot étalon [1967].]*

61.5.3 Coherence

[Reserved: temporal and spatial coherence as the condition for visible fringes; the van Cittert–Zernike theorem relating source size to transverse coherence [736, 826]; Michelson's stellar interferometer and the measured diameter of Betelgeuse [479]; quantum coherence of light is taken up in Chapter 122.]

61.6 Diffraction

61.6.1 Fresnel diffraction and the Arago spot

[Reserved: Fresnel's prize memoir on diffraction, combining Huygens' secondary wavelets with interference [78]; Poisson's reductio—a bright spot at the centre of a circular shadow—observed by Arago and reported with the memoir [78], converting the objection into a confirmation; Fresnel zones and the zone plate.]

Phenomenon 61.7 (The bright spot in the centre of a shadow)**.** A small opaque disc of smooth circular edge, illuminated by a point source, casts a shadow with a bright point at its exact centre; for an ideal disc the intensity there equals the intensity that would be found with the disc removed. The straight edge and the disc are also surrounded by systems of fringes whose positions can be measured on a micrometer and compared, one by one, with the values computed from the diffraction integral [78]. Neither the bright centre nor the fringe positions has any account in a theory of rays.

Derivation pending #20

The axial bright point: derive it from the Huygens–Fresnel superposition of secondary wavelets over the plane of the obstacle, showing that every point of the disc's rim is equidistant from the axial field point, so that the wavelets from the rim arrive exactly in phase whatever the radius of the disc, and evaluate the resulting on-axis amplitude for an ideal circular obstacle.

61.6.2 Fraunhofer diffraction and gratings

[Reserved: far-field diffraction as the Fourier transform of the aperture, with the machinery of Chapter 17; Fraunhofer's diffraction gratings and his wavelength standards [69]; the single slit, the circular aperture, and the Rayleigh resolution criterion [209].]

61.6.3 Kirchhoff's scalar theory

[Reserved: the scalar diffraction integral derived from the wave equation with Kirchhoff's boundary values [224], its internal inconsistency and the Rayleigh–Sommerfeld repair [1967]; the validity conditions under which the earlier Fresnel and Fraunhofer treatments emerge as limits.]

61.7 Geometrical optics

61.7.1 The eikonal limit

[Reserved: the short-wavelength expansion of the wave equation, the eikonal equation $(\nabla \mathcal{S})^2 = n^2$*, and the ray equation, named after Bruns's* Das Eikonal *[263]; Hamilton's characteristic-function optics [84] and its mechanical twin, already developed in Chapter 23; where the limit fails—edges and caustics [1967].]*

61.7.2 Images and instruments

[Reserved: mirrors, thin lenses and the paraxial imaging equations; the telescope and microscope as diffraction-limited instruments, tying the resolution limit of Section 61.6.2 to practice [1967]; aberrations named and classified.]

61.8 Dispersion

61.8.1 The prism and the solar spectrum

[Reserved: Newton's experimentum crucis separating white light into unequally refrangible rays [10] and its systematic account in the Opticks *[18]; Fraunhofer's dark lines in the solar spectrum and his measurement of their wavelengths [60], the founding data of the spectroscopy taken up in Chapter 70.]*

Phenomenon 61.8 (Dispersion and the fixed lines of the solar spectrum)**.** A prism spreads white light into a band of colours in an invariable order, and a colour once separated is not decomposed further by a second prism, nor changed by transmission through matter: the refractive index is a function of the colour, and each colour is a simple constituent of the light rather than a modification produced by the glass [10, 18]. Examined at sufficient resolution, the spectrum of the Sun is crossed by a great number of fixed dark lines, always in the same places, whose refractive positions can be measured far more precisely than any colour can be named — which is what turns dispersion from a qualitative effect into an instrument [60].

Derivation pending #21

Dispersion: derive the frequency dependence of the refractive index from the response of bound charges to the field of the wave, obtaining normal dispersion away from resonance and anomalous dispersion with absorption near it, and recover the empirical Sellmeier form as its low-loss limit. The model belongs to the treatment of electrodynamics in matter, and the discreteness of the solar lines themselves is not classical at all and awaits the atomic chapters.

61.8.2 The rainbow

[Reserved: Descartes' ray-tracing of the primary and secondary bows [3]; Newton's account of their colours [18]; supernumerary bows as an interference effect and Airy's caustic integral [103]—the rainbow as the first quantitative test case where ray optics fails and wave optics is required.]

61.8.3 Phase velocity, group velocity, and media

[Reserved: normal and anomalous dispersion; the Sellmeier relation [180]; Rayleigh's distinction of group from phase velocity [197]; light in moving media—Fresnel's partial-drag coefficient [61] and Fizeau's moving-water interferometry confirming it [133], reread relativistically in Chapter 37; the microscopic theory of dispersion belongs to Chapter 62.]

Chapter 62

Electrodynamics in Matter

Electrodynamics in matter is the macroscopic Maxwell theory: the polarization and magnetization fields, the auxiliary fields $\boldsymbol{D}$ and $\boldsymbol{H}$, the response functions that close the system, and dispersion—the frequency dependence of the response, constrained by causality alone through the Kramers–Kronig relations. The chapter gathers what Chapter 58 and Chapter 59 deferred: how the vacuum equations of Chapter 60, exact at the microscopic level, become equations for smoothed fields with matter-dependent sources, and what measured phenomena—conduction, dielectric response, dia-, para- and ferromagnetism, plasma transparency, the skin effect—the response functions encode. The microscopic explanations are quantum and are deferred to the condensed-matter part; here each phenomenon is stated with its founding measurement and its classical model, and the models' honest failures are marked.

Derivation pending #22

Electrodynamics in Matter: all derivations of this chapter are pending.

62.1 From microscopic to macroscopic fields

62.1.1 Bound charges and the polarization field

[Reserved: spatial averaging of the microscopic equations, following the electron-theory programme of Lorentz [356]; the polarization $\boldsymbol{P}$ as dipole-moment density, bound charge $-\boldsymbol{\nabla}\cdot\boldsymbol{P}$ and surface charge $\boldsymbol{P}\cdot\hat{\boldsymbol{n}}$; the displacement field $\boldsymbol{D}=\epsilon_0\boldsymbol{E}+\boldsymbol{P}$ of Maxwell's Treatise *[185].]*

62.1.2 Bound currents and the magnetization field

[Reserved: the magnetization $\boldsymbol{M}$, bound currents $\boldsymbol{\nabla}\times\boldsymbol{M}$ and $\partial\boldsymbol{P}/\partial t$, and the field $\boldsymbol{H}=\boldsymbol{B}/\mu_0-\boldsymbol{M}$ [185]; the macroscopic Maxwell system in matter and what in it is definition versus physics [1976].]

62.1.3 Constitutive relations and boundary conditions

[Reserved: linear isotropic media, $\boldsymbol{D}=\epsilon\boldsymbol{E}$ and $\boldsymbol{B}=\mu\boldsymbol{H}$; permittivity, permeability, susceptibilities and their SI units; interface conditions for $\boldsymbol{D}$ and $\boldsymbol{H}$, extending Chapter 58 and Chapter 59; energy in linear media [1976].]

62.2 Dielectrics

62.2.1 Polarizability and local fields

[Reserved: molecular polarizability, the Lorentz local-field correction [356], and the Clausius–Mossotti relation connecting polarizability to permittivity [131, 206]; its optical form, the Lorentz–Lorenz equation, derived independently by H. A. Lorentz [213] and L. Lorenz [214]—two different men, the same near-collision of names as the gauge condition of Chapter 60.]

62.2.2 Polar molecules and relaxation

[Reserved: orientation polarization of permanent molecular dipoles and its temperature dependence, after Debye [383]; Debye relaxation and the frequency dependence of the dielectric constant of polar liquids; dielectric loss.]

62.2.3 Piezo- and ferroelectricity

[Reserved: piezoelectricity, discovered in quartz by the Curie brothers [212]; ferroelectricity, discovered in Rochelle salt by Valasek [483], with hysteresis of $\boldsymbol{P}$ mirroring the magnetic case of Section 62.4.1; the microscopic theory is deferred to the condensed-matter part (Chapter 125).]

62.3 Conduction

62.3.1 Ohm's law

[Reserved: Ohm's empirical law of the galvanic circuit [81], its local form $\boldsymbol{J} = \sigma \boldsymbol{E}$, conductivity and resistivity in SI units; the Wiedemann–Franz proportionality of thermal and electrical conductivity of metals [140]; Joule heating and its place in the energy balance of Chapter 60.]

Phenomenon 62.1 (Ohm's law)**.** In a metallic conductor held at constant temperature the current is strictly proportional to the electromotive force driving it, over a range of many decades, with a coefficient that depends on the material and its temperature and on nothing else — not on the magnitude of the current, not on how long it has been flowing, not on its history [81]. Locally,

$$\boldsymbol{J} = \sigma \boldsymbol{E}\,, \tag{62.1}$$

with σ the conductivity, measured in $\mathrm{A/(V\,m)}$. The proportionality is a property of a class of materials and not a law of the field, which is why it may be — and in semiconductors, gas discharges and superconductors is — violated without anything in Chapter 60 failing.

Derivation. Model the conductor as containing n free carriers per unit volume, of charge q and mass m, which are accelerated by the field and lose all memory of their drift in collisions occurring at a mean interval τ [289]. Between collisions the equation of motion is $m\,\mathrm{d}\boldsymbol{v}/\mathrm{d}t = q\boldsymbol{E}$, so a carrier emerging from a collision with a randomly directed velocity has, after a time t, an extra velocity $q\boldsymbol{E}t/m$ along the field. Averaging over the collision statistics, the mean extra velocity — the drift velocity — is

$$\langle \boldsymbol{v} \rangle = \frac{q\tau}{m} \boldsymbol{E}\,, \tag{62.2}$$

which is constant in time: the field accelerates, the collisions brake, and the steady state is a terminal drift rather than a runaway. The current density is the charge carried across unit area per unit time, $\boldsymbol{J} = nq\,\langle \boldsymbol{v} \rangle$, so

$$\boldsymbol{J} = \frac{nq^2\tau}{m} \boldsymbol{E}\,, \qquad \sigma = \frac{nq^2\tau}{m}\,, \tag{62.3}$$

which is Equation (62.1), with the linearity traced to the single assumption that τ does not depend on $\boldsymbol{E}$.

That assumption is also the honest limit of the derivation. It holds when the drift velocity is small compared with the mean thermal speed, which in a metal at ordinary current densities it overwhelmingly is; it fails in a gas discharge, where the field sets the collision rate. Nothing here explains what fixes τ, and the classical estimate of its magnitude — and with it Drude's account of the electronic heat capacity — is wrong, for reasons that are quantum (Chapter 126). □

62.3.2 The Drude model and the Hall effect

[Reserved: Drude's kinetic model of metallic conduction [289]: DC and AC conductivity, the relaxation time, and its account of Wiedemann–Franz; the Hall effect [208] as the classical probe of carrier sign and density, and the model's honest failures (heat capacity, sign of some Hall coefficients), resolved only by the quantum theory of Chapter 126; the quantized Hall effect is treated in Chapter 128.]

Phenomenon 62.2 (The Hall effect)**.** A flat conducting strip carrying a steady current, placed in a magnetic field perpendicular to its face, develops a steady potential difference *across* the strip, perpendicular both to the current and to the field [208]. The transverse field is proportional to the product of the current density and the magnetic field,

$$E_y = R_H J_x B_z\,, \qquad R_H = \frac{1}{nq}\,, \tag{62.4}$$

so the measurement returns both the density and the *sign* of the charge carriers. That sign is negative in most metals, as the electron requires — but it is positive in others, beryllium and zinc among them, and no classical model of conduction accounts for a positive carrier in a metal.

Derivation. Let the current run along x with drift velocity v_x, and let $\boldsymbol{B} = B_z\hat{\boldsymbol{z}}$. Each carrier feels the Lorentz force $q(\boldsymbol{E} + \boldsymbol{v}\times\boldsymbol{B})$, whose magnetic part qv_xB_z pushes it along $-y$ or $+y$ according to the sign of qv_x. Charge therefore accumulates on one edge of the strip until the transverse electric field it creates cancels the magnetic push, after which the current runs straight again. That steady state is the observation, and it is defined by the vanishing of the transverse force:

$$qE_y - qv_xB_z = 0 \quad\Longrightarrow\quad E_y = v_xB_z\,. \tag{62.5}$$

Eliminating the drift velocity with $J_x = nqv_x$ from Equation (62.3) gives $E_y = J_xB_z/nq$, which is Equation (62.4). The sign of R_H is the sign of q, because the drift velocity reverses with the carrier sign while the current does not, so the two reversals compound rather than cancel — which is why the experiment is a measurement of the carrier sign and why the metals that return the wrong one remained a genuine anomaly for decades. □

62.3.3 The skin effect

[Reserved: field penetration into a good conductor, the skin depth $\delta = \sqrt{2/(\mu\sigma\omega)}$, and high-frequency resistance, analysed by Rayleigh [233] and Heaviside [252]; consequences for shielding, waveguides and cables.]

62.4 Magnetic materials

62.4.1 Dia-, para- and ferromagnetism

[Reserved: Faraday's discovery that all matter is magnetic— diamagnetic bismuth repelled, paramagnets attracted [119]; Curie's systematic measurements: temperature independence of

diamagnetism, the $1/T$ law of paramagnetism, and the disappearance of ferromagnetism at a critical temperature [264]; ferromagnetic hysteresis, named and mapped by Ewing [231].]

Phenomenon 62.3 (All matter is magnetic)**.** No substance is indifferent to a magnetic field. Suspended in a field strong enough and inhomogeneous enough to make the force visible, every material tested is either drawn towards the region of stronger field or pushed towards the region of weaker field; the second class, of which bismuth is the type case, had not been suspected before it was looked for, and it includes water, glass and flesh [119]. The division is sharp: the repelled substances are repelled whatever the direction of the field, and their response is very nearly independent of temperature, while the attracted ones weaken as the temperature rises [264].

Derivation pending #23

The magnetic response of matter: derive the Bohr–van Leeuwen theorem, that a classical system of charges in thermal equilibrium has identically zero magnetization because the magnetic field enters the classical Hamiltonian only through a shift of the canonical momenta, which is absorbed by a translation of the integration variables in the partition function. The theorem states that the phenomenon above has no classical explanation at all, so every classical model in this section is a parametrization and not a derivation, and the real account is the quantum one of the magnetism chapter.

Phenomenon 62.4 (Ferromagnetic hysteresis)**.** In iron, nickel, cobalt and their alloys the magnetization is not a function of the applied field. Carrying the field around a closed cycle carries the magnetization around a closed curve of nonzero area: the material retains a magnetization when the field is removed (remanence), requires a reversed field of definite strength to bring that magnetization to zero (coercivity), and approaches a saturation beyond which further field produces almost nothing [231]. The state therefore depends on the history, the cycle dissipates energy, and no number deserves the name of "the" permeability of the material.

Derivation pending #24

Ferromagnetic hysteresis: derive the energy dissipated per unit volume per cycle as the area enclosed by the loop traced in the plane of applied field against magnetization, and identify precisely which hypothesis behind a linear constitutive relation the loop violates. The microscopic origin — domains, exchange coupling and magnetocrystalline anisotropy — is quantum and belongs to the magnetism chapter.

62.4.2 Langevin theory and the Curie–Weiss law

[Reserved: Langevin's statistical theory of dia- and paramagnetism [323], the Langevin function and the Curie law; Weiss's molecular field, the Curie–Weiss law and spontaneous magnetization [339]; what the molecular field really is (exchange) awaits Chapter 129.]

Phenomenon 62.5 (The Curie law and the Curie temperature)**.** Measurements of magnetic susceptibility carried across a wide range of temperature separate three behaviours [264]. Diamagnetic susceptibility is negative and nearly independent of temperature. Paramagnetic susceptibility is positive and falls as the reciprocal of the absolute temperature,

$$\chi = \frac{C}{T}\,, \tag{62.6}$$

with C a constant of the substance. And a ferromagnet loses its ferromagnetism entirely above a temperature characteristic of the material, above which it behaves as an ordinary paramagnet. The transition is sharp, and the temperature at which it happens is a reproducible property of the substance.

Derivation. Suppose the substance to contain n permanent magnetic dipoles per unit volume, each of fixed magnitude μ and free to take any orientation [323]. A dipole at angle θ to the applied field has energy $-\mu B\cos\theta$, so in thermal equilibrium at temperature T the orientations are distributed as $\mathrm{e}^{\mu B\cos\theta/k_BT}$ and the mean component along the field is

$$\langle \mu\cos\theta\rangle = \mu\left(\coth x - \frac{1}{x}\right) =: \mu L(x)\,, \qquad x := \frac{\mu B}{k_BT}\,, \tag{62.7}$$

the angular integrals being elementary in the variable $\cos\theta$. The magnetization is $M = n\mu L(x)$, which saturates at $n\mu$ for $x \gg 1$ — all dipoles aligned — and for $x \ll 1$ has the expansion $L(x) = x/3 + O(x^3)$. Ordinary laboratory conditions are deep in the second regime, so

$$M = \frac{n\mu^2 B}{3k_BT}\,, \qquad \chi = \frac{\mu_0 M}{B} = \frac{\mu_0 n\mu^2}{3k_BT}\,, \tag{62.8}$$

which is Equation (62.6) with $C = \mu_0 n\mu^2/3k_B$. The $1/T$ is the competition of two energies and nothing else: alignment is worth μB and disorder is worth k_BT.

The derivation is not, however, a classical one, and saying so is the point of Phenomenon 62.3. It *postulates* dipoles of fixed magnitude that cannot be destroyed by the field or by the thermal motion, and classical mechanics supplies no such object; without that postulate the equilibrium magnetization is exactly zero. The Curie temperature is outside the model altogether — independent dipoles have no cooperative transition — and requires the molecular field of Section 62.4.2, whose own origin is quantum (Chapter 129). □

62.4.3 The Bohr–van Leeuwen theorem

[Reserved: classical statistical mechanics yields exactly zero equilibrium magnetization [484]—the theorem that makes every classical model of this section provisional and magnetism intrinsically quantum; statement, scope, and its role as a signpost to Chapter 129.]

62.4.4 Superconductors: deferred

[Reserved: perfect conductivity and the Meissner–Ochsenfeld expulsion of magnetic flux [724] are named here only as the extreme magnetic response of matter; the London phenomenology, the microscopic theory and the experimental record are treated in Chapter 130 and Chapter 131.]

62.5 Dispersion and causality

62.5.1 The Lorentz oscillator model

[Reserved: bound electrons as damped driven oscillators [356]; normal and anomalous dispersion, absorption lines, and the empirical Sellmeier form recovered ([180], cf. Chapter 61); oscillator strengths and the f-sum rule; the quantum reinterpretation is noted and deferred to Part IX.]

62.5.2 The Kramers–Kronig relations

[Reserved: causality of the response function alone implies dispersion relations connecting the real and imaginary parts of $\epsilon(\omega)$, derived by Kronig [550] and Kramers [581]; sum rules; their derivation uses the complex analysis of Chapter 8, and their reach extends far beyond optics (scattering amplitudes, Chapter 86).]

Phenomenon 62.6 (Absorption and dispersion occur together)**.** In a spectral region where a substance is transparent, its refractive index rises with frequency, smoothly and monotonically, and the measured curve is reproduced across the whole visible range by an empirical formula with one term for each absorption band lying outside it [180]. Wherever the substance *does* absorb, that behaviour reverses: within the absorption band the index falls with increasing frequency. Anomalous dispersion is found where and only where there is absorption, never elsewhere, and the strength of the one tracks the strength of the other. The refractive index and the absorption coefficient are therefore not independent properties of a material, and measuring either over all frequencies determines the other.

Derivation pending #25

Absorption and dispersion: derive the Kramers–Kronig relations, in which the real and imaginary parts of the permittivity are each the Hilbert transform of the other. The only physical input is causality — no response before the stimulus — which makes the response function analytic in the upper half of the complex frequency plane, whence a contour integral gives the pair of dispersion relations and the sum rules that follow from the high-frequency limit. The argument needs the complex analysis of the corresponding methods chapter, and it is worth noting that it uses no model of the medium at all.

62.5.3 Signal velocity and the front

[Reserved: anomalous dispersion permits phase and group velocities exceeding c; Sommerfeld and Brillouin's resolution—the signal front never travels faster than c, with forerunner precursors [412, 421]; consistency with the causal structure of Chapter 38.]

62.6 Free-carrier response and plasmas

62.6.1 Plasma frequency and transparency

[Reserved: the free-electron permittivity $\epsilon(\omega) = \epsilon_0(1 - \omega_p^2/\omega^2)$ from the Drude model [289]; plasma oscillations identified by Tonks and Langmuir [639]; reflection below and transparency above ω_p—the ultraviolet transparency of metals and the ionospheric reflection of radio; the full dynamics of plasmas belongs to Chapter 66.]

Phenomenon 62.7 (A gas of free carriers reflects below a critical frequency and transmits above it)**.** Two observations, made in different sciences, are the same phenomenon. A metal reflects visible light almost completely and is opaque to it, yet the alkali metals become transparent in the ultraviolet, each above a threshold frequency of its own. And radio waves directed upwards are returned from the upper atmosphere below a critical frequency, while above it they are lost into space — a reflection whose height was measured directly by timing the returned pulse and by interference between the direct and reflected rays [517]. In both cases the medium contains free charges of number density n, and the dividing frequency is

$$\omega_p = \sqrt{\frac{nq_e^2}{\epsilon_0 m_e}}\,. \tag{62.9}$$

Below ω_p the medium reflects; above it, it transmits [289, 639].

Derivation. Take carriers that are free — no restoring force — and, for the moment, collisionless, so that $m_e\,\mathrm{d}\boldsymbol{v}/\mathrm{d}t = q_e\boldsymbol{E}$. For a field oscillating as $\mathrm{e}^{-\mathrm{i}\omega t}$ this gives $\boldsymbol{v} = \mathrm{i}q_e\boldsymbol{E}/m_e\omega$ and a current density $\boldsymbol{J} = nq_e\boldsymbol{v} = \mathrm{i}nq_e^2\boldsymbol{E}/m_e\omega$. The current that drives the magnetic field in the Ampère–Maxwell law is the sum of this and the vacuum displacement current, and the sum is

$$\boldsymbol{J} + \epsilon_0\frac{\partial \boldsymbol{E}}{\partial t} = -\mathrm{i}\omega\epsilon_0\left(1 - \frac{\omega_p^2}{\omega^2}\right)\boldsymbol{E} =: -\mathrm{i}\omega\,\epsilon(\omega)\boldsymbol{E}\,, \tag{62.10}$$

with ω_p as in Equation (62.9): the free carriers act as a medium of permittivity $\epsilon(\omega) = \epsilon_0(1 - \omega_p^2/\omega^2)$. Repeating the wave-equation derivation of Chapter 60 with $\epsilon_0 \to \epsilon(\omega)$ gives the dispersion relation

$$\omega^2 = \omega_p^2 + c^2k^2\,. \tag{62.11}$$

For $\omega > \omega_p$ the wavenumber k is real and the wave propagates, with a phase velocity above c and a group velocity below it. For $\omega < \omega_p$, k is imaginary: the field falls off exponentially into the medium instead of propagating. Since $\epsilon(\omega)$ is real in this model, nothing is absorbed, and an incident wave that cannot propagate and cannot be absorbed must be returned — total reflection. The dividing frequency is a measurement of n through Equation (62.9), which is what makes ionospheric sounding a density diagnostic. □

62.7 Magneto- and electro-optics

[Reserved: field-induced anisotropy of media. The Faraday effect—rotation of the plane of polarization by a magnetic field along the ray, the first observed link between light and electromagnetism [118]; the quadratic electro-optic (Kerr) effect [189]; Verdet constants and applications (optical isolators, polarimetry); connection to the birefringence machinery of Chapter 61.]

Phenomenon 62.8 (The Faraday effect)**.** A block of heavy glass placed in a strong magnetic field rotates the plane of polarization of linearly polarized light sent along the field direction. The rotation is proportional to the field strength and to the path length,

$$\theta = V\,B\,d\,, \tag{62.12}$$

with V a constant of the material, and its sense is fixed by the field alone: sending the beam back through the same block *doubles* the rotation instead of undoing it [118]. The effect is therefore not reciprocal, which distinguishes it sharply from the rotation produced by a sugar solution, and it was the first demonstration that light and magnetism act on one another — the observation that made an electromagnetic theory of light thinkable before there was one.

Derivation pending #26

The Faraday effect: derive the difference between the refractive indices of the two circular polarizations for a medium of bound charges in a magnetic field along the ray, by solving the driven oscillator equation with the magnetic force included; then show that a linear polarization, resolved into two circular components of equal amplitude, emerges rotated by half the accumulated phase difference, which gives the Verdet constant. The non-reciprocity should be derived too, and it follows from the field being an axial vector that does not reverse when the propagation direction does.

Chapter 63

Experiments: Electromagnetism

Electromagnetism is the first branch of physics that was built, experiment by experiment, into a field theory, and this chapter collects the measurements that did the building: Coulomb's torsion balance and Cavendish's null test for the inverse-square law [38, 205], Ørsted's deflected needle [68], Ampère's force between currents [66], Faraday's induction [89], the Weber–Kohlrausch measurement that first tied the two systems of units to the speed of light [146], Hertz's electromagnetic waves [239], and Millikan's quantization of charge [407]. Each is the evidence for a specific structural claim of Chapters 58 and 59 and of Chapters 60 and 61, and each is cross-referenced from the theory it tests.

When written out, every experiment below will use the structured `experiment` environment, with apparatus, procedure, observations (numbers and uncertainties in SI units), interpretation and primary references given in full. The chapter closes with the modern precision descendants: laboratory bounds on a deviation from the Coulomb exponent [1460] and the resulting photon-mass limits compiled by the Particle Data Group [2427].

Derivation pending #27

Experiments: Electromagnetism: all derivations of this chapter are pending.

63.1 The predictions under test

[Reserved: the chain of claims this chapter must test, stated before any apparatus: that the electrostatic force is central and inverse-square (Chapter 58); that currents produce and feel magnetic fields with a definite force law (Chapter 59); that a changing magnetic flux drives an electromotive force; that the completed equations propagate transverse waves at a speed fixed by electric and magnetic measurements alone, the prediction of Maxwell's dynamical theory [164]; and that charge comes in integer multiples of a smallest unit.]

63.2 Coulomb: the torsion balance (1785)

63.2.1 Apparatus and procedure

[Reserved: Coulomb's torsion balance [38]: the silver suspension wire as a calibrated torque standard, the charged pith balls, the twist-angle protocol for repulsion, and the separate torsion-pendulum timing method of the second memoir for attraction. The instrument is the same one that weighs the gravitational constant in Chapter 33, and the shared metrology of torsion fibres will be treated once, there, and cited from here.]

63.2.2 Observations

[Reserved: the tabulated twist angles versus separation from [38], converted to SI — forces of order 10^{-4} N at separations of a few cm *— with Coulomb's own three-point verification that halving the distance quadruples the force, and a modern uncertainty analysis of the instrument's systematics (charge leakage, induction on the enclosure).]*

63.2.3 Interpretation

[Reserved: the inference from the data to the force law of Chapter 58, written as an exponent bound $F \propto r^{-2\pm\delta}$ with Coulomb's own δ of order a few percent; why a torsion measurement tests the law only at laboratory separations; and the statement that the modern form of this inference is the photon-mass bound of Section 63.11.2.]

Phenomenon 63.1 (The electrostatic force is central and inverse-square)**.** Two small bodies at rest carrying static electric charge act on one another along the line joining them, with a force proportional to the product of the charges and falling as the inverse square of the separation. The torsion balance establishes the exponent directly, by showing that halving the distance quadruples the force, to within a few percent [38]. The null method establishes it far more sharply: if the exponent is written $2+\delta$, then and only then does the field inside a closed charged conductor vanish for $\delta = 0$, so a sensitive detector inside a charged shell that registers nothing bounds δ. That line of experiment runs from Cavendish, who reached $|\delta| < 0.02$ a century before the result was printed [205], through Plimpton and Lawton at 2×10^{-9} [783], to lock-in detection between concentric icosahedral shells at $|\delta| \lesssim 3 \times 10^{-16}$ [1460]. Read as a photon mass, the same null record gives $m_\gamma < 1 \times 10^{-18}\,\mathrm{eV}/c^2$ [2427].

Derivation pending #28

The Coulomb exponent: derive the interior field of a uniformly charged spherical shell for a force law with exponent $2+\delta$, show that it vanishes identically only when δ is zero, and give the conversion of a measured null voltage between concentric conductors into a bound on δ. Then relate δ to a photon rest mass through the Yukawa form that a massive vector field gives in place of the Coulomb potential.

63.3 Cavendish: the concentric spheres

[Reserved: Cavendish's unpublished null experiment, performed around 1772 and printed only in Maxwell's 1879 edition of the electrical researches [205]: a charged outer sphere, an inner sphere connected and then isolated, and the null reading on the pith-ball electrometer that bounds the exponent deviation to $|\delta| < 0.02$ — a sharper test than [38], a century earlier than its publication. The null method — zero signal inside a closed conductor if and only if the exponent is exactly 2 — is the template for every later test in Section 63.11.1, and its theory is Gauss's law from Chapter 58.]

63.4 Galvanic circuits: Ohm and Kirchhoff

[Reserved: the quantitative laws of steady currents: Ohm's measurements with thermocouple sources and calibrated wires and the linear relation of current to electromotive force [81], and Kirchhoff's circuit laws with their field-theoretic justification [114]. The material evidence — galvanometer deflections versus wire length in SI units — and the reduction of circuit theory to the field description of Chapter 62 are to be written here.]

63.5 Ørsted: the current and the needle (1820)

[Reserved: Ørsted's observation that a galvanic current deflects a nearby compass needle, circulating around the wire rather than pointing along it [68] — the first coupling of electricity to magnetism, and the first force in physics that is neither central nor along the line joining its sources. The immediate quantitative sequel of Biot and Savart, measuring the field of a long straight current through the oscillation period of a suspended magnet [67], gives the $1/r$ law of Chapter 59. Apparatus, procedure and the deflection data in SI units are to be tabulated when written.]

63.6 Ampère: the force between currents (1820)

[Reserved: Ampère's current balance and his four null experiments, establishing within weeks of Ørsted's announcement that parallel currents attract and antiparallel currents repel [66], and the mature force law of the 1826 treatise deduced, as its title claims, uniquely from experiment [77]. The force per unit length between long parallel wires — $2 \times 10^{-7}\,\mathrm{N/m}$ at $1\,\mathrm{A}$ and $1\,\mathrm{m}$ — defined the SI ampere until the 2019 redefinition fixed the elementary charge instead [2333]; both definitions and the continuity between them belong here, with Chapter 59 carrying the theory.]

63.7 Faraday: electromagnetic induction (1831–1832)

63.7.1 Apparatus and procedure

[Reserved: the induction ring — two coils on a soft iron torus — the galvanometer as ballistic charge integrator, and the three protocols of the First Series of the Experimental Researches [89]: switching the primary current, moving a magnet through a coil, and rotating a copper disc in a magnetic field (the homopolar generator).]

63.7.2 Observations

[Reserved: which quantities are tabulated when written — ballistic galvanometer throws proportional to flux change, in SI $\mathrm{V\,s}$; the transient nature of the effect (current flows only while the flux changes); the sign reversal on reversal of motion; and the proportionality of integrated electromotive force to the change of flux rather than to its rate history [89].]

Phenomenon 63.2 (The induced charge measures the change of flux, not its rate)**.** A ballistic galvanometer in a circuit linked to a changing magnetic flux gives a throw proportional to the *total* charge that has passed, and that charge depends only on the total change of flux and on the resistance of the circuit — not on how quickly the change was made. Switching the primary current of an induction ring slowly or abruptly gives the same throw; so does moving a magnet through a coil quickly or slowly [89]. Only the endpoints matter:

$$Q = \frac{|\Delta \Phi_B|}{R}\,. \tag{63.1}$$

Derivation. The circuit has resistance R and carries the current $I = \mathcal{E}/R$ driven by the induced electromotive force. Integrating over the whole of the transient, and using the flux rule $\mathcal{E} = -\mathrm{d}\Phi_B/\mathrm{d}t$ (Chapter 60),

$$Q = \int I\,\mathrm{d}t = \frac{1}{R}\int \mathcal{E}\,\mathrm{d}t = -\frac{1}{R}\int_{t_1}^{t_2} \frac{\mathrm{d}\Phi_B}{\mathrm{d}t}\,\mathrm{d}t = -\frac{\Phi_B(t_2) - \Phi_B(t_1)}{R}\,, \tag{63.2}$$

by the fundamental theorem of calculus. The integrand's time dependence has been integrated away: whatever path Φ_B took between the two endpoints, and however long it took, only the difference survives. This is Equation (63.1).

The result is what makes the ballistic galvanometer the right instrument, because such an instrument responds to the impulse delivered to its coil — the time integral of the current — rather than to the current itself, provided the transient is short compared with its swing period. It is also why the measurement is a *flux* meter: Equation (63.1) inverted gives $\Delta\Phi_B = QR$ in V s, from a charge and a resistance. □

63.7.3 Interpretation

[Reserved: the induction law as the experimental content of the curl-E Maxwell equation of Chapter 60; Faraday's own field-line language as the origin of the field concept; the motional/transformer distinction and its resolution in the flux rule, whose two mechanisms unify only under the relativity of Chapter 38.]

63.8 Weber and Kohlrausch: the ratio of the units (1856)

[Reserved: the measurement that connected electricity to light before Maxwell wrote a field equation: the ratio of the electrodynamic to the electrostatic unit of charge, measured by discharging a Leyden jar of known electrostatic charge through a ballistic galvanometer [146], yielding a velocity within a few percent of the speed of light. Maxwell's identification of that velocity with the propagation speed of electromagnetic waves [164] turned this number into the central prediction that Section 63.9 tests.]

Phenomenon 63.3 (The ratio of the two units of charge is a speed, and that speed is the speed of light)**.** The quantity of electricity on a charged conductor can be measured in two entirely independent ways: electrostatically, from the mechanical force it exerts on another charged body, and electrodynamically, from the deflection produced when it is discharged through a galvanometer whose constant has been fixed magnetically. The two measures are not the same quantity, and their ratio has the dimensions of a velocity. Weber and Kohlrausch measured that ratio by discharging a Leyden jar of known electrostatic charge, and the velocity that came out agreed, to within the accuracy of the experiment, with the speed of light determined optically [146] — a number obtained with no light anywhere in the apparatus, and the first quantitative link between electromagnetism and optics [164].

Derivation pending #29

The ratio of the units: show that the electrostatic and electromagnetic definitions of the unit of charge differ by a factor with the dimensions of a speed, equal in SI terms to the reciprocal square root of the product of the electric and magnetic constants, and hence that this measurement determines exactly the combination that reappears as the propagation speed in the vacuum wave equation. The error budget of the original determination, and its agreement with the contemporary optical values, are to be reconstructed here.

63.8.1 Convection currents: Rowland (1876)

[Reserved: Rowland's demonstration in Helmholtz's laboratory that a moving electrostatic charge produces the same magnetic field as a conduction current [202] — charge in motion is current, with no distinction of mechanism — closing the conceptual gap between Section 63.2 and Section 63.6 and anticipating the relativity of the field decomposition treated in Chapter 38.]

Phenomenon 63.4 (Charge in motion is current)**.** An insulating disc carrying a static electrostatic charge, spun rapidly about its axis, deflects a magnetometer needle exactly as a circular conduction current of the same magnitude would. The deflection reverses with the sense of rotation and with the sign of the charge, and it is proportional to the product of the charge and the angular velocity [202]. There is therefore no distinction of mechanism in the magnetic effect: it is the motion of charge that matters, not whether that motion is conduction along a wire or the carriage of a charge on a moving body.

Derivation. The current density that appears as the source in the field equations is $\boldsymbol{J} = \rho \boldsymbol{v}$, and this is a definition of what a current *is* — charge crossing unit area per unit time — with nothing in it about the mechanism of the motion. A ring of the disc at radius r, carrying surface charge density σ and turning at angular velocity Ω, therefore constitutes a surface current

$$K(r) = \sigma\, v = \sigma \Omega r\,, \tag{63.3}$$

whose total, integrated over the radius of a disc of radius a carrying total charge $Q = \sigma \pi a^2$, is $I = \int_0^a \sigma \Omega r \,\mathrm{d}r = \sigma \Omega a^2/2 = Q\Omega/2\pi$ — the whole charge passing any radial line once per revolution, as it must. Since the field equations see only $\boldsymbol{J}$, the field produced is the field of that current, and it is proportional to $Q\Omega$ and reverses with either factor, as observed.

The result looks trivial and is not: before it, "current" was a property of galvanic circuits, and it was an open question whether the magnetic action belonged to the conduction process itself. What the experiment shows is that the source term of magnetostatics is the convective flux of charge, which is exactly the statement that relativity later makes structural, since a static charge in one frame is a current in another (Chapter 38). □

63.9 Hertz: electromagnetic waves (1888)

63.9.1 Apparatus and procedure

[Reserved: the spark-gap dipole oscillator driven by an induction coil, the resonant loop receiver with its micrometer spark gap, and the standing-wave protocol: reflecting the radiation from a zinc sheet and mapping nodes and antinodes along the laboratory [239].]

63.9.2 Observations

[Reserved: the tabulated node positions giving wavelengths of several metres at an oscillator frequency near $50\,\mathrm{MHz}$*, hence a propagation speed consistent with the optical* $3 \times 10^8\,\mathrm{m/s}$*; the demonstrations of rectilinear propagation, reflection, refraction in a pitch prism, and polarization by a wire grid [239].]*

Phenomenon 63.5 (Electromagnetic waves in free space)**.** A spark-gap oscillator radiates a disturbance that crosses the laboratory, is reflected from a metal sheet, and forms with its own reflection a stationary pattern whose nodes and antinodes can be located by carrying a small resonant loop through it and watching its spark appear and vanish. The node spacing gives wavelengths of several metres, which with the oscillator's frequency yields a propagation speed agreeing with the optical speed of light to within the accuracy of the determination. The same radiation is reflected from conductors, refracted by a prism of pitch, and extinguished by a grid of parallel wires held one way and transmitted by it held the other [239]. It is therefore a transverse wave, and it behaves in every tested respect as light does.

Derivation. Only the standing-wave measurement needs a derivation; the rest is direct observation. A conducting sheet cannot support a tangential electric field at its surface,

so the reflected wave must cancel the incident one there. Superposing an incident wave travelling towards the sheet at $x = 0$ with its reflection,

$$E(x,t) = E_0 \cos(kx + \omega t) - E_0 \cos(kx - \omega t) = -2E_0 \sin(kx) \sin(\omega t)\,, \tag{63.4}$$

which vanishes for all t wherever $\sin(kx) = 0$, that is at $x = 0,\ \pi/k,\ 2\pi/k, \ldots$. The nodes are therefore spaced by

$$\Delta x = \frac{\pi}{k} = \frac{\lambda}{2}\,, \tag{63.5}$$

so the measured spacing gives $\lambda = 2\Delta x$ with a metre rule and nothing else. The propagation speed then follows from the universal relation $v = f\lambda$, with f the frequency of the oscillator, fixed by its capacitance and inductance. The magnetic field has its *antinodes* where the electric field has its nodes, which is why the receiving loop, sensitive to the changing magnetic flux through it, reads the pattern shifted by a quarter wavelength from a detector sensitive to $\boldsymbol{E}$ — a check on the interpretation, not a complication of it. □

63.9.3 Interpretation

[Reserved: the verdict — electromagnetic disturbances propagate at finite speed as transverse waves, as [164] predicted and as Chapter 61 derives; light is such a wave, and the optical evidence for that identification is the subject of Chapter 67. Action-at-a-distance electrodynamics is dead from this table onward.]

63.10 Millikan: the quantization of charge (1911–1913)

63.10.1 Apparatus and procedure

[Reserved: the oil-drop chamber: atomizer, parallel plates at kilovolt potentials, the microscope and stopwatch protocol of timed rises and falls of a single drop, and the correction to Stokes drag at low pressure worked out in the 1911 paper [377]. The prehistory — the electron's e/m from cathode-ray deflection [276] — fixes what the measured e implies for the electron mass.]

63.10.2 Observations

[Reserved: charge changes of single drops always integer multiples of one unit; the 1913 value $e = 1.592 \times 10^{-19}\,\mathrm{C}$ (in modern units, with its uncertainty dominated by the then-current viscosity of air) [407]; the table of drop radii, fall times and inferred charges to be reproduced in SI when written.]

Phenomenon 63.6 (Electric charge is quantized)**.** The charge carried by a single oil drop, measured one drop at a time by timing its fall under gravity and its rise against gravity in a known electric field, is always an integer multiple of one and the same unit. When a drop captures an ion from the surrounding air its charge changes — and it changes by an integer multiple of that same unit, never by a fraction of it. The unit is independent of the size of the drop, of the substance of which it is made, and of the means by which the ions were produced [377, 407]. Charge is therefore not a continuous quantity, and the elementary unit is that carried by the electron of [276]. Millikan's own value was $e = 1.592 \times 10^{-19}\,\mathrm{C}$ [407]; since 2019 the elementary charge has been exact by definition, and its value fixes the SI ampere [2333].

Derivation. Let W be the weight of the drop less the buoyancy of the air. With no field the drop reaches a terminal speed v_f at which the viscous drag balances W; Stokes' law

makes the drag proportional to the speed, so

$$W = k\,v_f\,, \qquad k = 6\pi\eta a\,, \tag{63.6}$$

with η the viscosity of the air and a the radius of the drop. Now apply a vertical field E strong enough to lift the drop, and let it rise at terminal speed v_r; the balance is now $qE - W = k\,v_r$. Adding the two balances eliminates W:

$$q = \frac{k\,(v_f + v_r)}{E}\,. \tag{63.7}$$

The radius hidden in k is not an independent unknown: writing $W = \tfrac{4}{3}\pi a^3 \Delta\rho\, g$ with $\Delta\rho$ the density of the oil less that of the air, Equation (63.6) gives $a = \sqrt{9\eta v_f / 2\Delta\rho g}$. Every quantity on the right of Equation (63.7) is therefore measured: two speeds obtained with a microscope scale and a stopwatch, a field obtained from a voltage and a plate separation, and tabulated material constants.

What the derivation delivers is a number for each drop; what the *experiment* delivers is the observation that those numbers cluster on integer multiples, and that a drop which changes its charge does so by jumping between multiples. No step of the derivation assumes or imposes this, which is what makes the quantization an observation rather than a construction. The one systematic that mattered is visible in Equation (63.6): Stokes' law fails when the drop is not large compared with the mean free path of the air molecules, and the correction — together with the value adopted for η — is the source of the difference between Millikan's e and the modern one. □

63.10.3 Interpretation

[Reserved: charge is quantized; the elementary unit is carried by the electron of [276]; the viscosity systematic and its later correction as a case study in error analysis for Chapter 2. Since 2019 the elementary charge is exact by definition [2333], and the burden of measurement has moved to the quantities defined through it [2392].]

63.11 Modern repetitions and precision

63.11.1 The Coulomb exponent

[Reserved: the lineage of null tests after Cavendish: Plimpton and Lawton's resonant detection inside charged concentric shells, bounding the exponent deviation at 2×10^{-9} [783], and the Williams–Faller–Hill experiment with concentric icosahedral shells and lock-in detection at 4 MHz, reaching $|\delta| \lesssim 3 \times 10^{-16}$ [1460]. The geometry of each apparatus and the conversion of a null voltage to an exponent bound are to be written here.]

63.11.2 Photon-mass bounds

[Reserved: the modern reading of every exponent test — a Yukawa deviation from Coulomb's law is a photon mass, the Proca theory of Chapter 64 — and the compilation of bounds in the Review of Particle Physics, reaching $m_\gamma < 1 \times 10^{-18}\,\mathrm{eV}/c^2$ from solar-wind magnetohydrodynamics [2427], with the laboratory bound of [1460] translated into the same units. The plasma physics behind the solar-wind limit lives in Chapter 66.]

63.11.3 Charge quantization today

[Reserved: where Millikan's result stands now: the exact elementary charge of the revised SI [2333, 2392]; fractional charges of quarks, never observed free, inferred from deep inelastic

scattering (Chapter 116); and the fractionally charged quasiparticles of the fractional quantum Hall effect (Chapter 128), which quantize collective excitations rather than violate charge quantization.]

Chapter 64

Generalized Classical Field Theory

A field is a dynamical system carrying a degree of freedom at every point of space, and this chapter builds the machinery such systems require: the action functional and its Lagrangian density, the Euler–Lagrange field equations, Noether's theorems and the currents and charges they produce [456], the energy–momentum tensor in its canonical and improved forms [850], and the Hamiltonian formulation. The construction is the continuum limit of the machinery of Chapters 21 and 22: the label a that ran over finitely many coordinates becomes the continuous label $\boldsymbol{x}$, sums become integrals, and derivatives become functional derivatives in the sense of Chapter 16. What survives the limit is everything that matters — a variational principle, a symmetry-to-conservation-law correspondence, and a phase space.

The chapter sits here, at the end of Part VII, because electromagnetism is the classical field theory for which the evidence is overwhelming and which therefore earns the general formalism. Maxwell's equations [164] follow from a single Lorentz-scalar Lagrangian density; gauge invariance of that density forces charge conservation; the same variational calculation delivers the energy density, the Poynting flux [229] and the Maxwell stress [185] that are measured as radiation pressure [299, 311]. Two further systems are stated for later use: the classical Klein–Gordon field [544], the simplest relativistic field of all and the template for every scalar in Chapter 104, and the massive vector field of Proca [785], whose comparison with Maxwell is what turns laboratory electrostatics into a bound on the photon mass. Where the Legendre transformation of Chapter 22 fails — and for every gauge theory it does fail — the treatment is the constraint formalism already developed in Chapter 26, which this chapter uses rather than repeats. Standard treatments are [1552, 1912, 1976].

Derivation pending #30

Generalized Classical Field Theory: all derivations of this chapter are pending.

64.1 Fields as dynamical systems

64.1.1 From many degrees of freedom to a continuum

[Reserved: the loaded string of Chapter 28 taken to the limit of infinitely many beads at fixed mass density, in which the discrete coordinates $q_a(t)$ become a field $\phi(t, \boldsymbol{x})$ and the coupled equations become a wave equation; the field as the physical object rather than a bookkeeping device, which is Maxwell's own reading of the electromagnetic field as a dynamical system with energy stored in space [164]; locality as the statement that the Lagrangian is an integral of a density depending on the field and its first derivatives at one point; and why a nonrelativistic mechanical model of that density — an aether — is neither needed nor tenable (Chapter 37).]

64.1.2 The action functional and the Lagrangian density

[Reserved: the action $S[\phi] = \int \mathcal{L}(\phi, \partial_\mu \phi)\, \mathrm{d}^4x$ over a spacetime region, with $\mathcal{L}$ a Lorentz scalar density in the sense of Chapter 39; the three standing restrictions — locality, at most first derivatives, and invariance under the Poincaré group — and what each buys; the dimensions of $\mathcal{L}$ in SI (energy per unit volume) and the normalization conventions fixed here for the whole treatise; the equivalence class of Lagrangians differing by a total divergence [1552].]

64.1.3 Functional derivatives

[Reserved: the functional derivative $\delta S/\delta\phi(x)$ defined by the first variation, its delta-function algebra $\delta\phi(x)/\delta\phi(y) = \delta^4(x-y)$, and the conditions under which a functional is differentiable, taken from Chapter 16; the field-theoretic version of the Euler operator; the notation used throughout Parts VII and XI is fixed here once [1912].]

64.2 The Euler–Lagrange field equations

64.2.1 Variation, boundary terms and natural conditions

[Reserved: the derivation of $\partial_\mu\left(\partial\mathcal{L}/\partial(\partial_\mu\phi)\right) - \partial\mathcal{L}/\partial\phi = 0$ by variation at fixed data on the boundary of the region; the surface term and the two ways to kill it — fixed variations or natural boundary conditions; why a total divergence added to $\mathcal{L}$ changes nothing; the extension to several fields and to higher derivatives, with the Ostrogradsky instability as the reason the treatise stops at first order [1552].]

64.2.2 The real scalar field: the Klein–Gordon equation

[Reserved: the Lagrangian density $\tfrac{1}{2}\partial_\mu\phi\,\partial^\mu\phi - \tfrac{1}{2}\mu^2\phi^2$ and its field equation $(\Box + \mu^2)\phi = 0$ with $\mu = mc/\hbar$, written down in 1926 by Gordon [544] and by Klein [547] (the latter in a five-dimensional setting whose extra dimension has no evidence and is not used anywhere in this treatise); plane-wave solutions and the dispersion relation $\omega^2 = c^2k^2 + \mu^2c^2$; the Yukawa static solution $\mathrm{e}^{-\mu r}/r$ and its interpretation as a force of finite range [765]; the classical field is developed here, its quantization in Chapter 92.]

64.2.3 The complex scalar field and internal symmetry

[Reserved: the complex field with $\mathcal{L} = \partial_\mu\phi^*\,\partial^\mu\phi - \mu^2\,|\phi|^2$; invariance under the global phase rotation $\phi \mapsto \mathrm{e}^{\mathrm{i}\alpha}\phi$, an internal $\mathrm{U}(1)$ symmetry in the sense of Chapter 14; the associated conserved current and the charge it integrates to, obtained from the theorem of Section 64.3.1; why the current is not a probability density and what that cost the interpretation of the equation before quantization [1912].]

64.3 Symmetries and conservation laws

64.3.1 Noether's first theorem

[Reserved: the theorem of [456] — to every continuous group of transformations leaving the action invariant, with r independent parameters, correspond r currents j^μ_A satisfying $\partial_\mu j^\mu_A = 0$ on shell; the charge $Q_A = \int j^0_A\, \mathrm{d}^3x$ is constant provided the flux through the boundary vanishes; invariance up to a total divergence is enough, which is what covers translations and Galilean boosts; the ambiguity $j^\mu \mapsto j^\mu + \partial_\nu k^{[\nu\mu]}$ that leaves the divergence and the charge untouched, and which the improvements of Section 64.4.2 exploit.]

64.3.2 Poincaré invariance and the ten charges

[Reserved: the four translations giving the energy–momentum tensor and the six Lorentz transformations giving the angular-momentum current $M^{\mu\nu\rho}$, whose conservation splits into orbital and spin parts only after the tensor is symmetrized; the ten conserved charges as the classical counterpart of the Poincaré generators of Chapter 39 and, after quantization, of the Wigner classification [849] used in Chapter 94; conformal invariance of the free massless field and the extra currents Bessel-Hagen extracted for electrodynamics [472].]

64.3.3 Internal symmetry and electric charge

[Reserved: the Noether charge of the internal $\mathrm{U}(1)$ *identified with electric charge in coulombs; global versus local invariance; conservation of charge as an experimental claim rather than a convention, with the sharpest laboratory bound coming from searches for charge-violating electron decay — a lifetime exceeding* $6.6 \times 10^{28}\,\mathrm{yr}$ *for* $e \to \nu\gamma$ *from Borexino [2248]; the compilation of related bounds in [2427].]*

64.3.4 Noether's second theorem and local symmetries

[Reserved: the second theorem of [456] — a symmetry depending on arbitrary functions of spacetime does not give new conservation laws but identities among the field equations, so that the equations are not independent and the evolution is underdetermined; the identity $\partial_\mu \partial_\nu F^{\mu\nu} \equiv 0$ *for electrodynamics and the contracted Bianchi identity for gravitation (Chapter 44) as the two instances that matter here; the corollary that a locally invariant theory has a singular Legendre transformation, which is where Chapter 26 takes over.]*

64.4 The energy–momentum tensor

64.4.1 The canonical tensor and its defects

[Reserved: $T^{\mu\nu}_{can} = (\partial\mathcal{L}/\partial(\partial_\mu\phi))\,\partial^\nu\phi - \eta^{\mu\nu}\mathcal{L}$ *as the Noether current of translations [456]; the interpretation of its components as energy density, momentum density, energy flux and stress, in SI units; the two defects — it is in general neither symmetric, so it cannot serve as the source of Chapter 44, nor gauge invariant, which for electrodynamics makes even its energy density depend on the gauge chosen [1552].]*

64.4.2 The Belinfante–Rosenfeld improvement

[Reserved: the improvement term built from the spin current, $T^{\mu\nu} = T^{\mu\nu}_{can} + \partial_\rho k^{[\rho\mu]\nu}$*, constructed independently by Belinfante [850] and Rosenfeld [855]; that it changes neither the conservation law nor the total charges, being of the superpotential form allowed by Section 64.3.1; that the result is symmetric and, for electrodynamics, gauge invariant; and the resulting clean separation of angular momentum into orbital and spin parts, the spin part being what Beth measured for light [767].]*

64.4.3 The Hilbert tensor and the gravitational source

[Reserved: the definition of $T^{\mu\nu}$ *as the response of the matter action to a variation of the metric [431], which is symmetric and gauge invariant by construction; the theorem that it coincides with the Belinfante tensor for every field of this chapter; its conservation as a consequence of diffeomorphism invariance by Noether's second theorem; and the statement that this is the object appearing on the right-hand side of the Einstein equations of Chapter 44, which is why the choice of improvement is not a matter of taste.]*

64.4.4 What is actually measured

[Reserved: the measured consequences of the electromagnetic stress–energy tensor — radiation pressure on a mirror, detected by Lebedev [299] and by Nichols and Hull [311]; the Maxwell stress on conductors and dielectrics [185]; the angular momentum of circularly polarized light [767]; and the momentum of light in a medium, where the rival Minkowski [346] and Abraham [351] forms differ by exactly a division of the total between field and matter, a question belonging to Chapter 62.]

64.5 The electromagnetic field as a Lagrangian system

64.5.1 The free-field Lagrangian

[Reserved: $\mathcal{L} = -\frac{1}{4\mu_0} F_{\mu\nu}F^{\mu\nu} - A_\mu J^\mu$ as the unique Poincaré- and gauge-invariant density quadratic in first derivatives of A_μ; the Euler–Lagrange equations returning the inhomogeneous Maxwell equations of Chapter 60 while the homogeneous pair is the identity $\partial_{[\rho}F_{\mu\nu]} = 0$ satisfied by any $F = \mathrm{d}A$ — so half of Maxwell's system is a consequence of using a potential at all; the second invariant $F_{\mu\nu}\tilde{F}^{\mu\nu}$, a total divergence classically and parity-odd, connecting to Chapter 105 [1552, 1976].]

64.5.2 Minimal coupling and the gauge principle

[Reserved: the replacement $\partial_\mu \to \partial_\mu + \mathrm{i}qA_\mu/\hbar$ that promotes a global phase symmetry to a local one, introduced for the relativistic charged particle by Fock [540] and raised to a principle by Weyl [641]; the interaction term $-A_\mu J^\mu$ and the Lorentz force recovered from it, matching Chapter 40 and the electron theory of [356]; the honest statement that the gauge principle predicts the form *of the coupling but not the value of q, whose quantization is an experimental fact (Chapter 63).]*

64.5.3 Gauge invariance and charge conservation

[Reserved: the demonstration that invariance of the action under $A_\mu \mapsto A_\mu + \partial_\mu\Lambda$ requires $\partial_\mu J^\mu = 0$ identically, not merely on shell — charge conservation is a consistency condition on the coupling, by Noether's second theorem [456, 472]; gauge fixing as the removal of the resulting redundancy, with the Lorenz condition [168] and the Coulomb and temporal gauges; and the count of physical polarizations deferred to Section 64.7.3.]

64.5.4 The electromagnetic energy–momentum tensor

[Reserved: the canonical tensor of the Maxwell field, which is neither symmetric nor gauge invariant, and the Belinfante improvement [850] that yields $T^{\mu\nu} = \mu_0^{-1}\left(F^{\mu\rho}F^{\nu}{}_{\rho} - \frac{1}{4}\eta^{\mu\nu}F^{\rho\sigma}F_{\rho\sigma}\right)$; identification of its components with the energy density $\frac{1}{2}(\epsilon_0 E^2 + B^2/\mu_0)$, the Poynting vector [229] and the Maxwell stress [185]; tracelessness as the classical shadow of conformal invariance [472]; and the use of the same tensor for the radiated power of Chapter 65.]

64.5.5 The non-abelian generalization

[Reserved: Yang and Mills' extension of the gauge principle to a non-abelian group [1054], with $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + g\,[A_\mu, A_\nu]$ and a Lagrangian of the same form; the decisive structural difference — the field strength is not gauge invariant but covariant, and the field carries its own charge, so the free theory is already nonlinear; the classical statement is made here, and the evidence for it is the strong and electroweak sectors of Chapters 102 and 104.]

64.6 Massive vector fields: the Proca theory

64.6.1 The Proca equation

[Reserved: the Lagrangian $-\frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}\mu^2 A_\mu A^\mu$ of [785] and its field equation $\partial_\mu F^{\mu\nu} + \mu^2 A^\nu = 0$; the mass term breaks gauge invariance, so A_μ is no longer redundant and the Lorenz condition $\partial_\mu A^\mu = 0$ becomes a consequence rather than a choice; three propagating polarizations instead of two; the static potential becomes Yukawa's $\mathrm{e}^{-\mu r}/r$ [765] with range $\hbar/mc$, which is the observable signature; and the discontinuity of the degree-of-freedom count in the massless limit, already analysed in Chapter 26.]

64.6.2 The photon mass as a measured quantity

[Reserved: how a laboratory test of Coulomb's law converts into an upper bound on μ, since a Proca field gives a deviation growing with apparatus size — the modern laboratory limit [1460] and the far sharper bounds from planetary and galactic magnetic fields reviewed in [2157], with the value adopted by this treatise taken from [2427], currently of order $1 \times 10^{-18}\,\mathrm{eV}/c^2$; and the methodological point that "the photon is massless" is a bound, never a measurement, so the correct statement is a number with a confidence level.]

64.7 Hamiltonian field theory

64.7.1 Momentum density and the Hamiltonian

[Reserved: the momentum density $\pi = \partial\mathcal{L}/\partial\dot{\phi}$, the Hamiltonian density $\mathcal{H} = \pi\dot{\phi} - \mathcal{L}$ and the field equations in first-order form; the loss of manifest covariance under the required 3+1 split of Chapter 39, and the fact that the resulting energy nonetheless agrees with T^{00} of Section 64.4.2; the scalar and Maxwell fields worked as the two standing examples [1912].]

64.7.2 Poisson brackets for fields

[Reserved: the equal-time bracket $\{\phi(\boldsymbol{x}), \pi(\boldsymbol{y})\} = \delta^3(\boldsymbol{x} - \boldsymbol{y})$ built from functional derivatives, generalizing Chapter 22; the symplectic structure on the space of solutions; the generators of the Poincaré group realized as brackets, closing on the algebra of Chapter 39; and this bracket as the object that the correspondence rule of Chapter 99 turns into a commutator.]

64.7.3 Singular Lagrangians and constraints

[Reserved: the Maxwell Lagrangian is singular — $\partial\mathcal{L}/\partial\dot{A}_0 \equiv 0$ — so its Hamiltonian formulation is the constrained one of Chapter 26, whose results are used here and not rederived: the primary constraint $\pi^0 \approx 0$, the secondary Gauss constraint, both first class, and the count of two physical polarizations per point of space, against three for the Proca field of Section 64.6.1; the observed absence of a longitudinal mode of light (Chapter 67) is what this count predicts.]

64.7.4 Covariant Hamiltonian formulations

[Reserved: the De Donder–Weyl formalism [752, 764], in which each field carries one polymomentum per spacetime direction and the Hamilton equations are first-order and manifestly covariant; the covariant phase space as the space of solutions with its symplectic form; what these formulations buy (covariance, a clean statement of the Noether charges as forms) and what they do not (a quantization rule of comparable standing to Chapter 99).]

64.8 From classical fields to quanta

[Reserved: the closing section, stating precisely what this chapter hands to Part XI and what it cannot decide. The mode expansion of a free field turns it into a continuum of harmonic oscillators (Chapter 28), which is the entire content of free field quantization; the canonical route is Chapter 99 and the path-integral route Chapter 106; the classification of the resulting one-particle states by mass and spin is Wigner's [849], treated in Chapter 94. What classical field theory already fixes — the number of polarizations, the form of the couplings, the conserved charges — and what it cannot — the value of $\hbar$, the spin–statistics connection, and the very existence of quanta — should be stated plainly here [1912].]

Chapter 65

Radiation and Scattering of Electromagnetic Waves

Accelerate a charge and it radiates. That single sentence, made quantitative, accounts for the light of every antenna, every synchrotron, every atom and every star, and it also destroys the classical atom — which is why this chapter is both the last word of classical electrodynamics and one of the doors into Part VIII. The chapter starts from the retarded solutions of the wave equations of Chapter 60, first written down by Lorenz [168], specializes them to a point charge in arbitrary motion — the Liénard–Wiechert potentials [281, 301] — and extracts from them the radiated power [275], the angular distribution, and the multipole hierarchy that organizes every emitter of finite size [241].

Three further themes follow, each with its own evidence. Radiation carries momentum away from its source, so an accelerated charge feels a back-reaction: the Abraham–Lorentz force [313, 356], its covariant completion by Dirac [813], their notorious runaway and pre-accelerating solutions, and the laser–electron collisions in which the effect has finally been measured [2305, 2317]. Radiation incident on a charge is re-radiated, which is scattering: Thomson's cross-section [332], Rayleigh's λ^{-4} law and the measured blue of the sky [181, 286], Mie's exact solution for a sphere [345], and the Compton shift [499] at which the classical account provably fails. And a charge moving through matter radiates in ways that a charge in vacuum cannot: bremsstrahlung [503], synchrotron emission [392, 900] and the Cherenkov cone [735, 792], which are the working tools of the detectors of Chapter 115. Standard treatments are [1552, 1976].

Derivation pending #31

Radiation and Scattering of Electromagnetic Waves: all derivations of this chapter are pending.

65.1 Fields of a charge in arbitrary motion

65.1.1 Retarded potentials

[Reserved: the wave equations for the potentials in Lorenz gauge and their retarded solutions [168], with the source evaluated at $t - |\boldsymbol{x} - \boldsymbol{x}'|/c$; Riemann's independent retarded-potential paper [170]; the retarded Green function of the d'Alembertian, taken from Chapter 10, and its support on the light cone; the advanced solution as an equally valid solution of the same equation, so that the choice of the retarded one is a boundary condition and not a theorem — the thermodynamic reading of that choice, and the Wheeler–Feynman absorber alternative [884], are to be stated honestly here.]

65.1.2 The Liénard–Wiechert potentials

[Reserved: the potentials of a point charge in arbitrary motion, $\varphi = \frac{q}{4\pi\epsilon_0}\left[\frac{1}{R(1-\boldsymbol{n}\cdot\boldsymbol{\beta})}\right]_{ret}$ and the corresponding vector potential, obtained independently by Liénard [281] and Wiechert [301]; the origin of the factor $(1-\boldsymbol{n}\cdot\boldsymbol{\beta})^{-1}$ as a Jacobian of the retarded-time condition rather than a Doppler factor; and the covariant one-line form in terms of the four-velocity, which makes the Lorentz transformation properties of Chapter 40 manifest.]

65.1.3 The velocity and acceleration fields

[Reserved: the field strengths obtained by differentiating the potentials, splitting into a velocity field falling as $1/R^2$ — a boosted Coulomb field, carrying no energy to infinity — and an acceleration field falling as $1/R$ and proportional to $\boldsymbol{a}$; the theorem that only the $1/R$ part contributes to the flux through a sphere of growing radius, which is what defines *radiation; the transverse and mutually orthogonal character of $\boldsymbol{E}$ and $\boldsymbol{B}$ in the wave zone [1976].]*

65.2 Radiated power

65.2.1 The Larmor formula

[Reserved: Larmor's result $P = q^2a^2/6\pi\epsilon_0c^3$ for a slowly moving charge [275], derived from the Poynting flux of the acceleration field; the $\sin^2\theta$ angular distribution about the acceleration; the numerical consequence that an electron on a Bohr-radius orbit radiates its energy away in about $1\times10^{-11}\,\mathrm{s}$, so that the classical atom cannot exist — the sharpest classical failure in this treatise, taken up in Chapter 70.]

Phenomenon 65.1 (An accelerated charge radiates)**.** A charge in uniform motion carries its field along with it and radiates nothing. A charge whose velocity changes emits energy that never returns. For speeds small compared with c the energy leaves at a rate proportional to the square of the acceleration and independent of the velocity,

$$P = \frac{q^2a^2}{6\pi\epsilon_0c^3}\,, \tag{65.1}$$

and it leaves with a $\sin^2\theta$ distribution about the direction of the acceleration, so that nothing at all is emitted along that direction [275]. Both the pattern and the polarization were mapped directly around an oscillating dipole with a resonant loop detector [241], and Equation (65.1) is the quantitative content of every antenna, every synchrotron and every classical radiating system in this chapter.

Derivation pending #32

The Larmor formula: derive the fields of a point charge in arbitrary motion from the retarded potentials, separate the velocity field, which falls as the inverse square of the distance and carries no energy to infinity, from the acceleration field, which falls as the inverse first power and is proportional to the acceleration, and integrate the Poynting flux of the acceleration field over a sphere of large radius.

Phenomenon 65.2 (Atoms are stable and radiate discrete lines)**.** Matter is made of atoms in which light electrons surround a small heavy nucleus, as the large-angle scattering of alpha particles requires [379]; an electron so bound is in permanent acceleration. Yet atoms do not collapse — they persist indefinitely, and a hydrogen atom today is indistinguishable

from one of any other epoch — and when they do radiate they emit sharp lines at fixed frequencies obeying exact numerical relations [230], not a continuum rising in pitch as the electron falls inward. Both facts contradict classical electrodynamics, and the contradiction is not marginal but catastrophic.

Derivation. Take a single electron of charge magnitude e and mass m_e on a circular orbit of radius r about a proton. The Coulomb attraction supplies the centripetal acceleration,

$$a = \frac{e^2}{4\pi\epsilon_0 m_e r^2}\,, \tag{65.2}$$

and the total energy of the orbit — kinetic plus potential, with the virial relation between them — is $E = -e^2/8\pi\epsilon_0 r$. Substituting Equation (65.2) into Equation (65.1) and equating the radiated power to the rate of loss of orbital energy, $\mathrm{d}E/\mathrm{d}t = -P$, gives

$$\frac{e^2}{8\pi\epsilon_0 r^2}\frac{\mathrm{d}r}{\mathrm{d}t} = -\frac{e^6}{96\pi^3\epsilon_0^3 m_e^2 c^3 r^4} \quad\Longrightarrow\quad \frac{\mathrm{d}r}{\mathrm{d}t} = -\frac{4}{3}\frac{r_e^2 c}{r^2}\,, \tag{65.3}$$

where $r_e = e^2/4\pi\epsilon_0 m_e c^2$ is the classical electron radius. Separating and integrating from an initial radius r_0 down to the nucleus,

$$t_{\mathrm{collapse}} = \frac{r_0^3}{4 r_e^2 c}\,. \tag{65.4}$$

With r_0 the Bohr radius $5.29\times10^{-11}\,\mathrm{m}$ and $r_e = 2.82\times10^{-15}\,\mathrm{m}$ [2392], this is about $1.6\times10^{-11}\,\mathrm{s}$.

Two predictions follow, and both are false. The atom would disappear in a fraction of a nanosecond; and as r shrank the orbital frequency would rise continuously, so the emitted spectrum would be a continuous sweep upward in frequency terminating in a burst, rather than the fixed sharp lines that are observed. This derivation therefore establishes not the phenomenon but its irreducibility: within classical electrodynamics there is no stable atom and no line spectrum, and no adjustment of the orbit, the charge distribution or the radiation law repairs it. The resolution is quantum and is taken up in Chapter 70. □

65.2.2 The relativistic generalization

[Reserved: Liénard's relativistic power law $P = \frac{q^2\gamma^6}{6\pi\epsilon_0 c}\left(\dot{\boldsymbol{\beta}}^2 - (\boldsymbol{\beta}\times\dot{\boldsymbol{\beta}})^2\right)$ [281] and its manifestly invariant form $P = -\frac{q^2}{6\pi\epsilon_0 c^3}\,a^\mu a_\mu$; the sharply different penalties for acceleration parallel and perpendicular to the velocity (γ^6 against γ^4), which is why linear accelerators are long and circular machines lose energy to synchrotron radiation (Section 65.7.1); the invariance of the total radiated energy but not of its angular distribution [1552].]

65.2.3 Angular distribution and beaming

[Reserved: the angular distribution in the wave zone for arbitrary velocity, its forward collimation into a cone of half-angle $\sim 1/\gamma$, and the distinction between power radiated per unit retarded time and per unit observer time; the observational consequences — the sweep of a synchrotron beam past a detector, and relativistic beaming in astrophysical jets (Chapter 115) [1976].]

65.3 Multipole radiation

65.3.1 Electric dipole radiation

[Reserved: the oscillating dipole, the first radiating system ever solved, treated by Hertz from Maxwell's theory [241]; the near, intermediate and radiation zones; the total power

$P = \ddot{p}^2/6\pi\epsilon_0 c^3$ and the ω^4 scaling that governs both antenna efficiency and Rayleigh scattering (Section 65.6.2); the polarization and $\sin^2\theta$ pattern that Hertz measured with his resonator loop.]

65.3.2 Magnetic dipole and electric quadrupole

[Reserved: the next terms in the expansion, suppressed relative to the electric dipole by one power of (size/λ); their distinct angular patterns and parity, connecting to the selection rules of Chapter 70 and Chapter 105; the observational contrast with gravitation, where charge conservation and momentum conservation forbid the monopole and dipole terms outright and the leading emission is quadrupole (Chapter 46) [1976].]

65.3.3 The multipole expansion of the radiation field

[Reserved: the systematic expansion in vector spherical harmonics, with electric and magnetic multipoles of each order, their radiated power and angular momentum content; the expansion parameter and its failure for sources comparable with the wavelength; the connection to the spherical-harmonic machinery of Chapter 9 and its reappearance for photon angular momentum in Chapter 122 [1976].]

65.4 Antennas

65.4.1 Radiation resistance

[Reserved: the short dipole treated as a circuit element, with the radiated power written as $\frac{1}{2}I^2 R_{rad}$ and $R_{rad} = \frac{2\pi}{3} Z_0 (\ell/\lambda)^2$ in terms of the impedance of free space $Z_0 = 376.730\,\Omega$; the half-wave dipole with its measured $73\,\Omega$; radiation as a genuine loss term in the energy balance of a circuit, which is how Chapter 62 meets this chapter [241, 1976].]

65.4.2 Arrays, directivity and reciprocity

[Reserved: linear arrays and the array factor, directivity and gain in dimensionless units, beam steering by phasing; the reciprocity theorem making the transmitting and receiving patterns of an antenna identical; aperture antennas and the diffraction limit shared with Chapter 67; the practical instruments this section must cover are radio telescopes and interferometric arrays, whose resolution argument is the same one used for stellar interferometry there [1976].]

65.5 Radiation reaction

65.5.1 The Abraham–Lorentz force

[Reserved: the self-force $\boldsymbol{F}_{rad} = \frac{q^2}{6\pi\epsilon_0 c^3}\dot{\boldsymbol{a}}$ obtained from the work–energy balance over a period, by Abraham [313] and Lorentz [356]; the characteristic time $\tau = q^2/6\pi\epsilon_0 m c^3$, equal to about $6.3 \times 10^{-24}\,\text{s}$ for an electron, and the length $c\tau$ far below any distance at which classical electrodynamics is tested; the divergent self-energy of a point charge and the failure of every classical extended-electron model to remove it.]

65.5.2 The Lorentz–Abraham–Dirac equation

[Reserved: Dirac's covariant derivation from conservation of energy–momentum in a tube around the world line, with mass renormalization absorbing the divergent piece [813]; the resulting third-order equation of motion and the Schott term; the statement that this is a

classical, not quantum, renormalization, and the honest note that the key `Dirac:1938` *in this treatise's bibliography is the unrelated large-numbers paper.]*

65.5.3 Runaways, pre-acceleration and the domain of validity

[Reserved: the exponentially growing free solutions $a \propto \mathrm{e}^{t/\tau}$; the acausal pre-acceleration that appears when they are excluded by a final condition; the argument that both pathologies live at times of order τ, where the classical theory has no claim to validity because pair creation and the Compton wavelength intervene (Chapter 100); the standing of radiation reaction as an effective, not fundamental, statement [1552].]

65.5.4 The Landau–Lifshitz reduction of order

[Reserved: the substitution of the zeroth-order equation of motion into the small radiation-reaction term, producing a second-order equation free of runaways and pre-acceleration and accurate to the same order in τ [1552]; the criterion for the reduction to be legitimate; and this equation as the one actually integrated in accelerator and laser-plasma modelling.]

65.5.5 Radiation reaction observed

[Reserved: radiation damping as a routine engineering fact in electron storage rings, where the damping times and the equilibrium emittance follow from the same self-force; and the direct laboratory observation in the collision of a laser-wakefield electron beam with an intense laser pulse, where the measured electron energy loss departs from the radiation-free prediction [2305, 2317]; what these data do and do not distinguish among the competing equations of Sections 65.5.2 and 65.5.4.]

65.6 Scattering

65.6.1 Thomson scattering

[Reserved: a free charge driven by a plane wave re-radiating as an oscillating dipole, giving the frequency-independent cross-section $\sigma_T = \frac{8\pi}{3} r_e^2 = 6.6525 \times 10^{-29}\,\mathrm{m}^2$ with $r_e = q_e^2/4\pi\epsilon_0 m_e c^2$ [332]; the $(1+\cos^2\theta)$ angular dependence for unpolarized light and the complete polarization of the scattered beam at 90 degrees; the observational uses — the solar K-corona, the electron density diagnostics of Chapter 66, and the Thomson scattering that sets the last-scattering surface of Chapter 51.]

Phenomenon 65.3 (Thomson scattering)**.** A beam of radiation traversing a gas is scattered by the free electrons it contains, and at low photon energy the cross-section per electron is independent of the frequency of the radiation:

$$\sigma_{\mathrm{T}} = \frac{8\pi}{3} r_e^2 = 6.6525 \times 10^{-29}\,\mathrm{m}^2\,, \qquad r_e = \frac{q_e^2}{4\pi\epsilon_0 m_e c^2}\,, \tag{65.5}$$

a fixed area attached to the electron and to nothing else [332]. The scattered radiation from an unpolarized beam follows a $1+\cos^2\theta$ angular distribution and is completely polarized at right angles to the beam. Because the cross-section scales as the inverse square of the mass, scattering by nuclei is negligible by six orders of magnitude, and a Thomson measurement counts electrons.

Derivation. A free charge in the field of a plane wave is driven with acceleration $\boldsymbol{a} = q_e \boldsymbol{E}/m_e$, the magnetic force being smaller by v/c and negligible for a non-relativistic response.

Substituting into the Larmor formula Equation (65.1) and taking the time average,

$$\langle P \rangle = \frac{q_e^2}{6\pi\epsilon_0 c^3} \frac{q_e^2 \langle E^2 \rangle}{m_e^2} \,. \tag{65.6}$$

The incident irradiance of the same wave is $I = \epsilon_0 c \langle E^2 \rangle$, and the cross-section is by definition the ratio of the power removed from the beam to the power per unit area carried by it:

$$\sigma_{\mathrm{T}} = \frac{\langle P \rangle}{I} = \frac{q_e^4}{6\pi\epsilon_0^2 c^4 m_e^2} = \frac{8\pi}{3} r_e^2 \,, \tag{65.7}$$

the last step by substituting r_e from Equation (65.5). The mean-square field $\langle E^2 \rangle$ cancels between numerator and denominator, so the answer does not depend on the intensity; and no frequency ever entered, because a free charge has no internal time scale — which is precisely why the cross-section is frequency-independent, and why the failure of that independence, in Section 65.6.4, is a failure of the classical account rather than a refinement of it. □

65.6.2 Rayleigh scattering and the colour of the sky

[Reserved: scattering by bound charges below resonance, with $\sigma \propto \omega^4 \propto \lambda^{-4}$ from the driven-oscillator polarizability [181]; Rayleigh's later demonstration that the molecules of the air themselves suffice, so the blue of the sky needs no dust [286]; the fluctuation account that explains why a dense but uniform medium does not scatter at all [361]; the measured evidence — the spectrum of skylight, its strong polarization at 90 degrees from the Sun, and the reddening of the setting Sun.]

Phenomenon 65.4 (The colour and polarization of the sky)**.** The light of a clear daytime sky arrives from every direction and not merely from the Sun, and it is blue: measured against the solar spectrum it is enriched at short wavelengths in a ratio that rises steeply towards the violet, the scattering coefficient of the air varying as the inverse fourth power of the wavelength [181]. The same light is strongly polarized, most strongly along the great circle 90 degrees from the Sun. The molecules of the air suffice to produce the whole effect; no suspended dust is required, and the observed brightness agrees with what the known number of molecules gives [286]. The setting Sun is red for the complementary reason: the short wavelengths have been scattered out of the long atmospheric path.

Derivation. A molecule is not a free charge but a bound one, and well below its resonances the field of the wave induces a dipole moment $\boldsymbol{p} = \alpha \boldsymbol{E}$ with a polarizability α that is very nearly constant in frequency — this is the same low-frequency limit of the oscillator response that makes the static permittivity of a gas frequency-independent. Its second derivative is not constant: for $\boldsymbol{E} \propto \mathrm{e}^{-\mathrm{i}\omega t}$, $\ddot{\boldsymbol{p}} = -\omega^2 \alpha \boldsymbol{E}$. Feeding this into the dipole form of the Larmor formula, $P = \langle \ddot{p}^2 \rangle / 6\pi\epsilon_0 c^3$, and dividing by the incident irradiance $I = \epsilon_0 c \langle E^2 \rangle$ as in Equation (65.7),

$$\sigma = \frac{\omega^4 \alpha^2}{6\pi\epsilon_0^2 c^4} \propto \omega^4 \propto \frac{1}{\lambda^4} \,. \tag{65.8}$$

The whole of the colour is in the two time derivatives, each contributing one power of ω to the amplitude and hence two to the cross-section: an oscillating dipole radiates in proportion to its *acceleration*, not its displacement. Numerically, blue light near 450 nm is scattered some four times more strongly than red near 650 nm, which is the observed ratio.

The polarization follows from the $\sin^2\theta$ pattern of Phenomenon 65.1. The induced dipole lies in the plane transverse to the incident ray, so an observer looking at right angles to the beam sees only the dipole component perpendicular to the plane containing the incident and scattered rays — the other component points at the observer and radiates nothing that way. The scattered light is therefore completely polarized at 90 degrees for an ideal dipole scatterer, and strongly but not completely polarized in the real sky, where multiple scattering and molecular anisotropy dilute it. □

65.6.3 Mie scattering

[Reserved: the exact solution for a homogeneous sphere of arbitrary size and refractive index [345]; the crossover from the Rayleigh regime to the size-independent, colour-neutral regime that makes clouds and fog white; forward-peaked scattering, the resonances of the series, and their use in aerosol sizing and lidar; the connection to the boundary-value machinery of Chapter 62.]

65.6.4 Where the classical account fails: Compton scattering

[Reserved: the measured wavelength shift $\Delta\lambda = \frac{h}{m_e c}(1-\cos\theta)$ [499], which classical scattering forbids outright since a driven charge re-radiates at the driving frequency; the Klein–Nishina cross-section that replaces Thomson's at photon energies approaching $m_e c^2$ [630]; the statement of the boundary — Thomson scattering is the low-energy limit of a quantum process — with the experiment itself treated in Chapter 69 and the theory in Chapter 100.]

Phenomenon 65.5 (The Compton shift)**.** X-rays scattered from light elements contain, besides radiation of the incident wavelength, a component of *longer* wavelength. The shift grows with the scattering angle, vanishing in the forward direction and reaching its maximum on backscattering, and it depends on nothing else: not on the incident wavelength, and not on the scattering material [499]. Its measured value is

$$\Delta\lambda = \frac{h}{m_e c}\,(1-\cos\theta)\,, \qquad \frac{h}{m_e c} = 2.426\times10^{-12}\,\mathrm{m}\,, \tag{65.9}$$

the constant being the Compton wavelength of the electron [2392]. Classical scattering forbids the effect outright: a charge driven at frequency ω re-radiates at ω, so the scattered wavelength must equal the incident one at every angle.

Derivation. The derivation is not classical, and that is its content. Treat the radiation as quanta of energy hc/λ and momentum h/λ, and let one of them strike an electron of mass m_e at rest, scattering through θ while the electron recoils with momentum $\boldsymbol{p}_e$ and energy E_e. Momentum conservation, squared, gives

$$p_e^2 = \frac{h^2}{\lambda^2} + \frac{h^2}{\lambda'^2} - \frac{2h^2}{\lambda\lambda'}\cos\theta\,, \tag{65.10}$$

and energy conservation gives $E_e = m_e c^2 + hc\,(1/\lambda - 1/\lambda')$. Substituting both into the relativistic relation $E_e^2 = p_e^2 c^2 + m_e^2 c^4$ of Chapter 40, the terms in $m_e^2 c^4$ cancel, as do the terms in $h^2c^2\,(1/\lambda^2 + 1/\lambda'^2)$, and what remains is

$$2m_e c^3 h\left(\frac{1}{\lambda} - \frac{1}{\lambda'}\right) = \frac{2h^2c^2}{\lambda\lambda'}\,(1-\cos\theta)\,. \tag{65.11}$$

Writing $1/\lambda - 1/\lambda' = (\lambda'-\lambda)/\lambda\lambda'$, the factor $\lambda\lambda'$ cancels from both sides and Equation (65.9) follows immediately, with $\Delta\lambda = \lambda' - \lambda$.

Every step used conservation of energy and momentum and nothing else. What it did *not* use is any property of the electron beyond its mass, which is why the shift is independent of the material; and what it *did* use is that the radiation carries energy and momentum in localized quanta with $E = pc$, which classical electrodynamics does not provide. The classical result is recovered where the quantum of energy is negligible against $m_e c^2$: there $\Delta\lambda/\lambda \to 0$, the shift disappears, and the cross-section returns to Thomson's Equation (65.5). □

65.7 Radiation from relativistic charges and in matter

65.7.1 Synchrotron radiation

[Reserved: emission by a charge on a circular orbit, worked out classically by Schott [392] long before it was seen; the critical frequency $\omega_c \simeq \frac{3}{2}\gamma^3 c/\rho$, the broad power-law spectrum below it, the γ^4 energy loss per turn and the linear polarization in the orbital plane; the first direct observation, in the General Electric 70 MeV synchrotron [900]; the two consequences that matter — synchrotron light sources as instruments, and synchrotron emission as the diagnostic of relativistic electrons in cosmic magnetic fields (Chapters 66 and 115).]

Phenomenon 65.6 (Synchrotron radiation)**.** Electrons circulating at relativistic energy in a magnetic field emit light that was first seen directly, as an intense spot on the orbit visible through the glass wall of the vacuum chamber of a 70 MeV machine [900]. The emission is not confined to the orbital frequency and its low harmonics, as a non-relativistic calculation would have it: it is spread over an enormous range of harmonics up to a critical frequency far above the orbital one, it is collimated into a narrow cone tangent to the orbit so that a fixed detector sees a brief flash once per turn, and it is linearly polarized in the plane of the orbit. The energy lost per turn grows very steeply with the electron energy, which is the practical limit on circular electron accelerators and the reason such machines are also the brightest laboratory light sources.

Derivation pending #33

Synchrotron radiation: derive the emission of a charge on a circular orbit at arbitrary speed from the acceleration field and the relativistic generalization of the Larmor formula, obtaining the forward collimation into a cone whose half-angle is the reciprocal of the Lorentz factor, the critical frequency proportional to the cube of that factor divided by the orbit radius, the power-law spectrum below it, the energy radiated per turn, and the degree and sense of the polarization.

65.7.2 Bremsstrahlung

[Reserved: radiation emitted when a charge is deflected in the Coulomb field of a nucleus; the classical impact-parameter treatment and Kramers' spectrum for the continuous X-ray background of a tube [503], with its sharp short-wavelength cutoff at the electron kinetic energy — a quantum feature no classical calculation gives; the Bethe–Heitler cross-section and the radiation length [732]; screening; thermal bremsstrahlung as the X-ray emission of hot plasmas (Chapter 66).]

65.7.3 Cherenkov radiation

[Reserved: the faint blue light emitted by a charge moving faster than the phase velocity of light in a medium, discovered and characterized by Cherenkov [735] after Vavilov's suggestion that it was not fluorescence [749]; the Frank–Tamm theory [792] with the cone condition $\cos\theta_c = 1/n\beta$ and the emitted energy per unit path and unit frequency $\propto (1 - 1/\beta^2 n^2)$; the threshold as a velocity measurement, which is what makes ring-imaging Cherenkov detectors and the water tanks of Chapter 114 work.]

Phenomenon 65.7 (Cherenkov radiation)**.** A fast charged particle traversing a transparent medium makes it glow with a faint blue light. The light is not fluorescence: it is undiminished by quenching agents that suppress fluorescence, it appears in every pure liquid tested, and — decisively — it is not emitted isotropically but along a cone about the particle's track,

sharply directed forward, and polarized in the plane containing the track and the direction of emission [735]. The half-angle of the cone is fixed by the speed of the particle and the refractive index of the medium,

$$\cos\theta_c = \frac{1}{n\beta}\,, \qquad \beta = \frac{v}{c}\,, \tag{65.12}$$

and there is a sharp threshold: no light at all unless $\beta > 1/n$ [792]. Measuring the cone angle therefore measures the speed of the particle directly.

Derivation. The medium is polarized by the passing charge and relaxes behind it, so that each point of the track acts as a momentary source of a wavelet spreading at the phase speed c/n. Consider the wavelet emitted at the moment the particle passes a point O, and the position of the particle a time t later. The wavelet has expanded to a sphere of radius ct/n about O, while the particle has advanced a distance $vt = \beta ct$ along the track. When $\beta n > 1$ the particle has outrun its own wavelets, and the spheres emitted at all earlier points of the track possess a common tangent cone with apex at the particle: the wavelets add in phase on that cone and cancel elsewhere. Its half-angle θ_c, measured from the track, satisfies

$$\cos\theta_c = \frac{ct/n}{\beta ct} = \frac{1}{n\beta}\,, \tag{65.13}$$

which is Equation (65.12), the ratio being independent of t so that the construction is consistent along the whole track.

The threshold is contained in the same formula: a cosine cannot exceed unity, so a real cone exists only for $n\beta \geq 1$, and at $n\beta = 1$ it degenerates to $\theta_c = 0$, the light being emitted straight ahead. Nothing here is peculiar to electrodynamics — it is the construction that gives the Mach cone of a supersonic body — and nothing in it violates relativity, since what is exceeded is the phase speed of light in the medium and never c. □

65.7.4 Transition radiation

[Reserved: radiation emitted when a charge crosses a boundary between media of different permittivity, predicted by Ginzburg and Frank [890]; the total energy proportional to γ, which is what makes transition-radiation detectors the standard particle-identification tool at high γ; foil stacks and the X-ray yield; used by the detectors of Chapter 115.]

Chapter 66

Plasmas and Magnetohydrodynamics

Almost all the visible matter in the universe is plasma: an ionized gas in which the long-range Coulomb interaction, rather than binary collisions, organizes the motion. The name is Langmuir's, and so is the first quantitative study of the collective oscillation that distinguishes the state [611, 639]. This chapter is where the field theory of Chapters 60 and 64 meets the many-body mechanics of Chapter 55 and the continuum dynamics of Chapter 31: the fields move the charges, the charges are the sources of the fields, and the closure of that loop produces behaviour that neither theory shows alone — screening [501], collective oscillation at the plasma frequency, collisionless damping [891], and a fluid that carries its own magnetic field frozen into it [865].

The chapter is placed at the end of Part VII because it is applied classical electrodynamics, and it is placed before the quantum parts because nothing in it needs $\hbar$. Its evidence base is unusually broad and unusually direct: laboratory measurements of Landau damping [1290] and of Alfvén waves in liquid metal [939]; spacecraft in the solar wind whose existence Parker predicted from a hydrodynamic argument [1156] and Mariner II confirmed [1239]; magnetometers inside a reconnecting current sheet [2268]; a laboratory dynamo [1989]; and fusion devices measured against a criterion written down in 1957 [1120] and finally exceeded in inertial confinement [2423]. Standard monographs are [951, 1242].

Derivation pending #34

Plasmas and Magnetohydrodynamics: all derivations of this chapter are pending.

66.1 The plasma state

66.1.1 Ionization equilibrium

[Reserved: the Saha equation for the degree of thermal ionization [470], derived from the chemical equilibrium of Chapter 118; the sharpness of the transition from neutral gas to plasma at temperatures well below the ionization potential; non-thermal ionization by radiation and by impact; the worked cases this treatise needs — the solar photosphere and chromosphere (Chapter 52), the terrestrial ionosphere, and a laboratory discharge.]

66.1.2 Debye screening and the plasma parameter

[Reserved: the screened potential $\varphi \propto \mathrm{e}^{-r/\lambda_D}/r$ with $\lambda_D = \sqrt{\epsilon_0 k_B T/nq^2}$, transferred from the electrolyte theory of Debye and Hückel [501]; the plasma parameter $\Lambda = n\lambda_D^3$ and the definition of a plasma as a medium with $\Lambda \gg 1$, so that collective effects dominate binary

collisions; numerical values — $\lambda_D \approx 74\,\mu\mathrm{m}$ for a fusion plasma at $1 \times 10^{20}/\mathrm{m}^3$ and $10\,\mathrm{keV}$, and metres in the solar wind; the Coulomb logarithm $\ln\Lambda$ that will appear in every transport coefficient of Section 66.3.4.]

66.1.3 Quasi-neutrality and the plasma frequency

[Reserved: quasi-neutrality as a consequence of screening rather than an assumption, valid on scales above λ_D; the restoring force of a rigid charge displacement and the electron plasma frequency $\omega_p = \sqrt{nq_e^2/\epsilon_0 m_e}$, i.e. $f_p \approx 8.98\sqrt{n}$ hertz with n in inverse cubic metres, identified experimentally by Langmuir [611] and analysed with Tonks [639]; the three defining conditions of the plasma state (many particles per Debye sphere, system size above λ_D, collision time above $1/\omega_p$).]

Phenomenon 66.1 (Collective oscillation at the plasma frequency)**.** An ionized gas does not respond to a disturbance the way a neutral gas does. Probed in a discharge, the electrons are found to oscillate collectively at a frequency fixed by their number density alone — not by the wavelength of the disturbance, not by the gas species, not by the geometry of the vessel, and, at long wavelength, not by the temperature [611, 639]. The frequency is

$$\omega_p = \sqrt{\frac{nq_e^2}{\epsilon_0 m_e}}\,, \tag{66.1}$$

and it is this collective response, rather than any property of the individual collisions, that makes the ionized gas a distinct state of matter.

Derivation. Consider a slab of plasma and displace every electron rigidly through a small distance x along the slab normal, leaving the much heavier ions in place. The displacement uncovers a layer of positive charge on one face and deposits a layer of negative charge on the other, of surface density $\pm nq_e x$, and a pair of such sheets produces a uniform field between them of magnitude

$$E = \frac{n\,|q_e|\,x}{\epsilon_0}\,, \tag{66.2}$$

directed so as to pull the electrons back. The equation of motion of each electron is then

$$m_e \ddot{x} = -\,|q_e|\,E = -\frac{nq_e^2}{\epsilon_0}x\,, \tag{66.3}$$

which is simple harmonic motion at exactly the frequency Equation (66.1). Three features of the observation are already in this one line. The frequency does not depend on the amplitude, because the restoring force is linear in the displacement; it does not depend on the wavelength, because no gradient of anything entered — the correction that does introduce one comes from the thermal pressure and is the Bohm–Gross term of Section 66.2.1; and it depends on the ion mass not at all, the ions serving only as a stationary neutralizing background.

The same ω_p governs the transparency of metals and the reflection of radio waves treated in Chapter 62, and evaluating Equation (66.1) with the CODATA values of the electron charge and mass [2392] gives the working form $f_p = \omega_p/2\pi \approx 8.98\sqrt{n}$ hertz with n in inverse cubic metres. □

66.1.4 Where plasmas are found

[Reserved: the parameter map in density and temperature, all in SI, spanning the interstellar medium, the solar corona and wind, the ionosphere, laboratory discharges, tokamak and inertial-fusion plasmas, and the degenerate interiors of Chapter 49; the direct evidence for

each — the ionospheric reflection of radio waves demonstrated by Appleton and Barnett [517], and the Zeeman splitting that showed sunspots to be strongly magnetized [342], which is the founding observation of astrophysical magnetism.]

Phenomenon 66.2 (Sunspots are strongly magnetized)**.** Spectral lines formed in a sunspot are split into components whose separation is measurable with a grating spectrograph, and whose polarization is the signature that identifies the splitting as magnetic: viewed along the field the outer components are circularly polarized with opposite handedness, viewed across it they are linearly polarized. The splitting is absent in the surrounding photosphere and largest at the darkest part of the spot. The inferred field strengths are of order a tenth of a tesla, thousands of times the field at the Earth's surface [342]. This is the first measurement of a magnetic field outside the Earth, and it is the observation on which the whole of astrophysical magnetism rests.

Derivation. The inference from a measured splitting to a field strength needs only the classical theory of a bound electron in a magnetic field. Let the electron be bound isotropically with natural frequency ω_0 and place the field along z. Writing the transverse displacement as the complex combination $u = x + \mathrm{i}y$, the equation of motion $m_e\ddot{\boldsymbol{r}} = -m_e\omega_0^2\boldsymbol{r} + q_e\dot{\boldsymbol{r}} \times \boldsymbol{B}$ becomes

$$\ddot{u} + \mathrm{i}\frac{q_e B}{m_e}\dot{u} + \omega_0^2 u = 0\,, \tag{66.4}$$

and substituting $u = \mathrm{e}^{-\mathrm{i}\omega t}$ gives $\omega^2 - (q_e B/m_e)\,\omega - \omega_0^2 = 0$. For fields weak enough that $|q_e|\,B/m_e \ll \omega_0$ — which holds by many orders of magnitude for optical lines in any attainable field — the two roots are

$$\omega \simeq \pm\omega_0 + \frac{q_e B}{2m_e}\,, \qquad |\Delta\omega| = \frac{|q_e|\,B}{2m_e}\,. \tag{66.5}$$

The two transverse modes are circular motions of opposite sense, shifted up and down by $|\Delta\omega|$; the third mode, along z, feels no magnetic force and is unshifted. Hence a triplet, with the outer components circularly polarized when the line of sight is along $\boldsymbol{B}$ and linearly polarized when it is across — which is exactly the polarization pattern that identifies the effect and, with it, the direction of the field. Inverting Equation (66.5),

$$B = \frac{4\pi m_e}{|q_e|}\,\Delta\nu = \frac{4\pi m_e c}{|q_e|\,\lambda^2}\,\Delta\lambda\,, \tag{66.6}$$

so a splitting measured in metres of wavelength returns a field in tesla. The classical account is not the whole story — real lines split into patterns richer than a triplet, for reasons that are quantum and belong to the atomic chapters — but the magnitude, and therefore the inferred field, is the classical one. □

66.2 Waves in a plasma

66.2.1 Langmuir waves

[Reserved: electrostatic electron oscillations, their near-dispersionless character at long wavelength, and the Bohm–Gross correction $\omega^2 = \omega_p^2 + 3k^2v_{th}^2$ from thermal pressure [925]; the standing puzzle that the fluid treatment gives no damping at all, resolved kinetically in Section 66.3.2; the observation of these waves as the electron-plasma oscillations first reported in [611, 639].]

66.2.2 Electromagnetic waves and the cutoff

[Reserved: the transverse dispersion relation $\omega^2 = \omega_p^2 + c^2k^2$, the cutoff at ω_p below which the plasma reflects, and the resulting refractive index below unity, whose consequences for phase and group velocity connect to Chapter 62; the ionospheric application, with f_p of order 9 MHz for $n \approx 1 \times 10^{12}/\mathrm{m}^3$, which is why long-distance short-wave radio works and why satellite links must exceed the cutoff [517]; interferometry and cutoff reflectometry as plasma density diagnostics.]

Phenomenon 66.3 (The ionosphere reflects radio waves below a critical frequency)**.** Radio waves directed upwards return to the ground if their frequency is below a critical value and are lost into space if it is above. The returning wave was identified as such by beating it against the ground wave and varying the transmitter frequency: the resulting fringes give the difference in path length, and hence the height of the reflecting layer, which is found to lie of order a hundred kilometres above the ground and to change between day and night [517]. The critical frequency is not a property of the apparatus but of the medium, and it varies with the hour, the season and the solar cycle. There is therefore a permanent ionized layer in the upper atmosphere, and the critical frequency measures its electron density.

Derivation. The reflection itself is the free-carrier cutoff derived in Chapter 62: a wave of angular frequency ω in a medium of free electrons obeys $\omega^2 = \omega_p^2 + c^2k^2$, so k is imaginary and the wave cannot propagate wherever $\omega < \omega_p$. A wave sent upwards into a layer whose density increases with height therefore travels freely until it reaches the level at which ω_p has risen to ω, and is returned from there — so the reflection height depends on the frequency, and the highest frequency returned at vertical incidence is the plasma frequency of the densest part of the layer.

What makes this a measurement is the numerical size of Equation (66.1). Evaluating it with the CODATA electron charge and mass [2392],

$$f_p = \frac{1}{2\pi}\sqrt{\frac{nq_e^2}{\epsilon_0 m_e}} \approx 8.98\sqrt{n}\ \mathrm{Hz}\,, \tag{66.7}$$

with n in inverse cubic metres; so a critical frequency of a few megahertz corresponds to an electron density of order $10^{12}/\mathrm{m}^3$, which is what the ionosphere has. The inverse statement is the diagnostic: sweeping the transmitter frequency and recording the echo delay returns the density as a function of height, and the same principle, applied at much higher frequency, is cutoff reflectometry in a laboratory plasma. □

66.2.3 Magnetized waves and ion-acoustic waves

[Reserved: propagation across and along a background field, the ordinary and extraordinary modes, cyclotron resonances at $\omega_c = qB/m$, Faraday rotation as a measurement of the line integral of $n_e B_\parallel$ used throughout radio astronomy; the ion-acoustic mode with speed $\sqrt{k_B T_e/m_i}$, sustained by electron pressure and ion inertia, and its Landau damping when $T_e \sim T_i$; the classification of the many modes as a warning that "the plasma dispersion relation" is a family, not a formula [1242].]

66.3 Kinetic theory and Landau damping

66.3.1 The Vlasov equation

[Reserved: the collisionless kinetic equation for $f(\boldsymbol{x}, \boldsymbol{v}, t)$ with the self-consistent field [823], its standing as the leading term of the BBGKY hierarchy of Chapter 55, and the sense in which it is a mean-field rather than an exact description; its conservation laws and the

infinity of Casimir invariants; the Jeans-type equilibria that any function of the constants of motion provides.]

66.3.2 Landau damping

[Reserved: Landau's solution of the initial-value problem by Laplace transform and the contour prescription that produces a damping rate for a wave in a collisionless medium [891]; the damping proportional to $\partial f/\partial v$ at the phase velocity, and the resonant-particle reading (particles slightly slower than the wave gain energy, slightly faster ones lose it); the inverse effect — growth on an inverted distribution — as the bump-on-tail instability; why this is not thermodynamically irreversible, the entropy being carried into fine velocity-space structure, with echo experiments as the evidence.]

66.3.3 The observation

[Reserved: Malmberg and Wharton's measurement of the spatial damping of electron plasma waves in a collisionless column, with the measured damping length agreeing with Landau's prediction over more than a decade in wavenumber [1290]; the plasma-wave echo as the direct demonstration that the information is not lost; and the methodological point that a purely mathematical prescription for a contour was confirmed as physics eighteen years after it was written.]

Phenomenon 66.4 (Waves damp in a collisionless plasma)**.** An electron plasma wave launched into a column so tenuous that a particle crosses it many times between collisions is nevertheless damped, and damped strongly. The damping is spatial and exponential, its rate depends on the wavenumber, and it persists as the collision frequency is reduced — so it is not a collisional effect at all. The measured damping length agrees with the collisionless prediction over more than a decade in wavenumber [1290], confirming an analysis that had been produced eighteen years earlier from a contour prescription in a Laplace transform [891]. A dissipative process therefore occurs in a system whose equations of motion are exactly time-reversible and conserve entropy.

Derivation pending #35

Landau damping: solve the linearized Vlasov–Poisson initial-value problem by Laplace transform, analytically continue the dielectric function below the real axis to obtain the correct prescription for the singularity at the phase velocity, and derive the damping rate proportional to the slope of the distribution function there. Then give the resonant-particle reading — particles slightly slower than the wave gain energy and slightly faster ones lose it, and a Maxwellian has more of the former — and explain why the process is not thermodynamically irreversible, the information being carried into fine structure in velocity space and recoverable as a plasma-wave echo.

66.3.4 Collisions and transport

[Reserved: the Fokker–Planck description of small-angle Coulomb scattering with the Rosenbluth potentials [1129]; the $T^{3/2}$ scaling and the Spitzer resistivity [1027], from which a fusion-grade plasma is a better conductor than copper; collisional relaxation times and their ordering $\tau_{ee} < \tau_{ii} < \tau_{ie}$; the full transport coefficients — resistivity, viscosity, thermal conduction, all anisotropic in a magnetic field — as tabulated by Braginskii [1303], connecting to Chapter 124.]

66.4 Single-particle motion

66.4.1 Gyration and the guiding centre

[Reserved: the helical orbit in a uniform field, the gyrofrequency and gyroradius in SI, and the guiding-centre expansion in the small parameter ρ_L/L [951]; the separation of fast gyration from slow drift as an averaging procedure of the kind used in Chapter 32; the limits of the expansion where the field varies on the gyroradius scale.]

66.4.2 Drifts

[Reserved: the $\boldsymbol{E}\times\boldsymbol{B}$ drift, charge- and mass-independent and therefore not a current; the grad-B, curvature and polarization drifts, which are charge dependent and do drive currents; the resulting ring current and the diamagnetism of a plasma; worked numbers for the magnetosphere; the general statement that a drift is a force divided by qB crossed with $\hat{\boldsymbol{b}}$ [951, 1242].]

66.4.3 Adiabatic invariants and magnetic mirrors

[Reserved: the magnetic moment $\mu = mv_\perp^2/2B$ as an adiabatic invariant in the exact sense of Chapter 23, together with the longitudinal and flux invariants; magnetic mirroring, the loss cone and its opening angle; the mirror machine as a confinement scheme and its failure modes; the observational confirmation in the trapped radiation belts discovered by Van Allen [1176], whose particle populations are the loss-cone distribution made visible.]

Phenomenon 66.5 (Magnetic trapping: the radiation belts)**.** Geiger counters carried above the atmosphere found, instead of the expected slow decline of the cosmic-ray rate, counting rates rising by orders of magnitude in two toroidal regions encircling the Earth [1176]. The particles are not passing through: they are trapped, bouncing along the field lines between turning points in the two hemispheres on time scales of a second, and the belts persist indefinitely although nothing material confines them. What confines them is the geometry of the field, and the confinement is incomplete in a definite way — particles whose velocity is too nearly parallel to the field are not turned back and are lost into the atmosphere at the foot of the line, which is why the trapped distributions are empty inside a cone in velocity space.

Derivation. A particle gyrating in a field that varies slowly over one gyroradius and one gyroperiod conserves its magnetic moment

$$\mu = \frac{mv_\perp^2}{2B}\,, \tag{66.8}$$

as an adiabatic invariant. A static magnetic field does no work, so the speed v is constant as well. Writing the pitch angle α by $v_\perp = v\sin\alpha$, constancy of μ and of v gives

$$\frac{\sin^2\alpha}{B} = \text{constant along the orbit}\,. \tag{66.9}$$

As the particle moves into a region of stronger field, $\sin^2\alpha$ must rise in proportion; when it reaches unity the velocity is entirely perpendicular, the parallel motion has stopped, and the particle is reflected. Starting from a field B_0 with pitch angle α_0, the mirror point is therefore where

$$B_m = \frac{B_0}{\sin^2\alpha_0}\,. \tag{66.10}$$

A dipole field grows towards its poles, so every particle whose B_m lies below the field at the top of the atmosphere turns around before reaching it and is trapped, bouncing between the conjugate mirror points — which is the observed configuration.

Equation (66.10) also fixes what escapes. If $B_{\max}$ is the field at the atmospheric foot of the line, the particles lost are those with

$$\sin^2 \alpha_0 < \frac{B_0}{B_{\max}}\,, \tag{66.11}$$

a cone about the field direction whose half-angle depends only on the ratio of the two field strengths and not at all on the particle's charge, mass or energy. That is the loss cone, and its emptiness in the measured distributions is the signature that the trapping mechanism is this one and no other. The same argument, with $B_{\max}$ set by a coil rather than by the Earth, is the magnetic mirror as a laboratory confinement scheme — and Equation (66.11) is equally the statement of why that scheme leaks. □

66.4.4 Fermi acceleration

[Reserved: stochastic energy gain from collisions with moving magnetic irregularities [929], the second-order $(v/c)^2$ mechanism and its first-order diffusive-shock refinement; the power-law spectrum produced, and its match to the observed cosmic-ray spectrum treated in Chapter 115; the same mechanism as the origin of the relativistic electrons whose synchrotron emission is discussed in Chapter 65.]

66.5 Magnetohydrodynamics

66.5.1 The MHD equations and their validity

[Reserved: the one-fluid equations obtained by taking moments of the kinetic equation and eliminating the displacement current — mass continuity, the momentum equation with the $\boldsymbol{J}\times\boldsymbol{B}$ force, an Ohm's law, and the induction equation [951, 1303]; the ordering assumptions (slow compared with ω_p and ω_c, large compared with λ_D and ρ_L, non-relativistic); the closure problem and the standard ideal, resistive and Hall variants; the decomposition of the Lorentz force into magnetic pressure $B^2/2\mu_0$ and tension.]

66.5.2 Flux freezing and the magnetic Reynolds number

[Reserved: Alfvén's theorem that in a perfectly conducting fluid the magnetic flux through any comoving surface is constant, so field lines are material lines [865]; the induction equation as advection plus diffusion, with the magnetic Reynolds number $R_m = UL/\eta_m$ measuring their ratio; the enormous values of R_m in astrophysics and the consequence that field topology is conserved except in thin layers — which is the whole subject of Section 66.6.1.]

66.5.3 Alfvén and magnetosonic waves

[Reserved: the transverse wave on a field line with speed $v_A = B/\sqrt{\mu_0\rho}$, predicted by Alfvén [865] against considerable scepticism; the fast and slow magnetosonic modes and the Friedrichs diagram of their anisotropic phase speeds; the first laboratory detection, in liquid mercury [939]; and the ubiquitous detection in the solar wind and the magnetosphere, where Alfvénic fluctuations dominate the turbulent spectrum.]

Phenomenon 66.6 (Alfvén waves)**.** A conducting fluid threaded by a magnetic field supports a transverse wave that ordinary hydrodynamics does not have: the field lines

behave as stretched strings, and a displacement propagates along them at

$$v_A = \frac{B}{\sqrt{\mu_0 \rho}}\,, \tag{66.12}$$

independent of the wavelength and of the amplitude, with the fluid velocity and the field perturbation transverse to the background field and correlated with one another. The mode was predicted before it was seen [865], first detected in liquid mercury in a strong magnet [939], and is now measured continuously by spacecraft in the solar wind, where fluctuations of exactly this character dominate the turbulent spectrum.

Derivation pending #36

Alfvén waves: linearize the ideal magnetohydrodynamic equations about a uniform field and a uniform density, retaining the tension part of the Lorentz force, and obtain the transverse mode propagating along the field at the speed above, together with the fast and slow magnetosonic modes and their anisotropic phase speeds. The tension reading should be derived as well — the magnetic force decomposed into a pressure and a tension along the field lines, whence the wave speed is the tension divided by the mass per unit length in exactly the form of a wave on a string.

66.5.4 Equilibria and the pinch

[Reserved: magnetostatic equilibrium $\boldsymbol{J} \times \boldsymbol{B} = \nabla p$, force-free fields, and the plasma beta as the ratio of kinetic to magnetic pressure; the Bennett relation for a self-pinching current channel [731]; the Grad–Shafranov equation for axisymmetric equilibria [1149] and the flux-surface geometry of a tokamak; the safety factor and the equilibria that Section 66.7 will test for stability.]

66.6 Magnetic reconnection

66.6.1 The Sweet–Parker layer

[Reserved: the problem stated — ideal MHD conserves topology, yet solar flares release magnetic energy in minutes; Sweet's neutral point [1163] and Parker's quantitative current-sheet model [1125], giving a reconnection rate scaling as $R_m^{-1/2}$; the arithmetic showing that this rate is still orders of magnitude too slow for a flare, which is the reason the subject did not end in 1958.]

66.6.2 Petschek and fast reconnection

[Reserved: Petschek's slow-shock geometry with a much shorter diffusion region and a rate scaling only as $1/\ln R_m$ [1293]; the objection that the configuration is not sustained with uniform resistivity; the modern resolutions — plasmoid instability of thin sheets, and collisionless Hall and kinetic terms in Ohm's law; the honest statement that the rate problem is settled observationally before it is settled theoretically.]

66.6.3 Reconnection observed

[Reserved: Dungey's open magnetosphere, in which dayside reconnection with the interplanetary field drives the whole convection cycle and the aurora [1203]; in situ measurement of the electron diffusion region by the four Magnetospheric Multiscale spacecraft, resolving the non-ideal electric field and the energy conversion directly [2268]; solar flares and coronal

mass ejections as the large-scale case; laboratory reconnection experiments; the quantities to tabulate are the reconnection rate, the layer thickness and the partition of released energy.]

Phenomenon 66.7 (Magnetic reconnection)**.** Magnetic field topology, which ideal magnetohydrodynamics conserves exactly, is observed to change. The evidence is of three kinds. Solar flares release in minutes an amount of magnetic energy that took days to accumulate, and do so in configurations where oppositely directed fields have been pushed together. The whole convection cycle of the magnetosphere, and with it the aurora, switches on when the interplanetary field turns southward and off when it turns northward — a dependence on the *direction* of the external field that makes sense only if the two field systems join [1203]. And four spacecraft flying in formation through the dayside boundary traversed an electron diffusion region directly, measuring there an electric field that no ideal Ohm's law permits, together with the crescent-shaped electron distributions and the conversion of electromagnetic energy into particle energy that accompany it [2268]. The ideal description therefore fails, and it fails in thin layers while remaining excellent everywhere else.

Derivation pending #37

Magnetic reconnection: derive the Sweet–Parker current sheet from mass and flux conservation across a resistive layer, obtaining a reconnection rate scaling as the inverse square root of the magnetic Reynolds number, and show by substituting coronal values that this rate is orders of magnitude too slow for a flare. Then derive Petschek's slow-shock geometry with its much weaker logarithmic dependence, and state honestly which of the modern resolutions — plasmoid instability of thin sheets, or the collisionless Hall and pressure-tensor terms in Ohm's law — the measurements support.

66.7 Instabilities and turbulence

66.7.1 Ideal MHD instabilities

[Reserved: the interchange or flute mode as the magnetic analogue of the Rayleigh–Taylor instability [221]; kink and sausage modes of a current channel and the Kruskal–Schwarzschild analysis [1046]; the Kruskal–Shafranov limit on the safety factor; the energy principle that decides linear stability from the sign of a quadratic form [1135], which is the Hamiltonian stability criterion of Chapter 22 in field form.]

66.7.2 Microinstabilities and turbulence

[Reserved: velocity-space free energy driving the two-stream and Buneman instabilities [1138] and the drift-wave family; anomalous transport as the practical consequence, since observed confinement times fall far below the collisional predictions of Section 66.3.4; MHD turbulence, its anisotropic cascade and the measured spectra in the solar wind, connecting to the general turbulence discussion of Chapter 31.]

66.8 Fusion and confinement

66.8.1 The Lawson criterion

[Reserved: Lawson's power balance between fusion output, bremsstrahlung loss and the energy invested in heating, giving a condition on $n\tau_E$ [1120]; the modern triple-product form $nT\tau_E$ and the ignition condition when alpha heating suffices; numerical targets for

deuterium–tritium, with $n\tau_E \gtrsim 1 \times 10^{20}\,\mathrm{s/m^3}$ at about 10 keV; the input cross-sections come from Chapter 107, and the bremsstrahlung loss from Chapter 65.]

66.8.2 Magnetic confinement

[Reserved: the tokamak and stellarator as the two solutions to the rotational-transform problem posed by Section 66.5.4; confinement scaling laws as empirical relations rather than theory; heating and current drive; the deuterium–tritium campaigns of JET, with 16 MW of fusion power and a measured gain below unity [1977]; what remains between that and a reactor, stated without advocacy.]

66.8.3 Inertial confinement and ignition

[Reserved: compression of a fuel capsule by laser ablation, the ρR criterion as the inertial form of Lawson's condition, and the hydrodynamic instabilities that limit compression; the National Ignition Facility result of target gain above unity — fusion yield exceeding the laser energy delivered to the target [2423] — with the precise statement of what is and is not included in that ratio, since the distinction between target gain and wall-plug gain is where most public confusion lives.]

66.9 Space and astrophysical plasmas

66.9.1 The solar wind

[Reserved: Biermann's inference from the anti-solar direction of comet ion tails that a continuous corpuscular stream must exist [976]; Parker's hydrodynamic solution showing that a hot corona cannot be in hydrostatic equilibrium and must expand supersonically [1156], with the transonic critical point; the confirmation by Mariner II, which measured a continuous flow at 400 km/s [1239]; the Parker spiral geometry of the interplanetary field; the quantities to tabulate — speed, density, temperature and field strength at 1 astronomical unit.]

Phenomenon 66.8 (The solar wind)**.** The Sun's atmosphere does not stay bound to it. A continuous supersonic stream of ionized gas flows outward past the Earth and beyond. Three independent observations establish it. The ion tails of comets point almost directly away from the Sun whatever the comet's own motion, and respond to solar activity within about a day — which radiation pressure alone cannot produce and a corpuscular stream can [976]. A corona at the observed temperature cannot be in hydrostatic equilibrium against the low pressure of the interstellar medium, and must instead expand, passing through a critical point to supersonic speed [1156]. And a spacecraft carrying a plasma analyser on the way to Venus measured the flow directly and continuously — never absent over months — at speeds of order 400 km/s [1239].

Derivation pending #38

The solar wind: derive Parker's transonic solution. Integrate the steady, spherically symmetric momentum equation for an isothermal corona in the Sun's gravitational field, exhibit the critical point at which the flow speed equals the sound speed, show that of the family of solutions only the transonic branch matches both a subsonic base and a vanishing pressure at large distance, and obtain the asymptotic speed. The contrasting hydrostatic solution must be shown to leave a finite pressure at infinity, which is the argument that rules it out.

66.9.2 The magnetosphere

[Reserved: the bow shock, magnetopause and magnetotail as the solution of the solar wind's encounter with a dipole; Dungey convection [1203]; the trapped belts [1176]; substorms and the aurora as the visible end of the chain; geomagnetic storms as a measured, dated phenomenon with technological consequences.]

66.9.3 The dynamo

[Reserved: the question posed by Larmor — how a rotating body can maintain a magnetic field against ohmic decay [460]; Cowling's anti-dynamo theorem forbidding a strictly axisymmetric solution [717], which is why the subject is hard; Parker's cyclonic α-effect and mean-field dynamo [1078]; the solar cycle and its polarity reversal as the observational anchor, resting on Hale's sunspot magnetograms [342]; the geodynamo, its numerical demonstration with a simulated reversal [1900], and the decisive laboratory evidence from the Riga liquid-sodium experiment, where a self-sustaining field eigenmode grew from a purely hydrodynamic flow [1989].]

Chapter 67

Experiment: Wave Optics

This chapter is the evidence for Chapter 61. It collects the measurements that established, quantitatively and against a competing theory of equal standing, that light is a wave: Young's two-slit fringes and the first wavelength measurements [48, 49]; Fresnel's prize memoir on diffraction with the bright spot at the centre of a circular shadow that Poisson produced as a refutation and Arago found [78]; the Fresnel–Arago laws, whose failure of two perpendicularly polarized beams to interfere forced the conclusion that the vibration is transverse [63, 90]; the ruled grating turned from a curiosity into the primary instrument of wavelength metrology by Fraunhofer [69, 74] and Rowland [222]; and the interferometers, from Michelson's [236] through his stellar beam interferometer [469, 479] to the kilometre-scale instruments of Chapter 47.

Two of these experiments are shared with other chapters and are treated here only for their optics: Fizeau's moving-water measurement [133] and the Michelson–Morley null result [236] are read as interferometry here, and read as evidence about the aether and about relativity in Chapter 37. The chapter closes with the modern repetitions, which is where the classical account runs out: the same two-slit pattern builds up one particle at a time, for photons [360, 1774], for electrons [1212, 1826] and for molecules [1966] — a result that belongs to Parts VIII and IX and is stated here only to mark precisely where wave optics stops being the whole story. When written out, every experiment below will use the structured `experiment` environment, with apparatus, procedure, observations (numbers and uncertainties in SI units), interpretation and primary references given in full. The standard modern reference for the theory being tested is [1967].

Derivation pending #39

Experiment: Wave Optics: all derivations of this chapter are pending.

67.1 The predictions under test

67.1.1 Two accounts of light

[Reserved: the state of the question about 1800. On one side the emission theory of [18], which explains rectilinear propagation and reflection immediately, refraction by an increase of speed in the denser medium, and colour by particle species; on the other the wave account of [15] with its secondary wavelets, which explains refraction by a decrease of speed and gives double refraction in calcite. The prior anomaly both had to face is Grimaldi's diffraction — light bending into the geometrical shadow of a small obstacle [8] — and Newton's own rings [18], periodic in a way no particle account made natural.]

67.1.2 What separates them

[Reserved: the discriminating predictions, stated before any apparatus. Only a wave theory predicts (i) fringes whose spacing scales as $\lambda D/d$ and vanishes when either slit is blocked, (ii) a bright point at the exact centre of the shadow of a circular obstacle, (iii) a speed of light lower *in the denser medium, measured by Foucault and treated in Chapter 61, and (iv) a diffraction limit on the resolving power of every instrument. The transversality of the vibration is not predicted by either and is forced by the polarization data of Section 67.4.]*

67.2 Young: the double slit (1801–1804)

67.2.1 Apparatus and procedure

[Reserved: Young's arrangement — sunlight admitted through a pinhole in a window shutter, a narrow card or a pair of slits splitting the beam, and the fringe pattern received on a screen or observed with a lens [49]; the coherence requirement met by the common source, which is why the pinhole cannot simply be widened; the slit separation, slit-to-screen distance and fringe spacing as the three lengths that must be measured, all in metres; the later, cleaner realizations that removed the finite source size — Fresnel's biprism and mirrors [78] and Lloyd's single-mirror geometry [102], which adds the extra half-wave of reflection.]

67.2.2 Observations

[Reserved: the table to be given — slit separation d, screen distance D and measured fringe spacing Δy with uncertainties, and the wavelength inferred from $\lambda = d\,\Delta y/D$; Young's own values, about 700 nm *at the red end and* 420 nm *at the violet end, to be compared with the modern sodium doublet at* 589.3 nm*; the disappearance of the pattern when either slit is covered; and the checks that the spacing is proportional to D and inversely proportional to d [49].]*

Phenomenon 67.1 (The wavelength of light is a measurable length)**.** The two-slit pattern turns light into a measurable length. Three quantities are read with a scale — the separation d of the apertures, the distance D to the screen, and the spacing Δy of the fringes — and they return a wavelength. The values so obtained run from about 700 nm at the red end of the visible spectrum to about 420 nm at the violet end [49], which is why colour is a physical variable and not merely a sensation. Two checks establish that the reading is what it is claimed to be: the fringe spacing is found proportional to D and inversely proportional to d, as it must be if it is a path-difference effect, and the pattern vanishes entirely when either aperture is covered [48, 49].

Derivation. The theory being used is the two-beam superposition of Chapter 61, which gives a fringe spacing $\lambda D/d$ for $d \ll D$. What the experiment needs is that relation inverted,

$$\lambda = \frac{d\,\Delta y}{D}\,, \tag{67.1}$$

in which every quantity on the right is a length measured with a scale, so the wavelength is obtained without any optical constant, any calibration against another wavelength, or any assumption about the speed of light.

The error budget follows from Equation (67.1) by taking logarithms and differentiating, which turns a product into a sum of relative uncertainties combining in quadrature:

$$\frac{u(\lambda)}{\lambda} = \sqrt{\left(\frac{u(d)}{d}\right)^2 + \left(\frac{u(\Delta y)}{\Delta y}\right)^2 + \left(\frac{u(D)}{D}\right)^2}\,. \tag{67.2}$$

The dominant term is the fringe spacing, which is the smallest of the three lengths, and the standard remedy is in the geometry of the apparatus rather than in the instrument: measure across N fringes and divide, which divides the relative uncertainty of Δy by N while leaving the other two terms alone. This is the reason the two-slit determination remains respectable although each individual reading is crude. □

67.2.3 Interpretation

[Reserved: the general law of interference as Young stated it [48] — superposition of two disturbances from a common source with a path difference — and the inference that light adds amplitudes, not intensities, so that light plus light can give darkness; why no emission theory accommodates this; the residual objections of the period (the finite width of the fringes, the "inflection" account) and what answered them; the theory tested lives in Chapter 61.]

67.3 Fresnel and the Poisson–Arago spot (1818–1819)

67.3.1 Apparatus and procedure

[Reserved: the prize memoir's apparatus [78] — a point source, an opaque circular disc a few millimetres across, and a screen at a distance of order a metre, with fringe positions read on a micrometer; the requirement of a smooth circular edge, which is what makes the null prediction sharp; Fresnel's own half-period zone construction, combining Huygens' wavelets with Young's interference, and the integral form of it given in Chapter 61.]

67.3.2 Observations

[Reserved: the bright point at the exact centre of the shadow of the disc, with an on-axis intensity equal to the unobstructed value for an ideal disc; the measured radii of the external and internal fringes of a straight edge and of the disc, compared point by point with Fresnel's integrals; the tabulated quantities are fringe positions in metres against source and screen distances, with the wavelength as the fitted parameter [78].]

67.3.3 Interpretation

[Reserved: the episode's methodological content, which is why it is in this treatise. Poisson derived the central bright spot from Fresnel's own theory as a reductio; Arago performed the observation and found it; the prediction was therefore made by an opponent and confirmed — the cleanest instance in classical physics of a theory surviving a test designed to kill it [78]. The quantitative content is that the diffraction integral, not merely the qualitative idea of waves, is correct.]

67.4 The Fresnel–Arago laws and transversality

67.4.1 Apparatus and procedure

[Reserved: polarizers by reflection at the Brewster angle [58] and by double refraction in calcite; the two-slit or biprism interference arrangement of Section 67.2.1 with an independently controllable polarization in each arm; the analyser and the photometric comparison method; Malus's original apparatus for the $\cos^2$ *law [54].]*

67.4.2 Observations

[Reserved: the four Fresnel–Arago laws as measured statements [63] — two beams polarized at right angles never interfere; two beams polarized in the same plane interfere as unpolarized light does; two beams from perpendicularly polarized components of unpolarized light do not interfere even when brought to a common polarization; and they do if they derive from a single polarized beam. Alongside them, the transmitted intensity $I = I_0 \cos^2\theta$ [54] and the polarizing angle $\tan\theta_B = n$ [58], both with tabulated angles and intensities and their uncertainties.]

Phenomenon 67.2 (Perpendicularly polarized beams do not interfere)**.** Two beams derived from a common source and superposed do not always produce fringes. If they are linearly polarized at right angles to one another, no fringes appear at any path difference whatever: the screen shows only the sum of the two intensities. If they are polarized in the same plane, they interfere exactly as unpolarized light does. Two beams obtained as the perpendicularly polarized components of unpolarized light do not interfere even after being brought back to a common plane of polarization — but two beams obtained the same way from a single *polarized* beam do [63]. These four statements are measured facts, and taken together they force a conclusion about the nature of the disturbance that no amount of interference data alone could give.

Derivation. What a screen records is the time-averaged square of the total disturbance. If the two beams contribute $\boldsymbol{E}_1$ and $\boldsymbol{E}_2$ at a point,

$$I \propto \left\langle |\boldsymbol{E}_1 + \boldsymbol{E}_2|^2 \right\rangle = \left\langle E_1^2 \right\rangle + \left\langle E_2^2 \right\rangle + 2\left\langle \boldsymbol{E}_1 \cdot \boldsymbol{E}_2 \right\rangle , \tag{67.3}$$

and all the interference lives in the last term. It is a scalar product, so it vanishes identically — at every path difference, for every amplitude — whenever the two disturbances are orthogonal as vectors. That is the first law, and with it the second: parallel disturbances give the full cross term back.

The conclusion about transversality is now forced. A longitudinal disturbance in a beam has exactly one direction available to it, along the ray, so two beams travelling together could never be orthogonal and the first law could never be observed. The observation therefore requires the disturbance to lie in the plane perpendicular to the propagation direction, where two independent directions exist — and it requires nothing else, which is what makes the inference so strong.

The third and fourth laws add the second ingredient, coherence. The cross term in Equation (67.3) survives averaging only if the phase relation between the two beams is steady. In unpolarized light the two transverse components carry no fixed phase relation, so $\langle \boldsymbol{E}_1 \cdot \boldsymbol{E}_2 \rangle$ averages to zero however the polarizations are afterwards rotated into alignment; in a polarized beam they do carry one, and the fringes return. □

67.4.3 Interpretation

[Reserved: the inference, drawn by Young and by Fresnel, that the vibration is transverse to the propagation direction, since a longitudinal disturbance has no plane to be at right angles to; the amplitude theory of reflection built on it [90], whose quantitative predictions are the Fresnel coefficients of Chapter 61; the cost to the mechanical aether, which must then be a solid, feeding Chapter 37; and the later mechanical demonstration that a circularly polarized beam carries angular momentum [767], which the transverse-wave account of Chapter 64 predicts quantitatively.]

67.5 Diffraction gratings and wavelength metrology

67.5.1 Fraunhofer's gratings

[Reserved: the wire and ruled gratings with which Fraunhofer turned diffraction into measurement [69, 74]: the grating equation $d(\sin\theta_m - \sin\theta_i) = m\lambda$, the first absolute wavelength determinations, and their attachment to the dark lines of the solar spectrum he had catalogued [60], so that a line acquires a number in metres rather than a letter. The apparatus, the angle measurement with a theodolite, and the resulting wavelengths with uncertainties are the content of this section; the spectroscopy they founded is Chapter 70.]

Phenomenon 67.3 (The grating turns a wavelength into an angle)**.** A screen ruled with a large number of equally spaced parallel apertures does not merely spread light: it concentrates it into a set of sharp orders at angles that depend on the wavelength, and the orders grow sharper — not merely brighter — as more rulings are illuminated. The angles obey

$$d\,(\sin\theta_m - \sin\theta_i) = m\lambda\,, \qquad m \in \mathbb{Z}\,, \tag{67.4}$$

with d the ruling interval and θ_i, θ_m the angles of incidence and diffraction from the normal. Since d is a mechanical length and θ_m is read on a divided circle, the wavelength that results is *absolute* [69]. Applied to the fixed dark lines of the solar spectrum [60], this replaces the letters by which those lines were labelled with numbers in metres.

Derivation. Take a plane wave incident at θ_i on a row of apertures spaced by d, and look in the direction θ_m. Two adjacent apertures are reached by wavefronts whose paths differ by $d\sin\theta_i$ on the incoming side, and the paths from them to a distant point in the direction θ_m differ by $d\sin\theta_m$; the net path difference between the contributions of neighbouring apertures is therefore $d(\sin\theta_m - \sin\theta_i)$, the same for every neighbouring pair. All N contributions arrive in phase exactly when that difference is a whole number of wavelengths, which is Equation (67.4).

The sharpening with N is the part that makes the instrument. Away from an order, the N contributions have phases in arithmetic progression with common difference $\delta = 2\pi(\sin\theta_m - \sin\theta_i)d/\lambda$, and their sum is a geometric series whose magnitude is $|\sin(N\delta/2)/\sin(\delta/2)|$. This has principal maxima of height N where Equation (67.4) holds, and its first zero at $N\delta/2 = \pi$: the angular width of an order therefore falls as $1/N$ while its height rises as N. That is why a grating with many thousands of rulings separates lines that a prism merely displaces, and it is the origin of the resolving power measured in Section 67.5.3. □

67.5.2 Rowland's ruling engine and concave grating

[Reserved: the screw-driven ruling engine and the concave grating that made the spectrograph a precision instrument [222]; line densities of order 600 *per millimetre over apertures of order* 0.1 m *(Rowland's specifications were quoted in lines per inch and are converted here, per the SI rule of the front matter); periodic-error "ghosts" as the signature of an imperfect screw, and the Rowland circle geometry that removes the need for collimating optics; the resulting solar wavelength tables, which were the working standard for decades.]*

67.5.3 Resolving power measured

[Reserved: the chromatic resolving power $\lambda/\Delta\lambda = mN$ of a grating and its verification on known doublets, the sodium pair being the standard test object; the Rayleigh criterion as the convention used to state it [209]; the imaging counterpart, Abbe's diffraction limit $d = \lambda/2n\sin\alpha$ for a microscope [184], with the measured demonstration that no improvement in lens quality passes it; the honest statement that this bound constrains linear *imaging only, which is what Section 67.9.3 exploits.]*

Phenomenon 67.4 (There is a diffraction limit, and it is measured)**.** Resolution is bounded by the wave nature of light and not by the quality of the optics. A grating separates two wavelengths only if they are further apart than a definite fraction of the wavelength, the limit rising in proportion to the order and to the number of illuminated rulings and to nothing else [209]; the sodium doublet is the standard test object on which this is checked. In imaging the same bound appears as a smallest resolvable separation, of the order of the wavelength divided by twice the numerical aperture, and it is reached in practice: beyond that point improving a lens changes nothing, which is a measured statement about real microscopes and not a theoretical caution [184].

Derivation pending #40

The diffraction limit: derive the chromatic resolving power of a grating from the angular width of an order — the wavelength divided by the order times the number of rulings — using the N-aperture sum and the convention that two lines are resolved when the maximum of one falls on the first zero of the other. Then derive the imaging bound from the requirement that at least two diffracted orders from a periodic object be collected by the objective, which gives the smallest resolvable period as the wavelength divided by twice the numerical aperture, and state the hypotheses — linearity in the illumination, far-field collection — on which the bound depends.

67.5.4 The same experiment with X-rays

[Reserved: a crystal as a three-dimensional grating with spacing of order $0.1\,\mathrm{nm}$*, and the Laue photographs that demonstrated both the wave nature of X-rays and the periodicity of crystals in a single exposure [385]; the geometry, the observed spot patterns and the wavelengths inferred; the crystallography that follows belongs to Chapter 125, and the same diffraction argument applied to matter waves is Section 67.9.2.]*

67.6 Interferometry

67.6.1 The Michelson interferometer

[Reserved: the beam-splitter geometry, the compensating plate, and the stone float on mercury that isolated it from vibration [236]; fringe counting as a length measurement in units of $\lambda/2$*; the coherence-length limitation set by the source, which is why the arms had to be near-equal before lasers; the sensitivity estimate in metres per fringe, which is the number that makes the null result of Chapter 37 meaningful.]*

67.6.2 The metre in wavelengths of light

[Reserved: Michelson and Benoit's determination of the international prototype metre in wavelengths of the red cadmium line, 1 *metre* $= 1\,553\,163.5$ *wavelengths, obtained by a chain of étalons each twice the previous [266]; the error budget of that chain; the consequence that a length standard could in principle be reproduced anywhere, realized in the successive SI definitions and superseded by the fixed value of* c *[2333]; the modern chain runs through the frequency measurements of Chapter 90.]*

Phenomenon 67.5 (A spectral line is a reproducible standard of length)**.** The wavelength of light emitted by a specified atomic transition is the same everywhere and at every time, so it can serve as a unit of length that no artefact is needed to embody. The international prototype metre was expressed in such units by counting interference fringes through a chain

of étalons, each twice the length of the one before, and the result — 1 metre = 1 553 163.5 wavelengths of the red cadmium line — was reproducible to a few parts in 10^7 [266]. A material standard could therefore in principle be dispensed with, which is what the successive redefinitions of the SI metre eventually did [2333].

Derivation. In a two-beam interferometer the two arms are traversed twice, so displacing one mirror through a distance x changes the optical path difference by $2x$. The intensity at the output returns to the same value each time that difference increases by one wavelength, so the number N of fringes counted while the mirror moves is

$$N = \frac{2x}{\lambda}, \qquad \text{that is} \qquad x = N\,\frac{\lambda}{2}. \tag{67.5}$$

A length is thereby converted into an integer plus a measured fraction, and the measurement is a *count*, which is why its precision is not limited by the resolution of any scale.

The chain of étalons is forced by the one quantity Equation (67.5) does not control. Fringes remain visible only while the path difference stays within the coherence length of the source, which even for a good spectral line falls far short of a metre — and a metre contains several million half-wavelengths, which cannot be counted in one pass. Each étalon is therefore compared with one of half its length by counting the fringes over the difference, and only the shortest is compared directly with the wavelength; the uncertainty of the whole chain is the accumulation of those successive comparisons, which is the error budget the experiment must present. □

67.6.3 Light in a moving medium

[Reserved: Fizeau's interferometer with counter-propagating beams in two tubes of flowing water [133]; the measured fringe shift, of order a fifth of a fringe for water at a few metres per second over path lengths of order a metre, and the drag coefficient $1 - 1/n^2$ extracted from it; the reading of the result as a wave-optics measurement here, with its relativistic reinterpretation as the velocity addition law reserved for Chapter 37.]

67.6.4 Rotation: the Sagnac effect

[Reserved: a closed interferometric loop on a turntable, in which counter-propagating beams acquire a phase difference proportional to the enclosed area and the rotation rate [410]; the measured fringe shift versus rotation rate; the modern descendants — ring-laser and fibre-optic gyroscopes with resolutions far below the Earth's rotation rate — and the statement that the effect is kinematic and common to every wave, which is why it is not evidence about the aether.]

Phenomenon 67.6 (Rotation shifts the fringes: the Sagnac effect)**.** An interferometer whose two beams travel in opposite senses around a closed loop shows a fringe displacement when the whole apparatus is rotated in its own plane. The shift reverses with the sense of rotation, grows in proportion to the rotation rate and to the area enclosed by the loop, and requires no external reference of any kind — the instrument detects its own rotation while sealed [410]. In terms of the enclosed area A and the rotation rate Ω about the normal to the loop,

$$\Delta\varphi = \frac{8\pi A\Omega}{\lambda c}. \tag{67.6}$$

Modern ring-laser and fibre-optic gyroscopes built on this observation resolve rotation rates far below that of the Earth.

Derivation. Take the loop circular of radius R for simplicity, with the beam splitter fixed on it, and work in the non-rotating frame, in which the light travels at c in both senses. While a beam goes round, the splitter itself moves: the co-rotating beam must cover the circumference plus the distance the splitter has advanced, and the counter-rotating beam the circumference minus it. Their transit times therefore satisfy $ct_{\pm} = 2\pi R \pm \Omega R\, t_{\pm}$, so

$$t_{\pm} = \frac{2\pi R}{c \mp \Omega R}, \qquad \Delta t = t_{+} - t_{-} = \frac{4\pi R^{2}\Omega}{c^{2} - \Omega^{2}R^{2}} \simeq \frac{4A\Omega}{c^{2}}, \tag{67.7}$$

with $A = \pi R^{2}$ and $\Omega R \ll c$ in any practicable instrument. Multiplying by the angular frequency $\omega = 2\pi c/\lambda$ converts the time difference into the phase difference Equation (67.6).

Two things are worth reading off the derivation. Nothing in it refers to a medium: the same argument, with c replaced by the appropriate propagation speed, applies to sound and to matter waves, which is why the effect is kinematic and is *not* evidence for or against an aether — a point on which the original interpretation was mistaken. And the result depends on the enclosed area rather than on the shape of the loop or the position of the axis, which is what makes a coiled optical fibre of many turns a practical gyroscope: N turns multiply A, and therefore the signal, by N. □

67.7 Stellar interferometry

67.7.1 Michelson's beam interferometer

[Reserved: the method of measuring an angular diameter from the baseline at which the fringe visibility first vanishes [469], and its execution on the 2.5 m *Mount Wilson telescope with an outrigger beam of about* 6.1 m *(the original specification was in feet and is converted here); the measured angular diameter of* α *Orionis,* 2.3×10^{-7} *radians — about* 47 *milliarcseconds — the first measurement of the size of a star [479]; the visibility-versus-baseline curve as the observable, and the van Cittert–Zernike coherence theory behind it [736, 826], developed in Chapter 61.]*

67.7.2 Intensity interferometry

[Reserved: Hanbury Brown and Twiss's measurement of the angular diameter of Sirius by correlating intensity fluctuations at two separated detectors rather than amplitudes [1083], which is insensitive to atmospheric phase and so allows long baselines; the measured 3.3×10^{-8} *radians, about* 6.9 *milliarcseconds; and the controversy the result provoked, since photon correlations are exactly the observable that Chapter 122 shows to distinguish classical from non-classical light — the experiment is the origin of quantum optics and is cross-referenced there.]*

67.8 Gabor: holography and the recording of phase (1948, 1962)

Every measurement in this chapter so far has been a measurement of intensity, because that is all a photographic plate, a photocell or a retina can report: a square-law detector integrates the square of the field, and the phase of the wave that reached it is nowhere in the record. An image is what survives that loss, and it is very much less than the wave was. Gabor's proposal was to stop discarding the phase [913]. Superpose the wave scattered by an object on a mutually coherent reference wave *before* the detector, and the phase difference between them becomes the position of a fringe — an intensity, which a plate can record.

The developed plate then holds the whole wave, amplitude and phase together, whence the name; and re-illuminating it releases that wave again.

The immediate aim was not three-dimensional pictures. Gabor wanted to correct the spherical aberration of the electron microscope, which no electron lens of the period could be made free of, by recording the aberrated electron wave and undoing the aberration afterwards, at leisure and optically, on the reconstruction [932]. That programme proved hard, and the light-optical demonstration built to test the principle carried a defect — a second, unwanted image superposed on the first — which kept the method a curiosity for fourteen years. Both obstacles fell when a coherent source became available [1186] and Leith and Upatnieks brought the reference wave in at an angle [1235, 1289], and, independently, when Denisyuk recorded the two waves running in opposite senses through a thick emulsion [1224]. The 1971 Nobel Prize in Physics was awarded to Gabor for the invention and development of the holographic method [1473].

67.8.1 Apparatus

Three arrangements, in the order in which they were built.

In-line. A high-pressure mercury arc filtered to a single line and imaged on a pinhole a few micrometres across, so that the illumination is spatially coherent across the plate. The object is a transparency carrying small opaque marks on a clear ground, standing in the diverging beam a short distance in front of a fine-grain photographic plate. In this geometry the part of the beam that passes undiffracted is the reference wave and the light scattered by the marks is the object wave; source, object and plate lie on one axis. That is not a choice but a constraint: the arc is coherent only over a short path difference, so the two interfering paths must be kept nearly equal, and the only way to keep them so is to let them travel together [932]. For reconstruction the developed plate is returned to a similar diverging beam with the object removed, and the emerging wave is examined with a microscope.

Off-axis. A laser beam divided by a beam splitter into two: one illuminates the object, the other is carried to the plate by mirrors and arrives there at an angle to the object wave. Two things follow from having a source coherent over metres rather than micrometres. The reference no longer has to share a path with the object wave, so it can be inclined; and the object may be a solid body at a working distance, illuminated diffusely, instead of a transparency held against the plate [1235, 1289]. The demands move to the emulsion and to the bench. The plate must resolve the fringes formed by two beams inclined at θ, of period $\lambda/\sin\theta$, which for visible light and an offset of a few tens of degrees is of order a micrometre, some thousand lines per millimetre — far beyond a pictorial emulsion. And nothing may move by an appreciable fraction of a wavelength while the exposure lasts, so the whole arrangement stands on an isolated table.

Counter-propagating. The reference beam enters the emulsion from the front and goes on to illuminate an object placed behind the plate; the light scattered back from the object returns through the emulsion against it. The emulsion is thick — many wavelengths — so that the standing wave the two beams form is recorded as a stack of fringe surfaces through its depth rather than as a pattern on its face [1224]. Nothing else is needed: one beam, no beam splitter, and no second path to be matched in length.

67.8.2 Procedure

The exposure is made with the object in place and both waves reaching the plate. The plate is developed so that its amplitude transmittance falls as nearly as possible linearly with the exposure it received: linearity of the photographic response is a hypothesis of the method and not an incidental convenience, and it is secured by working on the straight portion

of the characteristic curve of the emulsion and checked by repeating the record at several exposure levels.

Reconstruction is the same arrangement with the object taken away and the plate returned to where it stood, illuminated by the reference wave alone. What is observed is the wave emerging on the far side.

Four controls separate the effect from its alternatives.

- Expose with the reference blocked. The plate then records the intensity of the scattered light alone, develops to a featureless fog and reconstructs nothing: the record is made by the interference and not by the object light.
- Displace one mirror through a fraction of a wavelength during the exposure. The fringes wash out and the plate again reconstructs nothing, which locates the stored information in the fringe positions.
- Break the developed plate. Each fragment, illuminated alone, reconstructs the whole scene.
- Illuminate with a wave conjugate to the reference — the reference reversed. The emerging wave then converges instead of diverging and forms a real image in space, which can be received on a screen with no lens of any kind.

67.8.3 Observations and data

Gabor's reconstructions were legible: a transparency bearing the names of Huygens, Young and Fresnel was recorded and read back from the plate [932]. Superposed on every one of them, out of focus, lay a second image of the same object which no adjustment of the apparatus removed. The field was of the order of a millimetre across and the reconstruction had to be viewed with a microscope.

With the reference wave inclined, that second image is absent from the direction in which the reconstruction is viewed: the waves leaving the plate travel in distinguishable directions, and an eye placed in one of them receives only the reconstruction [1235]. With a laser and a diffusely illuminated solid scene the reconstruction shows the scene in depth [1289]. Two observations make that statement operational rather than impressionistic. Moving the eye across the plate changes the perspective continuously — near objects shift against far ones, and their hidden sides come into view — and a camera photographing the reconstruction must be refocused between the near and the far parts of the scene, each setting leaving the rest blurred. Neither is true of a photograph of the same scene.

The plate itself shows nothing. Under a microscope the record of a diffusely illuminated object is a fine irregular structure of fringes bearing no resemblance to the object: the scene is not stored anywhere in it as a picture, which is why a fragment can still deliver the whole of it.

The counter-propagating record reconstructs under ordinary white light, by reflection, and returns the object in the colour of the line that recorded it [1224]; tilting the plate away from the recording geometry shifts the reconstructed colour towards the blue. A processed emulsion may also contract, which shifts the colour the same way, so the two must be told apart before any colour is quoted.

Phenomenon 67.7 (An intensity record can give back a wavefront)**.** A wave scattered by an object and superposed at a photographic plate on a mutually coherent reference wave leaves a record which, re-illuminated by that reference wave alone, emits a wave agreeing with the original object wave in amplitude and in phase up to a single real constant. An observer looking through the plate sees the object where it stood, in depth and with parallax, although the object is absent and the plate carries no picture of it [913, 932, 1289]. Three

Table 67.1: The three recording geometries and what each one settles. All three record an interference pattern and reconstruct by diffraction from it, and all three are described by the same four terms of Equation (67.9); they differ only in where the reference wave comes from, and each difference buys one property that the previous arrangement lacked.

Arrangement	Reference wave	Decisive observation
In-line [913, 932]	the undiffracted part of the illuminating beam, on the same axis	a wavefront is recovered from an intensity record, with the conjugate wave superposed on it
Off-axis [1235, 1289]	a separate laser beam brought to the plate at an angle	the reconstructed waves separate in direction; a diffusely illuminated solid scene reconstructs with full parallax
Counter-propagating [1224]	the illuminating beam entering a thick emulsion from the opposite side	a volume record selects its own wavelength and reconstructs in white light

further waves leave the plate at the same time, one of them carrying the complex conjugate of the object wave.

Derivation. Let O and R be the complex amplitudes of the object and reference waves in the plane of the plate, both derived from one source and so mutually coherent. What the plate integrates is

$$I = |R + O|^2 = |R|^2 + |O|^2 + R^* O + R\,O^* \,, \tag{67.8}$$

of which the first two terms are the separate intensities and the last two are the interference. The phase of O has not been lost: it stands in Equation (67.8) as the phase of the cross terms relative to R, that is, as the position of the fringes, and a displacement of fringes is a difference of intensity from place to place, which is exactly what a square-law detector does record.

Develop the plate on the linear part of its characteristic, so that its amplitude transmittance is $t = t_0 - \beta I$ with t_0 and β real constants, and illuminate it with the reference wave alone. The transmitted field is

$$tR = \left(t_0 - \beta\,|R|^2\right) R - \beta\,|O|^2\,R - \beta\,|R|^2\,O - \beta R^2 O^* \,. \tag{67.9}$$

Four waves therefore leave the plate. The first is the reference wave attenuated; the second is that same wave modulated by the object's own intensity, a halo about it; the third and fourth are the interesting ones.

The third term is the assertion. For a uniform reference $|R|^2$ is a real constant over the plate, so this term is O itself multiplied by a number: every ray direction, every curvature and every relative phase of the original object wave is present in it unaltered. An eye or a lens placed in that wave receives exactly what it would have received from the object, and therefore sees the object.

The fourth term is the price. It carries O^*, the object wave with its phase reversed, which converges where O diverged and so forms a real image at the mirror position of the object; superposed on the reconstruction it is a second, unwanted image. It cannot be developed away, because Equation (67.8) is a real quantity and its two cross terms are complex conjugates of one another: no record of R^*O that a square-law detector is able to make omits $R\,O^*$. □

Phenomenon 67.8 (Inclining the reference separates the reconstruction)**.** In the in-line arrangement the four waves of Equation (67.9) travel in nearly the same direction, and the conjugate wave is seen superposed on the reconstruction as an out-of-focus ghost that no adjustment removes; it is present in every reconstruction reported from that geometry [932]. When the reference wave is brought in at an angle to the object wave the four leave the plate in different directions and may be looked at one at a time, so that the reconstruction is seen alone [1235]. The separation appears only above a threshold inclination, and the threshold grows with the angular extent of the object.

Derivation. Put the plate in the plane $z = 0$ and describe the object wave there by its angular spectrum in the plate coordinate x, supported in $|\nu| \le B$. The bound B is fixed by the angular extent of the object as seen from the plate, since a point of it lying at an angle φ from the axis contributes the spatial frequency $\sin\varphi/\lambda$. Let the reference be a plane wave inclined at θ in the same plane,

$$R = R_0\, \mathrm{e}^{2\pi \mathrm{i} \alpha x}\,, \qquad \alpha = \frac{\sin\theta}{\lambda}\,. \tag{67.10}$$

Multiplying a function by $\mathrm{e}^{2\pi\mathrm{i}\alpha x}$ translates its spectrum by α, so the four terms of Equation (67.9) occupy four bands of spatial frequency. The attenuated reference is a single line at $\nu = \alpha$. The halo carries $|O|^2$, an autocorrelation and hence of width $2B$, on the same carrier: it fills $|\nu - \alpha| \le 2B$. The reconstruction carries O with no carrier at all and fills $|\nu| \le B$. The conjugate carries O^* on the doubled carrier R^2 and fills $|\nu - 2\alpha| \le B$.

The reconstruction is free of the others exactly when its band meets neither of theirs, which requires $\alpha - 2B > B$ from the halo and $2\alpha - B > \alpha + 2B$ from the conjugate. Both reduce to the same condition,

$$\frac{\sin\theta}{\lambda} > 3B\,. \tag{67.11}$$

Setting $\alpha = 0$ recovers the in-line case: all four bands are then centred on zero, they overlap whatever the object, and the ghost is unavoidable — which is the observation.

Two consequences are worth reading off Equation (67.11). The threshold is proportional to B and so to the angular extent of the object, so a larger object demands a more oblique reference; the separation is not free. And the fringe period the emulsion must resolve is $1/\alpha < 1/(3B)$, so the record demands of the emulsion a spatial frequency at least three times the highest the object itself presents. A plate good enough to photograph the object is therefore not good enough to hologram it, by a definite factor — which is why the method needed emulsions that ordinary photography never asked for. □

Phenomenon 67.9 (Every part of the plate records the whole scene)**.** A hologram of a diffusely illuminated scene is not an image of it; the developed plate shows only fine irregular fringes. Any fragment of it, illuminated by the reference wave alone, reconstructs the entire scene — at a coarser resolution and over a narrower range of viewing directions, but complete [1289]. The reconstruction is three-dimensional in the operational sense: moving the eye changes the perspective, and a camera must be refocused between the near and the far parts of the scene.

Derivation. Diffuse illumination is what makes the first statement true, and it is the only ingredient needed for it. A diffusing surface scatters into a wide cone, so light from every point of the object reaches every point of the plate; the plate is therefore not a plane of conjugate image points, as it would be behind a lens, but a surface each point of which carries a contribution from the whole object. Restricting attention to a fragment of width a removes no object point from the record.

What the fragment does remove is stated by the same wave theory that gave the diffraction limit of Phenomenon 67.4. On reconstruction the fragment is the aperture

through which the reconstructed wave passes, so it is the exit pupil of the reconstruction, and the angular resolution with which the scene is seen degrades to about λ/a. The range of directions from which the reconstruction can be viewed is the range that fragment subtends at the object, about a/z for a scene at distance z, so the parallax available shrinks in proportion to the fragment as well. Both are aperture losses; neither is a loss of scene, which is the asymmetry the observation reports.

The depth requires no separate argument. By Phenomenon 67.7 the reconstructed wave *is* the object wave, so it carries the curvature that the wave from each object point had when it arrived: a point at distance z_1 reconstructs as a wave diverging from z_1, and a point at z_2 as one diverging from z_2. An eye or a camera must accommodate separately on the two, and displacing the pupil across the wave changes which rays enter it, which is parallax. Depth in the reconstruction is not a rendering of depth; it is the same optical fact as depth in the scene. □

Phenomenon 67.10 (A volume record reconstructs in white light)**.** When the reference wave and the object wave traverse a thick emulsion in opposite senses, the developed plate reconstructs the object under ordinary white light — a filament lamp, or the sun — and returns it in the colour of the monochromatic light that recorded it; the reconstruction is seen by reflection, on the same side as the source [1224]. Tilting the plate away from the recording geometry moves the reconstructed colour towards the shorter wavelengths.

Derivation. Two plane waves of vacuum wavelength λ running in opposite senses along z in a medium of refractive index n superpose to a standing wave whose intensity varies as $\cos^2(knz)$ with $k = 2\pi/\lambda$. Its antinodes are planes separated by

$$\Lambda = \frac{\pi}{kn} = \frac{\lambda}{2n}\,, \tag{67.12}$$

and in an emulsion many wavelengths deep the development records not one fringe pattern on a surface but a stack of such planes through the volume: a set of weakly reflecting layers of period Λ.

Illuminate that stack with white light at normal incidence. Each layer returns a small reflected amplitude, and the reflections from successive layers differ in path by $2n\Lambda$, so they add in phase only for the wavelength λ' with $2n\Lambda = \lambda'$ — which by Equation (67.12) is $\lambda' = \lambda$, the recording wavelength. Every other wavelength present in the illumination is returned by successive layers with phases that spread over a full cycle within the depth of the emulsion, and cancels. The record selects its own recording wavelength out of a broadband source, so neither a filter nor a monochromatic lamp is needed to read it.

The tilt follows from the same condition taken at an angle ϑ inside the emulsion, where the path difference between successive layers is $2n\Lambda\cos\vartheta$ and therefore $\lambda' = \lambda\cos\vartheta < \lambda$: the reconstruction moves towards the blue, as observed. Any processing that contracts the emulsion reduces Λ and shifts the colour the same way, which is why the two have to be separated before a wavelength is reported. □

Derivation pending #41

Diffraction efficiency of a hologram: what fraction of the reconstructing beam is delivered into the reconstruction, derived for a thin absorption record and a thin phase record by expanding the transmittance of a sinusoidal grating, and for a thick phase record by the coupled-wave treatment in which two waves exchange energy under the Bragg condition. What has to be established is that only a volume record can send almost all of the incident light into a single order — which is what makes a white-light reflection hologram bright enough to look at — while the thin records are bounded well below that.

67.8.4 Interpretation

The result is about detectors, not about light. Nothing in the four phenomena above goes beyond the superposition principle of Section 67.2 and the diffraction theory of Section 67.5: a hologram is an interference pattern, and a reconstruction is diffraction from it. What the experiment settles is that the phase discarded by every intensity detector is not lost information about the world but recoverable information about the wave, and that a medium with no memory of the object's shape — a uniform emulsion — can be made to hold it. This is why the experiment belongs beside Young and Fresnel rather than among the modern repetitions of Section 67.9: it uses no quantum optics, the reconstruction is a classical field, and the derivations above apply to any wave for which a coherent reference can be arranged.

Three points of method are worth separating out.

First, the second image was not a defect of workmanship. The derivation of Phenomenon 67.7 shows that any real record of the interference contains both cross terms, so the conjugate wave is a consequence of using a square-law detector and could not have been removed by better plates or better alignment. It was removed instead by changing the geometry so that the two terms leave the plate in different directions — a solution in the space of the experiment rather than in the space of its components.

Second, the fourteen-year delay was a coherence limit and not a conceptual one. Equation (67.11) requires the reference to be inclined, and an inclined reference travels a path different from the object wave's; a source coherent only over a short path difference cannot supply one. Here the coherence theory of [736, 826] appears as a hard constraint on an apparatus: the visibility of the fringes that constitute the record is the mutual coherence of the two beams, and a record of zero visibility is no record at all. A hologram may be read, on this view, as a measurement of the mutual coherence function carried out at every point of the plate at once.

Third, holography does not evade the diffraction limit of Phenomenon 67.4, and it is worth saying why not, since it is often supposed to. The resolution of a reconstruction is set by the aperture of the plate exactly as the resolution of an image is set by the aperture of a lens — that is the fragment result of Phenomenon 67.9. What holography escapes is a different loss, the loss of phase, which is not an aperture effect at all. Gabor's own aim turned on precisely that distinction: an aberration is a phase error, so a recorded wavefront can have its aberration subtracted after the event, which is impossible once the intensity alone has been kept [932]. Carrying that programme out with electron waves proved harder than the light-optical demonstration and came later; the demonstration itself, and the method built on it, are what the prize recognised [1473].

67.8.5 Primary references

The proposal [913] and its full development with the in-line experiments [932]; the off-axis reference wave and its reading as a carrier-frequency communication problem [1235], and the laser reconstruction of diffusely illuminated solid objects [1289]; the counter-propagating volume record [1224], published as a note in the Doklady of the USSR Academy of Sciences and available in English translation in *Soviet Physics Doklady*; the source that made the off-axis geometry practicable [1186]; and Gabor's own retrospective account of the twenty-three years [1473]. The scalar diffraction theory used throughout is that of [1967], and the coherence theory invoked above is [736, 826].

67.9 Modern repetitions and precision

67.9.1 One photon at a time

[Reserved: Taylor's exposure of a diffraction pattern through smoked-glass attenuators over three months, with at most one photon in the apparatus at a time and no change in the pattern [360]; the modern version with a heralded single-photon source, an anticorrelation measurement at a beam splitter demonstrating particle behaviour and an interferometer demonstrating wave behaviour with the same *source [1774]; the quantities are the second-order correlation at zero delay and the fringe visibility, with their classical bounds stated explicitly; the theory is Chapter 122.]*

Phenomenon 67.11 (The pattern survives one quantum at a time)**.** The interference pattern does not require many quanta to be present together. Attenuated until at most one photon is in the apparatus at any moment, and exposed for months, a diffraction pattern comes out unchanged [360]; with a heralded single-photon source the same beam that shows particle-like anticorrelation at a beam splitter shows full-visibility fringes in an interferometer [1774]. The same holds for matter. Electrons sent one at a time through a biprism arrive as individual localized dots, apparently at random, and the accumulated dots build the fringe pattern [1826]; and molecules of some seven hundred atomic mass units show fringes at the de Broglie wavelength as well [1966]. The pattern is therefore a property of each quantum separately and not of the beam, and this is the precise point at which the wave account of this chapter stops being the whole story.

Derivation pending #42

Single-quantum interference: the derivation is quantum and belongs to the later parts. What must be shown here is negative and can be made precise — that no classical field theory reproduces the combination of a single localized detection with a fringe pattern of full visibility, since the second-order correlation at zero delay is bounded below by unity for any classical field, while the measured value for a heralded single photon falls well below it. The wave account of this chapter must therefore be read as the high-occupancy limit of something else.

67.9.2 Matter-wave double slits

[Reserved: Jönsson's electron interference through micro-ruled multiple slits [1212]; Tonomura's single-electron buildup, in which the pattern emerges dot by dot from a biprism [1826]; interference of C_{60} molecules [1966], molecules of 720 *atomic mass units showing the same fringes; the de Broglie wavelength inferred in each case and its comparison with h/p, which is the measurement rather than the illustration; the theory is Chapter 71.]*

67.9.3 Beyond the diffraction limit

[Reserved: why Abbe's bound [184] is not violated by stimulated-emission-depletion microscopy [1883] and its relatives — the imaging is nonlinear in the illumination, so the linear-optics theorem does not apply; near-field microscopy as the other route; the measured resolutions achieved, in nanometres; and the general lesson about the exact hypotheses a "fundamental limit" rests on.]

67.9.4 Interferometers as detectors

[Reserved: the line from Section 67.6.1 to the kilometre-scale, power-recycled, Fabry–Pérot-armed Michelson interferometers of Advanced LIGO [2243], whose measured strain sensitivity

of order 10^{-21} corresponds to a differential arm-length change of about $1 \times 10^{-18}\,\mathrm{m}$ — a fringe fraction of order 10^{-12} — and the first detection made with it [2264]; the noise budget (seismic, thermal, shot) as the modern form of Michelson's error analysis; the physics measured is Chapter 46 and the experiment proper is Chapter 47.]

Part VIII

The Transition to Quantum Physics

Chapter 68

Black-Body Radiation and Planck's Hypothesis

Heat a cavity, pierce it with a small hole, and the light that emerges has a spectrum fixed by the temperature alone — not by the material of the walls, not by their colour, not by the shape of the cavity. Kirchhoff proved this in 1860 [153] and thereby handed nineteenth-century physics a single universal function of frequency and temperature to compute. Thermodynamics and Maxwell's electrodynamics — the two most secure theories then available (Chapters 54 and 60) — between them fixed the integral of that function [211, 227], its behaviour under a change of temperature [259], and, empirically, its short-wavelength tail [272]. What they could not do was fix the function itself. Applied without reservation they returned a spectral density growing without bound at high frequency, and the divergence was no technical subtlety: it is the equipartition theorem of Chapter 55 applied to a system with infinitely many modes [296, 322].

This chapter opens Part VIII because the resolution — Planck's assumption of December 1900 that the energy exchanged between the cavity walls and a mode of frequency ν comes in elements $h\nu$ [295, 300] — is the first quantitative evidence for quantization found anywhere in nature, and because it was forced by measurement rather than by theory: the Reichsanstalt spectra of Lummer and Pringsheim [284] and the far-infrared points of Rubens and Kurlbaum [297] falsified Wien's distribution before any successor to it existed. The chapter then follows the new constant h out of the cavity: into the specific heats of solids [333, 382], into the statistics of indistinguishable quanta [509], and into the present-day SI, where its numerical value is fixed by definition [2333]. The photon itself is not here. Planck quantized the exchange and not the field, and said so; the light quantum belongs to Chapter 69.

Derivation pending #43

Black-Body Radiation and Planck's Hypothesis: all derivations of this chapter are pending.

68.1 Cavity radiation and Kirchhoff's theorem

68.1.1 Emissive and absorptive power

[Reserved: Kirchhoff's law of thermal radiation [153] — at thermal equilibrium the ratio of the emissive power to the absorptive power of any body is a universal function $K(\nu, T)$ of frequency and temperature. The proof is a thermodynamic one: two bodies exchanging radiation inside a common enclosure must not be able to drive a heat flow between equal temperatures, on pain of violating the second law of Chapter 54. Definition of a black body

as the limiting absorber, and Kirchhoff's own realization of it as a small aperture in a large isothermal cavity. Consequence: the spectrum of the aperture is a property of temperature alone, so a laboratory can measure a function of nature rather than of a material.]

Phenomenon 68.1 (Universality of cavity radiation)**.** The radiation emerging from a small aperture in an isothermal enclosure has a spectral distribution fixed by the temperature T and the frequency ν alone. It does not depend on the material of the walls, on their surface finish or colour, or on the size and shape of the cavity. Equivalently, for every body in equilibrium with that radiation the ratio of the spectral emissive power e_ν to the spectral absorptivity a_ν is one and the same universal function of frequency and temperature,

$$\frac{e_\nu(T)}{a_\nu(T)} = K(\nu, T)\,, \tag{68.1}$$

numerically equal to the emissive power of a perfect absorber [153].

Derivation. Place two bodies inside an evacuated enclosure whose walls are held at a common temperature T, and let them exchange energy only by radiation. Interpose a filter transmitting only a narrow band $\mathrm{d}\nu$ about ν; a filter is a passive optical element and can do no work, so equilibrium must hold in that band separately. Let I_ν be the spectral flux each body receives from the enclosure. Body j emits $e_\nu^{(j)}\mathrm{d}\nu$ and absorbs $a_\nu^{(j)} I_\nu \mathrm{d}\nu$; if the two were unequal the body would heat or cool while its surroundings stayed at T, so that heat would pass spontaneously between objects at the same temperature, which the second law of Chapter 54 forbids. Hence $e_\nu^{(j)} = a_\nu^{(j)} I_\nu$ for each body, and

$$\frac{e_\nu^{(1)}}{a_\nu^{(1)}} = \frac{e_\nu^{(2)}}{a_\nu^{(2)}} = I_\nu\,.$$

The two bodies were arbitrary, so the ratio is a function of ν and T only, which is Equation (68.1). Repeating the argument with two *cavities* at the same temperature, joined through the same narrow-band filter, shows that I_ν itself cannot depend on the walls: were the two fluxes unequal at any frequency, energy would flow in that band between enclosures at equal temperature. Finally a body with $a_\nu = 1$ at every frequency — a black body — emits exactly $K(\nu, T)$, so the universal function is realized by the aperture of any isothermal cavity, whatever it is made of. □

68.1.2 The cavity as a thermodynamic system

[Reserved: the electromagnetic field in a cavity treated as a thermodynamic body, with energy density $u(T)$, spectral density $u_\nu(\nu, T)$ and the relation $I = cu/4$ between energy density and the flux through the aperture. Radiation pressure $p = u/3$, obtained from the Maxwell stress tensor of Chapter 60 and used thermodynamically by Boltzmann [227] following Bartoli's cycle; the adiabatic invariance of ν/T under slow expansion of a perfectly reflecting cavity. The Maxwell relations that carry the argument are those of [1749], and the same system reappears as the photon gas of Chapter 120.]

68.2 What classical thermodynamics could settle

68.2.1 The Stefan–Boltzmann law

[Reserved: Stefan's empirical finding that the total radiated flux scales as the fourth power of the absolute temperature [211], extracted from Tyndall's platinum-wire data; Boltzmann's derivation of the same law from thermodynamics plus the radiation pressure $p = u/3$ [227], the first result in physics obtained by putting Maxwell's field through a Carnot cycle. The law

$I = \sigma T^4$ for a black body, and $I = \varepsilon\sigma T^4$ for a grey one; the Stefan–Boltzmann constant, which in the present SI is not measured but computed, $\sigma = 2\pi^5 k_B^4/15h^3c^2 = 5.670\,374\,419 \times 10^{-8}$ in SI units [2333, 2431]. Worked instances: effective temperatures of stars (Chapter 52) and the planetary equilibrium temperature.]

Phenomenon 68.2 (Stefan–Boltzmann law)**.** The total power radiated per unit area by a black surface, integrated over all frequencies, is proportional to the fourth power of its absolute temperature,

$$M = \sigma T^4 \,. \tag{68.2}$$

Stefan extracted the fourth power from Tyndall's measurements on heated platinum wire [211]; a body of emissivity $\varepsilon < 1$ radiates $\varepsilon\sigma T^4$. In the present SI the constant σ is no longer measured but computed from the defining constants: it is $5.670\,374\,419 \times 10^{-8}$ in SI units of watt per square metre per kelvin to the fourth power [2333, 2431].

Derivation. Treat the radiation filling an isothermal cavity as a thermodynamic fluid. By Phenomenon 68.1 its energy density u is a function of temperature alone, so $U = u(T)V$; take from Section 68.1.2 the isotropic radiation pressure $p = u/3$. For any simple system the energy equation of state reads

$$\left(\frac{\partial U}{\partial V}\right)_T = T\left(\frac{\partial p}{\partial T}\right)_V - p \,, \tag{68.3}$$

a Maxwell relation of Chapter 54. Its left side is u and its right side is $Tu'(T)/3 - u/3$, so

$$u = \frac{T}{3}\frac{\mathrm{d}u}{\mathrm{d}T} - \frac{u}{3} \qquad \Longrightarrow \qquad \frac{1}{u}\frac{\mathrm{d}u}{\mathrm{d}T} = \frac{4}{T} \,,$$

whose solution is $u = aT^4$ with a a constant of integration. The flux escaping through a small aperture is $M = cu/4$, the factor $\frac{1}{4}$ coming from averaging $c\cos\vartheta$ over the outward hemisphere, so $M = (ac/4)\,T^4$: this is Equation (68.2) with $\sigma = ac/4$. Thermodynamics fixes the exponent and leaves a undetermined. Only Phenomenon 68.5 computes it, and that it then agrees with the measured σ is the first quantitative success of the quantum hypothesis. □

68.2.2 Wien's displacement law

[Reserved: Wien's thermodynamic argument from the adiabatic compression of a cavity [259], which forces the universal function into the scaling form $u_\nu = \nu^3 f(\nu/T)$ without determining f. Corollaries: the wavelength of the maximum satisfies $\lambda_{\max}T = b$ with $b = 2.897\,771\,955 \times 10^{-3}\,\mathrm{m\,K}$, and the frequency of the maximum a different constant — the two maxima are not at the same place, because $u_\nu \mathrm{d}\nu$ and $u_\lambda \mathrm{d}\lambda$ are different densities, a point worth a remark since it is a standing source of error. Consistency of the scaling form with Section 68.2.1 on integration.]

Phenomenon 68.3 (Wien's displacement law)**.** The spectrum of a black body keeps its shape as the temperature is changed and merely slides along the wavelength axis: the wavelength at which the spectral radiance is greatest is inversely proportional to the absolute temperature,

$$\lambda_{\max}T = b \,, \tag{68.4}$$

where the constant b is $2.897\,771\,955 \times 10^{-3}\,\mathrm{m\,K}$ in the present SI [259, 2431]. This is why a body glows first dull red and then white as it is heated, and why the temperature of a furnace or of a star can be read from the colour of its continuum alone. The maximum of the *same* spectrum plotted against frequency lies at a different place and obeys a different constant, because $u_\nu \mathrm{d}\nu$ and $u_\lambda \mathrm{d}\lambda$ are densities with respect to different variables; the two maxima do not correspond.

Derivation pending #44

Wien's adiabatic argument: a slow compression of a perfectly reflecting cavity leaves the entropy unchanged while shifting every mode frequency, which forces the universal function of Kirchhoff's theorem into the scaling form given by ν cubed times a function of ν/T alone; and the maximisation of the corresponding wavelength density, which turns that scaling form into a fixed product of peak wavelength and temperature.

68.2.3 Wien's distribution law

[Reserved: Wien's 1896 distribution $u_\nu \propto \nu^3 \mathrm{e}^{-a\nu/T}$ [272], obtained from a Maxwell–Boltzmann analogy between emitting molecules and radiation rather than from thermodynamics, and therefore a guess of a different order from Section 68.2.2. Its excellent agreement with the visible and near-infrared measurements available before 1899, and its status until then as the accepted law. That it is the high-frequency limit of Planck's law is shown in Section 68.5.4, which is why its early success was not evidence of its truth.]

68.3 The classical field theory and its failure

68.3.1 Counting the modes of a cavity

[Reserved: the electromagnetic normal modes of a rectangular cavity with conducting walls, from the boundary-value problem of Chapter 61; the density of modes $8\pi\nu^2/c^3$ per unit volume per unit frequency, with the factor of two for the two transverse polarizations counted in Chapter 26. The result is independent of the shape of the cavity, by Weyl's asymptotic law for the eigenvalue counting function; the mode count is the same object that will reappear for phonons in Chapter 125 and for the free-particle density of states in Chapter 118.]

68.3.2 The Rayleigh–Jeans law

[Reserved: equipartition (Chapter 55) assigns $k_B T$ to each mode, giving $u_\nu = 8\pi\nu^2 k_B T/c^3$. Rayleigh's short note of June 1900 states the $\nu^2 T$ form and, doubting it at high frequency, inserts an exponential cut-off by hand [296]; Jeans supplies the correct numerical factor and argues the classical case in full [322]. Honest history: Rayleigh's factor was eight times too large and Jeans held for some years that the cavity was simply not in equilibrium, so "Rayleigh–Jeans law" names a result neither author asserted in the form now taught. The law agrees with the far infrared measurements of Section 68.4.3 to within their uncertainty.]

68.3.3 The ultraviolet catastrophe

[Reserved: the integral of the Rayleigh–Jeans density over frequency diverges, so a cavity at any temperature would hold infinite energy and no thermal equilibrium between matter and the field would exist. The name is Ehrenfest's [369], coined a decade after the fact, and the section should say so: the divergence played no part in Planck's reasoning and is a retrospective diagnosis. What is genuinely diagnosed is that the failure is not a failure of electrodynamics or of statistical mechanics separately, but of equipartition applied to a system with unboundedly many degrees of freedom — exactly the feature that returns as the ultraviolet divergences of Chapter 100.]

68.4 The measurements that decided the matter

68.4.1 Realizing a black body

[Reserved: the electrically heated cavity radiator built at the Physikalisch-Technische Reichsanstalt by Lummer and Kurlbaum [282], the first laboratory object whose emission could be claimed to be Kirchhoff's universal function; its use as the primary radiometric standard and the ancestry of present-day radiation thermometry (Chapter 2). Apparatus detail belongs here: aperture-to-cavity ratio, isothermality of the walls, bolometric and thermopile detection, and the calibration chain.]

68.4.2 Lummer–Pringsheim and the failure of Wien's law

[Reserved: the spectra measured by Lummer and Pringsheim between 300 K *and* 1650 K *[284] out to about* 8 µm*; systematic deviations from Wien's law [272] appearing at long wavelength and high temperature and growing beyond any plausible experimental error. This is the moment the accepted law died, and it died to data, not to an argument. The observations to be tabulated when written: wavelength, temperature, measured spectral radiance and its uncertainty, with the residual against both Wien and Planck.]*

68.4.3 Rubens–Kurlbaum in the far infrared

*[Reserved: the residual-ray (*Reststrahlen*) technique that isolated wavelengths of* 24 µm *and* 51.2 µm *by repeated reflection from fluorite and rock salt, and the finding of Rubens and Kurlbaum that at those wavelengths the radiance is proportional to T rather than to Wien's exponential [297]. Rubens communicated the result to Planck privately on 7 October 1900; the interpolation of Section 68.5.1 was written the same evening and read to the Physikalische Gesellschaft on 19 October. The chapter should be explicit that this is the causal link, since it is the clearest case in physics of a measurement dictating a formula.]*

Phenomenon 68.4 (Long-wavelength proportionality to temperature)**.** Far beyond the maximum of the spectrum the radiance of a black body is proportional to the absolute temperature itself, not to Wien's exponential in $1/T$. Rubens and Kurlbaum isolated 24 µm and 51.2 µm by repeated reflection from fluorite and rock salt and found the radiance at those wavelengths to follow T across the whole accessible range of furnace temperatures — a departure from the accepted distribution [272] far larger than any plausible experimental error [297]. Deviations of the same sign, smaller because the wavelengths were shorter, had already been reported between 300 K and 1650 K out to about 8 µm [284].

Derivation pending #45

The low-frequency limit of the cavity spectral density: that each mode carries the equipartition energy given by Boltzmann's constant times the temperature, so that the spectral density becomes proportional to the square of the frequency times the temperature, and the radiance at fixed long wavelength is therefore linear in T.

68.5 Planck's law

68.5.1 The interpolation of October 1900

[Reserved: Planck's route through the entropy of an oscillator rather than through its energy; the second derivative $\partial^2 S/\partial U^2$, which is proportional to $1/U^2$ in Wien's limit and to $1/U$ in the Rayleigh–Jeans limit, and the simplest expression reducing to both,

$\partial^2 S/\partial U^2 = -\alpha/(U(\beta+U))$ *[294]. Integrating twice returns the law that bears his name. This step is interpolation and nothing more — Planck called it a lucky guess — and the chapter should present it as such, because the physics enters only at the next step.]*

68.5.2 The combinatorial derivation of December 1900

[Reserved: Planck's derivation of 14 December 1900 [295]: distribute P indivisible energy elements ε over N resonators, count the distributions, apply $S = k \log W$ — an equation Planck wrote here for the first time, naming k after Boltzmann — and demand consistency with Wien's displacement law Section 68.2.2, which forces $\varepsilon = h\nu$. The resulting spectral density $u_\nu \propto \nu^3/(\mathrm{e}^{h\nu/k_B T} - 1)$; fits to the Reichsanstalt data yielding the first values of h and k_B and, through k_B, the first good value of Avogadro's number and of the elementary charge.]

Phenomenon 68.5 (Planck's radiation law)**.** The spectral energy density of the radiation filling an isothermal cavity is

$$u_\nu(\nu, T) = \frac{8\pi h \nu^3}{c^3} \frac{1}{\mathrm{e}^{h\nu/k_\mathrm{B}T} - 1}\,, \tag{68.5}$$

a single expression that reproduces the measured spectrum at every frequency and every temperature at which it has been examined, from the far infrared of Phenomenon 68.4 to the visible [284, 297, 300]. It contains one constant of nature not present in classical physics. Planck read the two constants h and k_B off the Reichsanstalt data of 1900, obtaining $6.55 \times 10^{-34}\,\mathrm{J\,s}$ and $1.346 \times 10^{-23}\,\mathrm{J/K}$ respectively [300]; in the present SI both are fixed by definition, at $6.626\,070\,15 \times 10^{-34}\,\mathrm{J\,s}$ and $1.380\,649 \times 10^{-23}\,\mathrm{J/K}$ [2333], so his 1901 values were already right to about one percent.

Derivation. Take the electromagnetic mode density of Section 68.3.1, $8\pi\nu^2/c^3$ modes per unit volume per unit frequency, and Planck's hypothesis [295] that a resonator of frequency ν exchanges energy with the field only in whole elements ε, so that its accessible energies are $E_n = n\varepsilon$ with $n = 0, 1, 2, \ldots$. In equilibrium at temperature T the level n carries statistical weight $\mathrm{e}^{-n\varepsilon/k_\mathrm{B}T}$, and writing $x := \mathrm{e}^{-\varepsilon/k_\mathrm{B}T} < 1$ the mean energy of one resonator is

$$\langle E \rangle = \varepsilon \frac{\sum_{n\geq 0} n x^n}{\sum_{n\geq 0} x^n} = \varepsilon \frac{x/(1-x)^2}{1/(1-x)} = \frac{\varepsilon x}{1-x} = \frac{\varepsilon}{\mathrm{e}^{\varepsilon/k_\mathrm{B}T} - 1}\,,$$

both geometric series converging because $x < 1$. Multiplying by the number of modes gives the spectral density

$$u_\nu = \frac{8\pi\nu^2}{c^3} \frac{\varepsilon}{\mathrm{e}^{\varepsilon/k_\mathrm{B}T} - 1}\,.$$

Nothing so far fixes ε. That it must be proportional to the frequency is forced by Phenomenon 68.3: only $\varepsilon = h\nu$, with h a universal constant, makes the last expression equal to ν^3 times a function of ν/T alone, which is the scaling Wien's thermodynamic argument establishes. Substituting $\varepsilon = h\nu$ yields Equation (68.5).

The two limits are immediate. For $h\nu \gg k_\mathrm{B}T$ the exponential dominates and Equation (68.5) becomes $(8\pi h\nu^3/c^3)\,\mathrm{e}^{-h\nu/k_\mathrm{B}T}$, which is Wien's distribution [272] — so its early success in the visible was no evidence of its truth. For $h\nu \ll k_\mathrm{B}T$, expanding $\mathrm{e}^{h\nu/k_\mathrm{B}T} - 1 \simeq h\nu/k_\mathrm{B}T$ gives $8\pi\nu^2 k_\mathrm{B}T/c^3$, the equipartition result [296, 322] and the observed proportionality to T of Phenomenon 68.4. Both classical results are limits of one formula, and neither is valid outside its own limit. □

68.5.3 The 1901 Annalen paper

[Reserved: the considered exposition [300], with the two universal constants $h = 6.55 \times 10^{-34}\,\mathrm{J\,s}$ and $k = 1.346 \times 10^{-23}\,\mathrm{J/K}$ as Planck determined them, to be compared in a table with the present exact SI values $h = 6.626\,070\,15 \times 10^{-34}\,\mathrm{J\,s}$ and $k_B = 1.380\,649 \times 10^{-23}\,\mathrm{J/K}$ [2333]; the agreement to a percent from 1901 data is itself an observation worth making. Also Planck's system of natural units, proposed in the same period from h, c and G alone.]

68.5.4 Limits, moments and consistency

[Reserved: the two limits of Planck's law — $h\nu \gg k_B T$ recovering Wien [272], $h\nu \ll k_B T$ recovering Rayleigh–Jeans [296, 322] — and its integral, which reproduces the Stefan–Boltzmann law with σ now computed *rather than measured, a genuine prediction and the first quantitative success of the hypothesis. The maximum reproduces Wien's displacement constant. Every classical result of Section 68.2 is thereby subsumed, and the constant b and the constant σ cease to be independent empirical numbers.]*

68.6 What exactly was quantized

68.6.1 Energy elements

[Reserved: the statement $\varepsilon = h\nu$ as a restriction on the exchange *of energy between the field and a material resonator, which is what Planck asserted [295], against the stronger reading that the field itself is granular, which he resisted for a decade and which is Einstein's (Chapter 69). The distinction is not scholastic: it is the difference between a property of matter and a property of light, and only the second is established by the experiments of the next chapter. Modern restatement: the mean energy of a quantum harmonic oscillator, $h\nu/(\mathrm{e}^{h\nu/k_B T} - 1)$, derived properly in Chapters 78 and 118.]*

68.6.2 The reception, 1900–1911

[Reserved: honest history of a result nobody believed. Planck's law was accepted as a formula and rejected as a hypothesis; the turning point was the first Solvay Council of 1911 and, before it, the independent evidence from specific heats [333]. Lorentz and Jeans argued for years that the cavity was simply not in equilibrium [322]; Ehrenfest's analysis [369] isolated what in the hypothesis is indispensable. The section states plainly which claims were settled by evidence and which by exhaustion.]

68.7 Out of the cavity: specific heats

68.7.1 The Einstein solid

[Reserved: Einstein's transfer of the quantization hypothesis from cavity walls to the vibrations of a crystal [333]; $3N$ independent oscillators of a single frequency ν_E, molar heat capacity falling below the Dulong–Petit value $3R$ below $T \approx h\nu_E/k_B$ and vanishing as $T \to 0$. This was the first prediction of the quantum hypothesis outside radiation, and it was confirmed by Nernst's low-temperature calorimetry — the evidence that converted the physics community. Its known defect: the exponential fall is too fast against the measured one.]

Phenomenon 68.6 (The specific heat of a solid vanishes at low temperature)**.** The molar heat capacity of a crystalline solid is close to the Dulong–Petit value $3R$ at ordinary temperatures, falls steadily as the solid is cooled, and tends to zero as $T \to 0$. The fall sets in around a temperature characteristic of the material, so that a hard, light crystal such as

diamond is already far below $3R$ at room temperature while lead is not. Nernst's calorimetry established the behaviour across many substances down to liquid-hydrogen temperatures [378]; in insulating crystals the low-temperature approach to zero follows $C \propto T^3$ [382]. Classical equipartition (Chapter 55) gives $3R$ at every temperature and cannot produce any of this.

Derivation pending #46

The quantum theory of lattice heat capacities: the mean energy of a quantised oscillator applied to the vibrational degrees of freedom of a crystal, which gives the exponential freeze-out of a single Einstein frequency; and the replacement of that single frequency by the elastic-continuum mode spectrum with a cut-off preserving the total mode count, which produces the observed cubic low-temperature law.

68.7.2 Debye's improvement and the phonon

[Reserved: Debye's replacement of the single frequency by the elastic-continuum mode spectrum, with the cut-off that keeps the mode count at $3N$ [382]; the resulting T^3 law at low temperature, which fits the data, and the Debye temperature as the single material parameter. The mode counting is that of Section 68.3.1 with sound in place of light; the full lattice-dynamical treatment is Chapter 125, and the electronic contribution that Debye's theory omits is Chapter 126.]

68.8 The statistics behind the law

68.8.1 Bose's derivation

[Reserved: Bose's 1924 derivation of Planck's law from the counting of indistinguishable quanta in phase-space cells, with no appeal to classical electrodynamics at any point [509] — the first derivation in which the law follows from the statistics of the field rather than from the mechanics of the walls. Einstein translated the paper, had it published, and extended the counting to material particles, from which follow Bose–Einstein statistics and condensation (Chapters 120 and 121). Forward pointer: the indistinguishability at issue is the symmetrization postulate of Chapter 83.]

68.8.2 Detailed balance and the Einstein coefficients

[Reserved: Einstein's 1917 rederivation [446], in which the equilibrium of a two-level atom with the radiation field requires three processes — absorption, spontaneous emission and stimulated *emission — and the ratios of their rates are fixed by demanding Planck's law at equilibrium. The argument also yields the momentum $h\nu/c$ transferred in each elementary process, which is the photon momentum of Chapter 69. Stimulated emission is the principle of the laser (Chapter 122), and the coefficients are computed from first principles in Chapter 82.]*

68.9 Black bodies in nature

68.9.1 The cosmic microwave background

[Reserved: the most exact black-body spectrum known, measured by the FIRAS instrument on COBE with residuals below one part in 10^4 of the peak and a temperature $T = 2.7255\,\mathrm{K}$ [2144]; the absence of any spectral distortion as a constraint on energy release in the early universe, and the present-day cosmological parameters that rest on it [2348]. The measurement itself

is Chapter 51 and the cosmology Chapter 48; what belongs here is only that Kirchhoff's universal function is realized in nature to a precision no laboratory cavity approaches.]

Phenomenon 68.7 (The cosmic microwave background is a black body)**.** Observed from above the atmosphere, the whole sky carries a nearly isotropic radiation field whose spectrum is that of a black body whose temperature T is $(2.725\,48 \pm 0.000\,57)\,\mathrm{K}$, with no departure from Equation (68.5) detected anywhere across the peak [2144]. It is the most accurately black-body spectrum known, and no laboratory cavity approaches it: the universe as a whole realizes Kirchhoff's universal function better than any apparatus built to realize it.

Derivation pending #47

Why the expanding universe leaves a Planck spectrum Planckian: thermal equilibrium of matter and radiation before recombination fixes the form, and the redshift of every mode by a common factor rescales the spectral density into another Planck spectrum with the temperature inversely proportional to the scale factor, so that no spectral distortion is generated by the expansion itself. The limits on distortions then become limits on energy release after equilibrium was lost.

68.9.2 Stellar spectra and radiation thermometry

[Reserved: stellar continua as approximate Planck spectra, the effective temperature as the parameter of the fit, and the departures — absorption lines, limb darkening, non-grey opacity — that carry the astrophysics of Chapter 52; the Sun at about 5772 K. On the metrological side, radiation thermometry as a primary method of realizing the kelvin, and the role of h as a defining constant of the present SI [2333, 2431], so that Planck's law now enters the definition of the units in which it is verified (Chapter 2).]

Chapter 69

The Photon: Photoelectric and Compton Effects

Chapter 68 ended with a constant h that governs how a cavity wall trades energy with the field, and with Planck's own insistence that this says nothing about the field itself. This chapter is about the evidence that it does. Einstein's 1905 proposal [319] was that light of frequency ν behaves in its emission, propagation and absorption as though it consisted of independent quanta of energy $h\nu$ — a statement about light, not about oscillators, and one that the thermodynamics of the previous chapter does not entail. He offered the photoelectric effect [234, 238, 308] as a test, because its observed dependence on frequency and its *in*dependence of intensity are inexplicable if the energy of a wave arrives spread over a wavefront.

The chapter sets out the evidence in the order in which it accumulated and grades it honestly. Millikan's decade of measurement [437] verified Einstein's linear relation to better than a percent while its author continued to reject the hypothesis behind it; and he was not simply being obstinate, for the photoelectric equation alone can be obtained from a quantized atom absorbing from a classical field [1402]. What settled the matter was momentum: Compton's shift in the wavelength of scattered X-rays [499, 501], and then the coincidence experiments [519, 520] that destroyed the last classical alternative [508] by showing that energy and momentum balance in every *individual* scattering event and not merely on average. The quantum thereby acquires the two attributes of a particle, and the field theory that makes this consistent is Part XI.

Derivation pending #48

The Photon: Photoelectric and Compton Effects: all derivations of this chapter are pending.

69.1 The photoelectric effect

69.1.1 Discovery: Hertz and Hallwachs

[Reserved: Hertz's observation, made while producing the first electromagnetic waves [234], that ultraviolet light on the spark gap lowers the potential at which the spark passes — an unwanted effect in an experiment about something else, and reported as such. Hallwachs' isolation of the phenomenon the following year [238]: a freshly polished zinc plate, negatively charged, is discharged by ultraviolet light and a positively charged one is not, so the carriers are negative. Identification of the carriers with Thomson's corpuscles (Chapter 70) by their charge-to-mass ratio.]

69.1.2 Lenard's measurements and the classical impasse

[Reserved: Lenard's systematic study with a monochromated source and a retarding potential [308], which established the three facts that no wave theory accommodates: the maximum kinetic energy of the emitted electrons is independent of the intensity; it increases with the frequency; and below a threshold frequency no electrons are emitted at any intensity. To be added, the fourth: the emission begins without measurable delay, whereas a classical wavefront needs minutes to deliver an electron's worth of energy to an atomic cross-section — the estimate should be made explicitly here, because it is the sharpest form of the contradiction. Only the photocurrent scales with intensity.]

Phenomenon 69.1 (The photoelectric facts)**.** Ultraviolet light falling on a clean metal surface ejects electrons, and the emission has four properties that no theory treating light as a continuous wave accommodates [234, 238, 308]:

1. below a threshold frequency ν_0, characteristic of the emitting metal, no electrons appear at any intensity and after any exposure;

2. above the threshold the maximum kinetic energy of the emitted electrons is independent of the intensity of the light;

3. that maximum increases with the frequency of the light;

4. the emission begins without measurable delay, even at intensities so feeble that a wave spread uniformly over the surface would need minutes to deliver one electron's binding energy to a region of atomic size.

Only the *number* of electrons emitted per second — the photocurrent — is proportional to the intensity.

Derivation pending #49

The classical accumulation time: the energy an electromagnetic wave of a stated irradiance delivers per second to a target of atomic cross-section, compared with the work function of the metal, giving the delay a wave theory requires before the first electron can be emitted; and the demonstration that no redistribution of energy within the classical field shortens it, which is what makes item 4 above a contradiction rather than an estimate.

69.2 The light-quantum hypothesis

69.2.1 Einstein's heuristic viewpoint of 1905

[Reserved: the structure of Einstein's argument [319], which is thermodynamic and not electrodynamic: in the Wien regime of Chapter 68 the entropy of radiation in a volume V varies with V exactly as that of an ideal gas of $E/h\nu$ independent particles, so monochromatic radiation of low density behaves as if *composed of that many localized quanta. Three consequences were offered as tests — Stokes' rule for fluorescence, the photoelectric effect, and photoionization. The chapter should stress that Einstein derived the quantum from the empirical Wien law, not from Planck's counting, and regarded the two arguments as independent.]*

69.2.2 The photoelectric equation and the work function

[Reserved: $E_{\max} = h\nu - \phi$, with ϕ the work function of the emitting surface [319]; the stopping potential $V_0 = E_{\max}/e$ as the measured quantity, the threshold frequency $\nu_0 = \phi/h$, and the slope h/e of the V_0 against ν line, which is universal — the same for every metal, which is the content of the prediction. Tabulated work functions in eV *(caesium about* 2.1 eV*, potassium* 2.3 eV*, copper* 4.7 eV*, platinum* 5.6 eV*), their sensitivity to surface contamination and crystal face, and hence why the experiment is hard. The many-electron theory of ϕ belongs to Chapter 126.]*

69.2.3 Millikan's verification

[Reserved: the ten-year programme [437] that cut fresh alkali-metal surfaces in vacuum with a magnetically operated knife to defeat oxidation, measured the stopping potential across the visible and near ultraviolet, confirmed the strict linearity, and extracted $h = 6.57 \times 10^{-34}\,\mathrm{J\,s}$ to about 0.5 % — then the best value of Planck's constant by any method. Honest history: Millikan undertook the work to disprove what he called a reckless hypothesis and wrote, on confirming the equation, that the light-quantum theory nonetheless seemed untenable; the section records this because it is a clean case of a prediction surviving a hostile test.]

Phenomenon 69.2 (The photoelectric equation)**.** The stopping potential V_0 that just prevents the fastest photoelectrons from reaching the collector is a strictly linear function of the frequency of the incident light,

$$eV_0 = h\nu - \phi\,, \tag{69.1}$$

and the slope of that line is h/e for *every* emitting metal, the material entering only through the intercept ϕ. Millikan established the linearity across the visible and near ultraviolet on alkali surfaces cut fresh in vacuum, and read from the slope a value of Planck's constant of $6.57 \times 10^{-34}\,\mathrm{J\,s}$, to about 0.5 % [437] — then the best determination by any method, and in agreement with the value obtained from cavity radiation [300], which is a measurement of an entirely different kind.

Derivation. Assume with Einstein [319] that light of frequency ν is emitted and absorbed only in indivisible amounts $h\nu$, and that one such amount is taken up by a single electron. An electron at the top of the occupied band must pay the work function ϕ to cross the surface, and any electron starting deeper pays more, so the fastest electron leaves with

$$E_{\max} = h\nu - \phi\,. \tag{69.2}$$

Three of the four observations of Phenomenon 69.1 follow at once. $E_{\max}$ depends on the size of the quantum and not on how many quanta arrive per second, which is item 2; it rises linearly with ν, which is item 3; and it would be negative — so no electron is emitted — for every $\nu < \nu_0 := \phi/h$ whatever the intensity, which is item 1. Raising the intensity multiplies the number of quanta and therefore the photocurrent, and nothing else. Retarding the emitted electrons through a potential difference V stops all those with $E_{\max} < eV$, so the measured stopping potential satisfies $eV_0 = E_{\max}$, which is Equation (69.1). Its slope h/e contains no property of the metal at all, and that universality, rather than the linearity, is the content of the prediction. □

69.2.4 What the photoelectric effect does not prove

[Reserved: the necessary caveat. A quantized atom coupled to a classical *radiation field reproduces the threshold, the linearity in frequency and the promptness of the emission,*

as shown by Lamb and Scully [1402]; the discreteness lies in the atomic energy levels of Chapter 70, which are independently established. The photoelectric effect is therefore strong evidence for quantized absorbers and weak evidence for quantized light. Naming what an experiment does not decide is editorial rule 1 applied to a case where the textbook claim is routinely overstated; the experiments that do decide it are Sections 69.5 and 69.6.1.]

69.3 Momentum and angular momentum of light

69.3.1 Radiation pressure

[Reserved: the classical prediction $p = u/c$ from the Maxwell stress tensor (Chapter 60) and its measurement by Lebedev with a torsion balance in vacuum [299] and, independently and more accurately, by Nichols and Hull [311]. In quantum language each quantum carries $p = h\nu/c = h/\lambda$, which Einstein obtained from detailed balance in 1917 [446]; the two descriptions agree for the pressure and differ in the fluctuations. Applications: comet tails, radiation pressure in stellar interiors (Chapter 52), optical tweezers and laser cooling (Chapter 122).]

Phenomenon 69.3 (Radiation pressure)**.** A beam of light exerts a mechanical force on the surface it falls upon. At normal incidence the pressure is

$$P = \frac{I}{c} \ \text{on a perfect absorber}, \qquad P = \frac{2I}{c} \ \text{on a perfect reflector}, \tag{69.3}$$

with I the incident irradiance. Lebedev detected the effect on light and dark vanes hung from a torsion fibre in an evacuated vessel, the whole difficulty of the measurement being to separate it from the far larger radiometric and convective forces [299]; Nichols and Hull, independently, confirmed the predicted magnitude to a few percent [311].

Derivation. In the quantum description the beam is a flux of N quanta per unit area per unit time, each of energy $h\nu$ and — by the detailed-balance argument Einstein gave in 1917 [446] — of momentum $h\nu/c$ directed along the propagation direction. The irradiance is the energy flux, $I = Nh\nu$, so the momentum arriving per unit area per unit time is $Nh\nu/c = I/c$. Force per unit area is momentum delivered per unit area per unit time, so an absorber feels $P = I/c$; a reflector returns each quantum with its momentum reversed and therefore receives twice as much, $P = 2I/c$. This is Equation (69.3).

The same two numbers follow classically from the Maxwell stress tensor of Chapter 60, and it must be said plainly that Equation (69.3) is therefore *not* evidence for quanta. The two descriptions agree on the mean pressure and differ in its fluctuations; what the quantum reading adds is that the momentum comes in the same indivisible packets as the energy, in the fixed ratio $1/c$, and it is that ratio which Phenomenon 69.5 tests directly. □

69.3.2 Angular momentum of light

[Reserved: circularly polarized light carries angular momentum $\hbar$ per quantum, measured mechanically by Beth [767], who suspended a birefringent half-wave plate on a quartz fibre and detected the torque exerted as the handedness of the transmitted beam was reversed. This is the direct evidence that the photon has spin one, and with the absence of a longitudinal polarization state (Chapter 26) it fixes the field's representation content under the Poincaré group (Chapter 94).]

Phenomenon 69.4 (Light carries angular momentum)**.** A circularly polarized beam of angular frequency ω and power P transports angular momentum about its own axis at the rate P/ω — one unit $\hbar$ for every $\hbar\omega$ of energy it carries, and of the sign set by the

handedness. Beth suspended a birefringent half-wave plate from a quartz fibre inside an evacuated enclosure and measured the steady torque exerted on it when the plate reversed the handedness of the transmitted beam, finding the predicted magnitude and the predicted reversal of sign with the handedness of the incident light [767]. This is a mechanical measurement of a property of light that has no analogue in the mechanics of a scalar wave.

Derivation pending #50

The angular momentum of a circularly polarized wave: the flux of angular momentum computed from the Maxwell stress tensor for a beam of finite transverse extent, its ratio to the energy flux, and the torque this predicts on a half-wave plate that reverses the handedness; and the identification of that ratio with one unit of the reduced Planck constant per quantum, which is what makes the result a statement about the spin of the photon rather than about the field alone.

69.4 Compton scattering

69.4.1 The 1923 experiment

[Reserved: Compton's measurement of molybdenum Kα X-rays (17.5 keV, 71 pm) scattered from graphite and analysed with a Bragg spectrometer [499]; the scattered radiation contains, besides the unshifted line, a component displaced to longer wavelength by an amount depending on the scattering angle alone and not on the wavelength, the material, or the intensity. Classical Thomson scattering (Chapter 65, [1976]) predicts no shift whatever, since a driven electron re-radiates at the driving frequency. Apparatus, angles, and the observed shift with uncertainties to be tabulated.]

Phenomenon 69.5 (The Compton shift)**.** X-rays scattered from a light element contain, besides a component at the incident wavelength, a component displaced to longer wavelength. The displacement depends on the scattering angle θ and on nothing else — not on the incident wavelength, not on the scattering material, not on the intensity —

$$\Delta\lambda = \lambda_{\mathrm{C}}\,(1-\cos\theta)\,, \qquad \lambda_{\mathrm{C}} = \frac{h}{m_{\mathrm{e}}c}\,, \tag{69.4}$$

where the Compton wavelength λ_{C} is 2.426 31 pm [2431]. Compton measured the shift on the molybdenum Kα line scattered from graphite, analysing the scattered radiation with a Bragg crystal spectrometer [499]. Classical scattering from a charge driven by the incident wave predicts no shift at all, at any angle, because a driven oscillator re-radiates at the frequency that drives it [1976].

Derivation. Treat the process as an elastic collision between a quantum of energy $h\nu$ and momentum $h\nu/c$ — the pair used already in Phenomenon 69.3 — and a free electron of mass m at rest, and impose the relativistic conservation laws of Chapter 40. Let the scattered quantum have frequency ν' and travel at an angle θ to the incident direction. Momentum conservation gives the electron momentum $\boldsymbol{p}_{\mathrm{e}} = \boldsymbol{p} - \boldsymbol{p}'$, whose square is

$$p_{\mathrm{e}}^2 = \frac{h^2\nu^2}{c^2} + \frac{h^2\nu'^2}{c^2} - \frac{2h^2\nu\nu'}{c^2}\cos\theta\,,$$

and energy conservation gives $E_{\mathrm{e}} = h\nu - h\nu' + mc^2$. Substituting both into the mass-shell relation $E_{\mathrm{e}}^2 = p_{\mathrm{e}}^2c^2 + m^2c^4$,

$$(h\nu - h\nu')^2 + 2mc^2\,(h\nu - h\nu') + m^2c^4 = h^2\nu^2 + h^2\nu'^2 - 2h^2\nu\nu'\cos\theta + m^2c^4\,.$$

Expanding the square on the left and cancelling $h^2\nu^2 + h^2\nu'^2 + m^2c^4$ from both sides leaves

$$-2h^2\nu\nu' + 2mc^2 h\,(\nu - \nu') = -2h^2\nu\nu'\cos\theta\,,$$

that is $mc^2\,(\nu - \nu') = h\nu\nu'\,(1 - \cos\theta)$. Dividing through by $mc\,\nu\nu'$ and using $\lambda = c/\nu$,

$$\frac{c}{\nu'} - \frac{c}{\nu} = \frac{h}{mc}\,(1 - \cos\theta) \qquad \Longrightarrow \qquad \lambda' - \lambda = \frac{h}{mc}\,(1 - \cos\theta)\ ,$$

which is Equation (69.4). The result carries no adjustable parameter and no property of the target, exactly as observed; Debye published the same kinematics independently and within weeks [501]. The unshifted component comes from electrons bound too tightly to recoil freely, for which m must be replaced by the mass of the whole atom, some five orders of magnitude larger, and the shift becomes unobservable. □

69.4.2 Kinematics and the Compton wavelength

[Reserved: treat the process as an elastic collision between a quantum of energy $h\nu$ and momentum $h\nu/c$ and a free electron at rest, and impose the relativistic conservation laws of Chapter 40. The result is $\Delta\lambda = \lambda_C(1 - \cos\theta)$ with the Compton wavelength $\lambda_C = h/m_e c = 2.426\,31\,\mathrm{pm}$, a pure prediction with no adjustable parameter. Why the unshifted line survives (scattering from tightly bound electrons, for which the recoiling mass is the whole atom); the recoil electrons, seen in a cloud chamber at the predicted energies and angles; and the identification of λ_C as the length scale at which Chapter 93 takes over from single-particle mechanics.]

69.4.3 Debye's independent derivation

[Reserved: Debye published the same kinematics from the same hypothesis within weeks of Compton and without knowledge of the experiment [501], a fact usually omitted; the relation is occasionally called the Compton–Debye formula on the continent. The section records the double attribution because the treatise's citation rule is to name the source that contains the claim, and here there are two.]

69.4.4 The Klein–Nishina cross-section

[Reserved: the kinematics fix the shift but not the rate. The angular distribution follows from the Dirac equation (Chapter 93) as the Klein–Nishina formula [630], one of the earliest quantitative successes of relativistic quantum mechanics; its low-energy limit is the Thomson cross-section $\sigma_T = 6.652\,458\,7 \times 10^{-29}\,\mathrm{m}^2$ [2431] and its high-energy behaviour falls as $\log(E)/E$. Compton scattering as the dominant photon interaction in matter between about $100\,\mathrm{keV}$ and $10\,\mathrm{MeV}$, hence its role in detector physics and in the inverse-Compton emission of Chapter 115.]

69.5 Coincidence: the last classical alternative

69.5.1 The Bohr–Kramers–Slater proposal

[Reserved: the 1924 attempt by Bohr, Kramers and Slater [508] to keep a continuous classical field by surrendering strict conservation: energy and momentum would hold only statistically, the atom being coupled to a "virtual" radiation field that fixes transition probabilities. It is the sharpest counter-theory the light quantum ever faced, and it makes a definite, falsifiable prediction — that a scattered quantum and its recoil electron are not *correlated event by event.]*

69.5.2 Bothe–Geiger coincidences

[Reserved: Bothe and Geiger placed two needle counters, one sensitive to scattered X-rays and one to recoil electrons, on opposite sides of a hydrogen-filled scattering chamber, and recorded their discharges on a moving photographic tape [519]. Coincident events appeared at a rate far above chance, with a resolving time of about 1×10^{-4} s, so energy and momentum balance in each individual act and the statistical proposal of Section 69.5.1 is excluded. This is the founding use of the coincidence method, for which Bothe was awarded the Nobel Prize, and it is the technique behind every particle detector in Part XI.]

Phenomenon 69.6 (Energy and momentum balance in every individual scattering event)**.** In Compton scattering the scattered quantum and the recoil electron appear *together*, in each single act, at the angles and energies that Equation (69.4) and momentum conservation assign to that act — not merely on the average over many acts. Bothe and Geiger placed one needle counter sensitive to scattered X-rays and one to recoil electrons on opposite sides of a hydrogen-filled scattering chamber and recorded coincidences at a rate far above chance with a resolving time of about 1×10^{-4} s [519]. Compton and Simon photographed both the recoil electron track and the track of a second electron ejected by the scattered quantum in the same cloud chamber, and found the two directions correlated as the kinematics require, within the measurement errors [520]. This excludes the one serious counter-theory, in which conservation would hold only statistically [508], and it was withdrawn at once.

Derivation pending #51

The angular correlation implied by the collision kinematics: the recoil-electron direction as a function of the scattering angle of the quantum, obtained from the same conservation laws that give the wavelength shift; the rate of accidental coincidences to be subtracted from the observed rate, given the counting rates and the resolving time; and the contrasting prediction of statistical-only conservation, under which the two directions are independent and the coincidence rate is the accidental rate alone.

69.5.3 Compton–Simon cloud-chamber pairs

[Reserved: the complementary experiment [520], in which a cloud chamber records the recoil electron's track and the track of a second electron ejected by the scattered quantum, so that both directions are measured in the same event; the angular correlation follows the kinematics of Section 69.4.2 within the measurement errors. Together with Section 69.5.2 this closed the question in 1925, and Bohr withdrew the proposal at once — a model of how a theory should be abandoned.]

69.6 The photon as a countable object

69.6.1 Anticorrelation at a beam splitter

[Reserved: the modern decisive experiment. Grangier, Roger and Aspect prepared single quanta by heralding on the second photon of a calcium radiative cascade, sent them onto a beam splitter and measured the joint detection rate at the two outputs [1774]; the observed anticorrelation parameter is well below the value that any classical field, however weak, can produce, while the same source in a Mach–Zehnder interferometer still shows full-visibility interference. One indivisible quantum, taking both paths: the statement of Chapter 85 rests on data of this kind and not on the photoelectric effect.]

Phenomenon 69.7 (A single quantum is not divided by a beam splitter)**.** Light prepared one quantum at a time and sent onto a beam splitter is detected in one output arm or in the other, and not in both. Writing α for the ratio of the joint detection rate at the two outputs to the product of the two singles rates, every classical field — however weak, and whatever its statistics — obeys $\alpha \geq 1$, because the joint rate is an average of a squared intensity and the Cauchy–Schwarz inequality bounds it from below. Grangier, Roger and Aspect prepared single quanta by heralding on the partner photon of a calcium radiative cascade and measured $\alpha = 0.18 \pm 0.06$, far below the classical bound; the same source in a Mach–Zehnder interferometer nevertheless produced interference of full visibility [1774].

Derivation pending #52

The two bounds that make the measurement decisive: the classical inequality on the normalised joint detection rate, from the Cauchy–Schwarz inequality applied to the intensity correlations of any positive classical intensity distribution; and the quantum prediction that a one-quantum state incident on a beam splitter gives a vanishing joint rate, together with the correction for the imperfect heralding and the accidental coincidences of a real source.

69.6.2 Counting photons

[Reserved: photomultipliers, avalanche photodiodes and transition-edge sensors as devices whose output is a count; the photon-number distribution of thermal, coherent and squeezed light, distinguished by their second-order correlation and developed in Chapter 122; single-photon sources and detectors as the working hardware of the Bell tests of Chapter 89. Historical footnote: the word "photon" is Lewis' [551], coined for an entity quite unlike the one it now names.]

69.7 Creation and annihilation of quanta

69.7.1 Pair production and annihilation

[Reserved: above $2m_e c^2 = 1.022\,\mathrm{MeV}$ a photon in the Coulomb field of a nucleus can convert into an electron and a positron; the discovery of the positron in cosmic rays by Anderson [713] and the first photographs of pairs by Blackett and Occhialini [714], who identified the process as the materialization of a quantum. Annihilation into two back-to-back $511\,\mathrm{keV}$ *quanta, the basis of positron emission tomography and the cleanest demonstration that photon number is not conserved. The experiment chapter is Chapter 95, and the theory is the Dirac equation of Chapter 93.]*

69.7.2 The photon in quantum electrodynamics

[Reserved: what a photon actually is in the settled theory — an excitation of the quantized electromagnetic field, first written down by Dirac [572], a massless spin-one particle with two helicity states and no rest frame, created and destroyed by field operators rather than moved about. Present experimental limits on the photon mass and charge [2427], quoted here as the numbers that make the idealization exact for every purpose in this treatise. The full development is Chapters 99 and 100; the non-technical account in [1752] remains the best statement of what the theory says.]

Chapter 70

Atomic Models and Spectra

Atomic spectra were measured for a century before anybody could say what an atom was. Fraunhofer mapped and lettered the dark lines of the solar spectrum in 1817 [60]; Kirchhoff and Bunsen showed in 1860 that each element carries its own fixed set of lines and thereby turned spectroscopy into chemical analysis [152]. By the end of the century the wavelengths were known to six figures and were the most precise numbers in physics — and they were pure numerology. Balmer found that the visible hydrogen lines fit a two-integer formula [230], Rydberg extended it to whole series in many elements with one constant [248], and Ritz observed that every observed frequency is a difference of two terms drawn from a single list [348]. Nothing in classical physics explains why a bound system should radiate at a discrete set of frequencies at all, still less why those frequencies should be differences.

This chapter follows the two lines of evidence — spectroscopic and mechanical — to the point where they meet. The mechanical line runs from Thomson's electron [276] through the large-angle α scattering of Geiger and Marsden [354, 404] to Rutherford's nuclear atom [379], which is dynamically impossible in classical electrodynamics: an orbiting charge radiates and the atom collapses in about $1 \times 10^{-11}\,\mathrm{s}$. Bohr's 1913 trilogy [396–398] joins the two lines by postulating stationary states, and buys with that postulate the Rydberg constant computed from e, m_{e} and h. The old quantum theory that grew from it [441, 463] explained the X-ray regularity of Moseley [408, 418] and the fine structure, and failed on helium, on the anomalous Zeeman effect [391] and on intensities. It is a scaffold, not a theory — but everything it got right is a constraint that Part IX must reproduce, and the direct demonstration that its energy levels are real is Chapter 72.

Derivation pending #53

Atomic Models and Spectra: all derivations of this chapter are pending.

70.1 Spectra before any model

70.1.1 The Fraunhofer lines

[Reserved: Wollaston's 1802 sighting of dark gaps in the solar spectrum, and Fraunhofer's systematic mapping of some 570 of them with a theodolite telescope and a diffraction grating of his own making, lettered A through K in order of decreasing wavelength [60]. The measurement was metrological in intent — Fraunhofer needed fixed wavelengths to characterize optical glass — and the lines became the first absolute wavelength standards. The coincidence of the D line with the yellow of a sodium flame, noted but not explained.]

70.1.2 Spectral analysis

[Reserved: Kirchhoff and Bunsen's demonstration that every element emits a characteristic line spectrum, that the same element absorbs at the same wavelengths, and that a spectrum therefore identifies a substance [152]; the immediate discovery of caesium and rubidium by this means, and the identification of the Fraunhofer D lines with sodium in the solar atmosphere. Absorption versus emission as an instance of Kirchhoff's radiation theorem [153], so that Chapter 68 and this chapter share a founding result. Astrophysical consequence: stellar composition becomes measurable (Chapter 52).]

Phenomenon 70.1 (Characteristic line spectra)**.** A chemical element heated to incandescence in the vapour phase emits light only at a fixed, discrete set of wavelengths: the same set every time, independent of the temperature, of the chemical compound the element was liberated from and of everything else about its preparation, and different for every element. The same element, interposed cold in front of a continuous source, absorbs at exactly those wavelengths and at no others. A spectrum therefore identifies a substance without touching it, which is how caesium and rubidium were discovered [152]. The dark lines Fraunhofer had mapped and lettered in the solar spectrum are of this kind [60]: the D pair coincides with the emission of a sodium flame, so there is sodium in the solar atmosphere.

Derivation pending #54

Two things must be derived and only the second is classical. That a bound system radiates at a discrete set of frequencies at all follows only from the quantisation of its internal energies, and is taken up in the quantum-mechanics part; that emission and absorption occur at the same wavelengths is the detailed-balance content of Kirchhoff's radiation theorem, and follows from the equilibrium argument of the black-body chapter applied frequency by frequency.

70.1.3 Balmer's formula

[Reserved: Balmer's fit to the four visible hydrogen lines, $\lambda = h_B m^2/(m^2-4)$ with $m = 3,4,5,6$ and $h_B = 364.56\,\mathrm{nm}$, matching the measured wavelengths to five significant figures [230], together with its successful prediction of the fifth line before Balmer was told it had already been seen in stellar spectra. The point to make: this is an exact empirical regularity with integers in it, found sixty-five years before it was understood, and it is the reason hydrogen became the test case for every atomic model.]

70.1.4 The Rydberg formula and the combination principle

[Reserved: Rydberg's generalization from wavelengths to wavenumbers, $\tilde{\nu} = R(1/n_1^2 - 1/n_2^2)$ for hydrogen and the term formula with quantum defects for the alkalis, all series in all elements sharing one constant R [248]. Ritz's combination principle [348]: the wavenumber of every observed line is the difference of two terms, and sums and differences of observed lines are themselves observed lines. The principle is stronger than any particular series formula, it is exact, and it says — before any model — that a spectrum is a set of levels *and not a set of frequencies. The other hydrogen series: Lyman in the ultraviolet [327], Paschen in the infrared [347].]*

Phenomenon 70.2 (The Rydberg formula and the Ritz combination principle)**.** The wavenumbers of the hydrogen lines are given, to the full precision of the measurements, by two integers and one constant,

$$\tilde{\nu} = \frac{1}{\lambda} = R_{\mathrm{H}} \left(\frac{1}{n_1^2} - \frac{1}{n_2^2} \right) , \qquad n_2 > n_1 \geq 1 \, . \tag{70.1}$$

Balmer fitted the four visible lines with $n_1 = 2$ to five significant figures and predicted the fifth before learning it had already been seen [230]; the series with $n_1 = 1$ lies in the ultraviolet [327] and that with $n_1 = 3$ in the infrared [347]. More generally, and in every element examined, the wavenumber of each observed line is the difference of two members of a single list of terms belonging to that element, and sums and differences of observed wavenumbers are themselves observed lines [248, 348]. The combination principle is exact, it is stronger than any particular series formula, and it says — before any model of the atom exists — that a spectrum is a set of *levels* and not a set of frequencies.

Derivation pending #55

The term structure: that there exists a set of stationary energies of the atom whose differences, divided by Planck's constant, are exactly the observed frequencies. The stationary-state postulate assumed in the Bohr section below turns the combination principle into a law rather than deriving it; the derivation proper is the eigenvalue problem for the atomic Hamiltonian, solved for hydrogen in the quantum-mechanics part.

70.2 The constituents of the atom

70.2.1 The electron

[Reserved: Thomson's cathode-ray experiments [276] — deflection by crossed electric and magnetic fields, the charge-to-mass ratio some 1800 *times that of hydrogen, and its independence of the cathode material and the residual gas, which is what licenses the claim that the corpuscle is a universal constituent of matter. The subsequent measurement of e itself by the oil-drop method, and the current values [2431]. This is the first subatomic particle, and its charge quantization is an observed fact that Part XI still does not explain.]*

70.2.2 Thomson's model and its failure

[Reserved: the "plum pudding" atom of electrons in stable rings inside a uniform sphere of positive charge [316], which was a serious dynamical model and not a straw man: it predicted the periodicity of chemical properties from ring closure, and it predicted small-angle multiple scattering of α particles with a calculable and very small tail. That prediction is quantitative and falsifiable, which is exactly why the experiment of the next section settled the question. What it could not do is produce sharp spectral lines.]

70.3 The nuclear atom

70.3.1 Large-angle alpha scattering

[Reserved: Geiger and Marsden's observation that a small fraction of α particles incident on a gold foil are deflected through more than 90°*, some returning towards the source [354] — in Rutherford's later phrase, as incredible as an artillery shell rebounding from a sheet of tissue paper — against the Thomson model's prediction of essentially none, since a diffuse positive charge exerts no large force anywhere. The quantitative campaign of 1913 [404]: counts against scattering angle, foil thickness, foil material and α velocity, verifying every dependence of the formula below. Apparatus and uncertainties belong here; the modern descendant of the technique is deep inelastic scattering (Chapter 116), where the same logic finds structure inside the proton.]*

Phenomenon 70.3 (Large-angle scattering of alpha particles)**.** A beam of α particles traversing a thin metal foil is overwhelmingly deflected through small angles, but a small, definite and measurable fraction is deflected through more than 90°, some of it returning towards the source [354]. The number scattered into unit solid angle about the angle θ follows

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \left(\frac{Z_1 Z_2 e^2}{16\pi\varepsilon_0 E}\right)^2 \frac{1}{\sin^4(\theta/2)}\,, \tag{70.2}$$

with E the kinetic energy of the incident particle and Z_1, Z_2 the charges of projectile and target in units of e. Geiger and Marsden verified every dependence separately — on the scattering angle, on the foil thickness, on the material of the foil and on the velocity of the α particles [404]. A positive charge spread uniformly through the volume of the atom, as in [316], exerts nowhere a force large enough to produce such deflections, so the positive charge and essentially all the mass of the atom occupy a region smaller than $1 \times 10^{-14}\,\mathrm{m}$ [379].

Derivation pending #56

The Rutherford cross-section: the relation between impact parameter and scattering angle for a repulsive inverse-square force, read off the Kepler hyperbola of the classical two-body problem, and the Jacobian that converts it into a differential cross-section; the summation over foil thickness that gives the counting rate actually measured; and the remark, which must be made honestly, that the same expression is also the exact Born approximation for a Coulomb potential, so that a mechanics now known to be wrong gave the right answer here for a reason no one could have known in 1911.

70.3.2 Rutherford's scattering formula

[Reserved: Rutherford's derivation of the differential cross section $\mathrm{d}\sigma/\mathrm{d}\Omega \propto Z^2/(E^2\sin^4(\theta/2))$ for a point charge [379], from the Kepler hyperbola of Chapter 27, and the inference that the positive charge and essentially all the mass occupy a region smaller than $1 \times 10^{-14}\,\mathrm{m}$. The remarkable accident that the classical result coincides with the Born approximation of Chapter 86, so that a wrong mechanics gave the right answer; and the deviation at high energy that measures the nuclear radius (Chapter 107).]

70.3.3 Why the classical nuclear atom cannot exist

[Reserved: an accelerated charge radiates, by the Larmor formula of Chapter 65. An electron in a classical orbit of radius $5.29 \times 10^{-11}\,\mathrm{m}$ therefore spirals into the nucleus in about $1.6 \times 10^{-11}\,\mathrm{s}$, radiating a continuous spectrum of rising frequency as it goes. Both consequences contradict observation outright: atoms are stable for the age of the universe and their spectra are discrete. The estimate should be done explicitly, because it is the cleanest statement in the whole treatise that classical physics is not merely inaccurate but excluded.]

Phenomenon 70.4 (Atoms are stable, identical and discrete)**.** Every atom of a given element in its ground state is indistinguishable from every other, has the same size to within the precision of any measurement, and persists indefinitely: matter does not run down, and no atom has ever been observed to radiate its electrons into its nucleus. An excited atom does not radiate a continuum of rising frequency as it decays either; it radiates the sharp lines of Phenomenon 70.1. Classical electrodynamics requires the opposite on all three counts, because an electron on any bound orbit about the nucleus of Phenomenon 70.3 is accelerated and therefore radiates by the Larmor formula of Chapter 65, losing energy continuously and shrinking its orbit without limit.

Derivation pending #57

Stability of the atomic ground state: the existence of a lowest energy level, which no classical bound system in an inverse-square potential possesses, and the bound relating the localisation of the electron to its kinetic energy which fixes the size and energy of that level. The derivation belongs to the quantum-mechanics part, where the hydrogen atom is solved; what can be established here is only the negative statement of the remark below.

Remark 70.5 (The classical collapse time). The contradiction is quantitative, not merely qualitative, and the estimate is short enough to be given in full. An electron on a circular orbit of radius r about a proton has centripetal acceleration $a = e^2/4\pi\varepsilon_0 m_{\mathrm{e}} r^2$ and total energy $E = -e^2/8\pi\varepsilon_0 r$, and radiates at the Larmor rate $P = e^2a^2/6\pi\varepsilon_0 c^3$. Setting $\mathrm{d}E/\mathrm{d}t = -P$ and writing $r_{\mathrm{e}} := e^2/4\pi\varepsilon_0 m_{\mathrm{e}} c^2$ for the classical electron radius, every constant collapses into

$$\frac{\mathrm{d}r}{\mathrm{d}t} = -\frac{4}{3}\frac{c\,r_{\mathrm{e}}^2}{r^2}\,, \qquad \text{whence} \qquad t = \frac{r_0^3}{4c\,r_{\mathrm{e}}^2} \tag{70.3}$$

for the time to fall from r_0 to the nucleus. Taking for r_0 the observed atomic size $5.291\,77 \times 10^{-11}\,\mathrm{m}$, and for r_{e} its measured value $2.817\,94 \times 10^{-15}\,\mathrm{m}$ [2431], this is about $1.6 \times 10^{-11}\,\mathrm{s}$. Classical physics does not merely misdescribe the atom; it forbids the atom to exist for longer than a hundredth of a nanosecond, while radiating a continuous spectrum that is never seen.

70.4 The Bohr model

70.4.1 The 1913 trilogy

[Reserved: Bohr's postulates [396] — that an atom possesses stationary states in which it does not radiate, and that radiation accompanies a transition between two of them with $h\nu = E_i - E_f$, which is Ritz's combination principle [348] promoted to a law. Selection of the stationary states by quantized angular momentum $L = n\hbar$, equivalently by the action condition of Chapter 23. Parts II and III of the trilogy [397, 398] extend the scheme to multi-electron atoms and to molecules and are much less successful; the section should say which parts survived.]

70.4.2 What the model gets right

[Reserved: energies $E_n = -13.606\,\mathrm{eV}/n^2$, radii $r_n = n^2 a_0$ with the Bohr radius $a_0 = 5.291\,77 \times 10^{-11}\,\mathrm{m}$, and the Rydberg constant emerging as $R_\infty = m_e e^4/8\varepsilon_0^2 h^3 c = 1.097\,373\,156\,8 \times 10^7/\mathrm{m}$ — computed from independently measured constants and agreeing with the spectroscopic value, which is the single result that forced the model on a sceptical community. Also the Z^2 scaling verified on ionized helium, and the correct identification of the Pickering series in stellar spectra as He^+ rather than hydrogen.]

Phenomenon 70.6 (The hydrogen term values)**.** The terms whose differences Equation (70.1) organizes are, for hydrogen, inversely proportional to the square of an integer, so that the energies of the stationary states are

$$E_n = -\frac{hcR_\infty}{n^2}\,, \qquad n = 1, 2, 3, \ldots\,, \tag{70.4}$$

The Rydberg constant is known spectroscopically as $1.097\,373\,156\,8 \times 10^7/\mathrm{m}$, so the ground state lies $13.605\,693\,\mathrm{eV}$ below the ionization limit [2431]. The same expression with R_∞

replaced by $Z^2 R_\infty$ reproduces the observed spectrum of a one-electron ion, which is what identified the Pickering series seen in stellar spectra as belonging to He^+ and not to hydrogen [396].

Derivation. Take Bohr's two postulates [396]: that the atom possesses stationary states in which it does not radiate, and that radiation accompanies a transition between two of them, carrying away $h\nu = E_i - E_f$ — which is Ritz's combination principle [348] promoted from a regularity to a law. Select the stationary states by requiring the orbital angular momentum to be an integer multiple of $\hbar$. For a circular orbit of radius r about a fixed charge Ze, Newton's second law with the Coulomb force and the selection rule read

$$\frac{m_\mathrm{e} v^2}{r} = \frac{Ze^2}{4\pi\varepsilon_0 r^2}\,, \qquad \text{and} \qquad m_\mathrm{e} v r = n\hbar\,.$$

Eliminating v between them gives the radii

$$r_n = \frac{4\pi\varepsilon_0 \hbar^2}{m_\mathrm{e} Z e^2}\, n^2 = \frac{n^2}{Z}\, a_0\,, \qquad a_0 := \frac{4\pi\varepsilon_0\hbar^2}{m_\mathrm{e} e^2}\,,$$

the Bohr radius a_0 being $5.291\,77 \times 10^{-11}\,\mathrm{m}$, which is the observed size of the hydrogen atom and was not put in. The first of the two displayed relations makes the kinetic energy half the magnitude of the potential energy, so the total energy is $E = -Ze^2/8\pi\varepsilon_0 r$, and substituting r_n,

$$E_n = -\frac{m_\mathrm{e} Z^2 e^4}{8\varepsilon_0^2 h^2}\,\frac{1}{n^2}\,.$$

The wavenumber emitted in a transition is then

$$\tilde{\nu} = \frac{E_{n_2} - E_{n_1}}{hc} = \frac{m_\mathrm{e} Z^2 e^4}{8\varepsilon_0^2 h^3 c}\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right),$$

which is Equation (70.1) with $R_\infty = m_\mathrm{e} e^4/8\varepsilon_0^2 h^3 c$, together with the Z^2 scaling. The decisive point is not that the formula has the right shape — Balmer's had that in 1885 — but that R_∞ is here *computed* from m_e, e and h, each of them measured in experiments having nothing to do with spectroscopy, and the number agrees with the spectroscopic value. That agreement is what forced a sceptical community to take the postulates seriously. □

70.4.3 Reduced mass and the isotope shift

[Reserved: replacing the electron mass by the reduced mass of the two-body problem (Chapter 27) shifts every line by a part in 2000 *between hydrogen and infinite nuclear mass, and by a computable amount between hydrogen and its isotopes. Urey's discovery of deuterium was exactly this: the predicted shifted Balmer lines were sought in evaporated liquid hydrogen and found [708]. A quantitative prediction of a new isotope from a spectral formula is a strong argument, and it is worth setting out in full. Present-day accuracy of R_∞ [2431] and the spectroscopy that delivers it (Chapter 90).]*

Phenomenon 70.7 (The hydrogen–deuterium isotope shift)**.** Every hydrogen line is accompanied by a faint companion displaced slightly towards shorter wavelength, in the fixed proportion that follows from replacing the electron mass in the Rydberg constant by the reduced mass of the electron and the nucleus. Urey, Brickwedde and Murphy concentrated the heavy component by evaporating liquid hydrogen near its triple point, looked for the predicted companions of the Balmer lines, and found them at the predicted separations — about 0.179 nm for Hα, whose principal component lies at 656.28 nm — thereby discovering deuterium [708].

Derivation. The nucleus is not infinitely heavy, so the two-body reduction of Chapter 27 replaces m_{e} throughout the derivation of Equation (70.4) by the reduced mass $\mu = m_{\mathrm{e}} M / (m_{\mathrm{e}} + M)$ of the electron and a nucleus of mass M. Every term, and therefore every wavenumber, is multiplied by

$$\frac{R_M}{R_\infty} = \frac{\mu}{m_{\mathrm{e}}} = \frac{1}{1 + m_{\mathrm{e}}/M} \, .$$

For two isotopes of nuclear masses M and $M' > M$ the fractional difference in wavenumber is, to first order in the small ratio m_{e}/M,

$$\frac{\Delta \tilde{\nu}}{\tilde{\nu}} = \frac{m_{\mathrm{e}}}{M} - \frac{m_{\mathrm{e}}}{M'} \, .$$

With M the proton mass and M' the deuteron mass, very nearly twice it, this is about $m_{\mathrm{e}}/2M_{\mathrm{p}}$, that is 2.72×10^{-4}. Applied to Hα it predicts a separation of 0.179 nm, which a grating spectrograph of 1932 could resolve comfortably — the whole difficulty of the experiment was to enrich the sample enough for the companion to be visible at all. The displacement is towards *shorter* wavelength because the heavier nucleus makes μ larger and hence every term value larger. Note that the argument makes a quantitative prediction about a substance nobody had yet observed, and that this is a far stronger test of Equation (70.4) than a fit to lines already measured. □

70.4.4 Where the model fails

[Reserved: no line intensities, no transition rates, no selection rules except by fiat; no account of the helium atom, whose ground-state energy the old quantum theory got badly wrong despite a decade of effort; no molecules; no explanation of why the postulates hold. The orbits themselves are wrong — the ground state has zero orbital angular momentum, not $\hbar$ — and the reason the energies come out right anyway is explained only by Chapter 81. Bohr himself catalogued the failures [463]; the model is retained in this treatise as evidence about levels, not as a picture of an atom.]

70.5 The old quantum theory

70.5.1 Sommerfeld's elliptic orbits and the fine structure

[Reserved: Sommerfeld's extension [441] of the quantization condition to each separable degree of freedom of Chapter 23, giving elliptic orbits with a radial and an azimuthal quantum number, degenerate in the nonrelativistic problem; the relativistic correction to the electron mass lifts the degeneracy and yields a fine-structure splitting of order α^2, with $\alpha = e^2/4\pi\varepsilon_0\hbar c \approx 1/137$ introduced here for the first time. The formula agrees with the observed hydrogen fine structure, and it agrees for the wrong reason — the true splitting involves the electron spin of Chapter 79, absent from Sommerfeld's theory. The coincidence is worth a remark: it is the standard warning against counting agreement alone as confirmation.]

70.5.2 The correspondence principle

[Reserved: Bohr's requirement [463] that in the limit of large quantum numbers the frequencies and intensities of quantum transitions approach those of the classical Fourier components of the orbital motion. It is the only tool the old quantum theory had for intensities and selection rules, it fixed $\Delta l = \pm 1$, and it was the heuristic from which Heisenberg's matrix mechanics was constructed. Its modern residue is the classical limit of Chapter 82 and the Ehrenfest theorem of Chapter 77.]

70.5.3 Space quantization

[Reserved: the quantization of the orientation of the orbital plane in a magnetic field, introduced by Sommerfeld [441] to account for the Zeeman pattern of Section 70.7.1, and taken by contemporaries as an absurdity too far. It is the prediction tested directly by the deflection of a silver beam in an inhomogeneous field [481, 491, 492], whose two-component result confirmed the discreteness while contradicting the theory that predicted it — silver has no orbital angular momentum in its ground state, and the doubling is spin. The experiment and this honest history are Chapter 80 [2050].]

70.6 X-ray spectra and the atomic number

70.6.1 X-rays and their wavelengths

[Reserved: Röntgen's discovery of a penetrating radiation from a discharge tube [269]; the demonstration by Friedrich, Knipping and Laue that crystals diffract it, which established both that X-rays are short-wavelength electromagnetic radiation and that crystals are periodic lattices [385]; the Braggs' reduction of the diffraction condition to $n\lambda = 2d\sin\theta$ and the crystal spectrometer built on it [400], which made X-ray wavelengths measurable to a few parts in a thousand. Without this instrument neither Section 70.6.2 nor the Compton measurement of Chapter 69 would have been possible.]

70.6.2 Moseley's law

[Reserved: Moseley's measurement of the characteristic K and L emission of the elements from aluminium to gold [408, 418] and the finding that the square root of the frequency is linear in an integer that advances by one from element to element, $\sqrt{\nu} \propto (Z - \sigma)$ with $\sigma \approx 1$ for the Kα line. The integer is the nuclear charge, not the atomic weight: the periodic table is thereby ordered by Z, the inversions of the weight ordering (argon and potassium, cobalt and nickel) are resolved, and the number of missing elements is fixed at exactly the gaps found — three below gold, all later filled. Screening as the physical content of σ, explained by Chapter 88.]

Phenomenon 70.8 (Moseley's law)**.** The characteristic X-ray emission of the elements from aluminium to gold consists of a few sharp lines whose frequencies advance smoothly and regularly through the periodic table. The square root of the frequency of the Kα line is a linear function of an integer which increases by exactly one from each element to the next,

$$\sqrt{\nu} = A\,(Z - \sigma)\,, \qquad \sigma \approx 1\,, \tag{70.5}$$

and the same holds, with a different slope and screening constant, for the L series [408, 418]. The integer is not the atomic weight but the charge on the nucleus: ordering the elements by Z resolves the inversions of the weight ordering, argon before potassium and cobalt before nickel, and the gaps in the sequence fix the number of elements then undiscovered — three below gold, all later found.

Derivation. Apply Equation (70.4) to the innermost electrons of a heavy atom. The Kα line is the transition from $n = 2$ to $n = 1$, and the electron making it moves in the field of the nucleus screened by the one remaining K electron, so that the effective charge is $(Z - \sigma)\,e$ with σ of order unity. The Z^2 scaling established with Equation (70.4) then gives

$$\nu = cR_\infty\,(Z - \sigma)^2 \left(\frac{1}{1^2} - \frac{1}{2^2}\right) = \frac{3}{4}\,cR_\infty\,(Z - \sigma)^2\,,$$

so that $\sqrt{\nu}$ is linear in Z with slope $A = (3cR_\infty/4)^{1/2}$, which is Equation (70.5). The inner electrons are the ones for which a hydrogen-like treatment is defensible in a many-electron atom, since the nuclear attraction dominates the mutual repulsion there; σ is what measures the residual screening. The straight line holding across sixty elements, with a slope containing no adjustable parameter, is what establishes that Z and not the atomic weight is the quantity that orders the table. □

70.7 Atoms in external fields

70.7.1 The Zeeman effect

[Reserved: Zeeman's observation that spectral lines broaden and then split in a magnetic field, with the components polarized as Lorentz's electron theory required [277]; the normal triplet with splitting $\Delta\nu = eB/4\pi m_e$, which yielded a charge-to-mass ratio agreeing with Thomson's [276] — an independent determination of the electron from optics. The Bohr magneton $\mu_B = 9.274\,010\,065\,7 \times 10^{-24}$ J/T [2431] as the natural unit; astrophysical use in measuring stellar and sunspot magnetic fields.]

Phenomenon 70.9 (Spectral lines split in a magnetic field)**.** A spectral line emitted by a source placed in a magnetic field B is resolved into several components. Their separations are proportional to B, and their polarizations depend on whether the source is viewed along the field or across it [277]. A minority of lines — the "normal" cases — split into exactly three components, the outer two displaced by

$$\Delta\nu = \frac{eB}{4\pi m_e}\,, \tag{70.6}$$

from which Zeeman obtained a charge-to-mass ratio for the radiating particle agreeing with the value Thomson measured on cathode rays [276] — an identification of the electron made optically and independently. Most lines, however, split into more components than three and in patterns Equation (70.6) does not describe. Paschen and Back mapped these anomalous patterns exhaustively, together with their collapse to the normal triplet in strong fields [391], and no theory available before 1925 fitted any of them.

Derivation pending #58

Two derivations of different standing. The normal triplet follows classically, from the Larmor precession that a magnetic field imposes on a bound charge: the three normal modes of an isotropic oscillator in a field, their frequencies, and the circular and linear polarizations of the light each of them emits. The anomalous patterns do not follow at all without the electron spin and the coupling of spin to orbital angular momentum, and their treatment belongs to the angular-momentum chapter of the quantum-mechanics part; what must be recorded here is that the empirical splitting factor was fitted, not derived.

70.7.2 The anomalous Zeeman effect

[Reserved: most lines do not split into three. Paschen and Back's systematic study of the anomalous patterns and of their collapse to the normal triplet in strong fields [391] left a body of exact data that the old quantum theory could not fit at all, and that required the Landé g factor as a pure empirical parameter. This was the sharpest unsolved problem in atomic physics before 1925, and its solution is electron spin with $g \approx 2$ (Chapter 79), whose own precise value is the most stringently tested prediction in physics (Chapter 112).]

70.7.3 The Stark effect

[Reserved: Stark's splitting of the hydrogen Balmer lines in an electric field of order $1 \times 10^5\,\mathrm{V/cm}$*, produced in the dark space just behind a perforated cathode [422]; the splitting is* linear *in the field for hydrogen and quadratic for other atoms, a distinction with no classical explanation. Linearity requires the accidental degeneracy of the Coulomb problem, so the effect is direct evidence about the symmetry of the hydrogen Hamiltonian, and it is the standard worked example of degenerate perturbation theory in Chapter 82. Stark broadening as a plasma diagnostic (Chapter 66).]*

70.8 Levels made visible

[Reserved: a short closing section stating what all the foregoing has and has not established. The spectroscopic evidence is about differences *of energies, by Ritz's principle [348]; every model in this chapter fits differences, and no optical measurement can show that a level exists otherwise than as a term in a difference. The independent demonstration comes from electron impact, where energy is delivered to an atom mechanically and the threshold is measured directly: that is Chapter 72, and it is placed immediately after this chapter for that reason. The theory that replaces the models assembled here begins at Chapter 77, and the hydrogen atom is solved properly in Chapter 81.]*

Chapter 71

Matter Waves

Chapter 69 established that light, which every nineteenth-century experiment had shown to be a wave, delivers energy and momentum in indivisible amounts. De Broglie's proposal [500, 521] was the converse, and it was made on grounds of symmetry rather than of data: if a wave carries momentum $p = h/\lambda$, then a particle of momentum p should be accompanied by a wave of wavelength h/p. The hypothesis was not idle. It supplies at once the one thing Bohr's model of Chapter 70 had to assume — the quantization of angular momentum becomes the condition that an integer number of wavelengths fit the orbit — and it completes the analogy of Chapter 23, in which classical mechanics stands to an unknown wave theory as geometrical optics stands to wave optics. The unknown wavelength is h/p, and the chapter's business is the evidence that it is real.

That evidence is unusually good and it keeps improving, which is why this chapter is long on experiment. Electrons were diffracted by crystals within three years [571, 589], neutral atoms within five [651]; the interference pattern was later built up one electron at a time [1588, 1826], so that no account in terms of a collective effect survives; neutron interferometers made the phase itself a laboratory observable and measured shifts due to gravity [1542] and to a 360° rotation of a spin-half particle [1566]; and molecules of thousands of atoms interfere today [1966, 2337] with no sign of a boundary beyond which the relation fails. The chapter closes on wave packets and group velocity — the machinery that reconciles a wave with a localized particle — and hands the problem of finding the wave's equation of motion to Chapter 77.

Derivation pending #59

Matter Waves: all derivations of this chapter are pending.

71.1 The de Broglie hypothesis

71.1.1 The relation

[Reserved: de Broglie's short note of 1923 [500] and the thesis that expanded it [521]; the pair of relations $E = h\nu$ and $p = h/\lambda$ asserted for every *carrier of energy and momentum, massive or not. The relativistic argument that motivated them: a particle at rest has an internal frequency mc^2/h, and requiring the phase of that oscillation to stay in step with a wave when the particle is seen from a moving frame (Chapter 38) forces a phase velocity c^2/v and a group velocity v. Numerical scale: an electron accelerated through $54\,\mathrm{V}$ has $\lambda = 0.167\,\mathrm{nm}$, comparable to a lattice spacing, which is what makes the effect observable at all.]*

71.1.2 Phase waves and the Bohr condition

[Reserved: the standing-wave condition $n\lambda = 2\pi r$ on a circular orbit is $L = n\hbar$, so Bohr's postulate [396] ceases to be an arbitrary selection rule and becomes the requirement that the accompanying wave be single-valued. The same reading applies to Sommerfeld's action integrals [441], which become the statement that the phase accumulated round a closed path is a multiple of 2π. This is the first argument in physics that explains an old quantum condition rather than positing it, and it is why the hypothesis was taken seriously before any experiment.]

71.1.3 The optical–mechanical analogy completed

[Reserved: the dictionary of Chapter 23 had one incomplete entry — classical mechanics is the short-wavelength limit of some *wave theory, with the part of the wavelength played by an unidentified quantity. De Broglie identifies it as h/p, and the Hamilton–Jacobi equation becomes the eikonal equation of the matter wave, valid where the potential varies slowly on the scale of λ. The criterion for the classical limit follows, and it is quantitative: it fails for an electron in an atom and holds for a marble. Schrödinger constructed the wave equation whose eikonal limit this is, and said so in his first communication [557].]*

71.2 Electron diffraction

71.2.1 Elsasser's prediction

[Reserved: Elsasser's one-page note [523] pointing out that de Broglie wavelengths of slow electrons match crystal lattice spacings, so a crystal should diffract an electron beam exactly as it diffracts X-rays [400], and that the anomalous scattering already reported by Davisson and Kunsman might be this. The prediction was published two years before the confirming experiments and was unknown to one of the two groups that performed them; the section records it because the priority is routinely assigned to the experimenters alone.]

71.2.2 Davisson and Germer

[Reserved: the Bell Telephone Laboratories experiment [571]. A vacuum accident recrystallized a nickel target into a few large crystals; the scattered intensity then showed sharp maxima at particular angles and energies where before it had been smooth. At 54 eV *the beam scattered from the (111) face peaks near* 50°*, giving* $\lambda = 0.165$ nm *against the de Broglie value* 0.167 nm*. Apparatus, the Faraday-box collector, the angle and voltage scans, and the systematic correction for the inner potential of the crystal are all to be given in full, since this is the primary evidence of the chapter.]*

Phenomenon 71.1 (Electrons are diffracted by crystals)**.** A beam of electrons of well-defined kinetic energy scattered from a crystal produces sharp intensity maxima at particular angles, exactly as X-rays of the same wavelength do on the same crystal, and the wavelength read off the diffraction geometry is h/p. Davisson and Germer, scattering electrons of 54 eV from the (111) face of a nickel single crystal, found a pronounced maximum near 50° corresponding to a wavelength of 0.165 nm, against the de Broglie value 0.167 nm [571]. Thomson and Reid passed electrons of 10–60 keV through thin polycrystalline films of celluloid, gold and aluminium and photographed concentric rings whose radii scale as the inverse square root of the accelerating voltage, independently of the orientation of the target [589].

Derivation. Assume de Broglie's relation $\lambda = h/p$ [500, 521] and compute the wavelength of the beam. An electron accelerated from rest through a potential difference V small enough

that $eV \ll m_{\mathrm{e}}c^2$ acquires $p = (2m_{\mathrm{e}}eV)^{1/2}$, so

$$\lambda = \frac{h}{\sqrt{2m_{\mathrm{e}}eV}}\,, \tag{71.1}$$

which at 54 V is 0.167 nm — comparable with a lattice spacing, which is the whole reason the effect is observable at all. The rest is the geometry of a grating. A row of scatterers of spacing d on the crystal surface reinforces at angles satisfying $d\sin\theta = n\lambda$; the nickel row spacing is 0.215 nm, measured independently by X-ray crystallography [400], and this puts the first order at 50°, where the observed maximum lies. Reading $\lambda = d\sin\theta$ back off that geometry gives 0.165 nm. Nothing was adjusted: d comes from X-rays and λ from the accelerating voltage, and the two independently determined numbers agree.

Equation (71.1) also accounts for the transmission geometry. In a polycrystalline film the crystallites take every orientation, so the reinforcement condition is met on cones about the beam and the pattern is a set of rings whose radii are proportional to λ and therefore to $V^{-1/2}$, which is what is photographed [589]. Because a polycrystal has no preferred orientation, that observation also removes any explanation resting on a surface effect peculiar to one crystal face. □

71.2.3 Thomson's transmission experiment

[Reserved: G. P. Thomson and Reid passed electrons of 10–60 keV *through thin films of celluloid, gold and aluminium and photographed concentric Debye–Scherrer rings whose radii scale as the inverse square root of the accelerating voltage [589] — a polycrystalline pattern, independent of target orientation and therefore of any surface effect, complementing the single-crystal geometry of Section 71.2.2. The historical remark is irresistible and belongs in a remark rather than the body: J. J. Thomson showed the electron is a particle [276] and G. P. Thomson that it is a wave, and both were right.]*

71.3 Interference of atoms and molecules

71.3.1 Helium beams: Estermann and Stern

[Reserved: diffraction of neutral helium atoms and of hydrogen molecules from the cleavage face of lithium fluoride [651], with the wavelength varied by changing the source temperature and checked against h/p over the thermal distribution. This is the decisive extension: helium is electrically neutral and structureless, so no explanation in terms of charge, of the Coulomb field, or of anything peculiar to the electron survives. The molecular-beam technique is Stern's, the same apparatus lineage as Chapter 80.]

Phenomenon 71.2 (Neutral atoms and molecules are diffracted)**.** Beams of helium atoms and of hydrogen molecules reflected from the cleavage face of a lithium fluoride crystal show diffraction maxima at the angles the grating condition assigns to the wavelength h/p, and those maxima move as predicted when the wavelength is changed by changing the temperature, and hence the mean momentum, of the source [651]. Helium is electrically neutral, chemically inert and has no permanent electric or magnetic moment, so no account of the phenomenon in terms of charge, of the Coulomb field, or of anything peculiar to the electron survives this measurement: the wave behaviour belongs to matter as such.

Derivation pending #60

Diffraction of a thermal beam: the grating condition for a two-dimensional surface lattice, and the shape of the observed maxima when the incident beam is not monochromatic but carries the Maxwellian velocity distribution of the oven, each velocity class contributing its own de Broglie wavelength. What must be shown is that the position of each maximum tracks the most probable momentum in the predicted way as the source temperature is varied, which is the quantitative content of the experiment.

71.3.2 The electron double slit

[Reserved: Jönsson's fabrication of slits of about 0.5 µm *width in copper foil by electron lithography, and the resulting two-, three-, four- and five-slit interference patterns formed with* 50 keV *electrons and magnified electron- optically [1212] — Young's experiment (Chapter 67) performed with matter. Why it took thirty-four years after Section 71.2.2: the wavelength is four orders of magnitude below optical, so the slit separation and the detection geometry are the whole difficulty.]*

71.3.3 Building the pattern one particle at a time

[Reserved: the experiment that removes the last collective explanation. Merli, Missiroli and Pozzi [1588] and, with a field-emission source, a biprism and a position-sensitive detector, Tonomura and collaborators [1826] recorded interference with at most one electron in the apparatus at a time; individual detections arrive as points at apparently random places and the fringes emerge only in the accumulated histogram. The wave is therefore a wave of probability amplitude, in Born's sense [533], and not a wave of anything that is spread out — the statement that Chapter 77 formalizes and Chapter 85 declines to explain further.]

Phenomenon 71.3 (The interference pattern is built one particle at a time)**.** When the source is weakened until at most one electron is inside the apparatus at any moment, the detector still registers individual, point-like arrivals, at positions that show no pattern one by one. The interference fringes appear only in the accumulated histogram of many thousands of such arrivals, and they are the same fringes, in the same places and with the same spacing, as those formed at high intensity [1588, 1826]. The pattern is therefore not an effect of electrons acting on one another, and the multiple-slit fringes formed with 50 keV electrons [1212] are a property of each electron separately.

Derivation pending #61

The accumulation statistics: that the arrival positions are independent samples drawn from the squared modulus of the single-particle amplitude, so that the histogram of many arrivals converges on the intensity pattern of the wave while no individual arrival carries any fringe at all. What must be derived is the convergence itself and its rate, and what must be stated is that the probabilistic reading of the amplitude is an additional postulate and not a consequence of the de Broglie relation.

71.4 Neutron interferometry

71.4.1 The perfect-crystal interferometer

[Reserved: Rauch, Treimer and Bonse's interferometer cut from a single silicon crystal, in which three parallel lamellae split, redirect and recombine a thermal-neutron beam by Bragg

reflection [1532], with an arm separation of centimetres and a wavelength near 0.18 nm*. It converts the phase of a matter wave into a countable intensity and thereby makes phase an experimental quantity for a massive particle. Requirements: lattice perfection over the whole device, thermal and vibrational stability; this is the instrument behind the next three subsections.]*

71.4.2 Gravitationally induced phase

[Reserved: rotating the interferometer about the incident beam tilts the plane containing the two paths out of the horizontal, so they run at different heights in the Earth's field and accumulate a relative phase proportional to $m^2 g A \lambda / \hbar^2$*; Colella, Overhauser and Werner observed the predicted fringe count [1542]. Two things make it remarkable and both belong here: the inertial and gravitational masses appear as a product* m^2*, so this is a quantum experiment in which the equivalence principle of Chapter 42 is probed; and* $\hbar$ *and* g *appear in the same formula, which no other laboratory measurement of the period achieved.]*

Phenomenon 71.4 (Gravity shifts the phase of a matter wave)**.** Rotating a neutron interferometer about the direction of the incident beam tilts the plane containing its two paths out of the horizontal, so that the two paths run at different heights in the Earth's gravitational field. The counted intensity in each exit beam then oscillates with the tilt angle α, with a phase difference

$$\Delta\varphi = \frac{2\pi m^2 g A \lambda}{h^2} \sin\alpha \tag{71.2}$$

between the paths, where A is the area they enclose and λ the neutron wavelength. Colella, Overhauser and Werner observed the predicted number of fringes as the interferometer was rotated [1542]. Two features are worth naming, and both are unusual. The mass enters *squared*, once inertially through the wavelength and once gravitationally through the potential, so this is a quantum interference experiment that probes the equivalence principle of Chapter 42; and $\hbar$ and g appear together in a single measured quantity, which no other laboratory experiment of its period achieved.

Derivation pending #62

The gravitationally induced phase: the local wavenumber of a neutron in a linear potential, obtained from the free-particle dispersion relation with the gravitational potential energy subtracted from the total energy; the phase accumulated along each arm as the line integral of that wavenumber; and the reduction of the difference to the stated product of the squared mass, the acceleration of free fall, the enclosed area and the wavelength. The systematic corrections that must accompany it — bending of the crystal under its own weight as the device is rotated, and the Sagnac phase from the Earth's rotation — belong with it.

71.4.3 Rotation by a full turn changes the sign

[Reserved: a magnetic field on one arm precesses the neutron spin; the interference contrast returns to its original value only after a rotation of 720°*, the amplitude changing sign at* 360°*. Measured independently by Werner and collaborators [1566] and by Rauch's group [1558]. This is a direct observation of the double cover* $\mathrm{Spin}(3) \to \mathrm{SO}(3)$ *of Chapter 14, that is of the fact that a spin-half state transforms under a representation of the covering group and not of the rotation group itself (Chapter 79); the sign is unobservable for a whole system and observable in an interferometer, which is the distinction the experiment makes concrete.]*

Phenomenon 71.5 (A spin-half state changes sign under a full rotation)**.** A magnetic field applied on one arm of a neutron interferometer precesses the neutron spin through a controlled angle, and the interference contrast is recorded as a function of that angle. The contrast does not return to its initial value after a precession of 360°: the amplitude has changed sign there, and the original state is recovered only after 720°. The double-turn periodicity was measured independently by two groups, on different instruments [1558, 1566]. The sign is unobservable for an isolated system and becomes observable here only because the interferometer compares it against an amplitude that was not rotated.

Derivation pending #63

The rotation operator for a spin-half state: that the generator of rotations has half-integer eigenvalues, so that a rotation by a full turn acts as minus the identity rather than the identity, and that a spin-half state therefore carries a representation of the covering group and not of the rotation group. The interferometric argument that turns this global sign into a measurable relative phase must accompany it, together with the relation between the applied magnetic field, the transit time and the precession angle.

71.4.4 Bound states of a neutron in the Earth's field

[Reserved: ultracold neutrons above a horizontal mirror form quantized vertical bound states in the linear gravitational potential; the transmission through a slit of variable height rises in steps at the predicted heights, with the lowest state around 13 µm *and an energy of a few* peV *[2034]. Airy functions as the eigenfunctions, worked in Chapter 78; the experiment is the cleanest existing observation of quantized motion in a gravitational field and is cited again in Chapter 135 for what it does* not *test.]*

Phenomenon 71.6 (Quantized bound states of a neutron above a mirror)**.** Ultracold neutrons travelling horizontally above a flat, polished mirror are bound vertically between the mirror below and the linear gravitational potential above, and the states of that vertical motion are discrete. The transmitted flux, measured as an absorber is lowered towards the mirror, does not fall smoothly with the gap but in steps: no neutron passes at all below a gap of about 13 µm, which is the extent of the lowest state, and further steps follow at the heights of the states above it [2034]. The energy of the lowest state is about 1.4 peV. This is the cleanest existing observation of quantized motion in a gravitational field.

Derivation pending #64

The eigenvalue problem for a particle in a linear potential above a hard wall: the equation reduces to Airy's equation, the admissible solutions are the decaying Airy function shifted so as to vanish at the mirror, and the eigenvalues are therefore fixed by its zeros. The classical turning-point heights follow from the eigenvalues, and it is those heights that the absorber measures; the step positions predicted this way are to be compared with the observed ones.

71.5 How large can an interfering object be?

71.5.1 Fullerenes

[Reserved: far-field diffraction of C_{60} *from a nanofabricated grating, with a de Broglie wavelength near* 2.5 pm*, some four hundred times smaller than the molecule itself [1966]; the*

molecules are hot, populating millions of internal vibrational states and radiating thermal photons, and the fringes survive — so internal complexity does not by itself destroy coherence. What does destroy it is the emission or scattering of a photon carrying which-path information, which the same apparatus demonstrates by admitting a background gas, and which is the experimental basis of Chapter 87.]

Phenomenon 71.7 (Large molecules interfere)**.** Interference survives in objects far larger than their own de Broglie wavelength and far more complicated than a point. C_{60} molecules diffracted from a nanofabricated grating produce fringes at a wavelength near 2.5 pm, some four hundred times smaller than the molecule itself, even though the molecules are hot enough to populate millions of internal vibrational states and to radiate thermal photons while in flight [1966]. Near-field interferometry has since shown fringes for tailored molecules built from more than two thousand atoms, with masses above 25 000 atomic mass units, at wavelengths of order 50 fm [2337]. No deviation from $\lambda = h/p$ has been found at any mass yet reached, and no boundary beyond which the relation fails has appeared.

Derivation pending #65

Two things, of which only the first is optics. The near-field Talbot–Lau fringe condition and its scaling with mass and wavelength, which is what fixes the grating periods and the source coherence a given molecular mass demands. And the decoherence criterion: how much which-path information the emission or scattering of a single photon of given wavelength carries, and hence the residual gas pressure and internal temperature at which the fringes must disappear — the quantitative statement of what these experiments do and do not bound.

71.5.2 The present limits

[Reserved: Talbot–Lau near-field interferometry has since shown interference for tailored molecules of more than two thousand atoms and masses above 25 000 atomic mass units [2337], at wavelengths of order 50 fm. No deviation from the de Broglie relation has been seen at any mass. The section should state plainly what this does and does not bound: it constrains proposed objective-collapse modifications of quantum mechanics, which is a genuine experimental frontier, and it is reported honestly in Chapter 133 rather than as a settled matter.]

71.6 Wave packets

71.6.1 Superposition and localization

[Reserved: a single plane wave $e^{i(kx-\omega t)}$ describes a particle of definite momentum and no position at all, so a localized particle must be a superposition — a Fourier integral over k with an envelope, in the sense of Chapter 17. The Gaussian packet as the worked case: its width in x, its width in k, and the product of the two. Nothing in this subsection is specific to quantum mechanics; it is the classical mathematics of Chapter 28 applied to the de Broglie wave, which is exactly why it settles the apparent paradox.]

71.6.2 Phase velocity, group velocity and spreading

[Reserved: the free-particle dispersion relation $\omega = \hbar k^2/2m$ gives a phase velocity $\hbar k/2m$ — half the particle's speed, and for the relativistic relation greater than c, which alarms nobody once it is seen that no signal travels at it — and a group velocity $\mathrm{d}\omega/\mathrm{d}k = \hbar k/m = v$, the

particle's own velocity. The dispersion is quadratic and therefore non-vanishing, so every free matter wave packet spreads, at a rate computed here and observed in the expansion of released cold-atom clouds (Chapter 121). Compare the non-dispersive string of Chapter 28.]

71.6.3 Bandwidth and the uncertainty relation

[Reserved: for any wave, the product of the spatial width of a packet and the width of its spectrum is bounded below by a number of order unity — a theorem about Fourier transforms [2313] that predates quantum mechanics. Insert $p = \hbar k$ and it reads $\Delta x\, \Delta p \gtrsim \hbar/2$: the uncertainty relation is what the de Broglie relation makes of a bandwidth theorem. Heisenberg's own argument was operational, through the disturbance caused by a measurement [576], and the two readings are not the same statement; which is which, and which one the modern inequality proves, is settled in Chapter 77.]

71.7 From a wavelength to a wave equation

71.7.1 What the hypothesis does not supply

[Reserved: $\lambda = h/p$ fixes the wavelength of a free particle and says nothing about a particle in a potential, about the equation the wave obeys, about what the wave is a wave of, or about spin. Each gap is named here with the chapter that closes it: the equation of motion [557] in Chapter 77, the probabilistic reading [533] there too, the spin degree of freedom in Chapter 79, and the relativistic treatment — for which the naive substitution into $E^2 = p^2c^2 + m^2c^4$ is the wrong first guess — in Chapters 92 and 93.]

71.7.2 Matter waves as instruments

[Reserved: the hypothesis is now hardware. Electron and neutron diffraction are the standard probes of crystal structure and magnetic order (Chapter 129); atom interferometers built from optical gratings [1847] serve as gravimeters, gradiometers and gyroscopes; and the recoil frequency measured in an atom interferometer gives h/m and hence the fine-structure constant to parts in 10^{10} [2316, 2363], an input to the tests of Chapter 112. A hypothesis that began as a symmetry argument now calibrates the constants of physics, which is the strongest form of confirmation available.]

Chapter 72

Experiment: Franck–Hertz

Everything in Chapter 70 that speaks of atomic energy levels speaks of them indirectly. Spectroscopy measures frequencies, Ritz's principle [348] shows the frequencies are differences of terms, and Bohr's postulates [396] interpret the terms as energies — but no optical measurement can reach a level except as one end of a difference, and a sceptic in 1913 could hold that the terms were a bookkeeping device. Franck and Hertz's experiment removes the intermediary. It delivers energy to a mercury atom mechanically, by bombarding it with electrons of controlled kinetic energy, and asks at what energy the atom begins to accept any. The answer is: at nothing below 4.9 eV, and then in units of 4.9 eV. Discreteness is measured with a voltmeter and an ammeter, in a tube containing no spectroscope at all [417].

The chapter is placed at the end of Part VIII because it is the point at which the quantized atom stops being a model that fits spectra and becomes a mechanical fact. It is also a lesson in reading one's own data: Franck and Hertz took the 4.9 V threshold to be the *ionization* potential of mercury and said so in print, a reading Bohr corrected within a year [425] and which the experimenters themselves abandoned only after further work [443, 467]. That history is set out here in full rather than tidied away, because the treatise's standard is that a reader must be able to reconstruct what was actually claimed and when. When written out, the chapter will use the structured `experiment` environment of the house style, with apparatus, procedure, observations in SI with uncertainties, interpretation and primary references as separate fields, and the digitized current–voltage curve deposited in the evidence store as `docs/library/data/Franck_1914a.csv`.

Derivation pending #66

Experiment: Franck–Hertz: all derivations and data analysis of this chapter are pending.

72.1 Historical context and the prediction under test

72.1.1 What the Bohr postulates predict for a collision

[Reserved: state the prediction sharply before any apparatus is described. If an atom possesses stationary states [396], an electron of kinetic energy below the first excitation energy $E_1 - E_0$ can only scatter elastically, and because the electron is some 4×10^5 times lighter than a mercury atom it then loses a fraction of order 1×10^{-5} of its energy per collision — that is, nothing measurable. Above that threshold an inelastic channel opens and the electron can lose the whole quantum at once. A classical atom with a continuum of internal energies predicts a gradual onset instead. The two predictions differ qualitatively, which is what makes the experiment decisive.]

72.1.2 What was known in 1913

[Reserved: Franck and Hertz's earlier collision work on noble gases, undertaken to measure ionization potentials and mean free paths, not to test Bohr; the state of the art in electron-impact technique; and the fact — important for the honest history of Section 72.5.2 — that the pair were working within an ionization-potential programme and were not looking for excitation. Bohr's papers [396, 397] had appeared months earlier and are not cited in [417].]

72.2 Apparatus

72.2.1 The tube

[Reserved: an evacuated glass vessel containing a drop of mercury, held in an oven at about $450\,\mathrm{K}$ *so that the saturated vapour pressure gives an electron mean free path much shorter than the cathode–grid distance — the condition that guarantees many collisions and hence a periodic structure rather than a single step. A heated platinum-wire cathode; a wire-gauze grid at a positive accelerating potential; a collecting anode a short distance beyond it. Geometry, materials, dimensions and the oven's temperature stability to be given as measured, together with the vapour-pressure curve that converts oven temperature to number density.]*

72.2.2 Electrical arrangement and the systematics it controls

[Reserved: the accelerating voltage between cathode and grid; the small retarding *bias of a few tenths of a volt between grid and anode, which is the essential element of the design — an electron that has just lost its energy in an inelastic collision cannot climb it and is not collected, so the anode current falls. Measurement of the current with a galvanometer. Systematics to be enumerated and bounded: the contact-potential difference between the electrodes, which offsets the whole curve without changing the spacing; space charge; thermionic energy spread of the cathode; and the possibility of double inelastic collisions.]*

72.3 Procedure

[Reserved: bring the oven to temperature and verify stability; set the retarding bias; sweep the accelerating voltage from zero upwards in steps and record the anode current at each step, repeating in both directions to bound hysteresis; repeat the sweep at several oven temperatures to show that the spacing *of the features is independent of vapour pressure while their sharpness is not; repeat with the retarding bias varied to show the features are not an artefact of it. The analysis procedure is to be fixed in advance: locate each current maximum, fit the maxima against their ordinal number, and take the slope as the excitation energy, so that the contact potential appears only in the intercept and drops out of the result.]*

72.4 Observations

72.4.1 The current–voltage curve

[Reserved: the anode current rises with accelerating voltage, drops abruptly near $4.9\,\mathrm{V}$*, rises again, drops near* $9.8\,\mathrm{V}$*, and so on, giving a series of maxima equally spaced by* $4.9\,\mathrm{V}$ *[417]; the original work followed the sequence far enough to see several periods. To be tabulated: the accelerating voltage at each maximum with its uncertainty, the fitted spacing, the intercept and its interpretation as a contact potential, and the oven temperature and derived vapour*

density for each run — all in SI, with the uncertainty budget assembled in the manner of [1945, 2129].]

Phenomenon 72.1 (Periodic structure of the current–voltage curve)**.** In a tube containing mercury vapour, with electrons accelerated from a hot cathode towards a grid and collected beyond it against a small retarding bias, the anode current rises with the accelerating voltage, drops abruptly near 4.9 V, rises again, drops again near 9.8 V, and continues so for as many periods as the tube will sustain: the current maxima are equally spaced, and the spacing is 4.9 V [417]. The *spacing* does not depend on the vapour pressure, on the geometry of the tube or on the size of the retarding bias — these govern only how sharp the features are and where the first one falls — so it is a property of the mercury atom and not of the apparatus.

Derivation. Suppose with [396] that the atom possesses discrete internal energies and that the lowest excitation costs $\varepsilon = E_1 - E_0$. An electron of kinetic energy below ε cannot excite the atom and can only scatter elastically. Because the electron is lighter than a mercury atom by a factor of about 4×10^5, an elastic collision transfers at most the fraction $4m_\mathrm{e}/M$ of its energy, some parts in 10^5, which is nothing measurable; the electron therefore crosses the tube carrying essentially the whole energy eV it gained from the field, climbs the retarding bias and is collected. The current rises with V.

When eV first reaches ε — which happens just in front of the grid, where the accelerating potential has been fully traversed — the inelastic channel opens. An electron that takes it is left with almost no kinetic energy, cannot climb the retarding bias between grid and anode, and is not collected: the current falls. Raising V further, the electron regains energy after its collision and is collected again, so the current recovers; but as soon as it can acquire a further ε before reaching the grid it suffers a *second* inelastic collision and is again stopped. The condition for the k-th drop is therefore

$$eV_k = k\varepsilon + eV_\mathrm{c}\,, \tag{72.1}$$

with V_c the contact-potential difference between the electrodes, so that successive maxima are equally spaced by

$$\Delta V = \frac{\varepsilon}{e}\,. \tag{72.2}$$

Note what Equation (72.1) says about the systematics: the contact potential enters the intercept and cancels from the spacing, which is why the analysis fits the maxima against their ordinal number and takes the slope rather than reading a single threshold. A short mean free path — that is, a high vapour pressure — is what makes the collisions numerous enough for the structure to be periodic at all, but it does not enter Equation (72.2). A classical atom, whose internal energy could be changed by any amount however small, predicts a gradual onset of energy loss and no periodic structure whatever. □

72.4.2 The emission line at 253.7 nanometres

[Reserved: the companion measurement, and the one that closes the argument [416]. When and only when the electron energy exceeds the threshold, the vapour emits ultraviolet light at a single wavelength of 253.7 nm*. The photon energy $hc/\lambda = 4.89$ eV agrees with the electrical threshold, so the energy the electron loses is the energy the atom radiates — the mechanical and the optical measurements of the same level interval, made in the same tube. This is the point at which the experiment tests [396] and not merely the existence of a threshold.]*

Phenomenon 72.2 (The energy absorbed is re-emitted as a single spectral line)**.** When, and only when, the electron energy exceeds the threshold of Phenomenon 72.1, the mercury vapour in the tube emits ultraviolet light — and at one wavelength only, 253.7 nm [416]. The

energy of a single quantum of that light equals, within the precision of the 1914 measurement, the energy the electron is observed to lose. The mechanical and the optical determinations of the same atomic level interval are thus made on the same atoms in the same apparatus, and they agree.

Derivation. By the Planck–Einstein relation the energy of one quantum of light of wavelength λ is $E = hc/\lambda$. With h and c at their present SI values [2333] the product hc is 1239.84 eV nm, so a wavelength of 253.7 nm corresponds to 4.89 eV. The electrical threshold of Phenomenon 72.1 is 4.9 V, so by Equation (72.2) the two numbers are the same quantity measured two ways.

The identification is Bohr's postulate [396] that a transition between stationary states emits a single quantum whose energy is the difference of the two level energies: the electron delivers ε to the atom by collision, and the atom returns ε to the field as one quantum on decaying. The agreement is what makes this a test of that postulate rather than of discreteness alone — a threshold by itself shows only that the atom accepts energy in a definite amount, whereas the coincidence of the threshold with hc/λ shows that the amount accepted is the energy of a level whose existence the spectrum independently records. □

72.4.3 Uncertainties and the dataset

[Reserved: statistical uncertainty from the current measurement and from locating a maximum on a rounded peak; systematic contributions from the voltage calibration, the electron energy spread, and residual gas. Present-day teaching-laboratory realizations reach a few parts in a thousand on the spacing, which is enough to resolve the discrepancy discussed in Section 72.6.2. The digitized curve and the fitted maxima are the chapter's dataset; the SI traceability of the voltage scale is that of Chapter 2 and rests on the defining constants of [2333].]

72.5 Interpretation

72.5.1 Discrete energy transfer

[Reserved: below threshold the electron loses essentially nothing per collision, so it arrives at the grid with the full energy eV; at threshold it can transfer exactly one quantum and is then stopped by the retarding bias; beyond that it re-accelerates and can transfer a second quantum after a further 4.9 V*, which is why the structure is periodic rather than a single edge. The spacing is therefore an atomic energy interval measured in volts, and its independence of vapour pressure, of tube geometry and of the retarding bias is what identifies it as a property of the mercury atom. This is the phenomenon environment the chapter will carry, with its derivation inline.]*

72.5.2 What the authors concluded, and why it was wrong

[Reserved: Franck and Hertz reported 4.9 V *as the ionization potential of mercury [417], on the reasoning that a sudden onset of energy loss meant an electron had been torn off, and they explicitly denied that their result supported Bohr. The reading is wrong: the true first ionization potential of mercury is* 10.44 V*, and* 4.9 eV *is the excitation energy of the lowest triplet state that radiates at* 253.7 nm*. The section states the error plainly and identifies what would have settled it at the time — the resonance line of Section 72.4.2 was in their own data.]*

72.5.3 Bohr's correction and its experimental confirmation

[Reserved: Bohr's reinterpretation [425], which identified the threshold as a resonance potential — an excitation, not an ionization — and noted that the emitted line is exactly what his postulates require of a return to the ground state. Independent confirmation by Davis and Goucher, who separated excitation from ionization in the same vapour by collecting positive ions [443], and by Franck and Einsporn's refined measurement [467], which resolved further excitation potentials and in which Franck accepted the correction. The episode is a case study for Chapter 1: a correct measurement, a wrong inference, and the further measurement that decided between them.]

72.6 Modern repetitions and precision

72.6.1 The neon variant

[Reserved: neon replaces mercury in most teaching laboratories — no oven is needed and the excitation region is visible as a sequence of orange glow layers that migrate towards the cathode as the voltage is raised, so the periodic structure can be seen as well as plotted. The spacing corresponds to excitation of the neon levels near 18.7 eV*, and because several close-lying levels contribute, the measured spacing depends on the current and on the geometry in a way that the mercury curve does not — a systematic studied and quantified by Rapior, Sengstock and Baev [2102].]*

Phenomenon 72.3 (The neon variant and its visible excitation layers)**.** With neon in place of mercury the current–voltage curve shows the same periodic structure, with a spacing near 18.7 V, and the excitation regions are directly visible: the tube glows in a sequence of orange layers, one more appearing for each further period, each layer migrating towards the cathode as the accelerating voltage is raised. The periodicity can therefore be seen as well as plotted. Because several close-lying neon levels are accessible at once, the measured spacing depends on the discharge current and on the electrode geometry in a way that the mercury spacing does not [2102].

Derivation pending #67

Why the glow layers sit where they do: an electron starting from rest at the cathode reaches the excitation energy after falling through a fixed potential difference, so the luminous shells mark equal potential intervals, and their migration towards the cathode as the voltage is raised follows from the field distribution in the tube. The dependence of the effective spacing on current and geometry requires in addition the branching among the accessible neon levels and the collision cross-section of each.

72.6.2 Fine structure of the mercury curve

[Reserved: the canonical figure hides real structure. Mercury has a metastable level at 4.67 eV *as well as the radiating one at* 4.89 eV*, and Franck and Einsporn resolved both [467]; higher-resolution modern curves show additional steps and a spacing that drifts with the number of the maximum [2102]. The honest statement is that "the" Franck–Hertz spacing is an effective quantity averaging over accessible levels, and that agreement to three figures with a single level energy is a coincidence of the usual apparatus, not a property of the method.]*

Phenomenon 72.4 (The spacing is an effective average over accessible levels)**.** The canonical mercury curve hides real structure. Mercury has a metastable level at 4.67 eV as well as the radiating one at 4.89 eV, and electrons excite both; Franck and Einsporn resolved

the two, together with further excitation potentials above them [467]. Higher-resolution modern curves show additional steps, and a spacing that drifts systematically with the ordinal number of the maximum rather than staying constant [2102]. What the experiment measures is therefore an effective interval averaging over the levels the electrons can reach in the particular tube; its agreement to three figures with a single level energy [2420] is a property of the usual apparatus, not of the method.

Derivation pending #68

The effective spacing: the excitation cross-sections of the competing mercury levels as functions of electron energy, and the weighted mean interval they produce in a tube of given vapour density and geometry; and the mechanism of the drift with maximum number, in which electrons surviving several accelerating stages sample a different mixture of levels from those excited near the first drop.

72.6.3 Present-day level energies

[Reserved: the mercury level energies as now known from precision spectroscopy [2420], quoted to the digits the experiment can be compared against, together with the current values of h and e [2333, 2431]; the electrical measurement of an atomic energy interval is today a demonstration rather than a determination, since the spectroscopic route (Chapter 90) is better by many orders of magnitude. A short table comparing the 1914 value, the 1920 refinement and the modern value belongs here.]

72.7 What the experiment settles

[Reserved: closing assessment. The experiment establishes, by a purely mechanical measurement, that an atom accepts energy only in discrete amounts, and it ties those amounts to the emitted spectrum; it does not establish anything about orbits, and the Bohr model's mechanical picture is not tested by it — which is why the result survives the model's abandonment intact and constrains Chapters 77 and 88 directly. Franck and Hertz received the Nobel Prize in Physics for 1925, awarded in 1926, and Franck's Nobel lecture [543] is also the clearest statement of how he came to accept Bohr's reading. Cross-references to the other experiments of this part (Chapters 67 and 80) and to the inelastic-collision formalism of Chapter 86.]

Chapter 73

Experiment: The Blackbody Spectrum Measured

Chapter 68 makes a prediction of an unusual kind. It does not say what some particular substance will do; it says that the light leaving a small hole in any isothermal cavity is governed by one universal function of frequency and temperature, that thermodynamics fixes the integral of that function and its behaviour under a change of temperature but not the function itself, and that the function is Planck's law — which contains a constant of nature absent from classical physics. That chapter derives the law. It does not show it being measured, and the omission matters more here than anywhere else in this treatise, because in this one case the measurement came *first*. Planck did not predict the spectrum and wait for the laboratory; the laboratory handed him a spectrum that no classical theory could produce, and he wrote down a formula to fit it. This chapter is that measurement.

Five experiments are reported, in the order in which they were made. Stefan reads a fourth-power law out of somebody else's thermopile deflections [211]; Lummer and Kurlbaum build the first object whose emission may honestly be called Kirchhoff's universal function [282]; Lummer and Pringsheim take its spectrum far enough into the infrared to kill the accepted distribution law [284]; Rubens and Kurlbaum, by fixing the wavelength and sweeping the temperature instead, produce the single result that Planck was told about on 7 October 1900 and answered the same evening [294, 297]. The fifth is modern: under the SI of 2019 the same cavity, viewed by a calibrated radiometer, is a primary realization of the kelvin [2333, 2334], so that the constant Planck read off the Reichsanstalt data now defines the units in which the measurement is expressed. Together they are the reason Part VIII exists.

Derivation pending #69

Experiment: The Blackbody Spectrum Measured: what is pending is the tabulation of the measured radiance against wavelength and temperature for each experiment, in SI with its uncertainty budget, together with the residuals against the Wien and the Planck distributions. The phenomena stated below each carry their derivation inline.

73.1 Stefan: the fourth power, from Tyndall's data (1879)

The first quantitative law of thermal radiation was obtained without an experiment. Stefan had no apparatus in this matter; he had Tyndall's published numbers for the total emission of an incandescent platinum wire [165], and he asked what power of the absolute temperature would reproduce them [211]. The experiment of record is therefore Tyndall's and the measurement of record is Stefan's re-analysis of it, a distinction this section keeps because

it is what makes the honest assessment of the result possible.

73.1.1 Apparatus

[Reserved: Tyndall's arrangement — a platinum wire heated electrically to incandescence in air, its temperature judged from its colour against a scale of known incandescent hues, and its total radiant emission collected and measured with a thermopile and galvanometer. To be given: the wire dimensions and its surface condition, the geometry that fixes what fraction of the emitted power reaches the pile, the thermopile's linearity, and above all the provenance and uncertainty of the two temperature values, which dominate everything that follows.]

73.1.2 Procedure

[Reserved: raise the wire through a sequence of temperatures and record the galvanometer deflection at each. The quantity used is a ratio *of deflections between a pair of temperatures, which cancels the absolute calibration of the thermopile and leaves only its linearity to be established — an economy worth stating explicitly, since it is the reason a crude instrument could settle an exponent. Stefan's own step is arithmetical: convert both temperatures to the absolute scale and ask what power of T reproduces the measured ratio.]*

73.1.3 Observations and data

[Reserved: the deflection at each temperature and the derived emission ratios, with Stefan's parallel re-analysis of the cooling measurements of Dulong and Petit, which he treated in the same paper and by the same method. To be tabulated when written: temperature pairs in kelvin, measured emission ratio, exponent implied by each pair, and the propagated uncertainty of that exponent.]

Phenomenon 73.1 (Total emission rises as the fourth power of the absolute temperature)**.** The total power radiated per unit area by a hot body, integrated over all frequencies, rises much faster than in proportion to its temperature. Stefan found that Tyndall's platinum wire, taken from 798 K to 1473 K, radiated 11.7 times as much power at the higher temperature as at the lower, and identified this as the fourth power of the ratio of the absolute temperatures [211]. The thermodynamic derivation of the same exponent, which requires the radiation pressure and no data at all, came five years later [227].

Derivation. Take the law in the form $M = \varepsilon\sigma T^4$ of Chapter 68 and suppose the emissivity ε of the wire to be the same at both temperatures. The absolute calibration then cancels from a ratio,

$$\frac{M_2}{M_1} = \left(\frac{T_2}{T_1}\right)^4 , \tag{73.1}$$

and with $T_1 = 798\,\mathrm{K}$ and $T_2 = 1473\,\mathrm{K}$ the temperature ratio is 1.8459, whose fourth power is 11.61. Against Tyndall's 11.7 that is agreement to better than one percent, which is how the law was found.

It is also better agreement than the data deserve, and the derivation should say so. Solving Equation (73.1) for the exponent instead of assuming it gives

$$n = \frac{\ln\left(M_2/M_1\right)}{\ln\left(T_2/T_1\right)} = 4.01 , \tag{73.2}$$

but the sensitivity of that number to the inputs is severe. From Equation (73.2), a fractional error δ in the measured emission ratio moves n by $\delta/\ln(T_2/T_1) \simeq 1.6\,\delta$, so one percent on the

ratio is worth 0.016 on the exponent and is negligible. An error in the hotter temperature is not: it enters as

$$\delta n = \frac{n}{\ln\left(T_2/T_1\right)} \, \frac{\delta T_2}{T_2} \,, \tag{73.3}$$

which for an error of 100 K in T_2 alone gives $\delta n \approx 0.44$. Tyndall judged his temperature from the colour of the wire, so an error of that size is optimistic rather than pessimistic, and the datum by itself is consistent with any exponent from roughly 3.5 to 4.5. Two further defects work in the same direction: platinum is not a black body, and its emissivity rises with temperature, so the assumption that ε cancels from Equation (73.1) is false in the direction that inflates the apparent exponent. The fourth power is right; it was not *established* here, and the sections that follow are the reason it is now believed. □

73.1.4 Interpretation

[Reserved: what the analysis does and does not establish. It establishes that the emission of a hot solid rises far faster than linearly with temperature and is consistent with a fourth power; it does not establish the exponent to better than a few tenths, nor does it concern a black body at all. The section should state plainly that the law became secure only when Boltzmann derived it from the second law together with the radiation pressure [227], and when the Reichsanstalt cavity of Section 73.2 made it testable on a radiator that really was black. Forward link: the Stefan–Boltzmann constant is today not measured but computed from the defining constants [2333, 2431], so this experiment has become a test of the defining constants rather than a determination of anything.]

73.1.5 Primary references

[211]; the thermodynamic derivation of the same law is [227]. Tyndall's measurements [165] are used here as Stefan reports them and the original was not consulted.

73.2 Lummer and Kurlbaum: a black body one can build (1898)

Kirchhoff's theorem tells a laboratory what to build — a small hole in a large isothermal enclosure — and says nothing about how well any actual hole will do [153]. Until that gap was closed there was no object in the world whose spectrum could be compared with the universal function, and every measurement of thermal radiation was a measurement of a material. The electrically heated cavity radiator of Lummer and Kurlbaum is where that changes [282]: it is the first artefact for which the departure from blackness can be estimated rather than hoped for, and it is the direct ancestor of every radiometric standard in use today.

73.2.1 Apparatus

[Reserved: a cylindrical cavity heated electrically along its whole length rather than from one end, so that the wall temperature is uniform; internal diaphragms and a blackened, roughened inner surface, both of which raise the number of reflections a ray must survive before it can leave; a small aperture at one end and a water-cooled front plate to define it; thermocouples distributed along the wall to establish isothermality rather than assume it. Detection is by the surface bolometer Lummer and Kurlbaum had developed for the purpose, with a thermopile as an independent check. To be given: cavity length and bore, aperture diameter, the resulting ratio of aperture area to total interior area, the wall temperature range and its uniformity, and the bolometer's time constant and noise floor.]

73.2.2 Procedure

[Reserved: bring the radiator to a chosen temperature and hold it there; verify isothermality by traversing a thermocouple along the wall and by comparing the emission through the aperture before and after reversing the heating current. Then the two tests that make the claim of blackness an experimental one rather than a design intention: vary the aperture diameter and show that the radiance emerging is unchanged (a black aperture has no memory of its size, a grey one does), and compare two cavities built of different wall materials at the same temperature and show that they agree. Finally, measure the total emission as a function of temperature and compare with the fourth-power law of Section 73.1, this time on a radiator that is actually black.]

73.2.3 Observations and data

[Reserved: total radiance against wall temperature over the working range, with the fitted exponent and the fitted Stefan–Boltzmann constant; the invariance of the radiance under change of aperture and of wall material, quoted as a bound rather than as an equality; the residual temperature non-uniformity along the wall and what it contributes to the uncertainty. All in SI with uncertainties.]

Phenomenon 73.2 (The aperture of an isothermal cavity is black to a computable accuracy)**.** An electrically heated isothermal enclosure viewed through a small aperture emits, to within a small and calculable correction, the universal function of [153], and its emission is insensitive to the material of the walls: a mediocre absorber makes an excellent cavity provided the aperture is small enough. This is what Lummer and Kurlbaum realized in hardware [282], and it is the reason every spectrum reported in the sections that follow is a measurement of a function of nature rather than of a surface.

Derivation. Let the enclosure be isothermal, let its wall have emissivity ε — equal to its absorptivity by Chapter 68 — and let

$$f := \frac{A_{\text{hole}}}{A_{\text{total}}} \tag{73.4}$$

be the fraction of the interior area occupied by the aperture. Compute the *absorptance* of the aperture, which by Kirchhoff's theorem is also its emissivity. Send unit flux in through the hole and assume, as an isothermal cavity with a rough wall makes reasonable, that after each diffuse reflection the flux is spread uniformly over the whole interior. The first encounter with the wall absorbs ε and reflects $1-\varepsilon$; of what is reflected, the fraction f finds the hole and escapes and the fraction $1-f$ meets the wall again. The survival factor per round trip is therefore $(1-\varepsilon)\,(1-f)$, and summing the geometric series of absorbed contributions,

$$\varepsilon_{\text{eff}} = \varepsilon \sum_{k\geq 0} \left[(1-\varepsilon)\,(1-f)\right]^{k} = \frac{\varepsilon}{1-(1-\varepsilon)\,(1-f)}\,,$$

and expanding the denominator, $1-(1-\varepsilon)(1-f) = \varepsilon + f - \varepsilon f$, gives

$$\varepsilon_{\text{eff}} = \frac{\varepsilon}{\varepsilon + (1-\varepsilon)\,f}\,. \tag{73.5}$$

The design rule follows by inspection. The wall material enters only through the product $(1-\varepsilon)\,f$, so it is the *aperture fraction* and not the blackness of the paint that carries the accuracy: a wall of $\varepsilon = 0.5$ — barely better than polished — with an aperture fraction $f = 10^{-3}$ gives $\varepsilon_{\text{eff}} = 0.999$, while the same wall with the lid off would be half a black body. Diaphragms and a roughened surface work by making the effective f seen by an escaping ray smaller still.

Two honesties are owed here. First, Equation (73.5) is the modern integrating-cavity estimate and not Lummer and Kurlbaum's own formula; they argued the case by construction and by the experimental invariances of the procedure above, which is the stronger argument since it does not assume perfect diffusion. Second, the formula assumes isothermality exactly, and a real cavity is graded in temperature along its length; that error is not covered by Equation (73.5) and has to be bounded separately, which is why the thermocouple traverse is part of the apparatus and not of the diagnostics. □

73.2.4 Interpretation

[Reserved: the significance is metrological before it is theoretical. Kirchhoff's universal function ceases to be an idealization and becomes an object with a serial number, so that a spectrum measured in Berlin can be compared with a formula and with a spectrum measured anywhere else. The cavity radiator became the primary radiometric standard of the Physikalisch-Technische Reichsanstalt and the ancestor of the fixed-point blackbodies of Section 73.5; the traceability chain and its uncertainty budget belong to Chapter 2. Worth recording plainly: the Reichsanstalt built this instrument to serve the German lighting industry, and the overthrow of classical physics was a by-product of a standards laboratory doing standards work.]

73.2.5 Primary references

[282]; the theorem the instrument realizes is [153].

73.3 Lummer and Pringsheim: Wien's law breaks (1899)

With a black body available, the universal function could at last be measured rather than guessed. Wien's distribution [272] was the accepted answer and fitted everything then in evidence; what Lummer and Pringsheim did was to push the measurement into the region where it was not in evidence, at long wavelength and high temperature, and there it failed [284, 292]. This is the point at which the accepted law of thermal radiation died, and it died to data rather than to an argument: no successor to Wien's formula existed for another year.

73.3.1 Apparatus

[Reserved: the cavity radiator of Section 73.2 as source; a spectrometer whose prism and windows are transparent well into the infrared, where glass and quartz are opaque, hence fluorite and rock-salt optics; a linear bolometer at the exit slit, with its galvanometer; and the calibration that the whole result rests on — the dispersion curve of the prism, which converts an angular position into a wavelength and an angular slit width into a bandwidth. To be given: prism material and apex angle, slit widths and the resolving power they imply, the bolometer strip dimensions, and the measured transmission of the optical train as a function of wavelength.]

73.3.2 Procedure

[Reserved: hold the radiator at a chosen temperature and scan the bolometer through the spectrum, recording deflection against angle. Reduce each scan to a spectral radiance: correct for the dispersion of the prism, so that equal angular steps become unequal wavelength intervals; for the transmission of prism, windows and mirrors; and for the spectral response of the bolometer. Repeat at each temperature over the working range. The comparison with

theory is then made by fitting the two constants of Wien's distribution to the short-wavelength part of each isotherm and examining the residuals at long wavelength — a procedure that must be fixed in advance, since a fit over the whole range would distribute the discrepancy and hide it.]

73.3.3 Observations and data

[Reserved: isotherms of spectral radiance against wavelength from about 300 K *to* 1650 K*, reaching about* 8 µm *[284], with the residuals against the fitted Wien distribution. The residuals are the observation: they are of one sign, they grow with the product of wavelength and temperature, and they exceed the estimated uncertainty of the measurement by a wide margin at the long-wavelength end. To be tabulated: wavelength, temperature, measured spectral radiance and its uncertainty, and the ratio of measurement to Wien's formula and to Planck's.]*

Phenomenon 73.3 (The measured spectrum exceeds Wien's distribution at long wavelength)**.** Measured with a black body of known temperature and a spectrometer transparent into the infrared, the spectral radiance of cavity radiation is systematically *greater* than Wien's distribution [272] predicts, and the excess is not random: it has one sign, it is negligible in the visible and near infrared where the formula had been tested, and it grows steadily with the product of wavelength and temperature. Lummer and Pringsheim found it out to about 8 µm over temperatures from about 300 K to 1650 K, far beyond any plausible error of their measurement [284].

Derivation. The excess is exactly what Planck's law of Chapter 68 requires, and its dependence on a single variable is the content of the phenomenon. Write the dimensionless variable

$$x := \frac{hc}{\lambda k_{\mathrm{B}} T} = \frac{c_2}{\lambda T}\,, \qquad c_2 := \frac{hc}{k_{\mathrm{B}}} = 1.438\,777 \times 10^{-2}\,\mathrm{m\,K}\,, \tag{73.6}$$

the second radiation constant, whose value is exact in the present SI because h, c and k_{B} are all defining constants [2333, 2431]. In terms of x the Planck spectral radiance carries the factor $1/(\mathrm{e}^{x}-1)$ and Wien's distribution the factor e^{-x}, with the same prefactor, so their ratio is

$$\frac{L_\lambda^{\mathrm{Planck}}}{L_\lambda^{\mathrm{Wien}}} = \frac{\mathrm{e}^{x}}{\mathrm{e}^{x}-1} = \frac{1}{1-\mathrm{e}^{-x}}\,. \tag{73.7}$$

This is greater than unity for every finite x, so the discrepancy can only have one sign, and it is a decreasing function of x — that is, an increasing function of λT — so it is invisible in the visible and unmistakable in the infrared. That it depends on λ and T only through their product is Wien's own displacement scaling of Chapter 68, which both formulas respect; it means the whole family of isotherms collapses onto one curve, and a residual that does not so collapse would indicate an instrumental error rather than a failure of the law.

Table 73.1 evaluates Equation (73.7). The numbers are computed here from Planck's law, not taken from any measurement, and they say what an experimenter had to reach before Wien's formula could be convicted: below $\lambda T \approx 3000\,\mu\mathrm{m\,K}$ the excess is under one percent and no instrument of 1899 could have seen it, which is why measurements confined to the visible and near infrared continued to support Wien's law while these did not. □

Table 73.1: The factor by which Planck's law exceeds Wien's distribution, from Equation (73.7), as a function of the product of wavelength and temperature. Computed from the formula; not a measurement. The short-wavelength end is the region in which Wien's law had been tested and found good.

λT	excess of Planck over Wien
3000 µm K	0.8 %
6000 µm K	10 %
9000 µm K	25 %
12 000 µm K	43 %

73.3.4 Interpretation

[Reserved: the accepted distribution law is falsified, and nothing replaces it. The section should resist the retrospective tidying that makes this look like a step towards Planck: for a year there was simply a measured curve with no formula, and the candidate interpolations then in circulation were fitted to it rather than derived. Also the methodological point, which Chapter 1 takes up: a law tested only where its predictions are insensitive to the thing at issue has not been tested, and the entire agreement of Wien's formula in the visible was of that kind — Table 73.1 shows the discrepancy there was below the noise. Honest caveat: the size of the deviations was disputed at the time, and settling the dispute needed the different and far more decisive measurement of Section 73.4.]

73.3.5 Primary references

[284, 292]; the distribution under test is [272] and the scaling law both formulas obey is [259].

73.4 Rubens and Kurlbaum: residual rays in the far infrared (1900)

This is the decisive measurement, and it is decisive because of an inversion of method. Every spectral measurement before it fixed the temperature and scanned the wavelength, so that the result depended on a dispersion calibration and a chain of transmission corrections. Rubens and Kurlbaum fixed the *wavelength* — at values far beyond anything a prism could reach — and swept the temperature [297]. What they obtained was a curve of radiance against temperature at one wavelength, needing no spectral calibration at all, and on that curve Wien's law and its successors make qualitatively different predictions. Rubens described the result to Planck privately on 7 October 1900; the formula that fits it was presented to the Deutsche Physikalische Gesellschaft twelve days later [294] and derived on 14 December [295].

73.4.1 Apparatus

*[Reserved: the cavity radiator of Section 73.2 as source, with the furnace extended downward in temperature by cooled baths; the residual-ray (*Reststrahlen*) train, in which the beam is reflected in succession from several polished crystal plates — fluorite for 24 µm, rock salt for 51.2 µm — each of which reflects strongly only in the narrow band near its lattice resonance and weakly elsewhere; and a bolometer or thermopile to measure what survives. To be given: the number of successive reflections, the measured reflectance of each plate in and out of band, the residual short-wavelength contamination of the emerging beam, and the detector's sensitivity and noise floor, which set the lowest temperature reachable.]*

73.4.2 Procedure

[Reserved: form the residual-ray beam and verify its purity, then hold the wavelength fixed and step the source through its temperature range, recording the detector deflection at each step.

Because the wavelength never changes, the dispersion curve, the transmission corrections and the detector's spectral response all drop out of the comparison, and only the linearity of the detector and the accuracy of the source temperature remain — this is the whole methodological advantage over Section 73.3. The candidate formulas of the day are then fitted to the measured curve and their residuals compared over the whole temperature range, not over a favourable part of it.]

73.4.3 Observations and data

[Reserved: radiance against source temperature at 24 µm *and at* 51.2 µm*, over a range extending from below room temperature to the upper limit of the furnace [297]. The observation is the* shape *of that curve: it rises without any sign of the ceiling Wien's distribution requires, and over the upper part of the range it is close to a straight line through the origin. To be tabulated: source temperature, measured radiance and its uncertainty at each wavelength, together with the residuals against each of the formulas Rubens and Kurlbaum tested — Wien's and the interpolations of Thiesen, of Rayleigh and of Planck.]*

Phenomenon 73.4 (At fixed long wavelength the radiance grows without bound, nearly in proportion to the temperature)**.** Far beyond the maximum of the spectrum the radiance of a black body does not saturate as the source is made hotter; it goes on rising, and over the upper part of the accessible range it rises very nearly in proportion to the absolute temperature. Rubens and Kurlbaum isolated 24 µm and 51.2 µm by repeated reflection from fluorite and rock salt and found this behaviour at both wavelengths [297]. Wien's distribution [272] requires the opposite: at fixed wavelength it approaches a finite ceiling as $T \to \infty$. The disagreement is not a matter of percentages, and it is what Planck was told about on 7 October 1900.

Derivation. Compare the two formulas of Chapter 68 at fixed λ as functions of T, using the variable $x = c_2/\lambda T$ of Equation (73.6). Wien's distribution carries the factor e^{-x}; as T grows, $x \to 0$ and $\mathrm{e}^{-x} \to 1$, so

$$L_\lambda^{\text{Wien}} \longrightarrow \frac{2hc^2}{\lambda^5} \qquad (T \to \infty)\ , \tag{73.8}$$

a ceiling fixed by the wavelength alone, which no temperature can exceed. Planck's law carries $1/(\mathrm{e}^x - 1)$ instead, and for $x \ll 1$ the expansion $\mathrm{e}^x - 1 \simeq x$ gives

$$L_\lambda^{\text{Planck}} \simeq \frac{2hc^2}{\lambda^5}\,\frac{1}{x} = \frac{2ck_{\mathrm{B}}T}{\lambda^4}\ , \tag{73.9}$$

in which h has cancelled: the radiance is proportional to T, grows without bound, and is the equipartition result of Chapter 55. One formula predicts a plateau and the other a rising straight line, so a single wavelength and a wide temperature range decide between them without any spectral calibration whatever — which is the point of the method.

The wavelengths chosen put the experiment squarely in the regime where Equation (73.9) applies. The crossover, $x = 1$, falls at $T = c_2/\lambda$, which is close to 600 K at 24 µm and to 281 K at 51.2 µm: above those temperatures the linear behaviour sets in, and at the longer wavelength every furnace temperature lies above it. The size of the resulting discrepancy is brutal. At 51.2 µm and a source at 1500 K one has $x = 0.187$, and by Equation (73.7) the true radiance exceeds Wien's by the factor $1/(1 - \mathrm{e}^{-x}) = 5.9$ — a factor of six, not a discrepancy of percentages, and beyond the reach of any excuse about calibration.

Two qualifications keep the statement honest. The proportionality to T is asymptotic, not exact: the next term of the expansion gives $L_\lambda \simeq (2ck_{\mathrm{B}}T/\lambda^4)(1 - x/2 + \dots)$, so the measured curve bends below the straight line at the cold end, by about 9 % at $x = 0.187$,

and the linear region has to be identified rather than assumed. And Equation (73.9) is a limit of Planck's law, not evidence for it: what the measurement establishes directly is that Wien's exponential is wrong at long wavelength. That a single formula reproduces both this limit and the visible spectrum of Section 73.3 is the additional claim, and it is what Rubens and Kurlbaum tested by fitting the competing interpolations to the same curve.

The purity of the residual-ray beam is what makes any of this measurable, and it is worth one line of arithmetic. A source at 1500 K emits overwhelmingly more power near its maximum, at a few micrometres, than at 51.2 µm, so a leak of short-wave radiation would swamp the signal. If a crystal plate reflects a fraction R_{in} in its residual-ray band and R_{out} outside it, then n successive reflections change the ratio of in-band to out-of-band flux by

$$\left(\frac{R_{\mathrm{in}}}{R_{\mathrm{out}}}\right)^{n}, \tag{73.10}$$

a geometric gain in purity for a merely linear loss of signal: a reflectance contrast of ten, which a strong lattice band easily provides, gives four orders of magnitude of suppression after four reflections. This is why a filter that no one can manufacture is replaced by a mirror used four times. □

73.4.4 Interpretation

[Reserved: the causal chain, which is the clearest instance in physics of a measurement dictating a formula and should be set out step by step with its dates. Rubens communicated the far-infrared result to Planck on 7 October 1900; Planck, who knew that the short-wavelength limit had to be Wien's, now knew that the long-wavelength limit had to be linear in T, and constructed the simplest expression for the second derivative of the entropy with respect to the energy that reduces to both — presented on 19 October [294]. That step is interpolation and Planck said so; the physics enters only with the combinatorial derivation of 14 December [295], in which the energy elements $h\nu$ appear. Fitting the new law to the Reichsanstalt data gave the first values of h and of k_B [300], and through the latter the first good values of the Avogadro constant and of the elementary charge — a bonus of the measurement that is often forgotten and that did more than anything else to make the formula credible before the hypothesis behind it was.]

73.4.5 Primary references

[297]; the formula it produced within the fortnight is [294], its derivation [295] and its considered exposition [300]. The distribution it falsified is [272], and the classical limit it exhibits is that of [296, 322].

73.5 Radiometric realization of the kelvin (2019)

The last experiment in this chapter is not a test of Planck's law but a use of it, and the change of status is the point. Since the revision of the SI that took effect in 2019 the kelvin is defined by fixing the numerical value of the Boltzmann constant, and h and c are fixed as well [2310, 2333]. Planck's law therefore contains no measured constant and no property of any substance: an absolute measurement of the spectral radiance leaving a cavity yields the thermodynamic temperature of its walls directly. The instrument of Section 73.2, which was built to make the universal function observable, has become a primary realization of a base unit.

73.5.1 Apparatus

[Reserved: a cavity radiator of the modern kind — either held at a fixed point of a pure metal or continuously variable — with an effective emissivity established by the argument of Phenomenon 73.2 and by direct reflectance measurement; a filter radiometer defining a narrow spectral band and a known solid angle, whose absolute spectral responsivity is the quantity everything rests on; and the chain that establishes that responsivity, running through a trap detector to an absolute cryogenic radiometer [1762], which equates optical power to electrical power dissipated in the same receiver and so ties the measurement to the watt and thence to the SI base units. To be given: the band centre and width, the aperture geometry and its dimensional metrology, the emissivity budget of the cavity, and the responsivity uncertainty.]

73.5.2 Procedure

[Reserved: calibrate the filter radiometer against the cryogenic radiometer; measure the spectral radiance of the cavity in the chosen band, with the geometry known dimensionally; invert Planck's law for T as in Equation (73.12) below. Cross-checks that make the result a realization rather than a reading: repeat in a second band, where the sensitivity factor of Equation (73.13) differs, and compare with an independent primary thermometer of a different physical kind. The comparison against the defined temperature scale in use, and the difference between a thermodynamic temperature and a scale value, belong to Chapter 2.]

73.5.3 Observations and data

[Reserved: measured spectral radiance in each band, the inferred thermodynamic temperature, and the uncertainty budget — which is dominated by the radiometric scale and by the cavity emissivity, and which shrinks relative to the temperature by the factor computed in the derivation below. To be tabulated when written: band, measured radiance, sensitivity factor, inferred temperature and combined standard uncertainty, in SI throughout.]

Phenomenon 73.5 (Thermodynamic temperature is readable from an absolute spectral radiance)**.** The spectral radiance emerging from a black cavity determines the thermodynamic temperature of its walls through Planck's law alone. In the SI that took effect in 2019 the constants entering that law — h, c and k_{B} — are all fixed by definition [2333, 2431], so no material property and no reference temperature intervene: the measurement is a primary realization of the kelvin [2334]. The same relation that was extracted from the Reichsanstalt spectra now supplies the unit in which those spectra would be reported.

Derivation. Write Planck's law of Chapter 68 as a spectral radiance,

$$L_\lambda(\lambda, T) = \frac{2hc^2}{\lambda^5}\,\frac{1}{\mathrm{e}^{x}-1}\,, \qquad x = \frac{c_2}{\lambda T}\,, \tag{73.11}$$

and solve for the temperature. Rearranging Equation (73.11) gives $\mathrm{e}^{x}-1 = 2hc^2/(\lambda^5 L_\lambda)$, hence x by a logarithm and hence

$$T = \frac{c_2}{\lambda}\left[\ln\left(1+\frac{2hc^2}{\lambda^5 L_\lambda}\right)\right]^{-1}. \tag{73.12}$$

Everything on the right of Equation (73.12) is either a defining constant or a measured quantity: the wavelength, which is metrology of the filter, and the absolute spectral radiance, which is metrology of the radiometer. No thermometer appears.

The design of such a measurement turns on how an error in L_λ propagates into T. Differentiating Equation (73.11) at fixed λ, and using $\mathrm{d}x/x = -\mathrm{d}T/T$,

$$\frac{\mathrm{d}L_\lambda}{L_\lambda} = -\frac{\mathrm{e}^x}{\mathrm{e}^x - 1}\,\mathrm{d}x = \frac{x\mathrm{e}^x}{\mathrm{e}^x - 1}\,\frac{\mathrm{d}T}{T}\,,$$

so that

$$\frac{\mathrm{d}T}{T} = \frac{1 - \mathrm{e}^{-x}}{x}\,\frac{\mathrm{d}L_\lambda}{L_\lambda}\,. \tag{73.13}$$

The factor in front is close to unity when $x \ll 1$ and close to $1/x$ when $x \gg 1$, so radiometric thermometry is done at short wavelengths, on the steep Wien side of the spectrum, where a coarse measurement of radiance buys a fine measurement of temperature. At $\lambda = 650\,\mathrm{nm}$ and $T = 1235\,\mathrm{K}$ — representative of a metal fixed point — Equation (73.6) gives $x = 17.9$, so the sensitivity factor is 0.056 and an error of 1 % in the measured radiance appears as 0.056 of a percent in temperature, about 0.7 K. The same one percent at $\lambda = 51.2\,\mu\mathrm{m}$, where x is small, would appear almost undiminished. The far infrared that decided the physics is the worst possible place to realize the unit, and for exactly the reason that made it decisive: there the spectrum has forgotten h.

One consequence should be stated plainly, because it inverts the logic of every earlier section. Since h, c and k_B are now defined rather than measured, Equation (73.12) cannot be used to test Planck's law — it presupposes it. The law is tested instead by comparing this realization against primary thermometers of a different physical kind, and, on a far more exacting scale, by the astrophysical spectrum of Chapter 51. □

73.5.4 Interpretation

[Reserved: what has and has not changed. The 1898 cavity and the present one are the same instrument serving opposite purposes: then a means of exhibiting an unknown universal function, now a means of realizing a defined unit. The section should be explicit that the present arrangement is not evidence for Planck's law and say what is: the mutual consistency of primary thermometers resting on different physics, and the cosmic microwave background spectrum of Chapter 51, which is the most exactly Planckian spectrum known. Also the closing of the historical circle — the constant Planck read off the Reichsanstalt data in 1900 [300] is now a defining constant of the SI [2333], so that his 1901 values may be quoted as a percent-level verification of a definition.]

73.5.5 Primary references

[2333, 2431]. These are the normative and the recommended-values documents; the primary literature of absolute cryogenic radiometry and of the filter-radiometer realizations is not cited here because `references.bib` carries no entry for it, and no key has been invented to stand in its place.

73.6 What the measurements settle

The sequence in Table 73.2 has a shape that is unusual in this treatise and worth naming. Elsewhere a theory predicts and an experiment checks; here the experiments arrive first and the theory is built to fit them, and the constant h enters physics not as a postulate but as the number required to reconcile two limits that were each measured before either was understood. Wien's exponential is the short-wavelength limit and was measured by 1896; the proportionality to T is the long-wavelength limit and was measured in October 1900; the formula joining them was written within days of the second, and the hypothesis that explains the formula came two months later [294, 295].

Table 73.2: The measurements reported in this chapter and what each establishes. The third column states the claim the experiment is entitled to, which in the first case is markedly weaker than the claim it is usually credited with.

Experiment	Quantity fixed	What it establishes
Stefan 1879	neither	total emission rises as a high power of T, consistent with the fourth but not resolving it
Lummer–Kurlbaum 1898	—	an artefact whose emissivity is calculable and near unity; the universal function becomes observable
Lummer–Pringsheim 1899	T fixed, λ scanned	the accepted distribution law is wrong at long wavelength, by more than any error of measurement
Rubens–Kurlbaum 1900	λ fixed, T swept	the radiance grows without bound and nearly linearly in T; Wien's ceiling does not exist
Radiometric kelvin 2019	all three constants	Planck's law realizes the unit of temperature rather than being tested by it

What the chapter does *not* settle should be as clear. None of these measurements shows that light is granular. They show that the energy exchanged between a cavity wall and the field comes in units proportional to the frequency, which is what Planck claimed and no more; the light quantum is a further and independent step, and the experiments that force it are those of Chapter 69. Nor does the chapter settle the exponent Stefan is remembered for — Phenomenon 73.1 gives it as an inference from a ratio whose uncertainty allows several tenths either way, and it is Boltzmann's derivation [227] together with the cavity work of Section 73.2 that makes it secure. The one thing established here beyond argument is negative and decisive: no distribution law derivable from classical electrodynamics and equipartition can fit the curve that Rubens and Kurlbaum measured at 51.2 µm, because equipartition gives the linear rise at long wavelength only at the cost of an infinite total energy [296, 322]. The measurement that forced quantisation is a measurement of the far infrared, made by a standards laboratory, in the service of the lighting industry.

Chapter 74

Experiment: The Photoelectric Effect and Compton Scattering

Chapter 69 states a hypothesis and derives its consequences: light of frequency ν is emitted and absorbed in indivisible amounts $h\nu$ carrying momentum $h\nu/c$, from which follow the photoelectric equation, the Compton shift, and the requirement that energy and momentum balance in each single scattering act. It names the experiments that bear on all three and reports none of them. This chapter is that report.

It is organized around one question, and the question is sharper than the textbook treatment usually admits: *which* of these measurements actually requires the light to be quantized, as opposed to the matter that absorbs it. The answer is unkind to the most famous of them. The photoelectric effect, in every form Hertz, Lenard and Millikan gave it, is reproduced by a quantized atom absorbing from an entirely classical field [1402], so the first three sections below establish the equation of Phenomenon 69.2 and the constant in it without establishing the light quantum at all. What carries the weight is momentum and indivisibility: the wavelength shift of Section 74.4, which no driven classical oscillator can produce; the coincidence experiment of Section 74.5, which excludes conservation-on-the-average and with it the last serious counter-theory; and the anticorrelation of Section 74.6, which is the modern experiment that no classical field of any strength or statistics can reproduce. The sections run in that order, which is also chronological, and the closing Section 74.7 states what each is and is not entitled to claim.

Derivation pending #70

Experiment: The Photoelectric Effect and Compton Scattering: what is pending is the tabulation of the measured numbers for each experiment, in SI with its uncertainty budget — stopping potential against frequency for each emitting metal, scattered wavelength against scattering angle, coincidence and singles counts against resolving time, and the gated detection probabilities of the beamsplitter experiment. The phenomena stated below carry their derivations inline except where a pending derivation is marked against them individually.

74.1 Hertz and Hallwachs: ultraviolet light discharges a metal (1887–1888)

The effect was found by a man who did not want it. Hertz was engaged in the experiment that produced the first electromagnetic waves and confirmed Maxwell's theory; the photoelectric effect entered his apparatus as an interference, was isolated because it would not go away,

and was reported as an anomaly whose explanation he could not offer [234]. Hallwachs turned it into a phenomenon the following year with an apparatus a school can build [238].

74.1.1 Apparatus

Hertz's arrangement is two spark gaps. An induction coil drives the primary gap, whose oscillatory discharge radiates; a wire loop of adjustable size serves as resonator, and the length of the spark that can be drawn across a micrometer gap in that loop measures the induced electromotive force. The relevant addition is optical, and it is the part that matters here: screens interposed between the two gaps, of glass and of quartz, and a quartz prism with which the light of the primary spark can be dispersed and one region of the spectrum at a time allowed to fall on the micrometer gap. Hallwachs' apparatus is a freshly polished zinc plate mounted on an insulating support and connected to a gold-leaf electroscope, illuminated by the light of a carbon arc.

74.1.2 Procedure

Hertz measured the maximum length of the resonator spark with the micrometer gap exposed to the light of the primary spark and again with it shielded. The diagnostic sequence is the interesting part: enclosing the resonator gap in an opaque box shortens the spark; the effect survives when the box is fitted with a quartz window and disappears when the window is glass; and dispersing the light with a quartz prism locates the active agent beyond the violet end of the visible spectrum. Hallwachs charged his zinc plate negatively, watched the electroscope leaf under illumination, then repeated with the plate charged positively, and finally with the plate initially uncharged.

74.1.3 Observations and data

Illumination of the micrometer gap by ultraviolet light lowers the potential difference at which the spark passes, so that a longer gap sparks at the same drive; glass extinguishes the effect and quartz does not, which places the agent in the ultraviolet [234]. On Hallwachs' plate the sign of the charge decides everything: a negatively charged plate loses its charge under illumination, a positively charged plate does not, and an initially uncharged plate charges up *positively* [238]. The carriers liberated are therefore negative.

[Reserved: the tabulation. For Hertz, the maximum resonator spark length in metres against the screening condition and against the position on the dispersed spectrum, with the reproducibility of the spark-length measurement, which is the whole uncertainty of the experiment. For Hallwachs, the rate of fall of the electroscope leaf against illumination and against the sign and magnitude of the initial charge, converted to a charge loss per second in SI. Neither original was consulted for this chapter and no figures are quoted from memory.]

Phenomenon 74.1 (Ultraviolet light liberates negative charge from a clean metal surface)**.** Light beyond the violet end of the visible spectrum, falling on a clean metal surface, releases negatively charged carriers from it. The release is blocked by glass and passed by quartz, which identifies the agent as ultraviolet [234]. Because the carriers are negative, an isolated illuminated conductor loses negative charge if it carries any and otherwise acquires a positive charge, while a positively charged conductor is not discharged at all [238].

Derivation. Only the sign asymmetry needs an argument, and it is a one-line retarding-field argument that will be used quantitatively in Section 74.2 and Section 74.3. Let the liberated carriers have charge $-e$ and leave the surface with kinetic energies up to some maximum $E_{\max}$, and let the isolated conductor sit at potential V relative to its surroundings. A carrier

escaping to infinity must do work eV against the field of the conductor it has just left more negative — or, for $V < 0$, gains that energy. Hence carriers escape whenever

$$E_{\max} > eV\,. \tag{74.1}$$

If $V < 0$ the condition holds for every carrier and the conductor discharges. If $V = 0$ it holds and the conductor charges positive, which raises V until Equation (74.1) fails and the process stops by itself — the plate reaches a steady potential $V = E_{\max}/e$ and no more. If $V > 0$ and already exceeds $E_{\max}/e$ the carriers cannot leave at all, and a positively charged plate keeps its charge. All three of Hallwachs' observations are the three cases of one inequality, and the same inequality read as a measurement is the stopping-potential method: $E_{\max}$ is obtained by finding the V at which emission just ceases.

Nothing here identifies the carriers or requires anything quantum. What Equation (74.1) does establish is that the interesting quantity is $E_{\max}$ and that it is measurable with an electrometer, which is the whole experimental programme of the next two sections. □

74.1.4 Interpretation

In 1887 this is an anomaly and nothing more; there is no theory it contradicts, because there is no theory of it. Its importance is that it makes a quantity measurable. The identification of the carriers came with the corpuscle [276]: their charge-to-mass ratio is that of cathode rays, so the photoelectric current is a current of electrons and the phenomenon is one of the atom's outer structure, treated in Chapter 70 and, for the metallic case, in Chapter 126. It is worth recording that the discovery is incidental in the strict sense: Hertz was verifying Maxwell's equations, the effect degraded his measurements, and he published it because he could not explain it. Chapter 1 takes up what this pattern implies about the difference between a prediction confirmed and an anomaly recorded.

74.1.5 Primary references

[234, 238]. The identification of the carriers with the electron rests on [276].

74.2 Lenard: the energy of the electrons ignores the intensity (1902)

This is the measurement that made the effect a problem. Hertz and Hallwachs establish that light liberates electrons; Lenard establishes *how much energy* they carry, and the answer contradicts the only theory of light then available [308].

74.2.1 Apparatus

An evacuated tube containing the illuminated cathode and a collecting electrode, with a quartz window admitting the light — quartz because glass absorbs precisely the wavelengths that work, as Section 74.1 had shown. The source is a carbon arc, mounted so that it can be moved towards and away from the window. A variable potential difference is applied between cathode and collector so that the emitted electrons may be retarded, and the current is read on a quadrant electrometer, the currents being of the order of picoamperes rather than milliamperes. A magnetic field can be applied across the electron path so that the deflection of the beam gives the charge-to-mass ratio of the carriers independently.

74.2.2 Procedure

Three variables are separated. First the retarding potential is raised until the collected current vanishes; by Equation (74.1) that potential is $E_{\max}/e$ and is the quantity of interest. Then the intensity is changed — by moving the arc towards or away from the window, which changes the irradiance at the cathode by the inverse square of the distance and changes nothing else — and the stopping potential is measured again. Then the spectral composition is changed, by interposing absorbing screens or by changing the source, and the stopping potential measured again. Separately, the time between the first illumination of a shuttered cathode and the first detectable current is looked for.

74.2.3 Observations and data

The photocurrent is proportional to the intensity of the illumination, as any theory would have it. The stopping potential is not: moving the arc changes the current in the ratio the inverse-square law demands and leaves the potential at which the current vanishes unaltered. Changing the spectral composition towards shorter wavelengths raises it. The charge-to-mass ratio of the carriers agrees with that of cathode rays. No delay between illumination and emission is detectable [308].

[Reserved: the tabulation. Stopping potential in volts against source distance — that is, against irradiance in $\mathrm{W/m^2}$ *at the cathode — over the accessible range, showing the constancy; photocurrent in amperes over the same range, showing the proportionality; stopping potential against the spectral band admitted; and the measured charge-to-mass ratio with its uncertainty, against the cathode-ray value. The upper bound on the emission delay, in seconds, is to be given as the resolving time of the electrometer circuit rather than as a measured delay, since no delay was seen.]*

Phenomenon 74.2 (The maximum electron energy is fixed by the colour of the light and not by its intensity)**.** For light of fixed spectral composition, increasing the irradiance at the emitting surface increases the number of photoelectrons per second in proportion and leaves their maximum kinetic energy unchanged; the maximum energy is raised only by shifting the light towards shorter wavelengths [308]. This is item 2 of Phenomenon 69.1 and it is the observation with which no theory treating light as a continuous wave can be reconciled.

Derivation. The two predictions must be set side by side, because the force of the result lies in their disagreement and not in either alone.

Under the hypothesis of Chapter 69 the energy available to one electron is the energy of one quantum, so Equation (69.2) gives $E_{\max} = h\nu - \phi$, in which the irradiance does not appear. Raising the irradiance multiplies the number of quanta crossing the surface per second and therefore the number of electrons ejected per second; it cannot enlarge the parcel any one of them receives. Proportionality of the current to the intensity and constancy of $E_{\max}$ are then the same statement.

Under any classical field the energy delivered to an electron is set by the work done on it by the field, which is quadratic in the field amplitude and therefore proportional to the irradiance. Doubling the irradiance doubles the rate at which energy arrives at every point of the surface, and there is no mechanism in Maxwell's equations by which an electron can decline the extra energy: $E_{\max}$ must rise with the intensity. It does not. The classical picture also predicts that $E_{\max}$ should be insensitive to the frequency, which is the reverse of what is measured. □

Phenomenon 74.3 (Emission begins at once, however feeble the light)**.** The photocurrent appears as soon as the light does, within the resolving time of the measuring circuit, and no accumulation period is observed at any intensity at which the current is detectable at all [308]. This is item 4 of Phenomenon 69.1.

Derivation. The estimate this observation contradicts is worth doing explicitly, because it is the sharpest form of the contradiction and it is arithmetic. Let a classical wave of irradiance I fall on the surface. An electron can absorb only the energy flowing through its own catchment area; take that area to be atomic, $A \approx \pi a^2$ with $a \approx 10^{-10}\,\mathrm{m}$, so $A \approx 3 \times 10^{-20}\,\mathrm{m}^2$. To escape it must accumulate the work function, $\phi \approx 2\,\mathrm{eV} \approx 3.2 \times 10^{-19}\,\mathrm{J}$ for an alkali surface. The waiting time before the first electron can appear is therefore

$$t \approx \frac{\phi}{IA}\,, \tag{74.2}$$

which for a feeble but perfectly ordinary illumination of $I = 10^{-2}\,\mathrm{W/m^2}$ gives $t \approx 10^{3}\,\mathrm{s}$ — of order a quarter of an hour of darkness before the first count. At $I = 1\,\mathrm{W/m^2}$ it is still of order 10 s. Nothing observed resembles either.

Two objections must be closed, or Equation (74.2) is only a straw man. First, one might let the metal collect over a larger area and funnel the energy to one electron; but a classical field exerts its force locally on each electron, and there is no interaction in classical electrodynamics that concentrates the energy of a wavefront onto a single charge faster than it arrives. Second, one might appeal to electrons that were already energetic before the light arrived; the thermal energy available at room temperature is $k_{\mathrm{B}}T \approx 0.025\,\mathrm{eV}$, two orders of magnitude below ϕ, and an appeal to the tail of the distribution predicts a current that depends violently on temperature, which is not observed.

The quantum reading has no waiting time to explain. One quantum is absorbed whole or not at all, so the first electron may leave at the instant the first quantum arrives, and lowering the intensity reduces the *rate* of emission without introducing any delay in the individual act. The full statement of this argument, including the demonstration that no redistribution within the classical field shortens Equation (74.2), is the pending derivation attached to Phenomenon 69.1 in the theory chapter; what is given here is the order-of-magnitude form that the experiment actually confronts. □

74.2.4 Interpretation

Lenard's result is the birth of the problem and, historically, not of its solution: he interpreted the emission as a triggering of electrons already in motion within the atom, the light merely releasing them, and he was still defending that reading long after it had failed. The reading fails on the frequency dependence, which a trigger cannot explain, and it fails on the threshold. But the sceptical structure of Lenard's argument should be preserved rather than smoothed away, because a great deal of what is loosely credited to the photoelectric effect is not established by it: what Phenomenon 74.2 excludes is a *classical field* delivering energy continuously to a target, and that is not the same as establishing that the field is granular. The energy could be granular because the absorber is. That is exactly the loophole Section 69.2.4 names and Section 74.6 closes.

74.2.5 Primary references

[308].

74.3 Millikan: the slope of the line is h/e (1916)

Millikan spent a decade on this measurement in order to disprove the hypothesis it confirms, and the experiment is the better for it: no one has ever had a stronger motive to find the linear law false [437]. What he obtained was the best value of Planck's constant then available by any method, from an experiment in optics and electrometry that touches no cavity and no thermometer.

74.3.1 Apparatus

The difficulty is entirely one of surfaces. An alkali metal exposed to air acquires an oxide layer in minutes, and the layer changes the work function by more than the effect being measured, so the experiment must present a clean surface to the light and keep it clean for the duration of a run. Millikan's answer was to put a machine shop inside the vacuum: a sealed and evacuated glass vessel containing cylinders of sodium, potassium and lithium mounted on a rotatable wheel, together with a cutting knife operated from outside by an electromagnet, so that a fresh surface could be shaved and turned to face the light without ever admitting air. The optical train selects one line at a time from the spectrum of a mercury arc, spanning the visible and the near ultraviolet from about 550 nm to about 250 nm. The emitted electrons are collected in a Faraday cylinder, the current read on a quadrant electrometer, and a known and variable retarding potential is applied between the illuminated surface and the collector.

74.3.2 Procedure

For each metal and each spectral line: shave a fresh surface, admit the line, and record the collected current as the retarding potential is raised, until it vanishes. The potential at which it does is the stopping potential V_0 of Equation (69.1). Repeat for each line; plot V_0 against the frequency ν of the line; and take the slope of the resulting line, which is the measurement. Repeat the whole procedure for a second and a third metal. Separately, determine the contact potential difference between the emitting surface and the collector, which displaces the whole line vertically and must be known before the intercept can be read as a work function — though, as the derivation below shows, not before the slope can be read as h/e.

74.3.3 Observations and data

For every metal the stopping potential is a strictly linear function of frequency over the whole range examined, with no detectable curvature, and the lines obtained for different metals are parallel: the slope is a constant of nature and the material enters only through the intercept. Reading Planck's constant from that slope, Millikan obtained

$$h = 6.57 \times 10^{-34}\,\mathrm{J\,s}\,, \tag{74.3}$$

to about 0.5 % [437].

[Reserved: the tabulation. For each metal, the wavelength and frequency of each mercury line used, the measured stopping potential in volts with its uncertainty, and the residual from the fitted straight line — the residuals being the actual evidence for linearity and the thing a summary slope conceals. Then the fitted slope in V s *with its standard error, the fitted intercept, the separately measured contact potential, and the work function that follows. All in SI.]*

Phenomenon 74.4 (The photoelectric slope determines Planck's constant)**.** The straight line of Equation (69.1) has a slope $\mathrm{d}V_0/\mathrm{d}\nu = h/e$ that is the same for every emitting metal and is independent of the work function, of the contact potential of the apparatus, and of the intensity of the light. Millikan established the linearity and the parallelism across the visible and near ultraviolet on alkali surfaces cut fresh in vacuum, and read from the common slope the value Equation (74.3), to about 0.5 % [437] — at the time the best determination of h by any method, and in agreement with the entirely independent value obtained from the spectrum of cavity radiation [300].

Derivation. The claim to be established is not the linearity, which Phenomenon 69.2 already derives, but the robustness of the slope: why an experiment plagued by surface chemistry and by an unknown contact potential nevertheless yields a clean value of h/e.

Let the illuminated surface have work function ϕ_{E} and the collector ϕ_{C}. The two are in electrical contact through the external circuit, so their Fermi levels coincide and their vacuum levels differ by a fixed contact potential difference $V_{\mathrm{c}} = (\phi_{\mathrm{C}} - \phi_{\mathrm{E}})/e$, whatever the electrometer reads. An electron leaving the surface with kinetic energy E and crossing to the collector against an applied potential difference V therefore arrives only if $E > eV + \phi_{\mathrm{C}} - \phi_{\mathrm{E}}$. The fastest electron just fails when

$$eV_0 = E_{\max} - (\phi_{\mathrm{C}} - \phi_{\mathrm{E}}) = h\nu - \phi_{\mathrm{E}} - \phi_{\mathrm{C}} + \phi_{\mathrm{E}} = h\nu - \phi_{\mathrm{C}}\,. \tag{74.4}$$

Two conclusions follow, and they pull in opposite directions.

The intercept is worthless as a measurement of the illuminated surface. By Equation (74.4) it reports the work function of the *collector*, and any oxide or adsorbed film on that electrode enters the answer; every early attempt to read ϕ off a photoelectric intercept was measuring the wrong electrode.

The slope is untouched. Neither ϕ_{E} nor ϕ_{C} depends on the frequency of the light, so differentiating Equation (74.4),

$$\frac{\mathrm{d}V_0}{\mathrm{d}\nu} = \frac{h}{e}\,, \tag{74.5}$$

in which no property of either metal survives. A contamination that changes the work function displaces the whole line vertically and does not tilt it; that is why the lines for sodium, potassium and lithium come out parallel, and why parallelism is a stronger check on the hypothesis than the value of any one intercept.

What Equation (74.5) measures is the ratio h/e and not h. In the SI in force since 2019 both constants are fixed by definition [2333, 2431], so the slope of this line is now an exact number,

$$\frac{h}{e} = 4.135\,667 \times 10^{-15}\,\mathrm{V\,s}\,, \tag{74.6}$$

and Millikan's experiment has become a test of a definition rather than a determination of a constant. Comparing Equation (74.3) with the defined $h = 6.626\,070\,15 \times 10^{-34}\,\mathrm{J\,s}$, his value is low by about 0.8 %, which is larger than the 0.5 % he quotes. The discrepancy is not in the slope. To convert h/e into h one must multiply by a separately measured elementary charge, and the charge Millikan used was his own oil-drop value [407], later found low because of the value then adopted for the viscosity of air. The lesson is generic and belongs to Chapter 2: an experiment's own precision bounds only the quantity it actually measures, and every constant imported to convert that quantity into another carries its error into the result undiminished. □

Derivation pending #71

The operational definition of the stopping potential. The measured current does not fall to zero at a sharp potential but approaches it along a tail, because the emitted electrons have a distribution of energies rather than a single maximum, because electrons originate at a range of depths below the surface, and because the collector is not equipotential. What is pending is the derivation of the shape of that current–voltage curve near its foot from the energy distribution of the photoelectrons, and the demonstration that the extrapolation Millikan used recovers the true intercept without bias — the point being that the linearity of the plotted line is a statement about a quantity defined by an extrapolation, and that extrapolation must be shown not to have manufactured it.

74.3.4 Interpretation

The equation is confirmed and its author's hypothesis is not, and Millikan said so. Having verified the linear relation to better than a percent, he continued to regard the light-quantum picture behind it as untenable, and he was not merely being stubborn: the photoelectric equation follows equally from a quantized atom absorbing energy from a classical field, as [1402] later showed explicitly and as Section 69.2.4 records. The discreteness that Phenomenon 74.4 demonstrates is a discreteness of *energy exchange*; the atomic energy levels of Chapter 70 supply it without any assumption about the field. The measurement's real and undisputed content is metrological: the constant that Planck extracted from a cavity spectrum [294, 300], by an argument about oscillators in thermal equilibrium, reappears to half a percent in a table-top electrometer experiment on a shaved sodium surface. Two measurements with nothing in common but the constant is the strongest kind of evidence that the constant is real, and it is why Part VIII treats h as a fact about nature before any interpretation of it is settled.

74.3.5 Primary references

[437]. The elementary charge used to convert the measured slope into h is [407]; the independent value of h from cavity radiation is [300]; the semiclassical account of the same equation is [1402].

74.4 Compton: the wavelength of scattered X-rays changes (1923)

Here the evidence changes character. Everything before this section concerns the energy the light delivers; this concerns the momentum it carries away, and the momentum of a wave packet is a property of the light itself that no rearrangement of the absorber can supply [499].

74.4.1 Apparatus

An X-ray tube with a molybdenum target, whose Kα line at about 17.5 keV and 71 pm provides a nearly monochromatic incident beam. A block of graphite serves as scatterer: a light element, so that most of its electrons are loosely enough bound to recoil freely. Slits define the incident beam and select the direction in which the scattered radiation is examined, fixing the scattering angle θ. The scattered radiation enters a Bragg spectrometer — a crystal of known lattice spacing on a divided circle, with an ionization chamber to measure the reflected intensity — so that a wavelength is read as an angle through Bragg's law [400].

74.4.2 Procedure

Set the scattering angle; scan the spectrometer crystal through its range and record the ionization current against crystal angle, converting angle to wavelength by $n\lambda = 2d\sin\vartheta$; identify the peaks in the resulting spectrum. Repeat at a series of scattering angles from small to large, and repeat with scatterers of different atomic number. The comparison to be made is between the wavelength of each peak and the wavelength of the primary beam measured in the same spectrometer, which cancels the calibration of the crystal spacing from the difference.

74.4.3 Observations and data

At every scattering angle other than zero the scattered spectrum contains two peaks, not one: an unmodified peak at the incident wavelength and a second peak displaced towards longer wavelength. The displacement grows with the scattering angle. It does not depend on the incident wavelength, on the material of the scatterer, or on the intensity of the beam [499].

[Reserved: the tabulation. Scattering angle in degrees; measured wavelength of the modified peak in picometres with its uncertainty; measured wavelength of the unmodified peak, as a control that the spectrometer calibration has not drifted; the difference; and the value predicted by Equation (69.4), together with the ratio of measured to predicted shift and its propagated uncertainty. Also the relative height of the two peaks against the atomic number of the scatterer, which is the evidence for the binding interpretation of the unmodified line.]

Phenomenon 74.5 (The shift depends on the scattering angle and on nothing else)**.** The wavelength displacement of the modified peak is a universal function of the scattering angle alone, given by Equation (69.4) with the Compton wavelength $\lambda_{\mathrm{C}} = h/m_{\mathrm{e}}c = 2.426\,31\,\mathrm{pm}$ [2431], and carries no adjustable parameter and no property of the scattering material [499, 501]. Classical scattering of a wave by a charge predicts no displacement at any angle, because a charge driven at one frequency re-radiates at that frequency [1976]; the observation is therefore not a quantitative refinement of the classical result but a contradiction of it.

Derivation. The relation itself is derived in Chapter 69 from the relativistic conservation laws of Chapter 40 applied to a collision between a quantum of energy $h\nu$ and momentum $h\nu/c$ and a free electron at rest. What is derived here is the experimental design that follows from it, because the reason this measurement was not made in 1905 is contained in the formula.

Evaluate Equation (69.4) at representative angles. The shift is $\lambda_{\mathrm{C}}\,(1-\cos\theta)$, so it vanishes in the forward direction, equals λ_{C} at 90°, and saturates at $2\lambda_{\mathrm{C}}$ in backscattering; the values are collected in Table 74.1. The absolute shift is a few picometres and no more, whatever one does.

The quantity an instrument must resolve is not the shift but the *fractional* shift, and that is where the choice of radiation enters:

$$\frac{\Delta\lambda}{\lambda} = \frac{\lambda_{\mathrm{C}}}{\lambda}\,(1-\cos\theta) = \frac{h\nu}{m_{\mathrm{e}}c^2}\,(1-\cos\theta)\ , \tag{74.7}$$

the second form making the physical content plain: the shift is appreciable only when the quantum energy is not negligible against the rest energy of the electron, 511 keV. For the molybdenum Kα line at 71 pm, Equation (74.7) at 90° gives $\Delta\lambda/\lambda \approx 0.034$, a three-percent change in wavelength — large for a crystal spectrometer, which resolves far better than that. For visible light at 500 nm the same formula gives $\Delta\lambda/\lambda \approx 5\times10^{-6}$, below anything a nineteenth-century spectroscopist could have separated from the width of a line. The Compton effect was not overlooked before 1923; it was inaccessible, and it became accessible when X-ray spectroscopy did [400].

The same formula explains the peak that does not move. An electron bound tightly enough that the whole atom recoils requires m_{e} in Equation (69.4) to be replaced by the atomic mass, which for carbon is some four orders of magnitude larger; the predicted shift falls by the same factor and becomes unobservable. Hence a light element scatters mostly into the modified peak and a heavy one mostly into the unmodified peak, which is a further prediction of the same kinematics and is what the scatterer-dependence measurement tests. □

Table 74.1: Wavelength shift predicted by Equation (69.4) at representative scattering angles, with the fractional shift for the molybdenum Kα line at 71 pm from Equation (74.7). Computed from the formula; these are not measurements.

θ	$\Delta\lambda$	$\Delta\lambda/\lambda$ at 71 pm
45°	0.711 pm	0.010
90°	2.426 pm	0.034

74.4.4 Interpretation

This is the first result in this chapter that a classical field cannot be made to yield. The photoelectric effect concerns what happens *inside* the absorber, and a quantized absorber suffices; the Compton shift concerns what happens to the radiation, and the radiation leaves with less energy and a changed direction in exactly the proportion that a particle of momentum h/λ would carry away. Two features make the evidence hard to evade. The shift is independent of the scattering material, so it cannot be a property of carbon; and it is independent of the incident intensity, so it cannot be a nonlinear response of the medium.

Three honest qualifications belong here. The kinematics were published independently and within weeks by Debye [501], from the same hypothesis and without knowledge of the experiment, and the treatise's citation rule requires that both be named. The kinematics fix the shift but not the rate: the angular distribution requires the relativistic theory of the electron and emerges as the Klein–Nishina cross-section [630], developed from Chapter 93, whose low-energy limit is the Thomson result of Chapter 65. And — the qualification that mattered most at the time — the experiment measures an *average* over very many scattering acts. A theory in which energy and momentum are conserved only statistically predicts the same mean shift, and one such theory was on the table within a year [508]. Closing that gap is the business of Section 74.5.

74.4.5 Primary references

[499]; the independent derivation of the same kinematics is [501]; the crystal-spectrometer technique the measurement rests on is [400].

74.5 Bothe and Geiger: the two products appear together (1925)

Bohr, Kramers and Slater proposed keeping the continuous classical field at the price of strict conservation: energy and momentum would hold only as statistical averages, the atom being coupled to a virtual radiation field that fixes transition probabilities [508]. It is the most serious counter-theory the light quantum ever faced, and its virtue is that it is sharply falsifiable, since it predicts that a scattered quantum and its recoil electron are uncorrelated event by event. This experiment measures that correlation [519].

74.5.1 Apparatus

Two needle counters — point-discharge counters of the kind Geiger had developed — mounted on opposite sides of a chamber filled with hydrogen, which is used as the scatterer because its single loosely bound electron per atom maximizes the modified scattering of Section 74.4 and minimizes absorption. One counter has a thin window and responds to the recoil

electrons themselves; the other is arranged to respond to the scattered X-ray quanta, which it registers through the secondary electrons they liberate in a foil. A collimated X-ray beam crosses the chamber between them. Each counter's discharge drives a string electrometer whose fibre is imaged onto a photographic film driven at constant speed, so that the two records are written side by side against a common time axis.

74.5.2 Procedure

Irradiate the hydrogen and let the film run. Develop it, and measure for every discharge in one trace the time interval to the nearest discharge in the other. Coincidences are then defined by a resolving time τ — set by how finely two deflections can be separated on the moving film, and here of order $1 \times 10^{-4}\,\mathrm{s}$ — and counted. The counting rate of each channel separately is measured on the same records. The number of chance coincidences expected from those singles rates and that resolving time is then computed and subtracted, and the excess is the quantity of interest. The whole experiment consists in showing that the excess is not zero, so the accidental rate must be computed rather than assumed small.

74.5.3 Observations and data

Coincidences between the two counters occur at a rate far above the rate expected from chance alone, with a resolving time of order $1 \times 10^{-4}\,\mathrm{s}$ [519]. Every recorded coincidence is therefore a single scattering act whose two products were both detected, and the scattered quantum and the recoil electron are produced together.

[Reserved: the tabulation. Singles counting rate in each channel in $1/\mathrm{s}$*; total observation time; number of observed coincidences; the computed accidental number from Equation* (74.8) *with its Poisson uncertainty; the excess and its significance. Also the control runs that establish that the excess vanishes when it should — with the X-ray beam off, and with an absorber interposed so that only one channel can respond.]*

Phenomenon 74.6 (Energy and momentum balance in each individual scattering act)**.** The scattered quantum and the recoil electron of a Compton scattering appear simultaneously, in the same act, and not merely at rates that agree on the average. Bothe and Geiger recorded coincidences between a counter responding to scattered X-rays and a counter responding to recoil electrons at a rate far exceeding the chance rate computable from the two singles rates and the resolving time [519]. The complementary measurement, in which a cloud chamber records the direction of the recoil electron and the direction of the scattered quantum in the same event and finds them correlated as the kinematics require, is [520]. This is Phenomenon 69.6, and it excludes the statistical-only conservation of [508].

Derivation. The two competing predictions are predictions about a *number of counts*, so the derivation is the calculation of that number under each hypothesis.

Let the two counters fire at rates N_1 and N_2, and let the apparatus register a coincidence whenever two discharges fall within a resolving time τ of each other. Suppose first that the two channels are statistically independent. In an observation of duration T, counter 1 produces $N_1 T$ discharges; each of them opens a window of total length 2τ, from τ before to τ after, within which a discharge of counter 2 will be recorded as coincident. Provided the windows do not overlap, that is $2\tau N_2 \ll 1$, the expected number of chance coincidences is

$$N_{\mathrm{acc}} = 2\tau N_1 N_2 T\,, \tag{74.8}$$

with Poisson fluctuation $\sqrt{N_{\mathrm{acc}}}$. This is the entire prediction of the statistical proposal [508]: on that theory the recoil electrons and the scattered quanta are emitted in unrelated acts, so there is no source of coincidences other than chance and the observed number must agree with Equation (74.8) within its fluctuation.

Under strict conservation each scattering act produces exactly one quantum and exactly one electron. If such acts occur at a rate R within the region both counters view, and the counters detect their respective products with efficiencies ε_1 and ε_2, the genuine coincidence number is

$$N_{\text{true}} = \varepsilon_1 \varepsilon_2 R T \,, \tag{74.9}$$

and the prediction is $N_{\text{obs}} = N_{\text{true}} + N_{\text{acc}}$, which exceeds Equation (74.8) by an amount that does not fall to zero however the apparatus is arranged.

The design rule follows by dividing the two. The singles rates are themselves proportional to the scattering rate, $N_i = \varepsilon_i R$, so

$$\frac{N_{\text{true}}}{N_{\text{acc}}} = \frac{\varepsilon_1 \varepsilon_2 R}{2\tau \varepsilon_1 \varepsilon_2 R^2} = \frac{1}{2\tau R} \,. \tag{74.10}$$

The genuine rate is linear in the beam intensity and the accidental rate is quadratic, so the discrimination *improves* as the source is weakened and as the resolving time is shortened — the opposite of the usual instinct to increase the signal. This is why the experiment is possible at all with counters of poor efficiency and a resolving time as long as $1 \times 10^{-4}\,\text{s}$, and Equation (74.10) is the reason the coincidence method went on to become the basic technique of particle detection in Part XI. □

Derivation pending #72

The angular correlation measured by the cloud-chamber experiment. What is pending is the direction of the recoil electron as a function of the scattering angle of the quantum, obtained from the same conservation laws that give the wavelength shift, together with the angular spread introduced by the initial motion of the struck electron and by multiple scattering of the recoil track in the chamber gas — the latter being what sets the accuracy with which the predicted correlation can be confirmed, and hence what the measurement is really comparing.

74.5.4 Interpretation

The proposal of Section 69.5.1 was withdrawn at once, and the manner of the withdrawal deserves recording: Bohr accepted the result immediately and without attempting to save the theory, which is the behaviour a falsifiable proposal earns. With it went the last scientifically serious attempt to keep a continuous classical electromagnetic field while accounting for the quantum phenomena, and conservation of energy and momentum was re-established as exact rather than statistical — a conclusion that reaches far beyond optics.

What the experiment establishes should be stated precisely, because it is often overstated. It establishes that the two products of a Compton scattering are correlated in time, event by event, and hence that the process is a collision between two objects and not a redistribution among many. It does not by itself establish that the incident radiation consists of localized quanta before the collision: a field that interacts with matter only in whole quanta, but propagates as a wave, survives this test intact. That last distinction — indivisibility of the propagating field itself — is what Section 74.6 measures.

Methodologically this experiment founded the coincidence technique, for which Bothe was later awarded the Nobel Prize, and Equation (74.10) is the design principle every coincidence measurement in this treatise still uses, from the cosmic-ray telescopes of Section 41.2 to the detectors of Part XI.

74.5.5 Primary references

[519]; the complementary cloud-chamber measurement of the angular correlation is [520]; the theory both of them exclude is [508].

74.6 Grangier, Roger and Aspect: a single quantum is not split (1986)

Everything so far is consistent with a classical field that happens to exchange energy in lumps. This experiment is not, and it is included because it is the one measurement in this chapter that no classical field of any strength or statistics can reproduce [1774]. The quantity it measures is bounded below for every classical field, by an inequality that follows from nothing but the positivity of intensity, and the measured value lies far beneath the bound.

74.6.1 Apparatus

A beam of calcium atoms, excited by two lasers to a state that decays by a two-photon radiative cascade, so that photons are emitted in pairs: one near 551 nm and one near 423 nm, well separated in colour and therefore separable by filters. One member of each pair is sent to a photomultiplier whose pulse opens an electronic gate of fixed duration — it is not measured further, it merely announces that a partner is on its way. The partner is directed onto a beamsplitter, and each of the two output ports carries its own photomultiplier. Coincidence electronics count, within each gate, the detections at the first output port, at the second, and at both. The same source can alternatively feed a Mach–Zehnder interferometer whose fringe visibility is recorded.

74.6.2 Procedure

Run the source at a rate low enough that the probability of two cascades falling in one gate is small, and accumulate three numbers over N gates: N_1 and N_2, the counts at the two output ports, and N_{c}, the number of gates in which both fired. Form the anticorrelation parameter

$$\alpha := \frac{N_{\mathrm{c}} N}{N_1 N_2}\,, \tag{74.11}$$

which is the joint detection probability per gate divided by the product of the single detection probabilities. Then replace the beamsplitter arrangement by the interferometer, without changing the source, and record the fringe visibility. The two configurations put the same light to the two incompatible tests — indivisibility and interference — and the point of the experiment is that both are passed.

74.6.3 Observations and data

The measured anticorrelation parameter is

$$\alpha = 0.18 \pm 0.06\,, \tag{74.12}$$

far below the classical lower bound $\alpha \geq 1$ derived below, and the same source in the interferometer produces interference fringes of high visibility [1774].

[Reserved: the tabulation. Gate duration in seconds; cascade rate in 1/s*; the three counts N_1, N_2 and N_c with their accumulation time; the accidental contribution computed as in Equation (74.8) from the same gate width; the resulting α with its statistical uncertainty; and the fringe visibility with its uncertainty. Also the measured dependence of α on the cascade*

rate, which is the control that identifies the residual α as double-cascade contamination rather than as a failure of the prediction.]

Phenomenon 74.7 (No classical field can give $\alpha < 1$; the measured value is far below it)**.** For light described by any classical field whatever — of any intensity, however feeble, and with any statistics — the anticorrelation parameter Equation (74.11) satisfies $\alpha \geq 1$. Light prepared one quantum at a time violates this: the measured value is Equation (74.12), some thirteen standard deviations below the bound [1774]. The same light, in an interferometer, nevertheless interferes with high visibility. This is Phenomenon 69.7.

Derivation. Take the classical bound first. Let the field arriving at the beamsplitter during a gate have intensity I, treated as a random variable over an ensemble of gates with any distribution whatever, subject only to $I \geq 0$. Let the beamsplitter transmit a fraction T and reflect $R = 1 - T$, and let each detector respond with a probability proportional to the intensity reaching it, with efficiency η. Then the single detection probabilities per gate are

$$P_1 = \eta T \langle I \rangle \,, \qquad P_2 = \eta R \langle I \rangle \,, \tag{74.13}$$

and, because the two detectors respond independently to the *same* field realization, the joint probability is

$$P_{\mathrm{c}} = \eta^2 T R \left\langle I^2 \right\rangle \,. \tag{74.14}$$

Note where the physics sits: the average of the product is the average of I^2, not the product of averages, precisely because a classical wave is present at both outputs at once. Dividing,

$$\alpha = \frac{P_{\mathrm{c}}}{P_1 P_2} = \frac{\langle I^2 \rangle}{\langle I \rangle^2} = 1 + \frac{\mathrm{Var}\,(I)}{\langle I \rangle^2} \geq 1 \,, \tag{74.15}$$

the last step because a variance cannot be negative — equivalently, by the Cauchy–Schwarz inequality applied to I and the constant function. Equality holds only for a field of perfectly steady intensity; any fluctuation makes α larger, never smaller. The efficiencies and the splitting ratio have cancelled, so the bound is not a statement about the apparatus. Neither is it a statement about brightness: making the beam weaker scales I and leaves the ratio in Equation (74.15) untouched. This is the crucial point, and it is what defeats the intuition that a sufficiently dim classical wave would behave like particles.

Now the quantum prediction. A one-photon state incident on port a of the beamsplitter goes over into a superposition of one photon in the transmitted mode and one photon in the reflected mode. That superposition has no component whatever in which both output modes are occupied, since there is only one excitation to distribute, so the joint detection probability vanishes identically and

$$\alpha = 0 \tag{74.16}$$

for an ideal single-photon input — again independently of the splitting ratio and of the detector efficiencies, which appear in P_{c} and in $P_1 P_2$ to the same order and cancel.

The measured Equation (74.12) is neither the classical bound nor the ideal quantum value, and the discrepancy from zero is understood and testable. The heralding is imperfect: if two cascades occur within one gate, the gate contains two photons, which can perfectly well be detected one at each output. The rate of such double-cascade gates grows with the square of the source rate while the single-cascade rate grows linearly, so α should fall towards zero as the source is weakened — which is why the dependence of α on the cascade rate is part of the data and not a diagnostic afterthought.

Finally, the quantity in Equation (74.15) is the normalized second-order correlation function at zero delay, and the inequality $\alpha \geq 1$ is the classical bound on it. The same inequality is violated by resonance fluorescence from a single atom, which was the first observation of the effect [1598], and its systematic theory belongs to Chapter 122. □

74.6.4 Interpretation

Two results are reported together and neither means much without the other. The anticorrelation says that the light is not divided by the beamsplitter: it goes one way or the other, and the classical field picture, in which an amplitude goes both ways and both detectors are illuminated, is excluded by Equation (74.15) at any intensity. The interference says that the very same light, given two paths that are later recombined, produces fringes — which the naive particle picture forbids, since a particle that took one arm cannot know the length of the other. The pair of observations, on one source, is the experimental content of what Chapter 85 discusses, and it should be noted that the discussion rests on data of *this* kind, not on the photoelectric effect.

The historical placement matters as much as the result. Feeble-light interference had been demonstrated as early as 1909, with an exposure of months at an intensity so low that, on a quantum accounting, the apparatus contained one photon at a time [360] — and it established nothing about granularity, because a weak classical wave interferes exactly as well as a strong one. The complementary error is equally old: photon-counting statistics, and even the correlations between the photocurrents of two detectors viewing one source [1083], are reproduced by a classical field of fluctuating intensity, as Equation (74.15) shows for the special case $\alpha \geq 1$. The first experiments to draw the distinction sharply were the tests of the classical field-theoretic predictions for photodetection [1521] and the observation of antibunched fluorescence from a single atom [1598]; what [1774] adds is a heralded single-photon source, so that the two tests — indivisibility and interference — are applied to the same prepared state. The same hardware, and the same calcium cascade, is what makes the Bell tests of Chapter 89 possible.

A closing note on the word. "Photon" was coined by Lewis [551] for an entity quite unlike the one this section measures; what the experiment establishes is the indivisibility of a one-excitation state of the quantized field, and the honest definition of that object is the one given in Chapter 69 and completed in Part XI.

74.6.5 Primary references

[1774]. Precursors that bear directly on the same distinction are [1521, 1598]; the feeble-light interference that does *not* establish granularity is [360]; the intensity correlations that a classical field does reproduce are [1083].

74.7 What the measurements settle

The chapter has a structure that Table 74.2 makes visible and that the standard textbook order conceals. The first three experiments are decisive against *one* classical picture — a continuous field pouring energy into a passive absorber — and are silent about the alternative in which the field stays classical and the absorber is quantized. That alternative is not a philosophical reservation: it reproduces the threshold, the linearity in frequency, the independence of intensity and the promptness of the emission [1402], which is to say every one of the four observations of Phenomenon 69.1. Anyone who says the photoelectric effect proves the existence of photons is asserting something the photoelectric effect does not contain, and Millikan, who measured it best, said so at the time.

What does the work is the second half. Section 74.4 shows that the radiation carries momentum in the fixed ratio $1/c$ to its energy and delivers it in a collision, which is a property of the light and not of the target — the shift is the same for graphite, for hydrogen and for paraffin. Section 74.5 shows that the collision is a single event with two products and not an average over many, which removes the only counter-theory that had survived [508]. And Section 74.6 shows that the propagating field is itself indivisible, by violating a

Table 74.2: The measurements reported in this chapter, and the claim each is entitled to. The third column is the point of the chapter: the experiments most often cited as proving that light is granular do not, and the ones that do are less famous.

Experiment	Quantity measured	What it establishes
Hertz–Hallwachs 1887–1888	sign of the carriers	ultraviolet light liberates electrons from a clean metal; an anomaly, not yet a test of anything
Lenard 1902	stopping potential	the electron energy ignores the intensity and follows the colour; no continuous classical field can deliver energy this way
Millikan 1916	slope $\mathrm{d}V_0/\mathrm{d}\nu$	the slope is h/e for every metal, giving $h = 6.57 \times 10^{-34}\,\mathrm{J\,s}$; quantized *exchange*, not quantized light
Compton 1923	$\Delta\lambda$ against θ	the radiation carries momentum h/λ; classical scattering predicts no shift at all
Bothe–Geiger 1925	coincidence excess	energy and momentum balance in each single act; statistical-only conservation excluded
Grangier *et al.* 1986	α at a beamsplitter	$\alpha = 0.18 \pm 0.06$ against the classical bound $\alpha \geq 1$; the field itself is indivisible

bound Equation (74.15) that follows from the positivity of a classical intensity and from nothing else. Only the third of these speaks about the field between the source and the detector; the first two speak about what it does when it arrives.

Two things this chapter does not settle should be named. It does not settle what a photon *is* — the answer is an excitation of the quantized electromagnetic field, with two helicity states and no rest frame, and it belongs to Part XI. And it does not settle the rate of any of these processes, only their kinematics: the angular distribution of Compton scattering requires Chapter 93 and appears as the Klein–Nishina cross-section [630], and the photoelectric cross-section requires the atomic structure of Chapter 70. What is established here, beyond argument and by measurements a century apart, is that light delivers energy in units $h\nu$, carries momentum $h\nu/c$, conserves both in every individual act, and cannot be divided at a beamsplitter.

Chapter 75

Experiment: Matter Waves Observed

Chapter 71 states a hypothesis that was made on grounds of symmetry and not of data: a carrier of momentum p is accompanied by a wave of wavelength h/p. That chapter draws out what follows — Bohr's quantization condition ceases to be a postulate, the optical–mechanical analogy of geometrical optics and classical mechanics acquires its missing entry, and a localized particle becomes a packet with a group velocity. It names the experiments in passing. It does not show them being done, and the omission is worth repairing at length, because the hypothesis was so nearly baseless when it was made: de Broglie had one relation transposed from light to matter and no measurement whatever to support it.

Six measurements are reported, in the order in which each removes an alternative explanation rather than in strict order of date. Davisson and Germer scatter slow electrons from a single crystal and find the wavelength written into the diffraction geometry [571]; Thomson and Reid send fast electrons through a thin film and photograph rings, so the effect is not peculiar to a surface [589]; Estermann and Stern diffract helium atoms and hydrogen molecules, so it is not peculiar to charge [651]; Jönsson opens two slits and Merli, Missiroli and Pozzi and later Tonomura and collaborators build the pattern one electron at a time, so it is not a collective effect [1212, 1588, 1826]; Colella, Overhauser and Werner tilt a neutron interferometer and read gravity off the fringe count, so the phase of a matter wave is an instrument reading [1542]; and molecular interferometry carries the relation to objects of thousands of atoms and shows what does end it [1966, 2337]. The prediction was published before any of them [500, 521], and the suggestion that a crystal would serve as the grating was published two years before the first two [523].

The arithmetic below uses the CODATA values of h, e, m_e and the neutron mass [2431].

Derivation pending #73

Experiment: Matter Waves Observed: what is pending is the apparatus and procedure of each measurement and the tabulation of its data — scattered intensity against angle and accelerating voltage, ring radii against voltage, diffraction angle against source temperature, fringe visibility against count, neutron intensity against tilt angle, and molecular fringe contrast against internal temperature and residual gas — each in SI with its uncertainty budget. The phenomena stated below each carry their derivation inline.

75.1 Davisson and Germer: electron diffraction by a crystal (1927)

The experiment was an accident twice over. Davisson and Kunsman had been measuring the angular distribution of electrons scattered from a nickel target and finding it smooth; a vacuum failure oxidized the target, and the prolonged heating used to reduce it recrystallized the nickel into a few large crystals. When the measurements resumed, the smooth distribution had been replaced by sharp maxima at particular angles and particular beam energies. What makes the result a measurement rather than a curiosity is that both quantities entering the comparison — the wavelength predicted from the accelerating voltage and the wavelength read off the diffraction angle — are fixed independently, one by the electrical circuit and one by X-ray crystallography, and neither is adjusted.

75.1.1 Apparatus

[Reserved: the sealed vacuum vessel; the electron gun delivering a collimated beam of a few tens of electronvolts with the accelerating potential adjustable and measurable; the nickel target, a single crystal presenting its (111) face, mounted so that it can be rotated about the beam axis and about the axis perpendicular to it; the movable Faraday-box collector, with a retarding potential on its aperture so that only elastically scattered electrons are counted, and the galvanometer that reads its current. To be given: the beam current and its stability, the collector acceptance angle — which sets the angular resolution and therefore, by Equation (75.3), the accuracy of the whole measurement — and the working pressure, since the recrystallization that made the experiment possible was itself a vacuum accident.]

75.1.2 Procedure

[Reserved: two scans, and the logic of taking both. At fixed accelerating voltage the collector is swept in angle and the elastic current recorded, giving the angular distribution; at fixed collector angle the voltage is swept, giving the excitation curve. A maximum must appear in both scans at the place where the grating condition and Equation (75.1) agree, and the joint appearance is the test: a feature of the target alone would not move with voltage, and a feature of the beam alone would not move with the crystal azimuth. The azimuthal scan, in which the crystal is rotated about the beam and the maxima reappear with the three-fold symmetry of the (111) face, is what identifies the scatterer as the lattice.]

75.1.3 Observations and data

[Reserved: the elastic scattered current against collector angle at each accelerating voltage, and against voltage at each collector angle, with the resulting map of maxima in the angle–voltage plane. To be tabulated when written: for each maximum, the accelerating voltage and its uncertainty, the collector angle and its uncertainty, the order assigned, the wavelength deduced from the geometry, the wavelength predicted by Equation (75.1), and their ratio — the whole set, not the single case worked below, since the strength of the result lies in the maxima moving together as the voltage is changed.]

Phenomenon 75.1 (The wavelength of an electron beam can be read off a crystal)**.** A beam of electrons of well-defined kinetic energy scattered from a single crystal produces sharp maxima at particular angles, as X-rays of the same wavelength do on the same crystal, and the wavelength deduced from the diffraction geometry agrees with h/p computed from the accelerating voltage. Davisson and Germer, scattering electrons of 54 eV from the (111) face of a nickel single crystal, found a pronounced maximum near 50°, corresponding to a wavelength of 0.165 nm against the de Broglie value 0.167 nm [571]. The lattice spacing

entering the first number was measured with X-rays [400] and the voltage entering the second with a voltmeter; no quantity was fitted.

Derivation. Two numbers are compared. The first is the wavelength the hypothesis assigns to the beam. An electron accelerated from rest through a potential difference V has kinetic energy $T = eV$ and momentum given by $(pc)^2 = T^2 + 2Tm_ec^2$, so

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2m_eeV}} \left(1 + \frac{eV}{2m_ec^2}\right)^{-1/2} . \tag{75.1}$$

The bracket is the relativistic correction. At $V = 54\,\mathrm{V}$ it departs from unity by 2.6×10^{-5} and may be dropped, leaving $\lambda = 0.167\,\mathrm{nm}$; it may not be dropped in Section 75.2, where the same electrons are accelerated a thousand times harder.

The second number is the wavelength the diffraction geometry assigns to the beam. A row of scatterers of spacing d in the surface reinforces at angles satisfying $d\sin\theta = n\lambda$, and the row spacing of nickel, $d = 0.215\,\mathrm{nm}$, is known from X-ray crystallography [400] — that is, from a measurement in which no electron appears. The observed first-order maximum at $\theta = 50^\circ$ therefore reads

$$\lambda = d\sin\theta = 0.215\,\mathrm{nm} \times 0.766 = 0.165\,\mathrm{nm}\,, \tag{75.2}$$

which agrees with Equation (75.1) to 1.2 %.

It is worth differentiating the comparison, because that says which measurement limits it. From Equation (75.1), $\delta\lambda/\lambda = -\tfrac{1}{2}\,\delta V/V$, so a beam energy known to 1 % fixes the predicted wavelength to 0.5 %. From Equation (75.2),

$$\frac{\delta\lambda}{\lambda} = \cot\theta\,\delta\theta + \frac{\delta d}{d}\,, \tag{75.3}$$

and $\cot 50^\circ = 0.84$, so an error of one degree in locating the maximum is worth 1.5 % of the wavelength. The angular measurement, not the beam energy, sets the accuracy of the test, and the residual 1.2 % is smaller than the spread that a degree of angular uncertainty alone permits. It is also of the size of a known systematic effect that any comparison of this kind must confront: the crystal presents a mean inner potential to the electron, which is accelerated on entering the solid and therefore has a shorter wavelength inside it than outside. The reduction of that effect is the business of the interpretation, not of the arithmetic here; what the arithmetic establishes is that a wavelength computed from a voltage and a wavelength read off a lattice agree to about one percent, which no theory of the electron as a corpuscle predicts at all. □

75.1.4 Interpretation

[Reserved: what the maxima are and what they are not. The azimuthal symmetry identifies the lattice as the scatterer; the joint motion of the maxima in angle and voltage identifies the wavelength as the quantity being diffracted. The section must then treat the two systematic effects honestly — refraction by the mean inner potential of the crystal, which shifts the deduced wavelength, and the distinction between the two-dimensional surface-grating reading and the three-dimensional Bragg reading of the same maxima, which the experiment does not by itself settle. The forward link is that Elsasser's prediction [523] preceded the observation by two years and was unknown to one of the two groups that confirmed it, so the priority customarily assigned to the experimenters alone is incomplete.]

75.1.5 Primary references

[571]. The prediction is [523]; the independently measured lattice spacing is X-ray crystallography [400]; the hypothesis under test is [500, 521].

75.2 Thomson and Reid: transmission rings from thin films (1927)

A reflection experiment on a single crystal leaves one evasion open: the maxima might be produced by something happening in the outermost atomic layer of that particular face of that particular metal. The transmission geometry closes it. Fast electrons sent through a thin polycrystalline film meet crystallites at every orientation, emerge on the far side, and land on a plate as a set of concentric rings; the target has no preferred direction, so there is no surface for the explanation to hide in, and the pattern is the electron counterpart of the Debye–Scherrer powder rings that X-rays make in the same apparatus.

75.2.1 Apparatus

[Reserved: the discharge tube and accelerating column delivering electrons at some tens of kilovolts, with the potential measured independently of the beam; the film target — a self-supporting celluloid film in the first communication, metal films evaporated or beaten thin in the later work — of thickness small enough to transmit and large enough to diffract; the drift space of known length between target and plate; the photographic plate; and the magnetic shielding, since a stray field bends the beam and the whole measurement is of a radius. To be given: film thickness and its uniformity, the drift length and its uncertainty, and the plate calibration used to convert blackening into a ring radius.]

75.2.2 Procedure

[Reserved: record the ring pattern at each of a series of accelerating voltages spanning the available range, then repeat with a target of a different material. Two comparisons are then available and neither needs an absolute calibration: at fixed voltage, the ratios of the ring radii within one pattern must equal the ratios of the inverse lattice spacings of the target, which are known from X-ray work; and at fixed target, every radius must scale with voltage as Equation (75.4) requires. Rotating or replacing the film must change nothing, which is the control that distinguishes a lattice effect from a surface or instrumental one.]

75.2.3 Observations and data

[Reserved: ring radii against accelerating voltage for each target material, with the plate scale and the drift length that convert them to angles. To be tabulated when written: voltage, ring order, measured radius, deduced scattering angle, deduced lattice spacing, and the spacing known from X-ray diffraction on the same material; and separately the test of the scaling law, as the measured radius times the square root of the voltage, which must be constant along a column to the precision of the plate measurement.]

Phenomenon 75.2 (Ring radii scale as the inverse square root of the accelerating voltage)**.** Electrons of some tens of kilovolts transmitted through a thin polycrystalline film produce concentric rings on a plate beyond it. The radii are set by the lattice spacings of the target material and scale with the accelerating voltage as $V^{-1/2}$, independently of the orientation of the film; the pattern is that produced by X-rays of the same wavelength on the same material [589]. Because a polycrystalline film has no preferred orientation and the beam passes through it, no account resting on a surface effect peculiar to one crystal face survives.

Derivation. For each set of lattice planes of spacing d, the crystallites oriented so as to satisfy $2d\sin\theta = n\lambda$ lie on a cone about the beam, and the plate at a distance L downstream records a ring of radius $r = L\tan 2\theta$. The angles are small, because the wavelength is far below the spacing: Equation (75.1) at $V = 40\,\mathrm{kV}$ gives $\lambda = 6.0\,\mathrm{pm}$, so for $d = 0.2\,\mathrm{nm}$ the

first order sits at $\theta = 0.86^\circ$ and the ring at $2\theta = 1.7^\circ$, which on a drift of 0.3 m is a radius of 9 mm. To that accuracy $\tan 2\theta \simeq 2\theta \simeq \lambda/d$, so

$$r \simeq \frac{L\lambda}{d} \propto \frac{1}{\sqrt{V}}\,, \tag{75.4}$$

the proportionality following from Equation (75.1) with the relativistic bracket set to unity.

Equation (75.4) is a parameter-free scaling law, and that is what makes it a test. The drift length L and the plate scale enter every radius alike and cancel from any ratio, so the prediction that $r\sqrt{V}$ is constant can be checked without calibrating the instrument at all. The lattice spacing d is likewise known from X-rays, so the ratios of radii within a single pattern are predicted too, and they are predicted differently for celluloid than for a metal.

One correction has become visible in moving from Section 75.1 to this geometry, and it is worth recording because it is a second, independent piece of physics appearing in the same data. The relativistic bracket of Equation (75.1), negligible at 54 V, shortens the wavelength by 0.5 % at 10 kV and by 2.8 % at 60 kV. An exact $V^{-1/2}$ law therefore cannot hold across the range: the rings at the top of it must come in about two percent tighter than the non-relativistic scaling predicts. At this precision the departure is at the edge of what plate measurements resolve, and the honest statement is that these experiments establish the scaling and are consistent with the correction rather than measuring it. □

75.2.4 Interpretation

[Reserved: the loophole closed — transmission through a target with no preferred orientation removes any surface explanation of Section 75.1 — and the loophole left open, which is that the electron might be diffracted as a corpuscle by a periodic force field rather than as a wave. That one is closed not here but by Section 75.4, where the interference is formed by two apertures in free space with no lattice at all. The historical remark belongs in a remark and not in the body: J. J. Thomson showed that the electron is a particle and G. P. Thomson that it is a wave, and both were right.]

75.2.5 Primary references

[589]. That first communication reports the effect for a celluloid film; the metal films that made the result independent of the chemistry of the target came in the fuller papers of the following year [621].

75.3 Estermann and Stern: helium and hydrogen diffracted (1930)

Everything so far has been done with electrons, and an electron is a charged point that a lattice of ions can grip in several ways. The decisive extension is to a projectile that offers nothing to grip. A ground-state helium atom is electrically neutral, chemically inert, and carries neither an electric nor a magnetic dipole moment; if such a thing is diffracted by a crystal surface, the wave behaviour belongs to matter as such and not to charge. The instrument is Stern's molecular-beam apparatus, the same lineage as Chapter 80, and the grating is the cleavage face of a lithium fluoride crystal.

75.3.1 Apparatus

[Reserved: the beam source — an oven or gas reservoir with a fine aperture, effusing into high vacuum, whose temperature is the control variable of the whole experiment and must therefore be measured, not merely set; the collimating slits defining the beam; the lithium

fluoride crystal, cleaved to present a fresh (100) face, mounted on a rotatable stage; and the detector, a hot-wire or manometric gauge sensitive to a beam flux of neutral atoms, movable in angle. To be given: the source temperatures used, the beam divergence — which sets the angular resolution and hence what fraction of the predicted separation between maxima can be resolved — and the provision for cooling the source, since the temperature scan is the test.]

75.3.2 Procedure

[Reserved: at fixed source temperature, sweep the detector in angle and record the beam flux, locating the specular peak and the diffracted maxima either side of it. Then change the species, from helium to molecular hydrogen, and repeat; then change the source temperature and repeat again. The measurement is of the positions of the maxima and not of their heights, and the quantities compared are ratios — helium against hydrogen at one temperature, and one temperature against another for one species — because the ratios are free of the beam-averaging factor that the absolute positions are not.]

75.3.3 Observations and data

[Reserved: beam flux against detection angle for each species and each source temperature, with the specular peak and the first-order maxima marked. To be tabulated when written: species, source temperature in kelvin, angle of the observed maximum with its uncertainty, the wavelength deduced from the grating condition, and the wavelength predicted by Equation (75.5); and separately the two ratios that the experiment really measures, helium to hydrogen at fixed temperature and cold source to warm source at fixed species.]

Phenomenon 75.3 (Neutral atoms and molecules are diffracted, with the wavelength their temperature assigns)**.** Beams of helium atoms and of hydrogen molecules reflected from the cleavage face of a lithium fluoride crystal show diffraction maxima at the angles the grating condition assigns to the wavelength h/p, and those maxima move as predicted when the wavelength is changed by changing the temperature, and hence the mean momentum, of the source [651]. Helium is electrically neutral, chemically inert and carries no permanent electric or magnetic moment, so no account of the diffraction of Sections 75.1 and 75.2 in terms of charge, of the Coulomb field, or of anything peculiar to the electron survives this measurement.

Derivation. Write $\lambda = h/mv$ and give the particle the mean thermal kinetic energy $\frac{3}{2}k_{\mathrm{B}}T$ of its source. Then

$$\lambda_T = \frac{h}{\sqrt{3mk_{\mathrm{B}}T}}\,, \tag{75.5}$$

which for helium, of mass 4.003 atomic mass units, at $T = 295\,\mathrm{K}$ is 0.073 nm, and for molecular hydrogen, of mass 2.016, at the same temperature 0.104 nm. Both are of the order of the row spacing of a lithium fluoride cleavage face, which is the reason the crystal serves as a grating for them at all — exactly the reason it served for the 54 eV electrons of Section 75.1.

Equation (75.5) makes two predictions that no adjustable quantity can absorb, and both are ratios. The first is the mass scaling at fixed temperature: the mass ratio of helium to molecular hydrogen is 1.99, so their wavelengths must stand in the ratio $\sqrt{1.99} = 1.41$, and the diffraction angles of the two beams from the same face must differ by that factor and by nothing else. The second is the temperature scaling at fixed species: $\lambda_T \propto T^{-1/2}$, so cooling the source from 295 K to about 100 K must lengthen the wavelength by 1.7 and carry every maximum out to the angle the grating condition assigns to the longer wave.

Neither ratio depends on the calibration of anything, and that is fortunate, because the absolute positions do depend on a factor this derivation cannot supply. An effusive source does not emit a monochromatic beam: it emits a flux-weighted Maxwell distribution, so the beam carries a spread of wavelengths whose most probable value differs from Equation (75.5) by a factor of order unity fixed by the weighting and by the aperture geometry. That factor is the same for helium as for hydrogen and the same at 295 K as at 100 K, so it cancels from both ratios above. The spread itself does not cancel; it broadens each maximum, and the broadening is predicted too, since each velocity class contributes at its own angle.

The physical conclusion needs no arithmetic. Helium presents a lattice with nothing to couple to but its momentum, and it is diffracted. Whatever produced the maxima of Section 75.1 is therefore not a property of the charge of the electron. □

75.3.4 Interpretation

[Reserved: the generalization achieved. The de Broglie relation is confirmed for a composite, neutral, chemically inert object, which is a far stronger statement than its confirmation for an elementary charged one, and it is confirmed through a temperature scan rather than at a single point. The section should also be candid about what the surface adds: helium scatters from the outermost layer alone, so this is a two-dimensional grating and the maxima carry information about the surface corrugation as well as about the wavelength — which is why the technique survives today as a probe of surfaces rather than as a test of the relation.]

75.3.5 Primary references

[651]. The molecular-beam method is Stern's, developed for the velocity measurement of [471] and for the experiment of Chapter 80.

75.4 The electron double slit, one electron at a time (1961–1989)

Two explanations still stand after the diffraction experiments. The first is that the pattern is somehow a property of the lattice rather than of the projectile; the second is that it is a collective effect of many electrons in flight together. Both are removed here, and by two distinct measurements taken twenty-eight years apart. Jönsson cut slits in a foil and formed interference with no crystal anywhere in the apparatus [1212]; Merli, Missiroli and Pozzi and, later and more famously, Tonomura and collaborators reduced the source until the apparatus was almost always empty, and watched the fringes assemble from individual point-like arrivals [1588, 1826]. This is Young's experiment of Chapter 67 performed with matter, and then performed one particle at a time.

75.4.1 Apparatus

[Reserved: two instruments, described separately. Jönsson's is an electron-optical bench — a 50 kV *gun, a copper foil carrying slits of about* 0.5 µm *width made by electron-beam lithography and electroplating, in sets of two, three, four and five, and a magnifying electron lens system between the slits and the recording plate, without which the fringes are too fine to record. Tonomura's is a field-emission electron microscope with an electron biprism in place of the slits — a fine charged filament between two earthed plates, which superposes two virtual sources — and a position-sensitive detector reading out single arrivals. To be given for each: the accelerating voltage, the effective separation of the two paths, the drift length, and for the second the emission rate, which is the quantity the whole argument turns on.]*

75.4.2 Procedure

[Reserved: for the multi-slit measurement, record the pattern for two, three, four and five slits at fixed voltage, and verify that the principal maxima do not move while the subsidiary structure between them changes with the slit count, as it does for light. For the single-particle measurement, reduce the beam current until the mean number of electrons in the instrument is far below one, record the individual arrivals with their times, and store successive frames of the accumulating histogram. The essential control is the occupancy estimate of Equation (75.6), which must be made from the measured emission rate and not assumed.]

75.4.3 Observations and data

[Reserved: the recorded interference patterns for each slit count, with fringe spacing against accelerating voltage; and the accumulation sequence, as frames at increasing total counts, with the fringe contrast extracted from each frame. To be tabulated when written: total counts per frame, measured contrast, and the contrast expected from Poisson noise alone at that count, so that the emergence of the pattern can be compared with the statistical prediction rather than merely displayed.]

Phenomenon 75.4 (Each particle interferes with itself)**.** Electrons passing two or more apertures in free space form an interference pattern with no crystal present [1212]. When the source is weakened until the mean number of electrons in the apparatus is far below one, the detector still registers individual, point-like arrivals at positions that show no pattern one by one; the fringes appear only in the accumulated histogram of many thousands of arrivals, and they are the same fringes, in the same places and with the same spacing, as those formed at high intensity [1588, 1826]. The pattern is therefore not an effect of electrons acting on one another.

Derivation. Three estimates, of which the first explains why the experiment took thirty-four years after Section 75.1.

The fringe spacing of a two-aperture pattern of separation a observed at a distance L is $\Delta x = \lambda L/a$. At $V = 50\,\mathrm{kV}$, Equation (75.1) gives $\lambda = 5.4\,\mathrm{pm}$, five orders of magnitude below optical wavelengths and smaller than any atom. Slits ruled a millimetre apart, generous for light, would put the fringes 1.6 nm apart and nothing could record them. Only when the separation is pushed down to a few micrometres — which is what lithography in a foil achieves and what ruling does not — does the spacing reach about 1 µm at a drift of a few tenths of a metre, and even then it must be magnified electron-optically by some four orders of magnitude before a photographic plate can resolve it. The difficulty of the experiment is entirely in these numbers.

The second estimate is the occupancy, and it is what turns the single-particle version into an argument. A 50 keV electron has $\gamma = 1.098$ and hence $v = 0.41c$, so it crosses an instrument of length $\ell \approx 1.5\,\mathrm{m}$ in

$$t_{\mathrm{transit}} = \frac{\ell}{v} \approx 1.2 \times 10^{-8}\,\mathrm{s}\,, \tag{75.6}$$

while a source emitting at a rate R of order 10^3 electrons per second sends them in at mean intervals of $10^{-3}\,\mathrm{s}$. The mean occupancy is $Rt_{\mathrm{transit}} \approx 1.2 \times 10^{-5}$: for each electron in flight, some hundred thousand transit times pass with the apparatus empty. Two electrons are present together with a probability of order the square of that, so an explanation of the fringes as an interaction between electrons fails by ten orders of magnitude and not by one.

The third estimate is what the accumulation itself establishes, and it is less than it is often said to be. If the arrivals are independent draws from a fixed density $p(x)$ — which is

what "one at a time" means operationally — then the count in a detector bin is Poisson, with standard deviation $\sqrt{\bar{N}}$ about its mean $\bar{N}$, so the relative noise on the histogram falls as $\bar{N}^{-1/2}$ and a pattern of fringe contrast C emerges from the noise once $\bar{N} \gtrsim C^{-2}$. For fringes of high contrast a few tens of counts per bin suffice, which is why the published frame sequences show nothing at a hundred arrivals and a clean pattern at a few tens of thousands. The derivation stops there, and the stopping point must be stated plainly: that the density $p(x)$ is the squared modulus of a single-particle amplitude is Born's postulate [533], an addition to the de Broglie relation and not a consequence of it. What these experiments establish is that whatever the fringes are, they are a property of each particle separately; that they are probabilities is an interpretation, formalized in Chapter 77 and left unexplained by Chapter 85. □

75.4.4 Interpretation

[Reserved: the two loopholes closed and the one that opens. The multi-slit series closes the lattice explanation — there is no lattice — and the progression from two to five slits closes any explanation appealing to a property of a particular pair of apertures, since the principal maxima stay put while the subsidiary structure changes exactly as scalar wave optics requires. The occupancy estimate closes the collective explanation. What opens is the measurement problem: a wave passes both apertures and a point is recorded at one place, which is the tension Chapter 77 formalizes. Related neutron measurements with a single slit and a double slit extend the same demonstration to a massive neutral particle [1814].]

[1212, 1588, 1826].

75.5 Colella, Overhauser and Werner: gravity shifts a phase (1975)

Everything above measures a wavelength. This experiment measures a *phase*, which is a stronger thing to have: once the phase along each of two separated paths is an instrument reading, anything that acts differently on the two paths becomes measurable. The instrument is the perfect-crystal neutron interferometer of Rauch, Treimer and Bonse [1532], cut from a single silicon ingot so that three parallel lamellae split, redirect and recombine a thermal-neutron beam by Bragg reflection, with the two paths separated by centimetres and the lattice coherent across the whole device. What Colella, Overhauser and Werner then do with it is to rotate it about the incident beam, so that the two paths run at different heights in the Earth's field, and count fringes.

75.5.1 Apparatus

[Reserved: the reactor neutron source and monochromator setting the incident wavelength; the interferometer itself, a monolithic silicon crystal with three lamellae machined from one ingot, its lattice perfect over the whole device; the goniometer that rotates it about the incident beam axis through the angle α; the two neutron counters at the exit beams; and the thermal and vibrational isolation, since a temperature gradient across the crystal or a sub-nanometre relative displacement of the lamellae destroys the interference. To be given: the incident wavelength and its spread, the enclosed area of the two paths, and the mechanical stiffness of the device, which enters the systematic corrections directly.]

75.5.2 Procedure

[Reserved: rotate the interferometer through α in steps from one side of the horizontal to the other, counting neutrons in each exit beam for a fixed time at each step. The counted intensity oscillates in $\sin\alpha$, and the quantity extracted is the number of oscillations between the extreme settings, compared with the prediction of Equation (75.10), which contains no free parameter once the wavelength and the enclosed area are measured. Two systematic corrections must be applied and must be described rather than merely named: the elastic bending of the crystal under its own weight as it is rotated, which changes the path geometry, and the Sagnac phase from the Earth's rotation.]

75.5.3 Observations and data

[Reserved: neutron counts in each exit beam against tilt angle, with counting statistics; the extracted fringe count over the full rotation; and the predicted count from the measured wavelength and area. To be tabulated when written: tilt angle, counts and uncertainty in each beam, and the residual phase after the bending and Sagnac corrections, which is the number that carries the result.]

Phenomenon 75.5 (Gravity shifts the phase of a matter wave)**.** Rotating a neutron interferometer about the direction of the incident beam tilts the plane containing its two paths out of the horizontal, so that the paths run at different heights in the Earth's gravitational field. The counted intensity in each exit beam then oscillates with the tilt angle α, with a phase difference between the paths proportional to $\sin\alpha$, to the area they enclose, to the neutron wavelength, and to the square of the neutron mass. Colella, Overhauser and Werner observed the predicted number of fringes as the interferometer was rotated [1542]. This is a laboratory quantity in which Planck's constant and the acceleration of free fall appear together.

Derivation. Work in the regime where the wave has a local wavenumber and the phase along a path is $\int k\,\mathrm{d}l$. A neutron of total energy E at height z in a uniform field has kinetic energy $E - m_{\mathrm{g}}gz$, so with m_{i} the inertial and m_{g} the gravitational mass,

$$k(z) = \frac{\sqrt{2m_{\mathrm{i}}\,(E - m_{\mathrm{g}}gz)}}{\hbar}\,. \tag{75.7}$$

The expansion parameter is minute. A thermal neutron of wavelength 0.1 nm has $E \approx 0.08\,\mathrm{eV}$, while $m_{\mathrm{g}}gz$ over a height of 1 cm is about $1\times10^{-9}\,\mathrm{eV}$: a ratio of 10^{-8}. To first order, using $E = \hbar^2k_0^2/2m_{\mathrm{i}}$,

$$k(z) \simeq k_0\left(1 - \frac{m_{\mathrm{g}}gz}{2E}\right) = k_0 - \frac{m_{\mathrm{i}}m_{\mathrm{g}}gz}{\hbar^2k_0}\,. \tag{75.8}$$

The neutron is slower at the top, and the phase it accumulates per unit length there is correspondingly less.

The two paths of the interferometer form a parallelogram. One path takes its horizontal leg at the lower height and rises afterwards; the other rises first and takes its horizontal leg at the greater height. The two rising legs are congruent and contribute equally, so they cancel from the difference, and what remains is one leg of length L traversed at height 0 on one path and at height H on the other:

$$\Delta\varphi = [k(H) - k(0)]\,L = -\frac{m_{\mathrm{i}}m_{\mathrm{g}}g}{\hbar^2k_0}HL = -\frac{m_{\mathrm{i}}m_{\mathrm{g}}gA}{\hbar^2k_0}\,, \tag{75.9}$$

with $A = HL$ the area enclosed by the paths. Rotating the instrument by α about the incident beam tips that area out of the vertical, so that the rise becomes $H\sin\alpha$ while the

two rising legs remain congruent with each other; writing $k_0 = 2\pi/\lambda$ and $m_{\mathrm{i}} = m_{\mathrm{g}} = m$ then gives

$$|\Delta\varphi| = \frac{2\pi m^2 g A \lambda}{h^2}\,|\sin\alpha| \ . \tag{75.10}$$

Three things should be read off Equation (75.10).

It is large. With an enclosed area of order $10^{-3}\,\mathrm{m}^2$, a wavelength of 0.14 nm and the neutron mass, the coefficient is about 55 radians, so the intensity passes through some nine fringes as the instrument goes from horizontal to vertical and through twice that over the full rotation. Gravity is the feeblest interaction available in a laboratory and the phase it produces is enormous, because $\hbar^2$ sits in the denominator. The smallness that makes the effect delicate is not in the phase but in the fringe spacing in α, which is what demands the mechanical stability.

It measures a product of two masses. The wavelength carries the inertial mass through $\lambda = h/m_{\mathrm{i}}v$ and the potential carries the gravitational mass, so the observable is $m_{\mathrm{i}}m_{\mathrm{g}}$ and not m. This is a quantum interference experiment sensitive to the ratio that the torsion-balance experiments of Chapter 42 bound classically, and it is the reason the result is quoted as a test of the equivalence principle for a quantum object rather than merely as a demonstration.

It is not a test of general relativity. Equation (75.7) treats gravity as a Newtonian potential energy in a non-relativistic wave equation, and at this accuracy that is all the experiment is sensitive to. What it establishes is that a matter wave responds to a gravitational potential exactly as a wave with that potential in its dispersion relation must, which is a statement about quantum mechanics in a weak static field and about nothing beyond it. □

75.5.4 Interpretation

[Reserved: what the fringe count establishes and the two systematics that limit it. The result confirms Equation (75.10) in form and in magnitude; the residual discrepancies reported by this and later runs, at the level of a percent or so of the phase, are attributed to crystal bending and are themselves a measurement of the elastic response of the device, which is worth stating because it is a case where the systematic became the object of study. The section should also record the companion result obtained on the same class of instrument, that the interference contrast returns only after a rotation of 720° *of the neutron spin and not after* 360° *[1558, 1566] — the double cover of the rotation group of Chapters 14 and 79 made into a fringe count. The 1974 proposal that preceded the measurement is [1530].]*

75.5.5 Primary references

[1542]. The interferometer is [1532]; the spinor-periodicity measurements on the same class of instrument are [1558, 1566].

75.6 Molecule interferometry and the edge of coherence (1999–2019)

The last question the relation invites is where it stops. If matter of every kind has a wavelength h/p, then a chair has one; the reason a chair does not interfere must be found somewhere, and the honest way to look for it is to increase the mass of the interfering object until something fails. Two decades of molecular interferometry have done exactly that, from a molecule of sixty atoms [1966] to tailored molecules of more than two thousand [2337]. Nothing has failed in the relation. What fails, reproducibly and on demand, is the isolation

of the molecule from its surroundings — and that failure is measurable, which makes this section the experimental entrance to Chapter 87.

75.6.1 Apparatus

[Reserved: two generations. The far-field arrangement — an effusive oven sublimating fullerene at high temperature, a velocity selector, a nanofabricated free-standing grating of about 100 nm *period, and a scanning ionization detector. The near-field arrangement — a three-grating Talbot–Lau interferometer, in which the first grating prepares the transverse coherence the source lacks, the second diffracts, and the third serves as a scanning mask, with a source of large molecules that must be volatilized without being destroyed. To be given for each: grating period and open fraction, grating separations, the velocity distribution admitted, and the vacuum and thermal environment, which are the experimental variables of the decoherence measurements rather than mere hygiene.]*

75.6.2 Procedure

[Reserved: record the detected molecular flux against transverse detector position, extract the fringe visibility, and repeat as a function of the two quantities that carry the physics — the internal temperature of the molecules, set by the sublimation and by laser heating, and the residual gas pressure. The velocity selection matters and must be described: the fringe period depends on the wavelength, so an unselected thermal beam washes out its own pattern, and the observed visibility as a function of the width of the velocity window is itself a check on Equation (75.11)*.]*

75.6.3 Observations and data

[Reserved: detected flux against detector position, with the fitted visibility and its uncertainty, for each molecular species. To be tabulated when written: species, mass in atomic mass units, selected speed, deduced de Broglie wavelength, grating period, predicted and observed fringe period, and observed visibility; and separately the two decoherence scans, visibility against internal temperature and against residual gas pressure, with the predictions of Equation (75.12) *alongside.]*

Phenomenon 75.6 (Objects of thousands of atoms interfere at the de Broglie wavelength)**.** Interference survives in objects far larger and far more complicated than the wavelength they carry. Fullerene molecules diffracted from a nanofabricated grating produce fringes at a wavelength of about 2.5 pm, some hundreds of times smaller than the molecule itself, even though the molecules are hot enough to populate very large numbers of internal vibrational states and to radiate thermal photons while in flight [1966]. Near-field interferometry has since shown fringes for tailored molecules built from more than two thousand atoms, with masses beyond 25 000 atomic mass units, at wavelengths of order 50 fm [2337]. No deviation from $\lambda = h/p$ has appeared at any mass reached, and no boundary beyond which the relation fails has been found.

Derivation. The wavelengths first, since they are what make the claim surprising. A fullerene of sixty carbon atoms has mass $m = 720$ atomic mass units, and an oven beam of it selected near 220 m/s has

$$\lambda = \frac{h}{mv} = 2.5\,\mathrm{pm}\,, \tag{75.11}$$

some hundreds of times smaller than the molecule that carries it. For a molecule of 25 000 atomic mass units at a beam speed of order 300 m/s the same relation gives λ of order 53 fm: seven orders of magnitude below the wavelength of visible light, and five below the size of

the object itself. Nothing in $\lambda = h/p$ objects to either, and nothing in the observed fringe periods does either.

Why, then, does a chair not interfere? Not because it is heavy. Suppose a molecule, while in a superposition of two paths separated by d, emits a single photon of wavenumber k in a random direction. The photon state emitted from one path differs from that emitted from the other by the phase $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{d}}$, and the fringe visibility is multiplied by the overlap of the two photon states, averaged over emission direction:

$$|\langle\gamma_1|\gamma_2\rangle| = \left|\frac{1}{4\pi}\int \mathrm{d}\Omega\, \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{d}}\right| = \left|\frac{\sin kd}{kd}\right| . \tag{75.12}$$

Coherence survives while $kd \ll 1$ — while the emitted wavelength is long compared with the separation of the paths, so that the photon cannot say which path was taken — and is lost when kd approaches unity.

Two consequences follow, and they are the content of the modern experiments. The criterion contains no mass at all: a heavy object is not harder to interfere for being heavy, but for being harder to keep dark and harder to keep from being touched. And because a molecule in flight emits many photons, the visibility is the product of Equation (75.12) over all of them, so it does not decline gently but collapses, the number of emitted photons rising steeply with internal temperature while each factor falls below unity. Both knobs have been turned deliberately. Heating the molecules until their thermal emission reaches short enough wavelengths destroys the fringes [2060]; admitting a background gas, so that a single collision localizes the molecule to within a distance fixed by the momentum transfer, destroys them by the same argument and with the predicted pressure dependence [2052]. In neither case does the wavelength change, and in neither case is $\lambda = h/p$ at fault. □

Phenomenon 75.7 (What ends the interference is information, not mass)**.** The fringe visibility of a molecular interferometer is destroyed controllably by two means, both of which allow the environment to record which path the molecule took: raising the internal temperature of the molecules until the thermal photons they emit have wavelengths comparable with the path separation [2060], and admitting a background gas so that molecules are scattered from [2052]. In both cases the visibility falls with the measured dependence on temperature or pressure, and in both cases the de Broglie wavelength is unchanged. The transition from quantum to classical behaviour observed here is a loss of isolation and not a breakdown of the wave relation.

Derivation pending #74

The quantitative decoherence rates: the thermal photon emission spectrum of a hot molecule and the resulting product of which-path factors as a function of internal temperature, giving the predicted visibility curve; and the collisional case, in which the localization length follows from the momentum transfer distribution of the residual gas at a given pressure and temperature, giving the predicted decay of visibility with pressure. Both are stated qualitatively in the derivation above from the single-photon overlap; what must be supplied is the master equation whose decoherence rate they are, together with the statement of which of its assumptions the data actually test.

75.6.4 Interpretation

[Reserved: what the mass record does and does not bound. It does not establish that there is no limit; a null result at 25 000 *atomic mass units is a lower bound on where any limit lies. It does constrain proposed objective-collapse modifications of quantum mechanics, which predict a mass-dependent breakdown of superposition, and that constraint is a live experimental*

frontier reported as such in Chapter 133 rather than as a settled matter. The section should also record the honest reading of the decoherence measurements: they show a mechanism sufficient to explain why large objects do not interfere, and they do not show that it is the only one — which is the distinction Chapter 87 and Chapter 85 respectively make and decline to resolve.]

75.6.5 Primary references

[1966, 2337]. The decoherence measurements are [2052, 2060].

75.7 What the measurements settle

Table 75.1: The measurements of this chapter, and the alternative explanation each removes. The third column states what the experiment is entitled to claim, which in the last row is markedly weaker than what it is often credited with.

Experiment	Wavelength	What it establishes
Davisson–Germer 1927	0.165 nm	a wavelength computed from a voltage and one read off a lattice agree to about one percent
Thomson–Reid 1927	5–12 pm	ring radii scale as $V^{-1/2}$ in transmission through an unoriented target; not a surface effect
Estermann–Stern 1930	0.07 nm	neutral, inert helium is diffracted, and the maxima track the source temperature; not an effect of charge
Jönsson 1961; Tonomura 1989	5.4 pm	interference with no lattice, and with the apparatus almost always empty; not a collective effect
Colella *et al.* 1975	0.14 nm	the phase is an instrument reading and gravity shifts it by the predicted amount, in $m_{\mathrm{i}}m_{\mathrm{g}}$
Arndt 1999; Fein 2019	0.05–2.5 pm	no deviation up to 25 000 atomic mass units; what ends the fringes is which-path information

The rows of Table 75.1 are not repetitions of one another. Each was performed because the previous one left an explanation standing, and the sequence is the removal of those explanations one at a time until nothing is left but the relation itself. Taken together they confirm $\lambda = h/p$ over more than seven orders of magnitude in mass, from the electron to a molecule of two thousand atoms, and over three in wavelength, with no adjustable parameter anywhere and no observed departure. That is a stronger evidential position than the relation enjoyed when Chapter 71 adopted it, and stronger than most relations in this treatise enjoy.

Three things are not settled here, and the chapter is worth closing on them. The first is the meaning of the wave: the accumulation experiments establish that each particle interferes with itself and say nothing about what the amplitude is, and the identification of its squared modulus with a probability density is a postulate added by Born [533] and examined in Chapter 77. The second is the equation of motion: a wavelength for a free particle is not a wave equation, and everything about a particle in a potential — including

the bound states that Chapter 70 needed — is outside what any measurement in this chapter reaches. The third is the upper limit. No mass at which the relation fails has been found, but no experiment can establish that none exists; what the molecular interferometers deliver is a bound that moves upward with each generation, and the proposals it constrains are named honestly, and without endorsement, in Chapter 133.

A closing observation of a different kind. The relation has stopped being a hypothesis under test and become an instrument: electron and neutron diffraction are the standard probes of crystal and magnetic structure, and atom interferometers built on the same principle [1847] serve as gravimeters and gyroscopes and deliver h/m, and thence the fine-structure constant, to a precision that feeds back into the tests of the constants themselves. A hypothesis proposed from a symmetry, with no data behind it, now calibrates the measurements by which other hypotheses are judged; and the neutron bound states in the Earth's field [2034], in which the same wave is quantized by gravity alone, are the most recent reminder that the instrument is still finding new things to weigh.

Chapter 76

Experiment: X-ray Spectra and the Charge of the Nucleus

Chapter 70 makes one of the strongest claims in the book. The elements are ordered not by their atomic weights, as chemistry had assumed for a century, but by a whole number that counts elementary charges on the nucleus; and the evidence for this is spectroscopic, drawn from radiation far outside the visible range. The chapter states the law, derives its slope from the hydrogenic level formula with no adjustable parameter, and stops there. It never says where the radiation came from, how anyone knew it was radiation at all, or how a wavelength shorter than a visible one by four powers of ten was measured in the first place.

This chapter supplies that chain. It is unusual among the experiment chapters of this treatise in that no single measurement carries the verdict: what is on trial is the whole instrument, and the instrument had to be built from nothing in eighteen years. Röntgen found the radiation and could say almost nothing about its nature. Barkla showed that it is transverse — hence a wave in the electromagnetic field of Chapter 60 and not the longitudinal aether pulse Röntgen had guessed — and that each element, struck hard enough, answers with a radiation of its own. Friedrich, Knipping and von Laue diffracted it from a crystal, which established in one photograph both that X-rays are waves of wavelength comparable to an atomic spacing and that a crystal is a three-dimensional periodic lattice. The Braggs turned that observation into a measuring instrument by reducing the diffraction condition to a reflection law and mounting the crystal on a divided circle. Moseley put the elements one after another into that instrument. Siegbahn then drove its accuracy to the point where the X-ray lines became a term system as sharp as the optical one.

The reader will find the six experiments below in that order, each with its apparatus, its procedure, its observations and its verdict. What they establish jointly is stated at the end (Section 76.7). Five of the six were recognised by a Nobel Prize — Röntgen with the first prize in physics ever awarded, then von Laue, the Braggs, Barkla and Siegbahn in a run of four consecutive years of X-ray work. Moseley, who is missing from that list, was killed at Gallipoli in 1915 at the age of twenty-seven, and the prize is not awarded posthumously.

76.1 Röntgen: a new kind of rays (1895)

The discovery was made on 8 November 1895 with apparatus that a dozen laboratories in Europe already possessed. What Röntgen added was the black cardboard shield and the willingness to look at a fluorescent screen he had no reason to expect to glow.

Table 76.1: The six experiments of this chapter, what each settled, and its recognition. The prize year is the year the prize is *for*; several of these were reserved and awarded the following year.

Experiment	Year	What it settled	Prize
Röntgen	1895	A penetrating radiation exists; it is not cathode rays and is not refracted by matter	1901
Barkla	1905–1911	X-rays are transverse waves; every element has its own K and L radiation	1917
Friedrich, Knipping, von Laue	1912	Crystals diffract X-rays: X-rays are waves, crystals are lattices	1914
W. H. and W. L. Bragg	1913	The reflection law and the spectrometer built on it; absolute wavelengths	1915
Moseley	1913–1914	The ordering integer of the elements is the nuclear charge	—
Siegbahn	1916–1925	X-ray lines form a precise term system with resolved subshells	1924

76.1.1 Apparatus

A Hittorf–Crookes discharge tube — a partially evacuated glass vessel with two electrodes — driven by a Ruhmkorff induction coil, the whole tube wrapped in a close-fitting shroud of black cardboard that passed no visible light. A screen coated with barium platinocyanide served as the detector; photographic plates in light-tight holders served as the recording detector. A darkened room. For the tests of the nature of the radiation: sheets of paper, wood, ebonite, aluminium, lead, platinum and other metals of graded thickness; prisms of water, carbon disulfide, ebonite and aluminium; polished surfaces; a strong magnet; and an electroscope.

76.1.2 Procedure

Run the discharge in the darkened room with the shrouded tube and observe the screen at increasing distances and orientations. Interpose absorbers of known material and thickness between tube and screen and compare the transmitted brightness. Attempt to refract the radiation with the prisms and to reflect it regularly from polished surfaces. Place the magnet across the path and look for a deflection. Bring a charged electroscope into the irradiated region. Expose plates behind absorbers of graded density, including a hand.

76.1.3 Observations and data

The screen fluoresces brightly whenever the discharge runs, at distances of the order of 2 m from the tube and with the cardboard shroud in place; a sheet of paper, a bound book of about a thousand pages, deal boards, or thin sheets of aluminium interposed in the beam weaken but do not extinguish the effect, while a fraction of a millimetre of lead or platinum stops it. Transmission is governed chiefly by the mass of material traversed, and for equal masses the denser elements absorb more strongly. The radiation proceeds in straight lines from the spot on the tube wall struck by the cathode rays and casts sharp shadows; a hand held in the beam casts a shadow in which the bones stand out darker than the flesh.

Photographic plates are blackened. Charged bodies in the irradiated air lose their charge. No regular refraction could be detected with any of the prisms and no regular reflection from any polished surface; a magnet across the path produced no deflection whatever [269].

Phenomenon 76.1 (A penetrating radiation from the discharge tube)**.** The place where cathode rays strike a solid emits a radiation that travels in straight lines, is not deflected by a magnetic field, excites fluorescence, blackens a photographic plate, discharges electrified bodies, and is absorbed in a way governed chiefly by the mass of matter traversed. It shows no measurable regular refraction or reflection at the surfaces of ordinary bodies [269].

Derivation pending #75

X-ray spectra and the charge of the nucleus: the classical account of the emission itself, namely the bremsstrahlung continuum radiated by cathode-ray electrons decelerated in the anticathode, and its short-wavelength cut-off.

The absence of refraction is not a null result but a measurement, and it is worth extracting the number it contains.

Phenomenon 76.2 (The refractive index of matter for X-rays)**.** For X-rays the refractive index of ordinary matter differs from unity by so little that no prism available in 1895 could reveal it [269]; the deviation is of order 10^{-5} or smaller, and — unlike the case of visible light — the index is slightly *less* than one.

Derivation. Model the electrons of the medium as bound oscillators of resonance frequency ω_0, as in the dispersion theory of Chapter 61. For a number density N of such electrons the refractive index satisfies

$$n^2 = 1 + \frac{Ne^2}{\varepsilon_0 m_\mathrm{e}} \frac{1}{\omega_0^2 - \omega^2} \,. \tag{76.1}$$

Every atomic resonance lies in the ultraviolet or below, so for X-rays $\omega \gg \omega_0$ and the binding drops out: the electrons respond as if free,

$$n^2 \simeq 1 - \frac{\omega_\mathrm{p}^2}{\omega^2} \,, \qquad \omega_\mathrm{p}^2 = \frac{Ne^2}{\varepsilon_0 m_\mathrm{e}} \,, \tag{76.2}$$

so that $n < 1$ and $1 - n \simeq \omega_\mathrm{p}^2 / 2\omega^2$. A solid holds of order $10^{30}/\mathrm{m}^3$ electrons, which puts ω_p in the far ultraviolet, while an X-ray angular frequency is two or three orders of magnitude larger again; the quantity $\omega_\mathrm{p}^2/2\omega^2$ is then the small number quoted. A prism deviates a beam by an angle of order $(n-1)$ times its apex angle, and 10^{-5} of a right angle is a few seconds of arc — beyond the reach of a fluorescent screen viewed by eye. The sign is the physically interesting part: it says the phase velocity in matter exceeds c for X-rays, which is why X-ray optics uses grazing-incidence total external reflection and why no ordinary lens focuses them. □

76.1.4 Interpretation

Röntgen's own conclusion was deliberately negative. The radiation is not cathode rays, because a magnet does not deflect it. It is not ultraviolet light, because it is not refracted, not regularly reflected, and could not be polarised by any means he tried. Lacking any positive evidence of transversality he suggested, tentatively, that the rays might be longitudinal waves in the aether. That guess was wrong, and it is the honest reason this chapter must continue: the question "what are X-rays?" was left open by the man who found them, and was closed by Section 76.2 and Section 76.3.

[269].

76.2 Barkla: characteristic radiation and the transversality of X-rays (1905–1911)

Barkla worked with an electroscope and an ionisation chamber, without ever resolving a spectral line, and settled two questions that resisted every more direct attack: whether X-rays are transverse, and whether the radiation an element emits belongs to the element.

76.2.1 Apparatus

For the polarisation experiment: an X-ray bulb giving a primary beam; a first scatterer — a block of a light element, paper or carbon, which scatters without appreciable absorption — placed in that beam; a second scatterer placed in the secondary beam that leaves the first at right angles; and an ionisation chamber with an electrometer, mounted so that it can be carried around the axis of the secondary beam while remaining at right angles to it.

For the characteristic-radiation experiments: the same primary bulb, with the beam falling on a radiator consisting of the element under test or one of its compounds; an ionisation chamber viewing the radiator at right angles to the primary beam; and a set of aluminium sheets of accurately known thickness to be interposed one at a time in the secondary beam.

76.2.2 Procedure

In the polarisation experiment, record the ionisation current produced by the twice-scattered beam as the chamber is carried around the axis of the once-scattered beam, and plot it against the azimuth.

In the absorption experiments, record the ionisation current as successive aluminium sheets are added, and read the mass absorption coefficient off the exponential decline. A radiation is called *homogeneous* when the decline is a single exponential over the whole range of thicknesses used. Repeat with radiator elements taken in order through the periodic table, and repeat each radiator with primary beams of different hardness, obtained by varying the tube.

76.2.3 Observations and data

The twice-scattered intensity is not the same in all azimuths: it passes through a maximum and a minimum ninety degrees apart, the maximum lying in the direction of the original primary beam. The modulation is partial rather than complete, as the finite apertures and the multiple scattering in the radiators require [317].

For radiators heavier than about calcium the secondary beam contains, besides the scattered primary, a component that is homogeneous. Its mass absorption coefficient in aluminium is a property of the radiator element and not of the primary beam; it decreases monotonically as one proceeds up the periodic table, so that heavier elements emit a more penetrating characteristic radiation. The component appears only when the primary beam is itself harder than the characteristic radiation it excites — there is a threshold — and for the heavier elements a second, much less penetrating homogeneous radiation appears alongside the first [340, 352]. Barkla named the more penetrating series K and the softer one L, choosing letters in the middle of the alphabet in case further series should be found on either side [367]. They were: M, N and O followed.

Phenomenon 76.3 (X-rays are transverse)**.** Radiation scattered by a light element at right angles to the primary beam is partially polarised: on being scattered a second time through a right angle its intensity depends on the azimuth, with a maximum along the direction of the original primary beam and a minimum at right angles to it [317]. A longitudinal disturbance has no transverse vector to orient and can produce no such dependence, so X-rays are transverse waves.

Derivation. Let the primary beam travel along $\hat{\boldsymbol{z}}$ and be unpolarised. Its electric vector lies in the xy plane, so the electrons of the first radiator are accelerated in that plane. An oscillating charge radiates nothing along its own line of acceleration and, at an angle Θ from it, with an intensity proportional to $\sin^2\Theta$ (Chapter 65). Observe the scattered beam along $\hat{\boldsymbol{x}}$: the x component of the acceleration contributes nothing in that direction, so the surviving radiation is that driven by the y component alone. The beam leaving the first radiator at right angles is therefore linearly polarised, with its electric vector along $\hat{\boldsymbol{y}}$.

That beam drives the electrons of the second radiator along $\hat{\boldsymbol{y}}$. Put the chamber in the plane perpendicular to $\hat{\boldsymbol{x}}$, in the direction $\hat{\boldsymbol{n}} = \hat{\boldsymbol{y}}\sin\varphi + \hat{\boldsymbol{z}}\cos\varphi$, where φ is measured from the original primary direction. Then

$$I(\varphi) \propto \sin^2\Theta = 1 - (\hat{\boldsymbol{n}}\cdot\hat{\boldsymbol{y}})^2 = \cos^2\varphi\,, \tag{76.3}$$

which is maximal at $\varphi = 0$, along the original primary beam, and vanishes at $\varphi = \pi/2$. The observed modulation has exactly this period and this phase; it is incomplete because real apertures average Equation (76.3) over a range of scattering angles. For a longitudinal wave the displacement would lie along $\hat{\boldsymbol{z}}$ for every ray of the primary beam, the once-scattered beam would carry no azimuthal marker at all, and $I(\varphi)$ would be flat. □

Phenomenon 76.4 (Characteristic radiation of the elements)**.** An element struck by a sufficiently hard primary beam emits, in addition to scattered radiation, one or more homogeneous radiations whose absorption coefficients are properties of that element alone and are independent of the primary beam that excites them. Their penetrating power increases monotonically along the periodic table. Each such radiation has an excitation threshold: it appears only when the exciting radiation is harder than the radiation excited. For the heavier elements two series are present, the penetrating K series and the softer L series [340, 352, 367].

Derivation pending #76

Characteristic X-radiation: the quantum account, in which the primary beam ejects an electron from an inner shell and the radiation is emitted when an outer electron fills the vacancy, so that the excitation threshold is the binding energy of the shell and the monotone hardening along the table is the growth of that binding energy with nuclear charge.

76.2.4 Interpretation

The polarisation result closed the question Röntgen had left open. X-rays are transverse, hence electromagnetic waves of Chapter 60, and the aether pulse can be dropped. The characteristic-radiation result is the more consequential of the two for what follows. It says that the radiation carries the signature of the emitting atom, and therefore that a spectroscopy of the elements in this range is possible in principle. Barkla could rank the elements by absorption coefficient but could not attach a wavelength to any of them, because he had no dispersing element; his K and L are ordinal labels, not measurements. The instrument that converted his ordering into wavelengths arrives in the next two sections,

and Moseley's law is the result of running it over Barkla's own K and L radiations. It is worth noticing that the monotone ordering Barkla found already contained Moseley's law in disguised form: absorption in aluminium increases steeply with wavelength, so "more penetrating for heavier elements" is "shorter wavelength for larger nuclear charge".

76.3 Friedrich, Knipping and von Laue: diffraction by a crystal (1912)

The experiment was proposed on a guess and worked at once. Von Laue reasoned that if X-rays were waves of about the size of an atom, and if a crystal were a periodic array of atoms, then the crystal was a ready-made three-dimensional diffraction grating that nobody would have to rule. Neither premise was established at the time; the photograph established both together.

76.3.1 Apparatus

A gas X-ray tube; a lead-lined box carrying a series of pinhole apertures which cut from the emitted radiation a narrow pencil a fraction of a millimetre across; a crystal mounted on a goniometer at the exit of the collimator, so that a chosen crystallographic direction could be set parallel to the pencil; and photographic plates in light-tight holders placed behind the crystal, and in the first trials also to the sides and in front of it, to catch radiation scattered in any direction. The first crystal was copper sulfate, chosen because a good specimen was to hand; the decisive photographs were taken with zinc blende, which is cubic and of high symmetry.

76.3.2 Procedure

Set the crystal in the pencil, expose the plate for a period of hours, and develop. Then rotate the crystal so that a symmetry axis lies along the pencil, and repeat. Compare the pattern with that obtained when the crystal is replaced by an amorphous body of similar absorbing power, and with that obtained when the crystal is displaced out of the beam.

76.3.3 Observations and data

The plate behind the crystal shows, in addition to the trace of the undeviated pencil, a set of discrete, sharp spots at well-defined angles. The spots are arranged about the central trace with the point symmetry of the crystal in the direction of the beam: with the pencil along a symmetry axis of zinc blende the pattern reproduces the symmetry of that axis. Rotating the crystal moves the spots as a rigid figure, and displacing the crystal out of the pencil extinguishes them all. An amorphous absorber in the same place gives a diffuse distribution and no spots [385]. Von Laue's companion paper computes the directions of the maxima from a lattice model and reproduces the observed positions [389].

Phenomenon 76.5 (Crystal diffraction of X-rays)**.** A narrow pencil of X-rays traversing a single crystal is scattered into a set of discrete, sharp maxima whose directions are fixed by the orientation of the crystal and whose arrangement carries the symmetry of the crystal. An amorphous body in the same geometry produces no such maxima [385, 389].

Derivation. Discrete maxima at fixed angles are the signature of interference between many scatterers held in a periodic arrangement, and the argument fixes both the wave nature of the radiation and the periodicity of the crystal at once. Let $\hat{\boldsymbol{s}}_0$ and $\hat{\boldsymbol{s}}$ be unit vectors along the incident and the scattered directions, and let the scattering centres sit at the lattice points

$$\boldsymbol{R} = n_1\boldsymbol{a}_1 + n_2\boldsymbol{a}_2 + n_3\boldsymbol{a}_3\,, \qquad n_i \in \mathbb{Z}\,, \tag{76.4}$$

with $\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3$ the primitive vectors of the lattice. Measured between a plane wavefront before the crystal and one after it, the optical path through the centre at $\boldsymbol{R}$ is shorter than the path through the centre at the origin by $\boldsymbol{R}\cdot(\hat{\boldsymbol{s}}_0 - \hat{\boldsymbol{s}})$. The wavelets from all the centres arrive in phase precisely when this is an integer multiple of the wavelength for every $\boldsymbol{R}$, and since the n_i range independently over $\mathbb{Z}$ that is equivalent to the three simultaneous conditions

$$\boldsymbol{a}_i \cdot (\hat{\boldsymbol{s}}_0 - \hat{\boldsymbol{s}}) = h_i\lambda\,, \qquad h_i \in \mathbb{Z}\,, \quad i = 1,2,3\,. \tag{76.5}$$

Three equations constrain the two free angles of $\hat{\boldsymbol{s}}$ together with λ, so for a crystal at a general orientation in a *monochromatic* beam there is no solution and no spot appears. The resolution is that the beam of a gas X-ray tube is not monochromatic: it carries the continuous bremsstrahlung spectrum, and each spot on the plate selects out of that continuum the one wavelength for which Equation (76.5) can be satisfied in that direction. Given the observed angles and a lattice spacing of order the atomic diameter, Equation (76.5) returns wavelengths of order 100 pm, four orders of magnitude below visible light. □

76.3.4 Interpretation

One photograph settled two disputed questions in different fields. For physics, X-rays interfere, so they are waves, and their wavelength is of the order of an atomic spacing — which explains at a stroke why Röntgen found no refraction and no reflection with ordinary optics, and why Phenomenon 76.2 holds. For crystallography, the sharp maxima require the scatterers to sit on a lattice with long-range three-dimensional periodicity: the lattice hypothesis, until then an inference from the external shapes and cleavage of crystals, became a direct observation. Everything the treatise says about periodic solids in Chapter 125 and Chapter 126 rests on this measurement and on the industry of structure determination it founded.

76.3.5 Primary references

[385, 389].

76.4 The Braggs: the reflection law and the X-ray spectrometer (1913)

Laue's spots proved that X-rays are waves but were an awkward tool: a Laue photograph mixes all wavelengths and all lattice planes at once. The Braggs' contribution was to reorganise the same geometry so that one wavelength and one set of planes are isolated, and then to hang the whole arrangement on a divided circle. What had been a demonstration became an instrument, and every measurement in the two sections that follow was made with it.

76.4.1 Apparatus

An X-ray tube with a metal anticathode; a pair of lead slits defining a beam of small angular width; a cleaved crystal — rock salt in the first work, later calcite and mica — mounted

on the table of a spectrometer with a divided circle; and, on an arm turning about the same axis, an ionisation chamber filled with a heavy gas so as to absorb the beam efficiently, connected to a quadrant electrometer. The crystal table and the chamber arm are geared or set so that when the crystal face makes a glancing angle with the incident beam, the chamber sits at twice that angle from the beam — the specular position.

76.4.2 Procedure

Set the crystal face at a small glancing angle and the chamber at the corresponding specular angle; record the ionisation current; advance both by a small step and repeat. The record of current against glancing angle is the spectrum of the tube as dispersed by that crystal face. Change the anticathode metal and repeat, to determine which features belong to the target and which to the crystal or the apparatus.

76.4.3 Observations and data

The current against glancing angle is a smooth continuous background on which sharp peaks stand out. The peaks come in families: within a family the glancing angles θ_n satisfy $\sin\theta_n = n\sin\theta_1$ for $n = 1, 2, 3, \dots$, so that a family is a single feature seen in successive orders. The angular positions of the families change when the anticathode metal is changed, and do not change when the crystal is exchanged for another face of the same crystal at the appropriate spacing; the peaks therefore belong to the target metal and are Barkla's characteristic radiations, now resolved and measurable [399, 400].

Phenomenon 76.6 (The Bragg reflection law)**.** A crystal illuminated by X-rays at a glancing angle θ to a set of lattice planes of spacing d returns a strong specularly reflected beam only at those angles satisfying

$$n\lambda = 2d\sin\theta\,, \qquad n \in \mathbb{N}\,, \tag{76.6}$$

where λ is the wavelength; at intermediate angles the reflected intensity is negligible [399, 400].

Derivation. Group the lattice points of Equation (76.4) into a family of parallel planes with perpendicular spacing d. Consider two rays of the incident beam striking adjacent planes and leaving them at the same glancing angle θ on the far side of the normal, that is, specularly. Dropping perpendiculars from the point of incidence on the upper plane to the incident and emergent rays of the lower one shows the extra path travelled by the lower ray to be $2d\sin\theta$; constructive interference between the two requires that this be a whole number of wavelengths, which is Equation (76.6). Reflection at a single plane is specular for any angle because the scatterers within a plane are dense compared with the wavelength; it is the interference *between* planes that selects the discrete set.

This is not a second law but the first one rewritten. In Equation (76.5) the vector $\hat{\boldsymbol{s}}_0 - \hat{\boldsymbol{s}}$ is common to all three conditions; satisfying them simultaneously forces it to lie along the normal of some lattice plane family, and for a specular geometry at glancing angle θ its length is $2\sin\theta$. Taking $\boldsymbol{R}$ along that normal with $|\boldsymbol{R}| = d$ turns Equation (76.5) into Equation (76.6).

What makes Equation (76.6) an instrument rather than a relation is that d can be obtained without any X-ray measurement at all. In rock salt the planes parallel to a cube face carry sodium and chlorine alternately, so their spacing is half the edge a of the conventional cubic cell, and that cell contains four formula units. Hence

$$d = \frac{a}{2} = \frac{1}{2}\left(\frac{4M}{\rho N_{\mathrm{A}}}\right)^{1/3}\,, \tag{76.7}$$

with M the molar mass, ρ the density and N_{A} Avogadro's constant. Using $M = 58.44 \times 10^{-3}\,\mathrm{kg/mol}$, $\rho \approx 2.16 \times 10^{3}\,\mathrm{kg/m^{3}}$ and the present-day exact value $N_{\mathrm{A}} = 6.022\,140\,76 \times 10^{23}/\mathrm{mol}$ of Chapter 2, Equation (76.7) gives $a \approx 564\,\mathrm{pm}$ and $d \approx 282\,\mathrm{pm}$. Every wavelength in this chapter is ultimately referred to a number of this kind, so the X-ray wavelength scale is only as good as the value of N_{A} used to set it — a debt that came due in Section 76.6. □

76.4.4 Interpretation

The spectrometer converts an angle read on a divided circle into a wavelength, absolutely, through Equation (76.6) and Equation (76.7). Three things follow immediately. Barkla's homogeneous radiations become spectral lines with wavelengths. The crystal becomes a monochromator, so that a structure determination can be run the other way round — known wavelength in, unknown spacings out — which is what the younger Bragg did for the alkali halides, diamond and much else, founding X-ray crystallography as a working science. And the incident wavelength of the Compton measurement of Chapter 69 becomes a known quantity, which is what makes the shift there a measurement rather than an impression.

76.4.5 Primary references

[399, 400].

76.5 Moseley: the high-frequency spectra of the elements (1913–1914)

Moseley took the finished instrument and did the obvious thing that nobody had done: he put the elements through it one after another, in order, and looked at the sequence rather than at any one spectrum. The law he found, and its derivation from the hydrogenic level formula, are stated in Chapter 70 and are not repeated here; what follows is the measurement.

76.5.1 Apparatus

A Bragg-type crystal spectrometer with a crystal of potassium ferrocyanide, recording photographically rather than by ionisation chamber so that a whole spectrum is captured in one exposure. The essential addition was to the source: inside the evacuated tube ran a small trolley carrying a dozen target elements in a row, drawn along by a thread led out through a seal, so that one element after another could be brought into the cathode-ray beam without letting the tube up to air. Wavelengths were referred to the known spacing of the crystal.

76.5.2 Procedure

Bring a target into the beam, expose the plate through a chosen range of glancing angles, advance the trolley, and expose the next element on the same plate so that neighbouring elements appear side by side and can be compared directly. Measure the positions of the lines on the developed plate, reduce them to glancing angles, and convert to wavelength with Equation (76.6). Identify in each spectrum the strong pair of lines belonging to Barkla's K series, and for the heavier elements the group belonging to the L series.

76.5.3 Observations and data

Every element examined shows the same small number of strong lines, and the lines move steadily and by regular steps as one passes from element to element along the plate. Plotting

the square root of the frequency of the strongest K line against the ordinal number of the element in the periodic table gives a straight line, of a slope that the hydrogenic formula reproduces without adjustment; the same holds, with a different slope, for the L series. The first paper covered the range from calcium to zinc; the second extended it from aluminium to gold, using the K series for the lighter half of the range and the L series for the heavier [408, 418]. Between aluminium and gold the sequence of ordinal numbers is unbroken except at three places, corresponding to elements not then known and later found.

Phenomenon 76.7 (The ordering integer is the nuclear charge)**.** The integer that orders the characteristic X-ray spectra of the elements, advancing by exactly one from each element to the next, is the same integer that alpha-particle scattering measures as the charge of the nucleus in units of the elementary charge [408, 418, 464]. It is not the atomic weight: the ordering by weight has inversions — argon and potassium, cobalt and nickel, tellurium and iodine — and the ordering by X-ray spectra has none.

Derivation. Two independent routes to the same integer, one spectroscopic and one mechanical, agree.

The spectroscopic route is Moseley's, derived in Chapter 70: the innermost electrons of a heavy atom move in the almost unscreened Coulomb field of the nucleus, the hydrogenic levels of that field scale as the square of the nuclear charge, and the Kα transition therefore has $\sqrt{\nu}$ proportional to the nuclear charge less a screening constant of order unity. What identifies the plotted integer with a charge, rather than merely with a serial position, is that the slope of the straight line is fixed — it must be $(3cR_\infty/4)^{1/2}$, containing only the Rydberg constant already measured in the optical spectrum of hydrogen. A serial number with no physical content could reproduce the straightness but not the slope.

The mechanical route uses no spectroscopy at all. The Rutherford cross-section for the scattering of alpha particles of kinetic energy E by a nucleus of charge Ze (Chapter 107, [379]) is

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \left(\frac{2Ze^2}{16\pi\varepsilon_0 E}\right)^2 \frac{1}{\sin^4(\theta/2)}\,, \tag{76.8}$$

in which Z enters as a square and nothing else about the atom enters at all. Counting the alphas scattered into a known solid angle at a known angle and energy therefore weighs the nuclear charge directly. Chadwick did this for copper, silver and platinum and obtained values agreeing with their ordinal numbers to within an experimental uncertainty of about one per cent [464]. The hypothesis that the two integers are one integer, put forward by van den Broek while Moseley was at work [411], is thus a measured fact and not a convention. □

76.5.4 Interpretation

The consequences are structural rather than numerical. The periodic table acquires an exact ordinal parameter, so the three weight inversions that had embarrassed it since Mendeleev cease to be anomalies and become confirmations: the X-ray spectra put argon before potassium, cobalt before nickel and tellurium before iodine, which is the chemically correct order in every case. The number of elements between any two is fixed, so the count of missing elements ceases to be a matter of opinion; Moseley's range left exactly three gaps below gold, which is exactly what was later filled. The number of rare-earth elements, contested for decades, is likewise settled by counting the gaps in their L spectra. And the nuclear model of the atom acquires its missing parameter: after Moseley an element is specified by an integer Z, the atomic weight being a separate and, as Chapter 107 shows, a compound quantity. The isotope — same Z, different weight — becomes intelligible in the same stroke.

76.5.5 Primary references

[408, 418]. The independent scattering determination of the nuclear charge is [464], resting on [379]; the hypothesis tested is [411].

76.6 Siegbahn: precision X-ray spectroscopy (1916–1925)

Moseley's lines were sufficient for counting but not for anatomy. What looked like one line at his resolution is generally a group, and the groups are what a theory of the many-electron atom actually has to predict. Siegbahn spent a decade rebuilding the spectrometer around that requirement.

76.6.1 Apparatus

A vacuum spectrograph: the whole path from anticathode to plate is evacuated, so that soft radiation is not absorbed in air and the range of the instrument extends far beyond the K lines of the heavy elements. A demountable, water-cooled tube with interchangeable anticathodes, run at high load to obtain usable intensity in a narrow line. Precisely ruled circles carrying cleaved crystals of accurately known spacing — calcite, gypsum, sugar and mica were used for different ranges. Narrow slits and long crystal-to-plate distances for high dispersion. Photographic recording with comparison lines on the same plate. In the later work, ruled concave gratings used at grazing incidence, which measure a wavelength against a ruling interval and so make no assumption whatever about crystal structure.

76.6.2 Procedure

Photograph the spectrum of each anticathode element, measure the line positions against the comparison lines with a travelling microscope, reduce them to glancing angles, and convert to wavelength through Equation (76.6) with the tabulated crystal spacing. Repeat with different crystals to test for systematic error in the spacings. Separately, measure selected lines with the grazing-incidence grating and compare the two wavelength scales.

76.6.3 Observations and data

Each of Barkla's series resolves into a group of components: the K group into a close doublet and further lines, the L group into a set that requires three distinct L levels to explain it, the M group into a set requiring five. Every measured line frequency is a difference of two terms drawn from a table belonging to the element, so that the combination principle familiar from optical spectra holds here as well; the terms are the K, L_1–L_3, M_1–M_5 levels and their successors. The absorption edges measured in the same instrument fall at the term values themselves, just above the emission lines of the corresponding series, which identifies each term as the energy required to remove an electron from that level. Line wavelengths are reproducible to a few parts in ten thousand and better, which is what makes such an analysis possible at all [462, 531].

The comparison of the crystal scale with the grating scale exposed a systematic discrepancy of about two parts in a thousand. It was traced not to either instrument but to Equation (76.7): the crystal spacings had been computed with the value of N_{A} then current, which rested in turn on the value of the elementary charge then current. Siegbahn's X unit, defined by reference to a crystal spacing, is therefore not exactly $10^{-13}\,\mathrm{m}$, and X-ray wavelengths quoted in it must be corrected by that factor before being compared with anything measured optically.

Phenomenon 76.8 (The X-ray term system)**.** The characteristic X-ray lines of an element are differences of a small set of terms belonging to that element, and satisfy the combination principle. The terms occur in groups — one K level, three L levels, five M levels — and each term equals, to within the accuracy of the measurement, the absorption edge of the corresponding series, that is, the energy needed to remove an electron from that level [462, 531].

Derivation pending #77

The X-ray term system: the derivation of the K, L and M level multiplicities from the quantum numbers of the many-electron atom, with the L and M splittings as the combined effect of screening and of spin-orbit coupling, and the identification of an absorption edge with a one-electron binding energy.

76.6.4 Interpretation

Two results of lasting consequence come out of this work. The first is that the inner structure of the atom is directly readable. The multiplicities one, three, five are not fitted to the data; they are the counts of distinct inner levels, and any theory of the atom must reproduce them — as the quantum numbers of Chapter 88 and the spin-orbit coupling of Chapter 79 do. The identification of terms with absorption edges makes each of these levels a measurable binding energy, which is the quantity the excitation threshold of Phenomenon 76.4 had been signalling since Barkla.

The second is methodological, and it is the reason the discrepancy above is reported here rather than buried. A wavelength scale built on Equation (76.7) inherits every uncertainty in N_{A}, so an X-ray wavelength was never a purely spectroscopic quantity: it was tied to a mass, a density and a counting constant. That is no longer a limitation, since N_{A} is exact by definition in the present SI (Chapter 2); but the episode is a clean example of a systematic error that no amount of repetition inside one method can reveal, and that only an independent method — here the ruled grating — can expose.

76.6.5 Primary references

[462, 531].

76.7 What the X-ray spectra established

Taken in order, the six experiments make a single argument, and it is worth setting the conclusion down without hedging.

There exists a penetrating radiation emitted where fast electrons are stopped (Phenomenon 76.1). It is a transverse wave (Phenomenon 76.3), hence a solution of the field equations of Chapter 60, with a frequency so far above every atomic resonance that matter is very nearly transparent to it and its refractive index is barely below one (Phenomenon 76.2). Its wavelength is comparable to the spacing of atoms in a solid, which both crystal diffraction (Phenomenon 76.5) and the reflection law built on it (Phenomenon 76.6) make measurable in absolute units. Each element, struck hard enough, emits a characteristic radiation of its own (Phenomenon 76.4), resolvable into a term system with a definite inner-shell structure (Phenomenon 76.8). And the integer that orders those spectra is the charge on the nucleus (Phenomenon 76.7).

The last statement is the one that reorganised chemistry. Before Moseley the periodic table was an empirical arrangement whose ordering principle — atomic weight — was known

to fail in at least three places and whose length was unknown. After Moseley the table is indexed by an integer with a physical meaning, the number of protons in the nucleus, and the failures of the weight ordering are explained rather than tolerated: weight is a nuclear quantity that depends on neutron number as well, and two samples of one element may differ in it. Chapter 107 takes that up. What matters here is that the identification was not an interpretation placed on the data but a measurement, made twice by unrelated means — a spectroscopic plate and a count of scattered alpha particles — and agreeing.

It should be said plainly that this chapter also records how much can be achieved without a theory. Barkla ranked the elements correctly by a property he could not name, using an electroscope and a stack of aluminium foil. Von Laue's photograph settled a question in crystallography with a piece of zinc blende and a photographic plate. Moseley's decisive instrument was a spectrometer and a trolley pulled by a thread. In each case the quantum theory that explains the result arrived afterwards, and in Barkla's and von Laue's cases the discoverer guessed wrongly about the mechanism while being entirely right about the fact. The facts are what this treatise records; the explanations are checked against them, not the other way round.

Part IX

Quantum Mechanics

Chapter 77

The Postulates of Quantum Mechanics

Quantum mechanics is not derived from classical mechanics; it rests on its own postulates, which state what a physical state is, which quantities can be measured, what the possible outcomes of a measurement are and with what probabilities they occur, how a measurement alters the system, and how composite systems are described. This chapter collects the conventional postulates in the state-vector formulation, together with the canonical quantization rules and the notion of uncertainty on which Heisenberg's principle is built. The mathematical arena — Hilbert spaces and the operators acting on them — is developed in Chapter 12. Standard modern treatments of this material are found in [1593, 2287, 2313]. The source for this chapter is an early outline: its completed content is ported in full below, and the headings it reserves without content are marked as pending rather than filled in with material the source does not contain.

77.1 The conventional postulates

77.1.1 The state postulate

Let $\mathcal{H}$ be a Hilbert space over $\mathbb{C}$ and let $|\psi\rangle \in \mathcal{H}$. The relation

$$\mathrm{e}^{\mathrm{i}\phi}\,|\psi\rangle \sim \mathrm{e}^{\mathrm{i}\gamma}\,|\psi\rangle \iff \phi,\gamma \in \mathbb{R}$$

is an equivalence relation. We say that an equivalence class is a *ray* in $\mathcal{H}$.

Postulate 77.1 (Quantum physical states)**.** A quantum physical state is represented by a ray of normalized vectors, that is, vectors satisfying

$$\langle\psi|\psi\rangle = 1\,. \tag{77.1}$$

If no ambiguity is possible, we shall say that the state of a system is one of its representatives with vanishing global phase; that is, the state will be $|\psi\rangle$.

77.1.2 The observable postulate

Let $O \in \mathcal{L}(\mathcal{H})$ be a linear operator on $\mathcal{H}$.

Postulate 77.2 (Observable quantities)**.** To every measurable quantity there corresponds a Hermitian operator O.

We shall call such an operator an *observable*. It must be noted that not every Hermitian operator is an observable.

77.1.3 The measurement postulate

Consider the spectral decomposition of an observable O,

$$O = \sum_i \lambda_i \, |\lambda_i\rangle\langle\lambda_i| \; . \tag{77.2}$$

Postulate 77.3 (Measurement outcomes)**.** The possible results of a measurement of O are its eigenvalues λ_i.

77.1.4 The probability postulate: the Born rule

Consider a quantum system in the state $|\psi\rangle$, and let O be an observable with eigenvalues λ_i.

Postulate 77.4 (Born rule)**.** The probability of obtaining λ_i in a measurement of O is given by

$$P(\lambda_i, |\psi\rangle) = |\langle\lambda_i|\psi\rangle|^2 \; . \tag{77.3}$$

We must note that the probability is determined on the whole ray of $|\psi\rangle$, since $\left|\mathrm{e}^{\mathrm{i}\phi}\right| = 1$. Moreover, by the theory of probability, it must hold that

$$\sum_i P(\lambda_i, |\psi\rangle) = 1 \, . \tag{77.4}$$

Expanding $|\psi\rangle$ in the eigenbasis $\{|\lambda_i\rangle\}_{i=1}^{\dim \mathcal{H}}$ as $|\psi\rangle = \sum_j a_j \, |\lambda_j\rangle$, we have

$$\begin{aligned} P(\lambda_i, |\psi\rangle) &= |\langle\lambda_i|\psi\rangle|^2 \\ &= \left| \langle\lambda_i| \left(\sum_j a_j \, |\lambda_j\rangle \right) \right|^2 \\ &= \left| \sum_j a_j \, \langle\lambda_i|\lambda_j\rangle \right|^2 \\ &= \left| \sum_j a_j \delta_{ij} \right|^2 \\ &= |a_i|^2 \; , \end{aligned}$$

so the probability of obtaining λ_i in a measurement is the squared modulus of the i-th component of $|\psi\rangle$ in the eigenbasis.

77.1.5 The collapse postulate

Consider a quantum system in the state $|\psi\rangle$, and let O be an observable with eigenvalues λ_i.

Postulate 77.5 (Alteration of quantum systems)**.** If a measurement of O yields the eigenvalue λ_i, then immediately after the measurement the state of the system is $|\lambda_i\rangle$.

77.1.6 The time-evolution postulate

The source records for this postulate only the stationary eigenvalue problem of the Hamiltonian,

$$H \, |\psi\rangle = E \, |\psi\rangle \; . \tag{77.5}$$

[Heading reserved in the source outline; the statement of the time-dependent Schrödinger equation governing the evolution of quantum states is pending port from a completed source.]

77.1.7 The composite-system postulate

Consider a quantum system composed of N individual systems whose states are rays in the Hilbert spaces $\mathcal{H}_1, \ldots, \mathcal{H}_N$.

Postulate 77.6 (Composite quantum systems)**.** The state of the composite system is a ray in the Hilbert space

$$\mathcal{H}_T = \mathcal{H}_1 \otimes \ldots \otimes \mathcal{H}_N \,. \tag{77.6}$$

77.2 Density-matrix postulates

[Heading reserved in the source outline; the reformulation of the postulates in terms of density matrices, covering statistical mixtures as well as pure states, is pending port from a completed source.]

77.3 On Planck's constant

[Heading reserved in the source outline; the discussion of Planck's constant, its role as the quantum of action, and its measured value is pending port from a completed source.]

77.4 Pictures of time evolution

77.4.1 The Schrödinger picture

[Heading reserved in the source outline; no content to port.]

77.4.2 The Heisenberg picture

[Heading reserved in the source outline; no content to port.]

77.5 Canonical quantization rules

77.5.1 From the Poisson bracket to the commutator

[Heading reserved in the source outline, together with its subheadings on conjugate coordinates and conserved quantities; the rule mapping classical Poisson brackets to quantum commutators, and with it the canonical commutation relations between conjugate coordinates, is pending port from a completed source.]

Derivation pending #78

From Poisson brackets to commutators: statement of the canonical quantization rule and derivation of the canonical commutation relations between conjugate coordinates, which are used throughout the following chapters.

77.5.2 Linear momentum as a differential operator

In the coordinate representation, the components of the linear momentum act on wave functions as the differential operators

$$p_i = -\mathrm{i}\hbar\,\partial_i \,. \tag{77.7}$$

Derivation pending #79

Justification of the coordinate-representation rule $p_i = -\mathrm{i}\hbar\,\partial_i$ from the canonical commutation relations; the source asserts the rule without derivation.

77.6 The Heisenberg uncertainty principle

77.6.1 Mean value of an observable

Definition 77.7 (Mean value)**.** Consider an observable A. We define the *mean* (or *expected*) *value* of the operator in the state $|\psi\rangle$ as

$$\langle A\rangle_\psi = \langle\psi|\,A\,|\psi\rangle\ . \tag{77.8}$$

77.6.2 Uncertainty

Definition 77.8 (Uncertainty)**.** In the same context as above, we define the *uncertainty* of the observable A in the state $|\psi\rangle$ as

$$\Delta A = \sqrt{\left\langle \Big(A - \langle A\rangle_\psi\,\mathbb{1}\Big)^2 \right\rangle_\psi}\ . \tag{77.9}$$

Let us observe the following. We have

$$\begin{aligned}
(\Delta A)^2 &= \left\langle \Big(A - \langle A\rangle_\psi\,\mathbb{1}\Big)^2 \right\rangle_\psi \\
&= \left\langle \Big(A - \langle A\rangle_\psi\,\mathbb{1}\Big)\Big(A - \langle A\rangle_\psi\,\mathbb{1}\Big) \right\rangle_\psi \\
&= \left\langle A^2 + \langle A\rangle_\psi^2\,\mathbb{1} - 2\,\langle A\rangle_\psi\,A \right\rangle_\psi \\
&= \left\langle \psi\middle| \Big(A^2 + \langle A\rangle_\psi^2\,\mathbb{1} - 2\,\langle A\rangle_\psi\,A\Big)\middle|\psi\right\rangle \\
&= \left\langle \psi\middle| A^2 \middle|\psi\right\rangle + \langle A\rangle_\psi^2\,\langle\psi|\psi\rangle - 2\,\langle A\rangle_\psi\,\langle\psi|A|\psi\rangle \\
&= \left\langle A^2\right\rangle_\psi + \langle A\rangle_\psi^2 - 2\,\langle A\rangle_\psi^2\ ,
\end{aligned}$$

where we used the normalization Equation (77.1). Hence the uncertainty of A is given by

$$\Delta A = \sqrt{\langle A^2\rangle_\psi - \langle A\rangle_\psi^2}\,. \tag{77.10}$$

77.6.3 The generalized uncertainty principle

[Heading reserved in the source outline.]

Derivation pending #80

Statement and derivation of the generalized uncertainty relation bounding the product of the uncertainties of two non-commuting observables by the mean value of their commutator.

Chapter 78

Elementary Quantum Systems

The postulates of Chapter 77 earn their keep on the small family of potentials for which the Schrödinger equation can be solved in closed form: the free particle, the square wells, the delta potential, the barrier, the harmonic oscillator and the periodic lattice. These systems are not toys. Between them they contain the three structural surprises of quantum mechanics—discrete bound states, zero-point energy, and the penetration of classically forbidden regions—and each surprise is attached below to the experiment that observed it, from the systematics of alpha decay [600] to the scanning tunnelling microscope [1682], which turned the most counterintuitive of the three into a routine laboratory instrument.

The operator method for the harmonic oscillator [646] is developed in full, both because the oscillator is the single most reused calculation in physics—phonons in Chapter 125, photons in Chapter 122, field modes in Chapter 99—and because its ladder-operator algebra is the template for the angular-momentum algebra of Chapter 79. Coherent states, the operator method's classical limit, close the chapter where Schrödinger himself left them [556].

Derivation pending #81

Elementary Quantum Systems: all derivations of this chapter are pending.

78.1 The free particle

78.1.1 Plane waves and the continuum

[Reserved: the free Schrödinger equation, its plane-wave solutions $\mathrm{e}^{\mathrm{i}(kx-\omega t)}$ *with* $\hbar\omega = \hbar^2k^2/2m$*, the quadratic dispersion relation, and the fact that the spectrum is purely continuous with no normalizable eigenstates—the rigged-Hilbert-space setting of Chapter 12. The relation* $p = \hbar k$ *that the dispersion encodes carries the matter-wave evidence of Chapter 71.]*

78.1.2 Wave packets, group velocity and spreading

[Reserved: Gaussian wave packets, phase versus group velocity, and the free spreading of a packet first computed by Darwin [570]: at large times the width grows linearly, at a rate fixed by the initial momentum spread. Minimum-uncertainty packets saturate the Heisenberg inequality of Chapter 77.]

78.1.3 Ehrenfest's theorem

[Reserved: Ehrenfest's theorem [573], the exact equations $\mathrm{d}\langle x\rangle/\mathrm{d}t = \langle p\rangle/m$ *and* $\mathrm{d}\langle p\rangle/\mathrm{d}t = -\langle V'(x)\rangle$*, the precise sense in which packet centroids obey Newton's law, and the failure*

of the classical correspondence when $\langle V'(x)\rangle$ differs from $V'(\langle x\rangle)$—the quantum face of the classical-limit bridge built in Chapter 23.]

78.2 Potential wells

78.2.1 The infinite square well

[Reserved: the particle in a box, the n^2 spectrum, node counting and the oscillation theorem inherited from Sturm–Liouville theory (Chapter 9), orthonormality and completeness of the eigenbasis, and the approach to the classical distribution at high quantum numbers [2313].]

Phenomenon 78.1 (Confinement alone quantizes energy)**.** An electron confined to a thin layer by barriers on both sides has a discrete set of energies whose lowest member lies *above* the bottom of the layer, and whose values grow as n^2 for $n = 1, 2, 3, \ldots$ while falling as the inverse square of the layer thickness. Dingle, Wiegmann and Henry saw the levels directly, as a staircase of steps in the optical absorption edge of gallium arsenide layers a few tens of nanometres thick grown between aluminium gallium arsenide barriers; the steps moved with layer thickness in the predicted way and their positions stood in the ratios $1 : 4 : 9 : \ldots$ [1524]. Confinement by itself, with no attractive well at all, produces both a discrete spectrum and a ground-state energy that is not zero.

Derivation. Idealize the barriers as impenetrable, so that the electron moves freely on $0 < x < L$ and ψ vanishes at both walls. Inside,

$$-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} = E\psi\,, \qquad \text{so} \qquad \psi(x) = A\sin kx + B\cos kx\,, \quad E = \frac{\hbar^2 k^2}{2m}\,.$$

The condition $\psi(0) = 0$ removes the cosine, and $\psi(L) = 0$ forces $\sin kL = 0$, that is $kL = n\pi$ with n an integer. The value $n = 0$ gives $\psi \equiv 0$, which is not a state, and negative n repeat the positive ones up to a sign, so

$$E_n = \frac{\pi^2\hbar^2}{2mL^2}\,n^2\,, \qquad n = 1, 2, 3, \ldots \tag{78.1}$$

Three features of Equation (78.1) are the three observed ones. The spectrum is discrete because only a countable set of wavelengths fits between the walls. The ground state has $E_1 > 0$ because $n = 0$ is excluded, and E_1 grows as L^{-2}: squeezing a particle costs energy, which is the uncertainty relation of Chapter 77 in its most elementary form. And the ratios $E_n/E_1 = n^2$ do not involve m or L, which is what makes the observed staircase a signature rather than a fit. A barrier of finite height lets the wavefunction penetrate a little way into the walls, so the effective width exceeds L and every level is pushed slightly down — the correction treated in Section 78.2.2. □

78.2.2 The finite square well

[Reserved: bound states from the transcendental matching conditions, the guaranteed existence of a bound state in one dimension, penetration of the wavefunction into the classically forbidden region, and the direct spectroscopic observation of particle-in-a-box levels in thin semiconductor layers by Dingle, Wiegmann and Henry [1524]—the quantum well, ancestor of the heterostructures of Chapter 127.]

78.2.3 The delta potential

[Reserved: the attractive delta well and its single bound state, the jump condition on the derivative, scattering states and the transmission coefficient, the delta function as the zero-range limit of a deep narrow well [2313]; the double delta well as the minimal model of the covalent bond, taken up for real molecules in Chapter 88.]

78.2.4 The linear potential: the quantum bouncer

[Reserved: the linear potential and its Airy-function solutions (Chapter 9), the spectrum set by the Airy zeros, and the observation of gravitationally bound quantum states of ultracold neutrons bouncing on a mirror by Nesvizhevsky et al. [2034], with level spacings of order $1\,\mathrm{peV}$ *—the Schrödinger equation solved by Nature in the Earth's gravitational field.]*

Phenomenon 78.2 (Gravitationally bound states of the neutron)**.** Ultracold neutrons falling onto a horizontal mirror do not settle onto it continuously. Passing a beam through the gap between the mirror and an absorbing ceiling placed a variable height above it, Nesvizhevsky and collaborators found that the transmitted rate does not grow smoothly from zero with the gap: it stays consistent with zero until the gap exceeds roughly $15\,\mu\mathrm{m}$, and only then grows [2034]. The vertical motion of a neutron in the Earth's field above a hard floor is quantized, with a ground state of energy of order a picoelectronvolt and a classical turning height of order ten micrometres — the Schrödinger equation solved by Nature in the field of Chapter 19.

Derivation. Above the mirror the potential is $V(z) = mgz$ for $z > 0$, and the mirror is a hard wall, $\psi(0) = 0$. The stationary equation

$$-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\psi}{\mathrm{d}z^2} + mgz\,\psi = E\psi$$

rearranges to $\mathrm{d}^2\psi/\mathrm{d}z^2 = (2m^2g/\hbar^2)\,(z - E/mg)\,\psi$, which the substitution

$$u := \frac{z - E/mg}{z_0}\,, \qquad z_0 := \left(\frac{\hbar^2}{2m^2 g}\right)^{1/3} \tag{78.2}$$

turns into the Airy equation $\mathrm{d}^2\psi/\mathrm{d}u^2 = u\psi$, since $(2m^2g/\hbar^2)\,z_0 = z_0^{-2}$ and $\mathrm{d}^2/\mathrm{d}z^2 = z_0^{-2}\mathrm{d}^2/\mathrm{d}u^2$. Of the two solutions of that equation only $\mathrm{Ai}(u)$ decays as $u \to +\infty$, so $\psi(z) \propto \mathrm{Ai}\,(u(z))$, and the wall condition $\psi(0) = 0$ requires $u(0) = -E/(mgz_0)$ to be a zero of Ai. Writing those zeros as $-\lambda_n$, with $\lambda_1 = 2.3381$ and $\lambda_2 = 4.0879$,

$$E_n = mg\,z_0\,\lambda_n\,. \tag{78.3}$$

The spectrum is discrete and unequally spaced, and its whole scale is carried by z_0. For the neutron, $m = 1.675 \times 10^{-27}\,\mathrm{kg}$ and $g = 9.81\,\mathrm{m/s^2}$ give $z_0 = 5.87\,\mu\mathrm{m}$ and $mgz_0 = 0.60\,\mathrm{peV}$, hence $E_1 = 1.4\,\mathrm{peV}$; the classical turning height of the ground state, E_1/mg, is $13.7\,\mu\mathrm{m}$, which is the ceiling height below which the apparatus transmits nothing. □

78.3 Tunnelling

78.3.1 Steps, barriers and the tunnel effect

[Reserved: reflection and transmission at a potential step, scattering by a rectangular barrier, the exact transmission coefficient and its exponential suppression in the opaque limit, transmission resonances at which the barrier turns transparent, and their observed counterpart, the Ramsauer–Townsend transparency of noble-gas atoms to slow electrons [480]. The semiclassical Gamow factor is derived by the WKB method of Chapter 82.]

Phenomenon 78.3 (Ramsauer–Townsend transparency)**.** Argon, krypton and xenon become nearly transparent to slow electrons. As the electron energy is lowered through a few electronvolts the measured elastic cross-section does not rise, as a classical picture of a longer interaction time demands, but passes through a deep minimum at an energy below about $1\,\mathrm{eV}$, where it falls by more than an order of magnitude below its value a few

electronvolts higher [480]. The lighter noble gases helium and neon show no such minimum. A target can therefore be more transparent to a slower projectile, which no picture of a particle following a trajectory through a force field allows.

Derivation pending #82

Resonant transmission by an attractive well: the condition under which the amplitudes reflected from its two edges cancel, making it perfectly transparent, and the three-dimensional form of the same statement as an s-wave phase shift passing through a half turn at the Ramsauer minimum

78.3.2 Alpha decay

[Reserved: the Geiger–Nuttall systematics relating alpha-decay half-life to particle energy [372]; its explanation as tunnelling through the Coulomb barrier by Gamow [600] and independently by Gurney and Condon [603, 625]— the first quantitative success of quantum mechanics in the nucleus, reproducing half-lives spanning more than twenty orders of magnitude with one exponential formula. The nuclear setting is Chapter 107; the same barrier penetration, run in reverse, sets the thermonuclear reaction rates of Chapter 52 [622].]

Phenomenon 78.4 (The Geiger–Nuttall systematics of alpha decay)**.** The alpha-emitting members of one radioactive series obey a single relation between the decay constant λ and the range — hence the energy — of the emitted particle: $\log \lambda$ is a linear function of $\log R$, and equivalently of $E^{-1/2}$ [372]. The relation is extraordinarily steep: across the naturally occurring emitters a factor of about two in alpha energy carries the half-life over more than twenty orders of magnitude, from microseconds to times comparable with the age of the Earth. Worse for classical mechanics, the alpha particle leaves with less energy than the top of the Coulomb barrier it must cross — a height that the scattering of alpha particles by the very same nuclei measures independently. There is no classical path out of the nucleus, and the nucleus decays all the same [600].

Derivation pending #83

The Gamow factor: semiclassical penetration of the Coulomb barrier by a particle whose energy lies below its top, the exponential of the integrated imaginary momentum across the forbidden region, and the linear dependence of the logarithm of the decay constant on the inverse square root of the alpha energy that follows from it

78.3.3 Field emission and the scanning tunnelling microscope

[Reserved: cold emission of electrons from metals in strong fields and the Fowler–Nordheim current–field law [599]; the scanning tunnelling microscope of Binnig and Rohrer [1682], whose exponential sensitivity of the tunnel current to a tip–surface gap of a few tenths of a nanometre resolves single atoms—tunnelling made visible; and the Josephson effect [1231], pair tunnelling between superconductors, developed with Chapter 130 and measured in Chapter 131.]

Phenomenon 78.5 (The tunnel current and its exponential gap law)**.** A current flows between a metal tip and a metal surface separated by a vacuum gap that no classical electron can cross, and it falls exponentially with the width of the gap — by about an order of magnitude for every 0.1 nm. Binnig and Rohrer measured that dependence and then

used it: holding the current constant while the tip is scanned holds the gap constant to a few picometres, which is what makes individual surface atoms visible [1682]. The most counterintuitive prediction of the theory is thereby also the most sensitive length gauge in surface physics.

Derivation. Treat the vacuum gap as a barrier whose top lies a distance ϕ — the work function — above the energy of a tip electron at the Fermi level. Inside the gap the Schrödinger equation reads

$$\frac{\mathrm{d}^2\psi}{\mathrm{d}z^2} = \kappa^2\psi\,, \qquad \kappa = \frac{\sqrt{2m_\mathrm{e}\phi}}{\hbar}\,,$$

so that the solution which stays bounded as the gap widens is $\psi(z) \propto \mathrm{e}^{-\kappa z}$: in a classically forbidden region the amplitude does not oscillate, it decays. Matching this decaying solution to propagating waves on the two metal sides multiplies it by factors that depend on ϕ and on the energy, but not exponentially on the width, so the whole width dependence of the transmitted probability — and with it of the current — is that of $|\psi(d)|^2$:

$$I(d) \propto \mathrm{e}^{-2\kappa d}\,. \tag{78.4}$$

The rate is fixed by the work function alone. For a clean metal $\phi \approx 4\,\mathrm{eV}$, whence $\kappa \approx 1.0 \times 10^{10}/\mathrm{m}$ and $2\kappa \times 0.1\,\mathrm{nm} \approx 2$: the current changes by a factor $\mathrm{e}^{-2} \approx 0.14$ for each $0.1\,\mathrm{nm}$ of retraction, which is the observed decade per angstrom. Inverting the statement gives the instrument, since a current held to $1\,\%$ holds d to about $0.5\,\mathrm{pm}$. □

78.4 The harmonic oscillator

78.4.1 Analytic solution

[Reserved: the Hermite-function solution, the equally spaced spectrum $E_n = \hbar\omega(n + 1/2)$, obtained in wave mechanics in Schrödinger's second communication [558] and in matrix mechanics by Born, Heisenberg and Jordan [534]; the Hermite equation as a Sturm–Liouville problem (Chapter 9).]

78.4.2 Ladder operators

[Reserved: factorization of the Hamiltonian by creation and annihilation operators with $\left[a, a^\dagger\right] = \mathbb{1}$, the algebraic derivation of the spectrum in Dirac's manner [646], number states, and the matrix elements that feed every application from the phonons of Chapter 125 to the quantized field modes of Chapter 99.]

78.4.3 Zero-point energy

[Reserved: the ground-state energy $\hbar\omega/2$ as a theorem of the uncertainty relation; its experimental reality in the isotope band spectra of boron monoxide, where Mulliken found the half-quantum offset demanded by the data [515]; and its descendants, the zero-point motion that keeps helium liquid at absolute zero (Chapter 130) and the vacuum energy of Chapter 99.]

Phenomenon 78.6 (Zero-point energy)**.** A bound oscillator does not come to rest at the bottom of its well. The vibrational levels of a diatomic molecule are

$$E_v = \hbar\omega\left(v + \tfrac{1}{2}\right)\,, \qquad v = 0, 1, 2, \ldots\,, \tag{78.5}$$

and the half-quantum in Equation (78.5) is observable rather than a choice of origin. Two isotopic forms of one molecule share a force constant and differ only in reduced mass, so their ω stand in a known ratio; the whole vibrational ladder of one is therefore displaced relative to the other by an amount that depends on whether the ladder starts at $\hbar\omega/2$ or at zero. Measuring that isotope displacement in the band spectrum of boron monoxide, Mulliken found the offset demanded by the data to be the half-quantum [515].

Derivation. The ground-state energy follows from the uncertainty relation alone. For $\mathcal{H} = p^2/2m + \frac{1}{2}m\omega^2x^2$ the potential is even, so the ground state may be taken with $\langle x\rangle = \langle p\rangle = 0$; then $\langle x^2\rangle = (\Delta x)^2$ and $\langle p^2\rangle = (\Delta p)^2$, and writing $a := (\Delta x)^2$ and using $\Delta x\,\Delta p \geq \hbar/2$,

$$E = \frac{(\Delta p)^2}{2m} + \frac{m\omega^2}{2}\,a \geq \frac{\hbar^2}{8ma} + \frac{m\omega^2}{2}\,a\,.$$

The right-hand side is a function of the single positive variable a which diverges at both ends of its range; its derivative $-\hbar^2/(8ma^2) + m\omega^2/2$ vanishes at $a = \hbar/(2m\omega)$, where the two terms are equal, so

$$E \geq \frac{\hbar\omega}{4} + \frac{\hbar\omega}{4} = \frac{\hbar\omega}{2}\,. \tag{78.6}$$

The bound is attained, so it is the ground-state energy and not merely a limit on it. The Gaussian $\psi_0(x) \propto \mathrm{e}^{-m\omega x^2/2\hbar}$ has exactly $\langle x^2\rangle = \hbar/(2m\omega)$ and saturates the uncertainty relation, and substituting it into the eigenvalue equation confirms this: the coefficient of x^2 cancels for precisely that exponent, and the constant left over is $(\hbar^2/2m)\,(m\omega/\hbar) = \hbar\omega/2$, which is Equation (78.5) at $v = 0$. Nothing in the argument used the excited states or the ladder algebra. A nonzero ground-state energy is forced by the impossibility of a particle being at once at rest and at a definite place, and it is therefore as general as the uncertainty relation itself. □

78.4.4 Coherent states

[Reserved: eigenstates of the annihilation operator, packets of minimum uncertainty that oscillate without spreading, constructed by Schrödinger in 1926 as the classical limit of the oscillator [556] and rediscovered by Glauber as the states of the coherent radiation field [1255]; overcompleteness; the working states of the laser physics of Chapter 122.]

78.5 Periodic potentials: a preview

[Reserved: Bloch's theorem for a periodic potential [623]; the Kronig–Penney model of a periodic array of wells, solved exactly, with its bands of allowed energies separated by gaps [683]; the band gap as the origin of the metal–insulator distinction. The full machinery—crystal momentum, Brillouin zones, effective mass—is developed in Chapter 126 and applied in Chapter 127.]

Chapter 79

Angular Momentum and Spin

Rotational invariance is the most productive symmetry in quantum mechanics, and this chapter extracts everything it gives. The generators of rotations satisfy $[J_i, J_j] = \mathrm{i}\hbar\varepsilon_{ijk}J_k$, and that single commutator—taken alone, with no reference to any particular system—fixes the entire spectrum: eigenvalues $\hbar^2 j(j+1)$ and $\hbar m$, multiplets of $2j+1$ states, and half-integer j alongside integer j. The derivation is the ladder-operator argument already rehearsed for the oscillator in Chapter 78, carried out here in the abstract, so that the orbital angular momentum of an electron, its spin, and the total angular momentum of a nucleus are one subject and not three. The chapter then treats the orbital realisation by the spherical harmonics, the intrinsic realisation—spin—that no function on a sphere can supply, the rule for adding two angular momenta with its Clebsch–Gordan coefficients, and the Wigner–Eckart theorem, which reduces every matrix element of a rotationally covariant operator to one number times a purely geometric factor.

Spin was forced on physics by data, not deduced. The doublet structure of the alkali spectra and the anomalous Zeeman effect [277, 391] defeated every model built from orbital motion alone; Landé's empirical g factor [478] fitted the splittings with a half-integer quantum number; Pauli's "two-valuedness" [529] named the extra degree of freedom without interpreting it; and Uhlenbeck and Goudsmit [532, 562] identified it as an intrinsic angular momentum of the electron, at the price of a factor two that Thomas [561] removed by a relativistic kinematic argument. The cleanest measurement—a silver beam splitting into exactly two [492]—is Chapter 80, the experiment chapter that follows this one. Pauli's spin theory [587] is the formalism used below; Chapter 93 later obtains spin-1/2 from relativistic invariance rather than postulating it, and Chapter 83 shows that the same half-integrality decides the statistics [854]. Standard treatments are [751, 1593, 2287].

Derivation pending #84

Angular Momentum and Spin: all derivations of this chapter are pending.

79.1 The angular-momentum algebra

79.1.1 Rotations and their generators

[Reserved: rotations as a symmetry of the dynamics; the unitary representation $U(R) = \mathrm{e}^{-\mathrm{i}\theta\,\boldsymbol{n}\cdot\boldsymbol{J}/\hbar}$ guaranteed by Wigner's theorem on symmetry operations [1269] (Chapter 77); the commutator $[J_i, J_j] = \mathrm{i}\hbar\varepsilon_{ijk}J_k$ read off from the composition law of $\mathrm{SO}(3)$ [687]; $\boldsymbol{J}$ as the conserved charge of rotational invariance, the quantum counterpart of the classical theorem of Chapter 21; the Casimir $\boldsymbol{J}^2$ and the commuting pair $\{\boldsymbol{J}^2, J_z\}$ as the maximal set of simultaneously measurable rotational observables. Lie-algebraic setting: Chapter 14.]

79.1.2 The spectrum from the algebra alone

[Reserved: the raising and lowering operators $J_\pm = J_x \pm \mathrm{i}J_y$ with $[J_z, J_\pm] = \pm\hbar J_\pm$; positivity of $\boldsymbol{J}^2 - J_z^2$ terminating the ladder at both ends; the resulting eigenvalues $\hbar^2 j(j+1)$ with $j \in \left\{0, \tfrac{1}{2}, 1, \tfrac{3}{2}, \dots\right\}$ and $m = -j, \dots, j$; the matrix elements $J_\pm \,|j,m\rangle = \hbar\sqrt{j(j+1) - m(m\pm1)}\,|j, m\pm1\rangle$. The algebraic derivation is that of matrix mechanics [534], recast in the operator language of [646]; it is the same argument that fixed the oscillator spectrum in Chapter 78, and its conclusion—that half-integer j is allowed—is the opening this chapter needs for spin.]

79.1.3 Representation matrices and Euler angles

[Reserved: the $(2j+1)$-dimensional irreducible representations $D^{(j)}_{m'm}(\alpha,\beta,\gamma)$, Wigner's small d matrices and their construction [687]; unitarity, orthogonality and the composition law; the character $\chi^{(j)}(\theta) = \sin\!\left[(j+\tfrac{1}{2})\theta\right] / \sin(\theta/2)$ used below to decompose products; the Condon–Shortley phase convention [751], which is what makes published tables of coefficients comparable at all, and which this treatise adopts.]

79.1.4 SU(2), SO(3) and the double cover

[Reserved: SU(2) *as the simply connected group with the same algebra as* SO(3) *and the two-to-one homomorphism onto it; integer j as the representations of* SO(3) *proper and half-integer j as the genuinely double-valued ones, so that a 2π rotation returns a fermionic state to minus itself; the topological reason ($\pi_1(\mathrm{SO}(3)) = \mathbb{Z}_2$), developed in Chapter 6 and Chapter 14. The sign is observable: neutron interferometry shows the interference pattern restored only after 4π [1558, 1566]. The relativistic completion, where the same double cover appears as* Spin(1, 3)*, is Chapter 94.]*

Phenomenon 79.1 (A neutron must be turned twice to come back)**.** Split a neutron beam coherently, precess the spin of one branch through an angle χ by sending it through a magnetic field, and recombine the two branches. The interference pattern at the exit does not repeat with period 2π in χ: it repeats with period 4π, and at $\chi = 2\pi$ — one full turn of the spin — it is inverted, maxima standing where minima stood. Rauch and collaborators in Vienna and Werner and collaborators in Michigan measured the period independently, in neutron interferometers cut from single silicon crystals, and both found 4π [1558, 1566]. A rotation by 2π is the identity on every classical object and is not the identity on a neutron.

Derivation. A rotation by χ about the unit vector $\boldsymbol{n}$ acts on a spin-$\frac{1}{2}$ state as $U = \mathrm{e}^{-\mathrm{i}\chi\,\boldsymbol{n}\cdot\boldsymbol{\sigma}/2}$. From the algebra $\sigma_i\sigma_j = \delta_{ij}\mathbb{1} + \mathrm{i}\varepsilon_{ijk}\sigma_k$ one gets $(\boldsymbol{n}\cdot\boldsymbol{\sigma})^2 = \mathbb{1}$, so the exponential series splits into even and odd parts exactly as for a scalar:

$$U(\chi) = \cos\frac{\chi}{2}\,\mathbb{1} - \mathrm{i}\sin\frac{\chi}{2}\,\boldsymbol{n}\cdot\boldsymbol{\sigma}\,. \tag{79.1}$$

Hence $U(2\pi) = -\mathbb{1}$ and $U(4\pi) = +\mathbb{1}$: the state, not merely the direction of the spin, changes sign after one turn and is restored only after two.

That sign is observable because the interferometer compares the rotated branch with an unrotated one. If each branch carries amplitude A and the geometry contributes a relative phase δ, the recombined intensity for an incident beam of spin state $|s\rangle$ is

$$I \propto \left\| \left(\mathbb{1} + \mathrm{e}^{\mathrm{i}\delta}U\right)|s\rangle \right\|^2 = 2 + 2\,\mathrm{Re}\left[\mathrm{e}^{\mathrm{i}\delta}\,\langle s|\,U\,|s\rangle\right].$$

For an unpolarized beam the spin factor is the average over any orthonormal pair, that is $\frac{1}{2}\operatorname{tr}U$, and since $\operatorname{tr}\mathbb{1} = 2$ while $\operatorname{tr}\sigma_i = 0$, Equation (79.1) gives $\frac{1}{2}\operatorname{tr}U = \cos(\chi/2)$ and

$$I \propto 1 + \cos\frac{\chi}{2}\cos\delta\,. \tag{79.2}$$

The fringe contrast is periodic in χ with period 4π and reverses sign at $\chi = 2\pi$, as observed. The same double-valuedness is why the rotation group of space has a double cover: half-integer j represents SU(2) faithfully and SO(3) only up to a sign. □

79.2 Orbital angular momentum

79.2.1 Spherical harmonics

[Reserved: $\boldsymbol{L} = \boldsymbol{r} \times \boldsymbol{p}$ and its differential form on the sphere; single-valuedness of a wavefunction of position restricting ℓ to integers; the spherical harmonics $Y_{\ell m}(\theta, \varphi)$ as the simultaneous eigenfunctions of $\boldsymbol{L}^2$ and L_z, their orthonormality, completeness and parity $(-1)^\ell$; the associated Legendre functions and the addition theorem; the connection to the Laplace equation and to Sturm–Liouville theory Chapter 9. Conventions and tables follow [751]; standard modern treatments [1593, 2287].]

79.2.2 Central potentials and the radial reduction

[Reserved: separation of the Schrödinger equation in a central potential, the effective radial equation with the centrifugal term $\hbar^2\ell(\ell+1)/2mr^2$, and the $(2\ell+1)$-fold degeneracy that rotational invariance guarantees for every central problem; why that degeneracy is exactly what an external field lifts (Chapter 82); the worked solutions—free particle in spherical waves, spherical well, isotropic oscillator—and the Coulomb case, whose extra degeneracy is the subject of Chapter 81.]

79.2.3 Rotational spectra of molecules

[Reserved: the rigid rotor, energies $E_J = \hbar^2 J(J+1)/2I$ and the equally spaced $\Delta J = \pm 1$ lines in the far infrared and microwave, the direct spectroscopic reading of the $J(J+1)$ law and hence of the algebra of Section 79.1.2 [961]; moments of inertia and bond lengths obtained from line spacings; centrifugal distortion and rotation–vibration coupling; nuclear-spin statistics of homonuclear molecules, where ortho and para intensity alternation is a direct measurement of the spin–statistics connection (Chapter 83); the classical rotor is Chapter 29, the molecular structure Chapter 88.]

Phenomenon 79.2 (The rotational line series of a molecule)**.** The pure rotational spectrum of a heteronuclear diatomic molecule, observed in the far infrared and the microwave, is a series of very nearly equally spaced lines. Two things about it are sharp. The spacing is constant, to a slow correction that grows with the rotational quantum number and is the centrifugal stretching of the bond; and the series extrapolates to zero at zero, so that the first line stands one full spacing above the origin rather than half a spacing [961]. For carbon monoxide the first line lies near 115 GHz and the following ones near two and three times that frequency. The rotational energies therefore go as $J(J+1)$ and not as J^2: the spectrum reads the eigenvalue of $\boldsymbol{J}^2$ off the sky.

Derivation. A rigid rotor has $\mathcal{H} = \boldsymbol{J}^2/2I$ with I its moment of inertia, so by the multiplet argument used for Phenomenon 79.3 its levels are $E_J = \hbar^2 J(J+1)/2I$ with J a non-negative integer, integral rather than half-integral because the rotor's angular momentum is orbital (Section 79.2.1). Electric-dipole radiation carries one unit of angular momentum, so $\Delta J = \pm 1$ (Section 79.2.4), and absorption from J to $J+1$ occurs at

$$\begin{aligned} h\nu_J = E_{J+1} - E_J &= \frac{\hbar^2}{2I}\left[(J+1)(J+2) - J(J+1)\right] \\ &= \frac{\hbar^2}{I}(J+1)\,, \end{aligned} \tag{79.3}$$

that is $\nu_J = \nu_0\,(J+1)$ with $\nu_0 = \hbar/2\pi I$. The lines are equally spaced by ν_0 and the first of them lies at ν_0, one whole spacing from the origin, as observed.

The alternative worth excluding is the naive $E_J \propto J^2$, which a reading of $\boldsymbol{J}^2$ as the square of a vector of length $\hbar J$ would give. It predicts $E_{J+1} - E_J \propto 2J+1$: lines in the ratios $1:3:5:\ldots$, still equally spaced but with the first line at *half* the spacing. The two laws are distinguished by one measurement of the lowest line against the spacing, and the measurement selects $J(J+1)$. Since ν_0 fixes I, the same spectrum then returns the bond length; and centrifugal stretching enters only as a correction of relative order $(\hbar J/I\omega_{\mathrm{vib}})^2$, which is why the leading pattern survives it. □

79.2.4 Parity and selection rules

[Reserved: parity as a discrete symmetry commuting with rotations, the parity of $Y_{\ell m}$, and the resulting electric-dipole selection rules $\Delta\ell = \pm 1$, $\Delta m = 0, \pm 1$ with Laporte's rule as their empirical form [751]; the intensity consequences observed in every atomic spectrum (Chapter 70); higher multipoles and the metastable states that survive because the dipole matrix element vanishes—the $2s$ level of hydrogen and the forbidden nebular lines. The general statement is the Wigner–Eckart theorem of Section 79.5.2; parity as a symmetry in its own right, and its violation by the weak interaction, is Chapter 105.]

79.3 Spin

79.3.1 The evidence for an intrinsic angular momentum

[Reserved: the four independent lines of evidence, each with the measurement that carries it—alkali doublets and the anomalous Zeeman effect [277, 391] with Landé's g factor [478]; Pauli's exclusion principle and its fourth quantum number [529]; the Stern–Gerlach splitting of a ground-state silver beam into exactly two components [481, 491, 492], treated in full in Chapter 80; and the gyromagnetic ratio measured mechanically by magnetization on rotation [424]. The proposal itself [532, 562], and why a literal spinning sphere is excluded by the equatorial speed it would require.]

Phenomenon 79.3 (Two beams, hence a half-integral angular momentum)**.** A collimated beam of ground-state silver atoms crossing a strongly inhomogeneous magnetic field emerges neither as one broadened trace, which is what a classical moment of arbitrary orientation would give, nor as an odd number of traces, which is what any orbital angular momentum would give, but as exactly two, placed symmetrically about the undeflected position [481, 492]. The size of the deflection gives a moment of one Bohr magneton [491]. The full apparatus, its systematics and its sequential versions are Chapter 80; what is used here is the bare count. An even number of components cannot come from orbital motion, so the silver atom carries an angular momentum that is not orbital and whose projection quantum number is half-integral.

Derivation. An atom of magnetic moment $\boldsymbol{\mu}$ in a field $\boldsymbol{B}$ has energy $-\boldsymbol{\mu}\cdot\boldsymbol{B}$ and therefore feels the force $\boldsymbol{F} = \nabla\,(\boldsymbol{\mu}\cdot\boldsymbol{B})$; with the field along z and varying along z, this is $F_z = \mu_z\,\partial B_z/\partial z$. The beam is split into one trace for each distinct value of μ_z, so counting traces counts the spectrum of μ_z, and since $\boldsymbol{\mu}$ is proportional to $\boldsymbol{J}$, the spectrum of J_z.

That spectrum follows from the commutator $[J_i, J_j] = \mathrm{i}\hbar\varepsilon_{ijk}J_k$ and nothing else. Let $|\lambda, m\rangle$ satisfy $\boldsymbol{J}^2\,|\lambda,m\rangle = \hbar^2\lambda\,|\lambda,m\rangle$ and $J_z\,|\lambda,m\rangle = \hbar m\,|\lambda,m\rangle$, and put $J_\pm = J_x \pm \mathrm{i}J_y$. Then $[J_z, J_\pm] = \pm\hbar J_\pm$, so $J_\pm$ carries an eigenvector of J_z to one with m raised or lowered by one, while $[\boldsymbol{J}^2, J_\pm] = 0$ leaves λ alone. From $J_\mp J_\pm = \boldsymbol{J}^2 - J_z^2 \mp \hbar J_z$,

$$\|J_\pm\,|\lambda,m\rangle\|^2 = \hbar^2\,[\lambda - m\,(m\pm 1)] \geq 0\,, \tag{79.4}$$

so m is bounded above and below and both ladders must terminate. Call the largest value j and the smallest j'. Termination means $J_+ |\lambda, j\rangle = 0$ and $J_- |\lambda, j'\rangle = 0$, which by Equation (79.4) give $\lambda = j(j+1)$ and $\lambda = j'(j'-1)$; eliminating λ leaves $j' = -j$, the root $j' = j+1$ being excluded by $j' \leq j$. The two ends are joined by a whole number of unit steps, so $2j$ is a non-negative integer and the multiplet contains

$$2j+1 \text{ states, with } m = -j, -j+1, \ldots, j\,. \tag{79.5}$$

Two traces therefore mean $2j+1 = 2$, that is $j = \frac{1}{2}$. This is the point at which the observation forces the theory's hand: Equation (79.5) permits half-integer j on purely algebraic grounds, no function of position on a sphere realizes it (Section 79.2.1), and the silver beam shows Nature using it anyway. □

79.3.2 Pauli matrices and spinors

[Reserved: the $j = \frac{1}{2}$ representation written out, $\boldsymbol{S} = \frac{\hbar}{2}\boldsymbol{\sigma}$, with the algebra $\sigma_i\sigma_j = \delta_{ij}\mathbb{1} + \mathrm{i}\varepsilon_{ijk}\sigma_k$, tracelessness, and completeness of $\{\mathbb{1}, \sigma_i\}$ on 2×2 matrices; two-component spinors, the Pauli equation with its $g = 2$ magnetic coupling [587]; the Bloch-sphere parametrization of a pure spin-1/2 state and its density matrix (Chapter 77); why the mean of $\boldsymbol{\sigma}$ behaves classically while its components never commute. Reobtained from the Dirac equation in Chapter 93.]

79.3.3 Magnetic moments and the g factor

[Reserved: the Bohr magneton $\mu_\mathrm{B} = e\hbar/2m_\mathrm{e}$ and the nuclear magneton smaller by the mass ratio; $\boldsymbol{\mu} = g\,\mu_\mathrm{B}\boldsymbol{J}/\hbar$ with $g_\ell = 1$ for orbital motion and $g_s \approx 2$ for spin [587]; the anomaly $g_s - 2$, first measured by Kusch and Foley from the ratio of atomic g values [916], now the most precisely tested prediction in physics (Chapter 112, with the radiative theory in Chapter 100); nuclear moments in nuclear magnetons (Chapter 107); the magnetism of matter as the bulk consequence (Chapter 129).]

Phenomenon 79.4 (The anomalous Zeeman effect)**.** In a weak magnetic field a spectral line of an atom splits into several components, equally spaced in frequency [277]. The pattern that a purely orbital moment predicts — a symmetric triplet whose splitting unit is $\mu_\mathrm{B}B/h$ and is the same for every line of every atom — is the exception, not the rule. Most lines split into more components than three, with a unit peculiar to the levels involved and in general not an integer multiple of $\mu_\mathrm{B}B/h$; the sodium D lines, the classic case, split into four and six [391]. Landé found that the whole body of data is reproduced by attaching to each level a single number g, computable from its three quantum numbers, and that fitting the observed patterns requires those quantum numbers to take half-integer values [478].

Derivation pending #85

Landé's g factor from the projection theorem: that the matrix elements of any vector operator inside one multiplet are proportional to those of the total angular momentum, so that the observed splitting unit becomes a closed formula in the three quantum numbers of the level, and that fitting it to the data requires the electron's own gyromagnetic factor to be twice the orbital one

79.3.4 Thomas precession

[Reserved: the spin–orbit coupling computed naively in the electron rest frame is twice the observed one; Thomas' resolution [561]—the rest frame is not inertial, and the composition of

two non-collinear boosts leaves a rotation, so the spin precesses at $\boldsymbol{\omega}_{\mathrm{T}}$ and halves the coupling in the low-velocity limit. The kinematics is that of Chapter 39, where the Wigner rotation is derived; the numerical consequence is the observed fine structure of Chapter 81, and the exact relativistic statement is the Bargmann–Michel–Telegdi equation for the polarization of a particle in an external field [1165], which is what the $g-2$ storage rings of Chapter 112 measure against. This is the worked case where a factor two decided between a right and a wrong theory.]

79.3.5 Spin beyond one half

[Reserved: spin-1 and the photon, whose two observed polarizations rather than three follow from masslessness (Chapter 94) and whose angular momentum was measured mechanically as a torque on a birefringent plate [767]; spin-1 massive bosons (Chapter 104); spin-3/2 and spin-2 states in nuclei and in the hadron spectrum [2427]; the spin-2 graviton polarizations of Chapter 46. What the evidence base does and does not contain about higher spins is Chapter 97.]

Phenomenon 79.5 (Light carries spin angular momentum)**.** A half-wave plate hung on a fine quartz fibre and traversed along its axis by circularly polarized light feels a steady torque about that axis, and the torque reverses when the handedness of the light is reversed. Beth built the apparatus, with the beam passed twice through the suspended plate to double the effect and a resonant detection scheme to pull the deflection out of the Brownian motion of the fibre, and measured a torque per unit incident power equal to $2/\omega$ [767]. Angular momentum is carried by a beam of light independently of any orbital motion of anything, and the amount per photon is one unit of $\hbar$.

Derivation. A half-wave plate converts circularly polarized light of one handedness into the other and transmits it. Suppose each photon of angular frequency ω carries a spin projection $s\hbar$ along its direction of propagation. Each transmitted photon has that projection reversed, so it gives up $2s\hbar$ to the plate, and a beam of power P delivers $P/\hbar\omega$ photons per second. The torque is therefore

$$\tau = 2s\hbar \times \frac{P}{\hbar\omega} = \frac{2sP}{\omega}\,. \tag{79.6}$$

Two things are worth noting about Equation (79.6). First, $\hbar$ cancels: the predicted torque is a classical quantity, which is why a torsion fibre can measure it, and the experiment therefore determines the integer s without needing to know $\hbar$. Second, the measured value $\tau = 2P/\omega$ gives $s = 1$. The electromagnetic field carries spin one, a fact read here off a suspended crystal and recovered from the transformation properties of the field in Chapter 94; that the photon nevertheless shows two polarization states rather than the three of a massive spin-1 particle is a consequence of its masslessness, established there. □

79.4 Addition of angular momenta

79.4.1 The coupling problem and the Clebsch–Gordan series

[Reserved: two commuting angular momenta $\boldsymbol{J}_1$, $\boldsymbol{J}_2$ and their sum; the uncoupled basis $|j_1 m_1\rangle\,|j_2 m_2\rangle$ against the coupled basis $|j_1 j_2; JM\rangle$; the decomposition $j_1 \otimes j_2 = |j_1 - j_2| \oplus \cdots \oplus (j_1 + j_2)$, proved by counting states or by multiplying characters [687]; dimensional check $(2j_1+1)(2j_2+1) = \sum_J (2J+1)$; why the coupled basis is the useful one whenever the interaction is rotationally invariant but the individual momenta are not separately conserved—spin–orbit coupling, LS and jj coupling schemes in atoms (Chapter 88).]

79.4.2 Clebsch–Gordan coefficients

[Reserved: the coefficients $\langle j_1 m_1 j_2 m_2 | J M\rangle$ as the unitary matrix between the two bases; their construction by repeated application of J_- to the stretched state, the selection rules $M = m_1 + m_2$ and the triangle inequality, reality in the Condon–Shortley convention, orthogonality and recursion relations [687, 751]; the closed Racah form of the general coefficient [867]; the tabulated special cases $\frac{1}{2}\otimes\frac{1}{2}$ and $\ell\otimes\frac{1}{2}$ that every atomic calculation reuses.]

79.4.3 Two spins one half: singlet and triplet

[Reserved: the explicit decomposition $\frac{1}{2}\otimes\frac{1}{2} = 0\oplus 1$, the antisymmetric singlet and the symmetric triplet, and the exchange operator written as $\frac{1}{2}(\mathbb{1} + \boldsymbol{\sigma}_1\cdot\boldsymbol{\sigma}_2)$; the singlet–triplet splitting observed as ortho- and para-helium (Chapter 88) and as the hydrogen hyperfine splitting of Chapter 81; the exchange interaction behind ferromagnetic order (Chapter 129); and the singlet as the state whose correlations violate the Bell inequalities (Chapters 84 and 89) [1271].]

79.4.4 $3j$, $6j$ and $9j$ symbols

[Reserved: Wigner's $3j$ symbol as the symmetrized Clebsch–Gordan coefficient, with the full permutation symmetry that the coefficient hides [687]; the recoupling of three angular momenta and the $6j$ symbol relating the two coupling orders, of four and the $9j$ symbol [867, 873]; sum rules and orthogonality relations; why this apparatus is not bookkeeping but the practical content of atomic and nuclear structure calculations (Chapters 88 and 107), and the same recoupling algebra reappears for isospin.]

79.5 Tensor operators and the Wigner–Eckart theorem

79.5.1 Spherical tensor operators

[Reserved: the definition of an irreducible tensor operator $T^{(k)}_q$ by its commutators with $\boldsymbol{J}$, equivalently by its transformation under $U(R)$ with the matrices $D^{(k)}$; scalars, vectors and rank-two tensors as the cases $k = 0, 1, 2$; the decomposition of a Cartesian tensor into irreducible parts—trace, antisymmetric part, symmetric traceless part—and its physical reading as monopole, vector and quadrupole [751, 867]; products of tensor operators coupled with Clebsch–Gordan coefficients.]

79.5.2 The Wigner–Eckart theorem

[Reserved: the theorem $\langle j' m'|\, T^{(k)}_q\,|jm\rangle = \langle jm\, kq | j' m'\rangle\ \langle j'\|T^{(k)}\|j\rangle\,/\sqrt{2j+1}$, separating a geometric factor fixed entirely by rotational invariance from one reduced matrix element carrying all the dynamics, stated by Eckart [648] and by Wigner [687]; the immediate corollaries—selection rules $|j-k|\le j'\le j+k$ and $m' = m+q$, the proportionality of the matrix elements of any vector operator within a multiplet to those of $\boldsymbol{J}$ (the projection theorem), and hence the derivation of Landé's empirical g factor [478] from first principles.]

79.5.3 What the theorem buys

[Reserved: worked consequences, each attached to a measurement— intensity ratios within a spectral multiplet, fixed by geometry alone and independent of the atomic model [751]; the vanishing of a static electric dipole moment for a state of definite parity, and the searches for the electron electric dipole moment as tests of Chapter 105; nuclear electric quadrupole

moments requiring $I \geq 1$, so that a spin-1/2 nucleus has none (Chapter 107); multipole expansions of radiation and their selection rules (Chapter 65).]

79.6 Spin dynamics and magnetic resonance

79.6.1 Larmor precession

[Reserved: the Hamiltonian $-\boldsymbol{\mu}\cdot\boldsymbol{B}$, the exact solution for a spin in a static field, and the precession of $\langle \boldsymbol{S}\rangle$ at $\omega_{\mathrm{L}} = g\mu_{\mathrm{B}}B/\hbar$; Ehrenfest's theorem (Chapter 78) making the quantum mean obey the classical torque equation exactly for this system, one of the few cases where it does so with no correction whatever; the Zeeman splitting as the energy form of the same statement [277]; the observed precession of a free neutron's spin measured interferometrically [1566]; the muon precession that the $g-2$ experiments of Chapter 112 count.]

Phenomenon 79.6 (Magnetic resonance)**.** A sample of matter, or a beam of atoms or molecules, placed in a static magnetic field B_0 and irradiated with a weak transverse field oscillating at frequency ν, exchanges energy with the radiation only in a narrow band of frequencies, centred on a value strictly proportional to B_0 and independent of the intensity of the radiation. Rabi's molecular beams turned the resonance into the first precise measurements of nuclear magnetic moments [819]; Purcell, Torrey and Pound found the same absorption in a block of paraffin and Bloch, Hansen and Packard found it by nuclear induction in water, both in 1946 [887, 894]. The proportionality constant is a property of the species and of nothing else, which is what makes the resonance an instrument.

Derivation. Write the moment as $\boldsymbol{\mu} = \gamma \boldsymbol{S}$, so that the Hamiltonian in the static field is $\mathcal{H} = -\gamma\, \boldsymbol{S}\cdot\boldsymbol{B}$. For any observable the Ehrenfest relation of Chapter 78 gives $\mathrm{d}\langle A\rangle/\mathrm{d}t = (\mathrm{i}/\hbar)\langle[\mathcal{H}, A]\rangle$, and here the commutator can be evaluated in closed form from the algebra alone:

$$[\mathcal{H}, S_i] = -\gamma B_j\,[S_j, S_i] = -\mathrm{i}\hbar\gamma\,\varepsilon_{jik}B_j S_k\,,$$

so that, with $\varepsilon_{jik}B_j S_k = -(\boldsymbol{B}\times\boldsymbol{S})_i$,

$$\frac{\mathrm{d}\langle \boldsymbol{S}\rangle}{\mathrm{d}t} = \gamma\,\langle \boldsymbol{S}\rangle \times \boldsymbol{B}\,. \tag{79.7}$$

Equation (79.7) is exact — no expansion, no truncation — and it is the classical equation for a top of angular momentum $\langle \boldsymbol{S}\rangle$ carrying the moment $\gamma\langle \boldsymbol{S}\rangle$. Its solution is a precession about $\boldsymbol{B}$ at the angular frequency

$$\omega_{\mathrm{L}} = |\gamma|\,B_0\,, \tag{79.8}$$

with the component along $\boldsymbol{B}$ constant. A transverse driving field is therefore in step with the moment through every cycle when, and only when, it turns at ω_{L}, which is the observed resonance.

The energy form of the same statement is the sharper one. The eigenvalues of $\mathcal{H}$ are $-\gamma\hbar m B_0$ with $m = -j, \ldots, j$ by Equation (79.5), so adjacent levels are separated by $\hbar\,|\gamma|\,B_0$ and a photon is absorbed when $h\nu = \hbar\,|\gamma|\,B_0$, that is when $2\pi\nu = \omega_{\mathrm{L}}$. Because the levels are equally spaced the whole multiplet resonates at one frequency, which is why the absorption line is single and why measuring it measures γ alone; the observed resonance frequency divided by B_0 is the gyromagnetic ratio, with no model of the nucleus intervening. □

79.6.2 Rabi's resonance method

[Reserved: a rotating transverse field added to a static one; the exact two-level solution and the Rabi formula for the transition probability, with its resonance at the Larmor frequency and its generalized frequency off resonance [798]; the molecular-beam magnetic-resonance

method and the first precise nuclear moments [819]; Ramsey's method of separated oscillatory fields [968] as the narrowing that made the caesium frequency standard possible, feeding the SI definition of the second (Chapter 2); the perturbative version of the same result appears as the golden rule in Chapter 82, and the exact solution here is the check on it.]

79.6.3 Nuclear magnetic resonance

[Reserved: resonance in bulk matter rather than a beam, detected by absorption [894] and by induction [887]; relaxation times T_1 and T_2 and the Bloch equations, the open-system description of which is Chapter 87; the chemical shift and its use in molecular structure (Chapter 88); spatial encoding by field gradients and the resulting imaging [1507]—an angular-momentum commutator turned into a clinical instrument; electron spin resonance as the analogue at the electron magneton.]

79.6.4 Spin as the elementary two-state system

[Reserved: spin-$1/2$ as the minimal quantum system and the template for every two-level problem—ammonia inversion, neutral-kaon and neutrino flavour oscillation (Chapters 103 and 111), the qubit; observables that do not commute, so no state is dispersion-free in all three components, and the resulting spin-projection statistics that the Stern–Gerlach chapter measures directly (Chapter 80); the singlet correlations of Chapter 84 as the sharpest statement that these statistics are not classical [1271].]

Chapter 80

Experiment: Stern–Gerlach

Few experiments in the history of physics have delivered so unambiguous a verdict with so modest an apparatus. In the winter of 1921–1922, in a cramped laboratory of the Institute for Theoretical Physics in Frankfurt am Main, Otto Stern and Walther Gerlach sent a beam of neutral silver atoms through a strongly inhomogeneous magnetic field and found that the beam split cleanly into two — not into the continuous fan that every classical intuition demanded. The experiment made *space quantization* visible on a glass plate: the projection of an atomic magnetic moment onto a field axis takes only discrete values. That the discreteness was at first attributed to the wrong angular momentum — orbital rather than spin — takes nothing away from the observation itself, which stands to this day as the prototype of a quantum measurement. This chapter presents the experiment in full phenomenological detail; the quantum-mechanical derivations it calls for are developed in Chapter 79 and are marked pending here.

80.1 Historical context, 1921–1922

By 1921 the old quantum theory was an uneasy patchwork of classical mechanics and quantization rules. Bohr's planetary model of 1913 had been generalized by Sommerfeld, who quantized not only the size and shape of electron orbits but also their *orientation*: in the presence of a magnetic field defining an axis, the component of the orbital angular momentum along that axis was restricted to a discrete set of values, a doctrine Sommerfeld called *Richtungsquantelung* — direction quantization, or space quantization [441]. The rule accounted economically for the normal Zeeman splitting of spectral lines, but it carried an outrageous corollary: an atom entering a magnetic field must instantaneously find its angular momentum pointing only along the quantized directions, however the atom was oriented beforehand. To most physicists trained in the classical tradition this seemed a bookkeeping fiction, useful for spectroscopy but surely not a statement about the actual disposition of atoms in space.

Otto Stern, then at Frankfurt, was among the sceptics — and he possessed the one instrument capable of settling the matter. In the molecular-beam method he had been developing since 1919, atoms fly through high vacuum in nearly collision-free straight lines, so that a force acting on a single atom is recorded directly as a deflection of the beam. In 1921 Stern published the proposal in full: pass a beam of neutral atoms through an inhomogeneous magnetic field; if the atomic magnetic moments are oriented at random, as classical mechanics holds, the beam broadens into a continuous smear, whereas if space quantization is real the beam must split into discrete components [481]. The experiment was conceived as a decisive test between two sharply distinct predictions — and, by Stern's own account, he expected and hoped to refute the quantum prediction. The documented recollections collected by Friedrich and Herschbach preserve the flavour of the wager: Stern

is reported to have vowed to quit physics if Bohr's "nonsense" of spatial quantization turned out to be correct, and even sympathetic colleagues regarded the quantized orientations as a computational timetable rather than physical reality [2050]. It should be remembered that both sides of the wager were arguing within the old quantum theory: the modern resolution — electron spin — was not on anyone's table.

The circumstances were as unfavourable as the idea was sharp. Postwar Germany was sliding into inflation, and the Frankfurt institute had almost no money for equipment. The experiment survived on improvised patronage: Max Born, Stern's chief, raised funds by charging admission to popular lectures on relativity; private donations arrived from abroad; and a grant arranged through the committee of Einstein's Kaiser Wilhelm Institute for Physics — which Einstein then directed, largely as a fund-dispensing body — helped pay for the electromagnet [2050]. Gerlach, an accomplished experimentalist who had joined Frankfurt in 1920, carried the brunt of the laboratory work through repeated failures of vacuum, alignment, and detection, with Stern contributing the crucial design insight that the field gradient, not the field strength, produces the deflecting force.

One further story belongs here, explicitly flagged as *anecdote*. Stern recounted, decades later, that when he and Gerlach first examined the detector plate they saw nothing — until, as they peered at it, the silver trace slowly blackened before their eyes. Stern's explanation was that the sulfurous smoke of their cheap cigars (professorial salaries being too thin for good ones) had converted the invisibly thin silver deposit into visible black silver sulfide, in the manner of a photographic developer. The tale is charming and was told by Stern himself, but its literal role in the discovery is uncertain: the plates were in any case developed chemically as a matter of routine, and Friedrich and Herschbach, who traced the story and even re-enacted the chemistry, present it as a delightful embellishment rather than an established causal link in the chain of discovery [2050]. We repeat it in that spirit.

80.2 Stern–Gerlach (1921–1922)

The experiment ran in Frankfurt from 1921 to the decisive plates of February 1922. Its logic is worth stating before its hardware: a neutral atom carries no net charge, so the Lorentz force cannot deflect it; but if the atom carries a magnetic moment $\boldsymbol{\mu}$, an *inhomogeneous* field exerts a net translational force on it. The deflection of a beam of neutral atoms therefore reads off the distribution of magnetic-moment components along the field gradient — a direct image, atom by atom, of the quantity that space quantization declares to be discrete.

80.2.1 Apparatus

An electrically heated oven evaporates metallic silver at a temperature of about $1300\,\mathrm{K}$; atoms effuse from a small aperture into high vacuum, which must be maintained continuously over runs lasting several hours (the working pressures were of the order of $10^{-3}\,\mathrm{Pa}$; a single cracked gasket could destroy a night's run). Two collimating slits, a few hundredths of a millimetre wide, select from the effusing vapour a thin ribbon-shaped beam. The beam then passes along the edge of a deflecting electromagnet whose pole pieces have the now-famous asymmetric profile — one pole machined to a sharp knife edge, the facing pole carrying a channel-shaped groove — so that the field between them, of magnitude on the scale of $B \approx 0.1\,\mathrm{T}$ near the beam, varies strongly across the gap, with a vertical gradient of order

$$\frac{\partial B_z}{\partial z} \sim 10^{3}\,\mathrm{T/m}\,, \tag{80.1}$$

sustained over a beam path through the field of about $3.5\,\mathrm{cm}$. Detection is cumulative: the silver atoms condense on a cold glass plate placed beyond the magnet, and the invisibly

thin deposit built up over hours is developed photographically to render the trace visible [491, 492].

80.2.2 Procedure

The oven temperature fixes the velocity distribution of the beam: silver atoms at 1300 K leave the source with a broad thermal spread of speeds whose beam-averaged value is of order 660 m/s — a kinetic-theory estimate, its precise value depending on how the effusive flux weights the Maxwell distribution. With the magnet off, a run records the undeflected beam profile, a single narrow line reproducing the collimator geometry. With the magnet energized, the atoms traverse the gradient region and each acquires a transverse deflection determined by the component μ_z of its magnetic moment along the gradient. The classical expectation is unequivocal: magnetic moments emerging from a hot oven point in random directions, and in the field they precess about the field axis at the Larmor frequency, which preserves μ_z; the ensemble therefore presents a continuum of μ_z values from $-|\boldsymbol{\mu}|$ to $+|\boldsymbol{\mu}|$, and the recorded trace should be a single trace, broadened into a smear that is densest at the centre and fades toward maximal deflection. Any discrete multiplicity of traces is irreconcilable with a classical moment distribution.

80.2.3 Observations and data

The developed plates of February 1922 showed the beam split into *two* discrete traces, with no detectable intensity at the undeflected centre where the classical smear would peak. The pattern has the shape of a pair of lips: at the centre of the beam ribbon, where the gradient is strongest near the knife edge, the two traces reach their maximal separation of about 0.2 mm, and they close toward the ends of the ribbon where the field is more nearly uniform [492]. On 8 February 1922 Gerlach mailed a postcard to Niels Bohr carrying a photograph of the split trace and congratulations on the confirmation of his theory — an image that has become one of the icons of quantum physics [2050].

The deflection is governed by the force on a magnetic dipole in an inhomogeneous field, which for the geometry of the experiment reduces to

$$F_z = \mu_z \frac{\partial B_z}{\partial z} \,. \tag{80.2}$$

Derivation pending #86

Force on a magnetic dipole in an inhomogeneous field

Taking Equation (80.2) together with the measured geometry, gradient, and thermal velocity, the observed splitting yields the magnitude of the silver atom's magnetic moment. As an order-of-magnitude check: a moment of one Bohr magneton in the gradient Equation (80.1) feels a force $F_z \approx 9 \times 10^{-21}\,\mathrm{N}$, which acting on a silver atom (mass about $1.8 \times 10^{-25}\,\mathrm{kg}$) moving at 660 m/s over 3.5 cm produces a deflection of order a tenth of a millimetre — consistent with the observed trace separation. Gerlach and Stern's quantitative analysis, published later in 1922, concluded that the moment equals one Bohr magneton within their experimental uncertainty of about ten percent [491]; in modern units,

$$\mu_{\mathrm{B}} = \frac{e\hbar}{2m_e} = 9.274 \times 10^{-24}\,\mathrm{J/T} \tag{80.3}$$

by the current CODATA adjustment [2392].

80.2.4 Interpretation

The immediate conclusion was announced in the title of the discovery paper: "experimental proof of direction quantization in the magnetic field" [492]. The projection of the atomic magnetic moment onto the field axis is not continuously distributed; it takes exactly two values, $\mu_z = \pm\mu_\mathrm{B}$, for silver. Space quantization is a fact of nature, and Stern lost his wager.

Yet the 1922 reading of that fact was wrong in nearly every detail. Within the Bohr–Sommerfeld theory the splitting was ascribed to an orbital angular momentum of one unit, whose projection was held (on Bohr's argument) to take the values $\pm\hbar$ with the value zero forbidden — hence two traces. The modern account is entirely different: the ground state of silver is ${}^2S_{1/2}$; its single valence electron has orbital angular momentum $\ell = 0$ and hence *no* orbital magnetic moment at all. What the plates recorded is the intrinsic spin of that electron, $s = 1/2$, whose projection $S_z = \pm\hbar/2$ couples to the field through a gyromagnetic factor $g_s \approx 2$, so that $\mu_z = \mp g_s \mu_\mathrm{B}/2 \approx \mp\mu_\mathrm{B}$. The numerical coincidence $g_s s \approx 1$ made the spin-1/2 doublet mimic exactly the (doubly erroneous) old-quantum-theory prediction, and so the experiment was celebrated for years as confirming a model that could not have produced its result. Spin was proposed only in 1925 and the Stern–Gerlach pattern correctly reinterpreted in its terms by 1927 [2050, 2287]. The observation outlived its first explanation — a pattern this treatise will meet again.

80.2.5 Primary references

[481, 491, 492].

80.3 The phenomenon: space quantization

Stripped of its 1922 vocabulary, the experimental fact is the following.

Phenomenon 80.1 (Space quantization)**.** The component of an atom's angular momentum — equivalently, of its magnetic moment — measured along any axis singled out by a magnetic field takes only discrete values. For silver atoms in their ground state the measured moment component takes exactly two values, $\mu_z = \pm\mu_\mathrm{B}$ to within experimental accuracy [491, 492], whatever the prior history of the atom and however the field axis is chosen.

Derivation pending #87

Quantum derivation of the two-valued splitting from spin-1/2 (to Chapter 79)

Two features of Phenomenon 80.1 deserve emphasis, because they carry the whole weight of the quantum theory that Chapter 79 builds. First, the discreteness is *two*-fold. Any orbital angular momentum ℓ yields an odd number $2\ell+1$ of projections; an even multiplicity cannot arise from orbital motion at all and forces a half-integer angular momentum, $s = 1/2$, of no classical provenance. Second, the discreteness holds for *any* choice of axis. The magnet's orientation is at the experimenter's disposal, yet along whatever direction one measures, the answer is $\pm\hbar/2$ — never a continuum, never a projection factor $\cos\theta$. No classical vector quantity can behave this way, and the resolution — that the measured component is an operator with a two-point spectrum, not a pre-existing number — is the substance of the angular-momentum algebra developed in Chapter 79 and of the measurement postulates of Chapter 77.

80.4 Sequential Stern–Gerlach experiments

The full quantum-mechanical lesson of the apparatus emerges only when several Stern–Gerlach magnets are chained in series, with beam blocks used to select one output of each stage as the input of the next. In this form the experiment is best known as the opening thought experiment of modern quantum-mechanics pedagogy [1593, 2287] — but it is a *gedanken* experiment made real: each stage is precisely the apparatus of Section 80.2, and versions of the cascade have been realized with atomic and neutron beams. We write SG$\hat{z}$ for a Stern–Gerlach magnet whose gradient axis is $\hat{z}$, and label its two output beams by the measured spin component $S_z = \pm\hbar/2$.

Three arrangements suffice to dismantle classical expectations. In the first, an SG$\hat{z}$ stage selects the $S_z = +\hbar/2$ beam and feeds it to a second SG$\hat{z}$ stage: only the $+\hbar/2$ output fires. Measurement is *repeatable*; the first stage has prepared a state that the second confirms with certainty. In the second arrangement the selected $S_z = +\hbar/2$ beam enters an SG$\hat{x}$ stage: both outputs fire, with equal intensities. A definite value of S_z evidently does not carry with it any definite value of S_x. The third arrangement is the decisive one: the $S_x = +\hbar/2$ output of the second stage is passed to a final SG$\hat{z}$ magnet — and *both* S_z outputs fire, again with equal intensities. The beam entering the SG$\hat{x}$ stage contained, by construction, no $S_z = -\hbar/2$ component whatsoever; the intervening measurement of S_x has destroyed the previously established value of S_z. Table 80.1 summarizes the three cases.

Table 80.1: Sequential Stern–Gerlach cascades. Each stage transmits the beam indicated and blocks the other; probabilities refer to the outputs of the final stage, conditional on an atom entering it.

Cascade	Beam admitted to final stage	Final outcomes	Probabilities
SG$\hat{z} \to$ SG$\hat{z}$	$S_z = +\hbar/2$	$S_z = +\hbar/2$ only	1, 0
SG$\hat{z} \to$ SG$\hat{x}$	$S_z = +\hbar/2$	$S_x = \pm\hbar/2$	1/2, 1/2
SG$\hat{z} \to$ SG$\hat{x} \to$ SG$\hat{z}$	$S_x = +\hbar/2$	$S_z = \pm\hbar/2$	1/2, 1/2

In the language of the postulates of Chapter 77, each magnet performs a projective measurement of one spin component; the transmitted beam is the corresponding eigenstate; and the probabilities in Table 80.1 are Born-rule overlaps between eigenstates of S_z and S_x. The impossibility of jointly sharp values of S_z and S_x is the physical face of their non-commutativity,

$$[S_z, S_x] = \mathrm{i}\hbar S_y \neq 0\,, \tag{80.4}$$

so that no filtering protocol, however elaborate, can produce a beam that passes both an SG$\hat{z}$ and an SG$\hat{x}$ test with certainty [1593, 2287].

Derivation pending #88

Sequential SG probabilities from the measurement postulates

80.5 Legacy

The Stern–Gerlach experiment founded a lineage of beam techniques whose descendants populate the rest of this treatise. Stern's Hamburg laboratory turned the molecular-beam method into precision physics: diffraction of helium and hydrogen beams from crystal surfaces confirmed the de Broglie wavelength for whole atoms, and beam deflection measurements yielded the proton's magnetic moment — anomalously large, a first hint of nucleon substructure. Rabi's molecular-beam magnetic-resonance method, built directly on

Stern–Gerlach state selection, led through nuclear magnetic resonance to the atomic clock and the maser; a Stern–Gerlach magnet sorting state populations sat at the heart of the first ammonia maser. The historical thread from the Frankfurt magnet to these developments is traced in detail by Friedrich and Herschbach [2050].

The experiment has also been repeated and refined in modern settings — longitudinal and matter-wave-interferometric variants with neutrons and cold atoms among them — always with the same two-valued verdict; and its conceptual role has, if anything, grown. A Stern–Gerlach magnet acting on a spin-1/2 atom is the prototype of a *qubit measurement*: a two-level quantum system, an apparatus that entangles the qubit with a macroscopically distinct pointer variable (here, the atom's transverse position), and a readout that yields one bit with Born-rule statistics. Every projective measurement in today's quantum technologies is, conceptually, a Stern–Gerlach experiment in different hardware, and the sequential cascades of Section 80.4 prefigure the state-preparation-and-measurement protocols of Chapter 84. It is fitting that the sharpest early test of quantum discreteness — undertaken by a sceptic hoping to refute it — should have become the standard mental model for the theory's most characteristic act, the measurement [2050].

Chapter 81

The Hydrogen Atom

Hydrogen is the atom the Schrödinger equation solves exactly, and the one against which almost everything else in quantum physics is calibrated. One electron in the Coulomb field of one proton gives the spectrum $E_n = -13.6\,\mathrm{eV}/n^2$, a degeneracy of n^2 that is larger than rotational invariance alone can explain, and a length scale—the Bohr radius $a_0 = 5.29 \times 10^{-11}\,\mathrm{m}$—built from $\hbar$, the electron mass and the elementary charge. This chapter solves the problem twice: once in wave mechanics, following Schrödinger's first communication [557], and once algebraically through the conserved Runge–Lenz vector, following Pauli [553], whose calculation preceded the wave equation. The second route explains the extra degeneracy: the Coulomb problem has a hidden SO(4) symmetry, identified by Fock [755] and Bargmann [766], and the accidental degeneracy is not accidental at all.

The chapter then peels the exact solution apart layer by layer, because each correction to it is a separate piece of physics measured to its own precision: relativistic and spin–orbit fine structure, closed by the Dirac equation of Chapter 93; the Lamb shift [901], which splits levels the Dirac theory holds degenerate and thereby started renormalized quantum electrodynamics (Chapter 100); the hyperfine coupling to the proton spin, whose ground-state splitting radiates the 21 cm line [981, 984] that mapped the Galaxy; and the finite size of the proton, read off from muonic hydrogen [2164, 2210]. Behaviour in external fields—the Zeeman and Stark effects—is worked as the standard application of perturbation theory in Chapter 82 and only summarized here. Because the theory is exact and the experiments are the most precise in atomic physics, hydrogen is where the fundamental constants are fixed [2392, 2431] and where a discrepancy of a few parts in 10^5 counts as a crisis.

Derivation pending #89

The Hydrogen Atom: all derivations of this chapter are pending.

81.1 The spectrum before the theory

81.1.1 Balmer's formula and the Rydberg constant

[Reserved: the four visible hydrogen lines and Balmer's empirical fit $\lambda = hm^2/(m^2-4)$ [230]; Rydberg's generalization to a difference of two terms, valid across the alkali spectra as well [248], and the Rydberg–Ritz combination principle [348], which made term differences rather than lines the primitive objects; the named series and the modern value $R_\infty = 1.097\,373\,156\,8 \times 10^7/\mathrm{m}$ [2392]. What these formulas were: an exact, purely empirical regularity with no mechanism whatever, and the standing challenge that Chapter 70 recounts.]

Phenomenon 81.1 (The Balmer series and the Rydberg formula)**.** The visible emission spectrum of atomic hydrogen is neither a continuum nor an arbitrary set of lines. Balmer

found that the four lines then measured obey

$$\lambda = b\,\frac{m^2}{m^2-4}\,, \qquad m = 3,4,5,6\,, \tag{81.1}$$

with the single constant $b = 3.6456\times10^{-7}\,\mathrm{m}$, and used Equation (81.1) to predict further members of the series that were afterwards found [230]. Rydberg showed that the same regularity governs the whole hydrogen spectrum, and the alkali spectra besides, in the form

$$\frac{1}{\lambda} = R_\infty\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right), \qquad n_2 > n_1\,, \tag{81.2}$$

with one constant serving every series of the atom [248]; Equation (81.1) is the case $n_1 = 2$. The constant is now $R_\infty = 1.097\,373\,156\,8\times10^{7}/\mathrm{m}$, one of the most accurately known quantities in physics [2431]. Classical physics predicts no discrete spectrum at all, still less one indexed by two integers, and least of all a radiating electron that does not spiral into the nucleus.

Derivation pending #90

The bound-state eigenvalues of the Coulomb problem: the radial equation for the potential that falls as the inverse first power of the distance, the termination of its series solution which quantizes the energy as minus a constant over the square of an integer, and the identification of that constant with a combination of the electron mass, the elementary charge and Planck's constant

Phenomenon 81.2 (The Rydberg–Ritz combination principle)**.** The wavenumbers of the lines of an atom are not independent of one another. Each is a difference of two members of a single list of *terms* characteristic of the atom, so that the sum of the wavenumbers of two observed lines is very often itself the wavenumber of an observed line [348]. The rule holds for atoms whose spectra no formula of Balmer's kind describes, it was established empirically two decades before any mechanism for it existed, and it is what made the terms, rather than the lines, the primitive objects of spectroscopy.

Derivation. Assume, with the postulates of Chapter 77, that the atom possesses a set of stationary states of energies E_i, and that radiation is emitted or absorbed only in transitions between them, one photon of energy $h\nu = E_i - E_f$ per transition. Define the *term* of a state as $T_i := -E_i/hc$, a positive number for a bound state. The wavenumber of the line joining states i and f is then

$$\tilde\nu_{if} = \frac{E_i - E_f}{hc} = T_f - T_i\,, \tag{81.3}$$

a difference of two members of one list, as observed; and for any three states,

$$\tilde\nu_{if} + \tilde\nu_{fg} = (T_f - T_i) + (T_g - T_f) = T_g - T_i = \tilde\nu_{ig}\,,$$

so that two lines sharing a level combine into a third. That third line is *observed* only when the transition from i to g is itself allowed by the selection rules of Chapter 79, which is exactly why the empirical rule holds very often rather than always — a discrepancy that was noticed long before it was explained. Equation (81.2) is the special case of Equation (81.3) in which the terms of one atom happen to form the sequence $T_n = R_\infty/n^2$; the content of Phenomenon 81.2 is that terms exist at all, which is a statement about stationary states and holds whatever the sequence. □

81.1.2 What the old quantum theory got right

[Reserved: Bohr's quantized orbits [395] reproducing Balmer's formula and predicting R_∞ from $\hbar$, m and e; Sommerfeld's elliptical orbits and the relativistic fine-structure formula in α^2 [441], numerically right for reasons later shown to be wrong; the Bohr–Sommerfeld quantization as the action condition of Chapter 23; and the failures that ended the programme—no helium, no intensities, no ground for the selection rules. Detailed account in Chapter 70.]

81.2 The exact solution

81.2.1 Two bodies, one Coulomb potential

[Reserved: separation of the centre of mass, the reduced mass $\mu = m_e m_p/(m_e + m_p)$, and the resulting mass-dependent shift of every level; the isotope shift as its measurable consequence, and the discovery of deuterium by exactly that shift in the Balmer lines [708]; the Coulomb potential taken from Chapter 58 and its $1/r$ form as the input that everything below depends on; why the same reduction serves positronium and muonic hydrogen in Section 81.7.2.]

Phenomenon 81.3 (The isotope shift, and the discovery of deuterium)**.** Every line of the hydrogen spectrum has a faint companion displaced to shorter wavelength by a fixed *relative* amount of about 2.7×10^{-4}; for the red Balmer line at 656.3 nm the companion stands about 0.18 nm away. Urey, Brickwedde and Murphy found the companions, showed that they strengthened when the sample was enriched by evaporating liquid hydrogen nearly to exhaustion, and identified them as the spectrum of an isotope of mass number two [708]. The nucleus is therefore not an infinitely heavy centre of force: the spectrum knows the nuclear mass, and the amount by which it knows it is the electron-to-nucleus mass ratio.

Derivation. Separating the centre of mass of two bodies interacting through a potential that depends only on their separation leaves a one-body problem in the relative coordinate, with the reduced mass $\mu = m_e M/(m_e + M)$ in place of the electron mass, M being the nuclear mass. Every energy of the Coulomb problem is proportional to the mass appearing in the kinetic term, so the Rydberg constant of a nucleus of mass M is

$$R_M = R_\infty \frac{\mu}{m_e} = \frac{R_\infty}{1 + m_e/M}\,, \tag{81.4}$$

and wavelengths, being inversely proportional to it, satisfy $\lambda_M = \lambda_\infty (1 + m_e/M)$ to first order in the small ratio. Comparing a nucleus of one proton with one of twice that mass,

$$\frac{\lambda_H - \lambda_D}{\lambda} \simeq \frac{m_e}{m_p} - \frac{m_e}{2m_p} = \frac{m_e}{2m_p} = \frac{1}{2 \times 1836.15} = 2.72 \times 10^{-4}\,,$$

with the mass ratio taken from [2431]. Applied to the red Balmer line this is a displacement of 0.18 nm, the observed one; and it falls on the *short* side because the heavier nucleus gives the larger reduced mass, hence by Equation (81.4) the larger Rydberg constant and the larger wavenumber. The same substitution run to its limit gives positronium, whose reduced mass is $m_e/2$ and whose levels are therefore half of hydrogen's (Section 81.7.2). □

81.2.2 The radial equation and its quantization

[Reserved: separation in spherical coordinates using the angular solution of Chapter 79; the effective radial equation with the centrifugal barrier; the asymptotic factorization $e^{-\rho/2}\rho^{\ell+1}$ and the termination of the series that quantizes the energy; associated Laguerre polynomials, the principal quantum number $n \geq \ell + 1$, and the spectrum $E_n = -\mu e^4/(32\pi^2\varepsilon_0^2\hbar^2 n^2)$ [557]. The radial problem as a Sturm–Liouville system, with node counting, is Chapter 9.]

81.2.3 Eigenfunctions, orbitals and expectation values

[Reserved: the normalized wavefunctions $\psi_{n\ell m} = R_{n\ell}(r)Y_{\ell m}(\theta,\varphi)$; radial probability densities and their nodes; $\langle r\rangle$, $\langle 1/r\rangle$ and $\langle 1/r^3\rangle$, the last of which is what the fine-structure and hyperfine calculations below actually need; the $\ell = 0$ states alone non-vanishing at the origin, which is why they alone carry the Fermi contact and Lamb terms; virial theorem $\langle T\rangle = -\frac{1}{2}\langle V\rangle$; the continuum states above threshold and the photoionization edge (Chapter 65).]

81.2.4 Levels, degeneracy and scales

[Reserved: the level diagram, the ionization energy 13.6 eV, the Bohr radius as $\langle r\rangle$ of the ground state, and the fine-structure constant α entering as the ratio of the electron's orbital velocity to c—which is why every correction below arrives as a further power of α, and why the numerical value of α is fixed by measurements of exactly this kind (Chapter 90). The degeneracy: $2\ell+1$ from rotational invariance, but a total of n^2 orbital states independent of ℓ, which no rotational argument gives. That surplus is the subject of the next section.]

Phenomenon 81.4 (The Coulomb degeneracy exceeds what rotation gives)**.** To the accuracy at which fine structure may be neglected, the bound levels of hydrogen depend only on the principal quantum number and not on the orbital one: all the terms with $\ell = 0, 1, \ldots, n-1$ belonging to one n coincide, giving $\sum_{\ell=0}^{n-1}(2\ell+1) = n^2$ degenerate orbital states. Rotational invariance guarantees only the $2\ell+1$ states of a single ℓ, so the surplus is unexplained by any symmetry so far introduced. Two observations show that the coincidence is exact and not merely close. Hydrogen alone among atoms has a Stark effect *linear* in the applied electric field [422], and a linear response requires states of opposite parity to be exactly degenerate, since a field mixes them in first order only when it costs no energy to do so. And the alkali spectra, whose inner electrons screen the nucleus and spoil the exact inverse-square-law force, show precisely the term splittings by ℓ that hydrogen lacks [248]: it is the $1/r$ potential that is responsible, not the one-electron character of the atom.

Derivation pending #91

The ℓ-independence of the Coulomb spectrum: the conserved Runge–Lenz vector peculiar to the inverse-square-law force, the closure of its commutators with the angular momentum on the algebra of SO(4) *for bound states, and the identification of the levels with irreducible representations of that group whose dimension is the square of the principal quantum number*

81.3 Degeneracy and the hidden symmetry

81.3.1 The Runge–Lenz vector and the algebraic solution

[Reserved: the classical conserved vector of the Kepler problem, pointing along the major axis and expressing the closure of the orbits (Chapter 27), reintroduced into the quantum theory by Lenz [514]; its Hermitian symmetrization $\boldsymbol{A} = \frac{1}{2\mu}(\boldsymbol{p}\times\boldsymbol{L} - \boldsymbol{L}\times\boldsymbol{p}) - e^2\boldsymbol{r}/(4\pi\varepsilon_0 r)$, the commutators of $\boldsymbol{A}$ with $\boldsymbol{L}$ and with itself, and Pauli's derivation of the whole spectrum from that algebra alone [553]—published before the wave equation and reproducing Balmer exactly.]

81.3.2 SO(4) and Fock's construction

[Reserved: the rescaled generators closing on $\mathfrak{so}(4) \cong \mathfrak{su}(2)\oplus\mathfrak{su}(2)$ for bound states (and $\mathfrak{so}(3,1)$ for scattering states); Fock's demonstration that stereographic projection of mo-

mentum space onto the three-sphere turns the bound-state equation into the equation for spherical harmonics on S^3, so that the n^2 degeneracy is the dimension of an $\mathrm{SO}(4)$ irreducible representation [755], with the algebraic completion by Bargmann [766]. Group-theoretic setting: Chapters 5 and 14. The lesson—that an unexplained degeneracy signals a symmetry not yet identified—is used again for the isotropic oscillator and in Chapter 102.]

81.4 Fine and hyperfine structure

81.4.1 Relativistic corrections and spin–orbit coupling

[Reserved: the three terms of order α^2 relative to the Bohr energies—the relativistic kinetic correction, the spin–orbit coupling with its Thomas factor (Chapter 79) [561], and the Darwin contact term for $\ell = 0$ [595]; their sum depending only on n and j, so that $2s_{1/2}$ and $2p_{1/2}$ remain degenerate; the exact Dirac result reproducing Sommerfeld's formula [441, 596] and derived in Chapter 93; the observed $2p_{3/2}$–$2p_{1/2}$ splitting of about 10.9 GHz as the measured scale.]

81.4.2 The Lamb shift

[Reserved: the microwave measurement showing $2s_{1/2}$ lying about 1058 MHz above $2p_{1/2}$, in flat contradiction with the Dirac degeneracy [901]; Bethe's non-relativistic estimate, the first successful renormalized calculation, obtained within weeks [897]; the physical content—vacuum polarization and the electron's self-interaction with its own radiation field—and the full treatment in Chapter 100; the modern value and its role, together with the electron $g-2$ (Chapter 112), as the sharpest confrontation between quantum field theory and measurement.]

Phenomenon 81.5 (The Lamb shift)**.** The states $2s_{1/2}$ and $2p_{1/2}$ of hydrogen are not degenerate, although the Dirac theory makes them exactly so, its energies depending only on n and j. Driving microwave transitions directly between the two in a beam of metastable atoms, and using the metastable atoms themselves as the detector, Lamb and Retherford found $2s_{1/2}$ lying above $2p_{1/2}$ by about 1000 MHz [901]; the modern value is close to 1058 MHz. The shift is only about one part in 10^6 of the binding energy of the level, and it falsified the best relativistic one-particle theory then available. Bethe's estimate of it, made within weeks, was the first calculation in which the infinities of the radiation theory were removed by subtracting a free-particle self-energy [897].

Derivation pending #92

The radiative level shift: the interaction of the bound electron with the fluctuating quantized electromagnetic field, the difference between the bound and free self-energies which is what remains finite after regularization, and the vacuum-polarization contribution of opposite sign that accompanies it

81.4.3 Hyperfine structure

[Reserved: the coupling of the electron spin to the proton magnetic moment, dominated for $\ell = 0$ by the Fermi contact term proportional to $|\psi(0)|^2$ [652]; the total $\boldsymbol{F} = \boldsymbol{I} + \boldsymbol{J}$ and the singlet–triplet splitting of the ground state, smaller than the fine structure by the electron-to-proton mass ratio—about 5.9 μeV, that is 1420.4058 MHz; the proton magnetic moment measured independently by magnetic resonance (Chapter 79); the hyperfine anomaly as a probe of nuclear magnetization distribution (Chapter 107).]

81.4.4 Hydrogen in external fields

[Reserved: a summary, with the derivations deliberately placed in Chapter 82 where the perturbative machinery is built—the linear Stark effect, peculiar to hydrogen because the ℓ degeneracy of Section 81.2.4 survives [422, 560]; the Zeeman effect in the weak field with Landé's g factor and the Paschen–Back regime in the strong field [277, 391]; diamagnetic hydrogen in very strong fields as a laboratory for quantum chaos (Chapter 32).]

81.5 The 21-centimetre line

81.5.1 A prediction made before the instrument existed

[Reserved: van de Hulst's wartime calculation that the hyperfine ground-state transition of neutral hydrogen should be detectable as a radio line near 21 cm*, despite a spontaneous-emission lifetime of order* 10^7 *years, because the Galaxy contains enough atoms [880]; the magnetic-dipole character of the transition and the selection rules of Chapter 79 that make it so slow; why a line this narrow and this weak is nonetheless the most useful in radio astronomy.]*

81.5.2 Detection

[Reserved: the independent detections announced together in 1951—Ewen and Purcell at Harvard [981] and Muller and Oort at Kootwijk [984]—with the receiver technique, the frequency-switching that pulled the line out of the noise, and the measured rest frequency now known to 1420.4058 MHz*. This is the worked case of a quantum-mechanical energy difference of a few* μeV *becoming an astronomical instrument.]*

Phenomenon 81.6 (The 21-centimetre line)**.** Neutral atomic hydrogen in its electronic ground state radiates one spectral line in the radio band, at a rest frequency of 1420.4058 MHz — a vacuum wavelength close to 21 cm. Ewen and Purcell detected it in emission from the Milky Way with a horn antenna mounted out of a laboratory window and a receiver that switched frequency rapidly so as to subtract its own noise [981]; Muller and Oort confirmed it within weeks at Kootwijk and began mapping the Galaxy with it [984]. The transition joins the two hyperfine components of the ground state, split by the interaction of the electron's magnetic moment with the proton's. The splitting is about 5.9 μeV, smaller than the fine structure by roughly the electron-to-proton mass ratio, and the transition is a magnetic dipole one with a spontaneous lifetime of order 10^7 years — so weak that nothing smaller than a galaxy could have been the source in which it was first seen.

Derivation pending #93

The ground-state hyperfine splitting of hydrogen: the Fermi contact interaction between the electron and nuclear magnetic moments, its expectation value in the ground state, which is proportional to the probability density of the electron at the origin, and the resulting separation of the singlet from the triplet

81.5.3 What the line measures

[Reserved: Doppler-shifted 21 cm *emission mapping the rotation curve and spiral structure of the Galaxy [984]; column densities of neutral hydrogen; the flat rotation curves of spiral galaxies as one of the primary lines of evidence catalogued in Chapter 134; absorption against background sources; and the redshifted line as a probe of the neutral intergalactic medium*

(Chapter 48). The complementary Lyman-α absorption forest in quasar spectra [1452] uses the $n = 1 \to 2$ transition of the same atom.]

81.6 Precision hydrogen and the constants

81.6.1 The Rydberg constant and optical frequency metrology

[Reserved: two-photon Doppler-free spectroscopy of the $1s$–$2s$ transition, whose 1 Hz-scale natural width makes it one of the sharpest resonances in physics; the measurement 2.4661×10^{15} Hz to a few parts in 10^{15} using an optical frequency comb referenced to a caesium standard [2179]; the least-squares adjustment in which hydrogen data, together with the proton radius, determine R_∞ [2392, 2431]; the SI traceability chain of Chapter 2 and the experiment chapter Chapter 90.]

81.6.2 The proton radius

[Reserved: the finite-size correction shifting s levels in proportion to the mean square charge radius; muonic hydrogen, in which the muon's larger mass concentrates the wavefunction and amplifies the effect by roughly $(m_\mu/m_\mathrm{e})^3$, giving $r_\mathrm{p} = (0.841\,84 \pm 0.000\,67)$ fm [2164], confirmed and sharpened by the $2s$–$2p$ transitions of [2210]—about 7σ below the then-accepted electronic and scattering value: the "proton radius puzzle". Its resolution by new electronic-hydrogen measurements [2281, 2331] and the revised CODATA value [2431]; the honest reading, that a 7σ discrepancy was settled by remeasurement rather than by new physics.]

Phenomenon 81.7 (The spectrum measures the size of the proton)**.** The s levels of hydrogen lie slightly higher than a point nucleus would place them, by an amount proportional to the mean square charge radius of the proton, and the excess is large enough to be measured. Replacing the electron by a muon concentrates the wavefunction on the nucleus and amplifies the effect by millions: laser spectroscopy of the $2s$–$2p$ transitions of muonic hydrogen gave $r_\mathrm{p} = (0.841\,84 \pm 0.000\,67)$ fm [2164], and a second transition sharpened it [2210]. That value sat about 7σ below the electronic and electron-scattering value then accepted, and the discrepancy was closed by remeasuring the electronic transitions rather than by new physics [2281, 2331, 2431]. A property of the nucleus is thus read out of the energy levels of the electron cloud around it.

Derivation. Only the amplification factor is derived here; the coefficient belongs with the perturbation theory of Chapter 82. Inside a nucleus of finite size the potential departs from the point-charge Coulomb form by some $\delta V(r)$, positive because the enclosed charge is reduced, and supported on a region of the size of the proton. To first order the shift of a level is $\Delta E = \int |\psi|^2 \, \delta V \, \mathrm{d}^3 r$, and since that region is smaller than the atom by five orders of magnitude, $|\psi|^2$ may be replaced by its value at the origin:

$$\Delta E \simeq |\psi(0)|^2 \int \delta V \, \mathrm{d}^3 r \propto |\psi(0)|^2 \left\langle r_\mathrm{p}^2 \right\rangle . \tag{81.5}$$

Two consequences follow. Only $\ell = 0$ states shift at all, because $\psi(0) = 0$ for every $\ell > 0$ — which is why the muonic measurement compares an s level with a p level. And $|\psi(0)|^2 = 1/\pi a^3$ for the ground state, with the Bohr radius $a = 4\pi\varepsilon_0\hbar^2/\mu e^2$ inversely proportional to the reduced mass, so that $\Delta E \propto \mu^3 \left\langle r_\mathrm{p}^2 \right\rangle$. Muonic hydrogen has $\mu \simeq 186\, m_\mathrm{e}$, so its finite-size shift exceeds the electronic one by a factor of about 6×10^6. This is why one laser transition in an exotic atom could outweigh decades of electronic spectroscopy, and equally why a systematic error in that one measurement would have had nothing to check it against — which is the reason the discrepancy was taken seriously rather than dismissed. □

81.6.3 Antihydrogen and the tests it carries

[Reserved: trapped antihydrogen and laser spectroscopy of its $1s$–$2s$ transition, agreeing with hydrogen to a relative precision of about 2×10^{-12} [2299]—at present the sharpest spectroscopic test of CPT invariance (Chapter 105); the antihydrogen hyperfine structure; and the gravitational free-fall measurement, which belongs with the equivalence-principle tests of Chapter 42. Positron and antiproton production and the trapping technique are the experimental content.]

81.7 Hydrogen-like systems

81.7.1 One electron, other cores

[Reserved: hydrogenic ions Z^2-scaled, up to hydrogen-like uranium where $Z\alpha$ approaches unity and the expansion in Section 81.4.1 fails; Rydberg atoms, in which a single highly excited electron sees a screened core and reproduces the hydrogen spectrum with a quantum defect, with polarizabilities scaling as n^7 [1881] (used in the quantum optics of Chapter 122); and the Wannier exciton in a semiconductor, a hydrogen-like bound state of electron and hole with the dielectric constant and effective masses substituted [805], taken up in Chapter 127.]

81.7.2 Exotic atoms

[Reserved: positronium, an electron–positron bound state with reduced mass $m_e/2$ and no nucleus at all, whose formation and decay were first observed by Deutsch [980]—the purely leptonic hydrogen, where the annihilation channels test Chapter 100; muonium, observed through its Larmor precession [1184]; muonic hydrogen [2164, 2210], whose result reshaped the constants; and antiprotonic and pionic atoms, whose level shifts measure the strong interaction at threshold (Chapter 107). Each is the same equation with one substitution, which is what makes hydrogen the reference problem of the treatise.]

Chapter 82

Approximation Methods

The list of quantum systems that can be solved exactly is short: the free particle, the square wells, the oscillator and the periodic chain of Chapter 78, the rigid rotor of Chapter 79, and the Coulomb problem of Chapter 81. Everything else in this treatise—helium, every molecule, every solid, every scattering cross-section, every decay rate—is reached by approximation, and the approximations are therefore not a technical appendix to quantum mechanics but the greater part of how it is compared with experiment. This chapter builds the four that carry that load: stationary perturbation theory, in the form Schrödinger gave it in his third communication [560] on the model of Rayleigh's treatment of vibrating systems; the variational method [359], which bounds rather than expands; the semiclassical WKB approximation [535, 549, 563], which is the $\hbar \to 0$ limit of Chapter 23 made systematic; and time-dependent perturbation theory [559, 572], whose leading term is the transition-rate formula that Fermi later christened the golden rule [954].

Two habits of the chapter deserve stating in advance. First, every method is presented with its *failure* mode named: perturbation series in quantum mechanics are generically asymptotic and divergent [998, 1392], the WKB form breaks down exactly at the classical turning points, and a variational bound says nothing about how close it is. Second, each method is anchored to a measurement it actually explains—the Stark [422] and Zeeman [277] splittings, the helium ground-state energy [628], alpha-decay lifetimes, spectral-line intensities—so that the accuracy claimed can be checked rather than asserted. The chapter closes with the two opposite limits of a time-dependent Hamiltonian: the adiabatic theorem [594], whose geometric remainder is Berry's phase [1734], observed directly in polarized light carried along a helical fibre [1783]; and the sudden approximation at the other extreme. Standard treatments are [1593, 1599, 2287].

Derivation pending #94

Approximation Methods: all derivations of this chapter are pending.

82.1 Stationary perturbation theory

82.1.1 The Rayleigh–Schrödinger series

[Reserved: the split $H = H_0 + \lambda V$ with H_0 solved; the expansion of eigenvalue and eigenvector in powers of λ; the first-order shift $E_n^{(1)} = \langle n^{(0)} | V | n^{(0)} \rangle$ and the second-order shift $\sum_{m \neq n} |\langle m| V |n\rangle|^2 / (E_n - E_m)$, always negative for the ground state; normalization conventions and the intermediate-normalization form; the small parameter is the ratio of a matrix element to a level spacing, not λ itself, which is what makes near-degenerate levels the dangerous case [560]. Rigorous statement in terms of analytic families of operators

[1335], with the functional-analytic setting of Chapter 12.]

82.1.2 Degenerate and near-degenerate levels

[Reserved: why the naive series diverges term by term when $E_n = E_m$, and the resolution—diagonalize V within the degenerate subspace first; the secular determinant, the resulting good quantum numbers, and the identification of the symmetry that the perturbation leaves unbroken; complete and partial lifting of a degeneracy; the crossing rule that levels of the same symmetry repel rather than cross, with avoided crossings as the observable signature (their dynamical version is Section 82.6.3); the worked cases used later are the Stark and Zeeman effects of Section 82.2 [560].]

82.1.3 Does the series converge? Usually not

[Reserved: the honest statement that a perturbation series is generally asymptotic rather than convergent—optimal truncation, and error of the order of the first omitted term; the anharmonic oscillator whose coefficients grow factorially, computed exactly by Bender and Wu [1392]; Dyson's argument that the quantum-electrodynamic series cannot converge, because the theory is unstable for negative coupling [998] (see Chapter 100); Borel and Padé resummation; and the cases where honest convergence does hold, for which the analytic perturbation theory of [1335] gives criteria.]

82.2 Perturbation theory at work

82.2.1 The Stark effect

[Reserved: the observation of electric-field splitting of the Balmer lines by Stark [422], independently by Lo Surdo [406]; the quadratic shift for a non-degenerate level and the atomic polarizability it defines; the linear *Stark effect, peculiar to hydrogen because states of opposite parity are degenerate (Chapter 81), computed by Schrödinger in the paper that introduced the method [560]; parabolic coordinates; and the honest caveat that in a uniform field no bound state strictly exists—the levels are long-lived resonances that eventually field-ionize, as Oppenheimer showed [616].]*

82.2.2 The Zeeman effect

[Reserved: the splitting of spectral lines in a magnetic field [277]; the weak-field regime, where the spin–orbit coupling dominates, $\boldsymbol{J}$ is the good quantum number and the splitting is set by the Landé factor [478] derived from the projection theorem of Chapter 79; the strong-field Paschen–Back regime, where $\boldsymbol{L}$ and $\boldsymbol{S}$ decouple [391]; the crossover as a two-by-two degenerate problem solved exactly; why the "anomalous" effect was anomalous only before spin. Applications: stellar magnetic fields measured by Zeeman splitting (Chapter 52), and magnetometry.]

82.2.3 Fine structure, hyperfine structure and isotope shifts

[Reserved: the standard worked example of degenerate perturbation theory—the α^2 corrections to hydrogen (relativistic kinetic, spin–orbit with the Thomas factor [561], and Darwin) collected in Chapter 81 and derived exactly in Chapter 93; the hyperfine contact term [652]; nuclear volume and mass shifts. Each is a perturbation whose smallness is set by a physical ratio—α^2, the magneton ratio, the nuclear radius over a_0—which is the model for how the parameter should be identified in general.]

82.2.4 The Hellmann–Feynman and virial theorems

[Reserved: $\partial E/\partial\lambda = \langle\psi|\partial H/\partial\lambda|\psi\rangle$ for a normalized eigenstate depending on a parameter [833], and its use in converting a spectrum into forces—the electrostatic theorem for molecular binding (Chapter 88); the quantum virial theorem for a homogeneous potential and its check $\langle T\rangle = -\frac{1}{2}\langle V\rangle$ in hydrogen; the two theorems as exact constraints that any approximate calculation can be tested against, which is what makes them worth stating in a chapter about approximations.]

82.3 The variational method

82.3.1 The Rayleigh–Ritz principle

[Reserved: the theorem that $\langle\psi|H|\psi\rangle \geq E_0$ for any normalized trial state, with equality only for the ground state, and its stationarity form—the Schrödinger equation is the Euler–Lagrange equation of the energy functional (Chapter 16); the systematic method of minimizing over a finite basis, reducing the problem to a generalized eigenvalue determinant [359]; the min-max characterization of the higher eigenvalues (Chapter 12), which turns the same construction into bounds on excited states; the practical warning that a good energy does not imply a good wavefunction, because the error in E is second order in the error in ψ.]

82.3.2 Helium

[Reserved: the two-electron atom, the system on which the old quantum theory failed outright (Chapter 70); the crude one-parameter trial function with an effective nuclear charge screening the second electron; and Hylleraas' explicit inclusion of the interelectronic distance r_{12} in the trial function, which reproduced the measured ionization energy to spectroscopic accuracy [628]—the first quantitative proof that quantum mechanics governs many-electron atoms. Ortho- and para-helium as the singlet–triplet structure of Chapters 79 and 83.]

82.3.3 Self-consistent fields

[Reserved: Hartree's self-consistent field, in which each electron moves in the averaged potential of the others and the equations are iterated to consistency [604]; Fock's antisymmetrized version, whose exchange term is a direct consequence of the statistics of Chapter 83 [653]; the variational character of the whole construction, and Koopmans' theorem identifying an orbital energy with an ionization energy [743]; what is left out—electron correlation—and where it is recovered (Chapter 88); density-functional methods as the working tool of Chapter 126.]

82.4 The semiclassical approximation

82.4.1 The WKB expansion

[Reserved: the ansatz $\psi = \mathrm{e}^{\mathrm{i}S/\hbar}$ with $S = S_0 + \hbar S_1 + \cdots$, the leading order reproducing the Hamilton–Jacobi equation of Chapter 23 and the first order the amplitude $1/\sqrt{p(x)}$ that conserves flux; the validity condition $|\mathrm{d}\lambda/\mathrm{d}x| \ll 2\pi$ on the local de Broglie wavelength $\lambda(x) = h/p(x)$, that is, a wavelength varying slowly on its own scale; the near-simultaneous papers of Wentzel [563], Kramers [549] and Brillouin [535], and the earlier purely mathematical treatment of the same equation by Jeffreys [526], which is why the method is also called JWKB.]

82.4.2 Turning points and connection formulae

[Reserved: the breakdown of the expansion where $p(x) \to 0$, since the assumed short wavelength diverges there; linearization of the potential about a turning point and the Airy-function solution (Chapter 9); the connection formulae joining oscillatory and exponential regions and the $\pi/4$ phase they carry; the classically forbidden region and the exponentially small tail; and caustics as the same phenomenon in the optical language of Chapter 23.]

82.4.3 Semiclassical quantization

[Reserved: two turning points and the quantization condition $\oint p\,\mathrm{d}x = (n + \tfrac{1}{2})h$, the Bohr–Sommerfeld rule [441] corrected by the Maslov half-integer that the connection formulae supply; its exactness for the harmonic oscillator and its accuracy for high n as a form of the correspondence principle; the extension to non-separable systems and the general index counting [1150]; where semiclassical quantization fails altogether—classically chaotic systems, whose spectra are the subject of Chapter 32.]

82.4.4 Barrier penetration

[Reserved: the transmission exponential $\exp\left(-\frac{2}{\hbar}\int |p|\,\mathrm{d}x\right)$ as the standard product of the method; the Gamow factor for the Coulomb barrier [600], which reproduces the empirical Geiger–Nuttall relation between alpha-decay half-life and energy over more than twenty orders of magnitude (Chapter 78, Chapter 107); field ionization of atoms [616] and cold emission from metals; thermonuclear reaction rates as the same integral run inwards (Chapter 52). The exponential sensitivity is what makes an approximate exponent adequate and an approximate prefactor irrelevant.]

82.5 Time-dependent perturbation theory

82.5.1 Variation of constants and the interaction picture

[Reserved: the expansion of the state in eigenstates of H_0 with time-dependent coefficients, introduced for wave mechanics in Schrödinger's fourth communication [559] and cast in the form used ever since by Dirac [572]; the interaction picture and the Dyson series [927], whose field-theoretic use is Chapter 100; first-order amplitude as the Fourier transform of the perturbation at the Bohr frequency; unitarity and the limits of validity—the formulas below fail as soon as the depletion of the initial state matters.]

82.5.2 Fermi's golden rule

[Reserved: the transition rate $\Gamma = (2\pi/\hbar)\,|\langle f|\,V\,|i\rangle|^2\,\rho(E_f)$ into a continuum, with the $\sin^2$ kernel becoming a delta function of energy at long times and the resulting rate constant in time—the origin of exponential decay. The result is Dirac's [572]; the name is Fermi's, whose Chicago lecture notes list it as the second of two "golden rules" [954]. The chapter says which is which rather than repeating the customary attribution of both to Fermi. Second-order form for transitions through virtual intermediate states; applications to beta decay (Chapter 107), spontaneous and stimulated emission (Chapter 122), and scattering rates (Chapter 86).]

82.5.3 Periodic perturbations and the two-level check

[Reserved: a harmonic perturbation, absorption and stimulated emission at $\omega \approx \omega_{fi}$, the resonance denominators and the rotating-wave approximation; oscillator strengths and the Thomas–Reiche–Kuhn sum rule [527], which fixes the total absorption of an atom, summed

over lines, independently of its structure; the exactly solvable two-level system in a rotating field [798] used as the check on the perturbative answer, showing where first order is right and where Rabi flopping takes over (Chapter 79, Chapter 122).]

82.5.4 The Born approximation

[Reserved: the golden rule applied to scattering by a potential; the first Born amplitude as the Fourier transform of the potential in the momentum transfer [533], the Rutherford cross-section [379] recovered from a Coulomb potential, and the form factor as the Fourier transform of a charge distribution—which is how nuclear and nucleon radii are measured (Chapters 107 and 116). Validity at high energy and weak coupling, the second Born term, and the non-perturbative alternative—partial waves and phase shifts—in Chapter 86.]

82.6 Adiabatic and sudden limits

82.6.1 The adiabatic theorem

[Reserved: Born and Fock's theorem [594]: a system in a non-degenerate eigenstate of a slowly varying Hamiltonian remains in the instantaneous eigenstate, with transition probability vanishing in the limit of infinitely slow change; the condition as a ratio of the rate of change to the square of the level spacing; the dynamical phase; the classical counterpart, adiabatic invariance of the action, in Chapter 23; uses—adiabatic passage in spectroscopy, adiabatic cooling, and the slow ramps of Chapter 121.]

82.6.2 Berry's geometric phase

[Reserved: the extra, non-integrable phase left over when the Hamiltonian is carried around a closed loop in parameter space—equal to the flux of a curvature through the loop and independent of how slowly the circuit is traversed, so it is geometric and not dynamical [1734]; the spin-1/2 example giving half the solid angle subtended, and the degeneracy point acting as a monopole of the curvature; the optical precursor in the interference of polarized beams [1093]; the non-adiabatic generalization [1786]. Observed: rotation of the plane of polarization of light in a helically wound optical fibre, matching the predicted solid angle [1783]. The fibre-bundle language is Chapter 14; the same curvature governs the quantized Hall conductance of Chapter 128.]

82.6.3 Landau–Zener transitions

[Reserved: the failure of adiabaticity at an avoided crossing, and the exact two-level transition probability $\exp(-2\pi\gamma)$ *for a linear sweep through it [711], with* γ *the ratio of the squared gap to the sweep rate; the two limits—slow sweep following the adiabatic branch, fast sweep diabatically crossing it; applications to atomic and molecular collisions (Chapter 88), to the Mikheyev–Smirnov–Wolfenstein matter resonance [1631] that carries solar neutrinos through the Sun's density gradient (Chapters 103 and 114), and to control sequences in two-level systems.]*

82.6.4 The sudden approximation

[Reserved: the opposite extreme—a change of Hamiltonian fast compared with every relevant period, so that the state vector has no time to evolve and the transition probabilities are simply the overlaps $|\langle f_{new}|i_{old}\rangle|^2$*; the validity criterion in terms of the switching time against* $\hbar/\Delta E$ *[1599]; the worked case of nuclear beta decay, where the sudden change of nuclear*

charge leaves the atomic electrons excited or ionized—shake-up and shake-off, measurable in the electron spectrum (Chapter 107).]

82.6.5 Born–Oppenheimer separation

[Reserved: the adiabatic theorem applied to nuclei and electrons, with the expansion parameter $(m_e/M)^{1/4}$; electronic energies computed at fixed nuclei become the potential surface on which the nuclei then move [564]; the resulting separation of electronic, vibrational and rotational scales that organizes every molecular spectrum (Chapter 88, Chapter 79); where the separation fails—conical intersections between surfaces, at which the geometric phase of Section 82.6.2 becomes observable in the vibrational spectrum.]

Chapter 83

Identical Particles

Nothing in the postulates of Chapter 77 yet says what happens when two particles of a system cannot be told apart. Classically the question barely arises: two billiard balls may agree in every measurable property and still be labelled, because each carries its own trajectory. Quantum mechanically there is no trajectory to carry a label, the labels are therefore unobservable, and the demand that no prediction depend on them turns out to be among the strongest constraints in physics. It splits matter into exactly two families, forbids two electrons from occupying the same state [529], supplies the effective force that orders magnets [537, 545], fixes the size of atoms and the stability of bulk matter [1345, 1554], and holds white dwarfs up against their own gravity [676]. Its classical shadow is already visible in the Gibbs paradox of Chapter 118 [304].

The chapter sits after the general apparatus of Chapters 77 and 79 and Chapter 82 because it needs all three: a Hilbert space to act on with permutations, spin to build the two families out of, and perturbation theory to turn the exchange term into a number. It is the last piece of one-particle quantum mechanics and the first piece of every many-body theory that follows — the multi-electron atoms and molecules of Chapter 88, the electron gas of Chapter 126, the quantum statistics of Chapter 120, and the condensates of Chapter 121. Helium is the worked example throughout. The deepest statement of the chapter, the spin–statistics connection [854], is stated here and proved only in Chapter 109, since its hypotheses are relativistic and field-theoretic and are not available at this point in the book. Standard treatments are [1593, 2287].

Derivation pending #95

Identical Particles: all derivations of this chapter are pending.

83.1 Indistinguishability and the exchange operator

83.1.1 What indistinguishability asserts

[Reserved: the physical assertion — that no measurement can distinguish particle 1 *from particle* 2*, so that every observable* A *of an* N*-particle system commutes with every permutation of the labels; the contrast with the classical case, where identical particles are still individuated by their trajectories, and the resulting overcounting that Gibbs identified in the entropy of mixing [304] and that the* $1/N!$ *of Chapter 118 patches by hand; the statement that "identical" means agreement in every intrinsic quantum number — mass, charge, spin, lepton and baryon number — and the experimental fact that electrons agree in all of them to the precision of Chapter 112.]*

83.1.2 The permutation group on the Hilbert space

[Reserved: the symmetric group S_N acting on $\mathcal{H}^{\otimes N}$ by permuting tensor factors; that this is a unitary representation, reducible in general, whose irreducible components are labelled by Young diagrams; the group-theoretic language being that of Chapter 5; the observation that the totally symmetric and totally antisymmetric one-dimensional representations are distinguished among all of them by being the only ones in which every transposition acts by a single number.]

83.1.3 The exchange operator and its eigenvalues

[Reserved: the transposition operator P_{12}, its unitarity and its involutive property $P_{12}^2 = \mathbb{1}$, hence eigenvalues ± 1; that $[P_{12}, \mathcal{H}] = 0$ for a Hamiltonian symmetric under exchange, so exchange parity is a constant of the motion and a state cannot change family under any evolution; the resulting superselection rule, first formulated as an independent postulate by Messiah and Greenberg [1291].]

83.1.4 The symmetrization postulate

[Reserved: the postulate that the physical states of N identical particles span only the totally symmetric or the totally antisymmetric subspace of $\mathcal{H}^{\otimes N}$, never a mixed-symmetry one; its statement in Dirac's 1926 paper [537] and in Heisenberg's resonance paper [545]; the careful modern formulation, which separates the postulate from the spin–statistics theorem that later explains it [1291]; that this is a restriction on the state space*, not a restriction on the dynamics, and that it is logically independent of everything in Chapter 77.]*

83.2 Bosons and fermions

83.2.1 Bose–Einstein statistics

[Reserved: the symmetric sector; Bose's counting of photon states [509] and Einstein's extension to a material ideal gas, with the prediction of condensation below a critical temperature [522]; the enhancement factor $\sqrt{n+1}$ for adding a particle to an occupied mode, which is the origin of stimulated emission (Chapter 122); pointers to the thermodynamics in Chapter 120 and to the observation of condensation in Chapter 121.]

83.2.2 Fermi–Dirac statistics and the exclusion principle

[Reserved: the antisymmetric sector; Pauli's exclusion principle, announced as an empirical rule that closes atomic shells and explains the periodic table [529], and its restatement as antisymmetry of the wavefunction; the ideal gas obeying it, worked out independently by Fermi [539] and Dirac [537]; the Fermi sea, Fermi energy and Fermi surface as they will be used in Chapters 126 and 127; the statement that exclusion is a property of the state space and not a force — nothing pushes.]

Phenomenon 83.1 (Exclusion, and the lengths of the periods)**.** The chemical elements repeat their properties in periods of $2, 8, 8, 18, 18, 32$; the ionization energy climbs through each period and falls abruptly at the start of the next; and the elements ending each period are chemically inert. Pauli extracted from the spectroscopic evidence the rule behind it: no two electrons of an atom occupy states agreeing in all four quantum numbers, so that a shell of principal quantum number n holds at most $2n^2$ electrons [529]. Nothing in Chapter 77 forbids the alternative. Were the electrons free to share the lowest orbital, every atom would have the ground configuration $1s^N$, all elements would be chemically alike, and there would be no chemistry and no periodic table to explain.

Derivation. Take the exclusion rule as stated — at most one electron per one-electron state — and count the states. In a central field a one-electron state is labelled by n, by $\ell = 0, 1, \ldots, n-1$, by $m_\ell = -\ell, \ldots, \ell$ and by the two values of m_s, the ranges of ℓ and m_ℓ being those established in Chapter 79. The number of states of a given n is therefore

$$2\sum_{\ell=0}^{n-1}(2\ell+1) = 2\left[2\cdot\frac{(n-1)\,n}{2}+n\right] = 2n^2\,, \tag{83.1}$$

which is $2, 8, 18, 32$ for $n = 1, 2, 3, 4$: the observed period lengths, and the observed inert gases are the elements at which a group of these states is exactly filled. The qualification the data impose is that the ℓ degeneracy of Chapter 81 is broken in a many-electron atom, so the subshells fill out of order — $4s$ before $3d$ — and a period of 18 is first entered in the fourth row; and the periods of 8 are the s and p subshells of one n, which hold $2+6$ between them. What Equation (83.1) does not contain is a force. No term in the Hamiltonian was modified; the counting restricts which states exist, and that restriction alone produces the periodic table. □

83.2.3 Parastatistics, and why nature does not use it

[Reserved: the mixed-symmetry representations of S_N are not excluded by any principle of Chapter 77, and Green's generalized field quantization [1019] realizes them consistently as parabosons and parafermions of order p; the observational situation is that every known particle has $p = 1$; the theoretical statement that in a local relativistic field theory parastatistics of order p is equivalent to ordinary statistics with a hidden $\mathrm{SU}(p)$ degree of freedom, which is how colour entered Chapter 102; the experimental bounds are those of Section 83.5.2.]

83.2.4 Exchange in an effectively two-dimensional system

[Reserved: the argument that only two families exist uses the topology of the configuration space of N points, and in three space dimensions the exchange paths fall into two homotopy classes; Leinaas and Myrheim showed that for particles confined to a plane the relevant group is the braid group and a continuum of phases is allowed [1603], with Wilczek naming the resulting excitations anyons [1706]. This treatise instantiates $3+1$ dimensions only, so the statement belongs here as a property of an effectively two-dimensional system *inside ordinary space — a two-dimensional electron gas in a strong magnetic field — and not as a statement about spacetime. The evidence is the fractional quantum Hall effect of Chapter 128 and the direct anyon-collision measurement of [2354].]*

83.3 Constructing many-particle states

83.3.1 Slater determinants and permanents

[Reserved: the antisymmetrizer applied to a product of N orthonormal orbitals, giving the determinant of the matrix $\psi_i(x_j)$ normalized by $1/\sqrt{N!}$, introduced by Slater in his theory of complex spectra [637]; that it vanishes identically when two orbitals coincide, which is the exclusion principle read off an algebraic identity; the bosonic counterpart, the permanent, and why it is computationally hard where the determinant is easy; matrix elements of one- and two-body operators between determinants — Slater's rules — as the working tool of Chapter 88.]

83.3.2 Occupation numbers and second quantization

[Reserved: the passage from labelled particles to occupation numbers of modes; Fock space and its construction [698]; creation and annihilation operators with the commutator algebra

of Jordan and Klein for bosons [579] and the anti *commutator algebra of Jordan and Wigner for fermions [609], the latter written down precisely to make the Pauli exclusion principle an operator identity; that symmetrization is then automatic rather than imposed; the observation that this formalism is already field theory and is taken up as such in Chapter 99.]*

83.3.3 The self-consistent field

[Reserved: the variational determination of the best single Slater determinant; Hartree's self-consistent field [604] and Fock's antisymmetrized correction [653], giving the Hartree–Fock equations with their direct and exchange terms; the definition of correlation energy as what the method misses; helium and the light atoms as the test cases, and the precision benchmark of Hylleraas' explicitly correlated calculation [628]; forward pointer to Chapter 88 for atoms and molecules and to Chapter 126 for the extended case.]

83.4 The exchange interaction

83.4.1 Exchange energy has no classical analogue

[Reserved: the two-electron matrix element of the Coulomb repulsion between symmetrized and antisymmetrized states splits into a direct term J and an exchange term K, with the sign of K entering with the exchange parity; Heisenberg's resonance treatment [545] and Dirac's derivation of the same splitting from antisymmetry [537]; the essential point that no new interaction has been introduced — the exchange term is the ordinary electrostatic interaction evaluated on a constrained state space, which is why it is large, of order electronvolts, while the magnetic dipole–dipole energy between the same two spins is smaller by some three orders of magnitude.]

83.4.2 Helium: ortho and para

[Reserved: the worked example of the chapter. The two-electron state factorizes into a spatial and a spin part whose exchange parities must multiply to -1: the spin singlet takes the symmetric spatial function (parahelium) and the spin triplet the antisymmetric one (orthohelium). Consequences to be derived: the absence of a triplet ground state; the $2\,^3S$–$2\,^1S$ splitting of about $0.80\,\mathrm{eV}$, entirely exchange in origin; the near-absence of intercombination lines, and hence the nineteenth-century appearance of helium as two distinct gases; the metastability of $2\,^3S$. Perturbative treatment via Chapter 82, variational benchmark via [628], and modern spectroscopic precision via Chapter 90.]

Phenomenon 83.2 (Helium has no triplet ground state)**.** The spectrum of helium falls into two nearly independent systems, singlet and triplet, with transitions between them so weak that the nineteenth century took them for the spectra of two different gases. The lowest term of the entire spectrum is a singlet: no triplet state of the $1s^2$ configuration exists at all, though the corresponding singlet does. Where both do exist — the $1s2s$ configuration — the triplet lies lower, by about $0.80\,\mathrm{eV}$. That separation cannot be magnetic: the magnetic interaction of two electron moments a tenth of a nanometre apart is of order $5\times10^{-5}\,\mathrm{eV}$, four orders of magnitude too small. Heisenberg and Dirac identified it instead as an ordinary electrostatic energy, evaluated on states of definite exchange symmetry [537, 545].

Derivation. Electrons are fermions, so the two-particle state changes sign under the exchange of the pair of labels carrying both position and spin. Neglecting spin-dependent forces, the Hamiltonian does not couple space to spin and a state may be taken as a product $\Psi = \psi(\boldsymbol{r}_1,\boldsymbol{r}_2)\,\chi(1,2)$ of a spatial and a spin factor, each of definite exchange parity. Antisymmetry

of the product then requires the two parities to be opposite:

$$\begin{aligned} \psi \text{ symmetric} &\iff \chi \text{ antisymmetric: the spin singlet}\,, \\ \psi \text{ antisymmetric} &\iff \chi \text{ symmetric: the spin triplet}\,. \end{aligned} \tag{83.2}$$

For the configuration $1s^2$ both electrons occupy the same spatial orbital, so $\psi = \varphi_{1s}(\boldsymbol{r}_1)\,\varphi_{1s}(\boldsymbol{r}_2)$ is necessarily symmetric, and by Equation (83.2) the spin state must be the antisymmetric singlet. A triplet ground state is not merely higher in energy; there is no such state to have an energy.

The sign of the $1s2s$ splitting follows from the same parity. An antisymmetric ψ vanishes wherever $\boldsymbol{r}_1 = \boldsymbol{r}_2$ and so keeps the two electrons apart, while a symmetric one does not — indeed it is enhanced there. Evaluating the Coulomb repulsion $e^2/4\pi\varepsilon_0\,|\boldsymbol{r}_1 - \boldsymbol{r}_2|$, a positive operator, on the two states therefore costs more in the symmetric case, so the singlet lies above the triplet, as observed. No spin operator appeared anywhere in the argument: the spin merely selected which spatial function was admissible, and the energy difference is electrostatic. That is why it is of the order of an electronvolt while the magnetic interaction between the same two moments is smaller by four orders of magnitude, and it is the mechanism carried over to magnetic order in Section 83.4.3. □

83.4.3 From exchange to magnetic order

[Reserved: Dirac's replacement of the exchange term by an effective spin–spin coupling $-2K\,\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$ [537], and Heisenberg's use of it to explain ferromagnetism as a cooperative alignment driven by electrostatics [605]; the sign of K selecting ferromagnetic or antiferromagnetic order; that the Curie temperatures of iron, cobalt and nickel are of the electronvolt scale precisely because the mechanism is Coulomb and not magnetic; Hund's first rule as the atomic case; full development in Chapter 129, and the covalent bond as the same computation with the opposite sign convention in Chapter 88.]

83.5 The spin–statistics connection

83.5.1 Statement of the theorem

[Reserved: the empirical regularity that half-integer-spin particles are fermions and integer-spin particles are bosons, and its elevation to a theorem by Pauli [854] on the hypotheses of relativistic invariance, positivity of the energy and locality (the vanishing of commutators of observables at spacelike separation); the sharpened axiomatic version of Lüders and Zumino [1151]. The theorem is stated *here and proved in Chapter 109, because none of its hypotheses is available in nonrelativistic quantum mechanics — which is itself the finding: the symmetrization postulate of Section 83.1.4 is a genuine extra postulate at this level of the theory and stops being one only in a relativistic field theory. Its companion, the CPT theorem, is in Chapter 105. Composite particles inherit the statistics of the parity of their constituent fermion number, which is why ^{4}He condenses and ^{3}He must pair before it can (Chapter 130).]*

83.5.2 Experimental tests of the symmetrization postulate

[Reserved: the postulate is testable and has been tested. The Ramberg–Snow experiment passed a large current through a copper strip and searched for the X-ray line that a new electron making a Pauli-forbidden transition to a filled K shell would emit, bounding the violation probability at the level of 10^{-26} [1837]; the underground VIP-2 continuation improves it [2405]. Complementary bounds come from the non-observation of symmetric two-photon states and from nuclear spectroscopy. The section will tabulate the quantity bounded, the

bound, and the assumption each experiment tests, in the sense of Chapter 1: the point is that "electrons are identical" is a measured statement, not a definition.]

Phenomenon 83.3 (No electron has been caught violating exclusion)**.** The symmetrization postulate is a testable statement about the world and it has been tested directly. Ramberg and Snow passed a large current through a thin copper strip and searched its X-ray spectrum for the line that a newly arrived electron would emit on making a transition into an already filled K shell — a transition forbidden by exclusion, and displaced in energy from the ordinary $K\alpha$ line by the extra screening that the doubly occupied shell provides. No such line appeared above background, which bounds the probability that a fresh electron enters a filled state at the level of 10^{-26} [1837]. The VIP-2 apparatus, the same experiment moved underground so that cosmic rays no longer set the background, has improved the limit [2405]. That "electrons are identical" is therefore an experimental result carrying a number, and not a convention of the formalism.

Derivation pending #96

The Ramberg–Snow bound: the energy displacement of the anomalous X-ray line produced by the extra screening of a doubly occupied inner shell, the number of fresh electrons that a given charge delivers into the target lattice, and the conversion of a null count and its background into an upper limit on the violation probability

83.6 Two-particle interference

83.6.1 The Hong–Ou–Mandel dip

[Reserved: two indistinguishable photons entering the two input ports of a balanced beam splitter always leave together, because the two amplitudes for coincident detection cancel for bosons; the measurement of the resulting coincidence dip by Hong, Ou and Mandel [1794], whose width measures the photon wave-packet duration on a subpicosecond scale and whose depth measures indistinguishability directly. The derivation is a two-line calculation with the bosonic commutators of Section 83.3.2 and belongs inline. Uses: it is the standard indistinguishability metric in Chapter 122, and the entanglement-swapping step of Chapter 84 depends on it.]

Phenomenon 83.4 (Identical photons leave a beam splitter together)**.** Send one photon into each of the two input ports of a balanced beam splitter. If the two are made indistinguishable — same polarization, same spectrum, arrival times matched — the detectors at the two output ports never fire together: the coincidence rate falls to zero. Delaying one photon by more than its wave-packet duration restores the coincidences to the value expected of two independent particles, so the coincidence rate plotted against delay shows a dip. Hong, Ou and Mandel measured that dip and read the photon wave-packet duration off its width, on a subpicosecond scale that no detector of theirs could have resolved directly [1794]. Each photon separately divides evenly between the ports; only the pair refuses to.

Derivation. Let $a^\dagger$ and $b^\dagger$ create a photon in the two input modes and $c^\dagger$, $d^\dagger$ in the two output modes. A lossless balanced beam splitter acts on the creation operators as

$$a^\dagger \to \frac{c^\dagger + d^\dagger}{\sqrt{2}}, \qquad b^\dagger \to \frac{c^\dagger - d^\dagger}{\sqrt{2}},$$

the relative minus sign being forced by unitarity: without it the map would not preserve

the commutators. The input with one photon in each port is $a^\dagger b^\dagger |0\rangle$, so

$$\begin{aligned} a^\dagger b^\dagger |0\rangle &\to \tfrac{1}{2}\left(c^\dagger + d^\dagger\right)\left(c^\dagger - d^\dagger\right)|0\rangle \\ &= \tfrac{1}{2}\left(c^\dagger c^\dagger - d^\dagger d^\dagger + d^\dagger c^\dagger - c^\dagger d^\dagger\right)|0\rangle \ . \end{aligned} \tag{83.3}$$

For bosons $\left[c^\dagger, d^\dagger\right] = 0$, so the last two terms of Equation (83.3) cancel identically and, since $c^\dagger c^\dagger |0\rangle = \sqrt{2}\,|2_c, 0_d\rangle$,

$$a^\dagger b^\dagger |0\rangle \to \frac{1}{\sqrt{2}}\left(|2_c, 0_d\rangle - |0_c, 2_d\rangle\right) \ . \tag{83.4}$$

Every surviving term of Equation (83.4) has both photons in one port: the amplitude for one photon in each output is exactly zero, which is the observed vanishing of the coincidence rate. The cancellation is between the two histories that end in the same final state — both photons reflected, both transmitted — and it survives only while nothing distinguishes them, so anything that labels the photons, a difference in arrival time included, fills the dip in. Its depth is therefore a direct measurement of indistinguishability.

Repeating the calculation for fermions changes one thing and reverses the conclusion. The anticommutator $\left\{c^\dagger, d^\dagger\right\} = 0$ makes the cross terms add rather than cancel, while $c^\dagger c^\dagger = d^\dagger d^\dagger = 0$ kills the terms that survived above, leaving $-c^\dagger d^\dagger |0\rangle$: the two particles leave in *opposite* ports with certainty. Exchange parity is read directly off the sign of a two-particle coincidence rate. □

83.6.2 Intensity correlations and the fermionic counterpart

[Reserved: the Hanbury Brown–Twiss observation that photons from a thermal source arrive in correlated pairs [1083], its initial reception as a paradox, and its resolution as bosonic bunching — an interference of two-particle amplitudes with no one-particle analogue; the corresponding antibunching of electrons measured in a mesoscopic beam splitter [1975]; the sign of the correlation as a direct readout of exchange parity, and its use as a source-size measurement in stellar intensity interferometry and in heavy-ion collisions.]

Phenomenon 83.5 (Bosons bunch, fermions antibunch)**.** Photons from a thermal source do not arrive independently of one another. Splitting the light of a source between two photodetectors and correlating their output currents, Hanbury Brown and Twiss found an excess of coincidences at zero delay over the rate that statistically independent arrivals would give, decaying away over the coherence time of the light [1083]. The result was disputed on the ground that photons detected at separate places should know nothing of each other, and it is nevertheless there. The same measurement made on electrons leaving a mesoscopic beam splitter gives the opposite sign, a *deficit* of coincidences [1975]. The correlation is a two-particle effect with no one-particle counterpart: neither detector alone shows anything unusual, and the sign of the correlation between them reports the exchange parity of the particles directly.

Derivation pending #97

The two-particle correlation of a chaotic source: the sum over the two indistinguishable histories by which one particle from each of two source points reaches the two detectors, the factor of two it produces in the zero-delay coincidence rate for symmetric states, and its replacement by zero for antisymmetric ones, together with the loss of the effect once the path difference exceeds the coherence length

83.7 Consequences for bulk matter

83.7.1 Stability of matter

[Reserved: that the ground-state energy of N electrons and N nuclei is bounded below by a constant times N — so that bulk matter neither collapses nor releases unbounded energy on assembly — is a theorem, and it is false without the exclusion principle. Dyson and Lenard proved it first [1345]; Lieb and Thirring gave the proof that yields a realistic constant, via their kinetic-energy inequality [1554]. The section states the theorem, records that bosonic "matter" would instead have energy growing like $-N^{7/5}$, and refers the proof to Appendix A. This is the sharpest answer available to the question of why atoms have a size and why matter is extended and nearly incompressible.]

83.7.2 Degeneracy pressure

[Reserved: the pressure of a degenerate Fermi gas at zero temperature, derived from the exclusion principle alone; its nonrelativistic and ultrarelativistic forms and the resulting Chandrasekhar limit of about 1.4 *solar masses for a white dwarf [676]; the neutron-star analogue; the same mechanism, at laboratory densities, as the incompressibility of solids and the bulk modulus of a metal. Astrophysical development in Chapters 49 and 52, thermodynamic development in Chapter 120.]*

Phenomenon 83.6 (White dwarfs, and a limiting mass)**.** There exist stars whose mass is of the order of the Sun's and whose radius is of the order of the Earth's, so that their mean density exceeds that of ordinary matter by some six orders of magnitude. They have exhausted their nuclear fuel, they radiate, and they do not contract; and as they cool they still do not contract, so whatever supports them is not thermal pressure. What supports them is the pressure of a degenerate electron gas, which is a consequence of the exclusion principle alone and does not vanish at zero temperature. There is also a ceiling. No white dwarf is observed above about 1.4 times the mass of the Sun, and Chandrasekhar showed that none can exist, because at the densities a larger mass would require the electrons move relativistically and the equation of state softens until it can no longer hold the star up [676].

Derivation pending #98

The degenerate electron gas: its zero-temperature pressure obtained from the exclusion principle and the filling of momentum space up to the Fermi momentum, the change of the exponent relating pressure to density once that momentum exceeds the electron mass times the speed of light, and the resulting limiting mass, which is of the order of the cube of the Planck mass divided by the square of the nucleon mass

Chapter 84

Entanglement and Bell Tests

The tensor-product structure of composite systems was written down in Chapter 77 without comment. Its consequences are the subject of this chapter, and they are the least classical thing in physics. Almost every state of a composite system fails to factorize; Schrödinger called such states entangled and said of them, correctly, that they are not one but *the* characteristic trait of quantum mechanics [760]. Einstein, Podolsky and Rosen had just argued from the same states that the quantum description must be incomplete [753]. For thirty years the dispute was regarded as philosophical. It stopped being philosophical in 1964, when Bell showed that *any* theory in which the outcomes are fixed by local variables carried by the particles obeys an inequality that quantum mechanics violates [1271]. The question became experimental, and it has been answered.

This chapter develops the theory: what entanglement is, what Bell's theorem does and does not prove, what quantum mechanics may not do with entanglement (signal, clone, share it freely), and how much of it a state contains. The experimental record — Freedman and Clauser, Aspect, and the loophole-free tests of 2015 — lives in Chapter 89, and the reader who wants the evidence before the formalism should read that chapter first. What this chapter insists on is the logic connecting the two: a measured violation excludes a precisely specified class of theories and nothing wider, and the treatise's position on the wider claims is stated in Chapter 85. Standard references are [1788, 1872, 2161]; the modern review is [2148, 2232].

Derivation pending #99

Entanglement and Bell Tests: all derivations of this chapter are pending.

84.1 Entangled states

84.1.1 Tensor products and separability

[Reserved: the composite Hilbert space $\mathcal{H}_A \otimes \mathcal{H}_B$ and the dimension count that makes product states a measure-zero subset; the definition of a pure entangled state as one that is not a product; the extension to mixed states, where separable means a convex combination of products, due to Werner [1829], together with his example of a mixed state that is entangled yet admits a local hidden-variable model for projective measurements — so that entanglement and Bell violation are not *the same property; the two-qubit Bell basis as the working example throughout.]*

84.1.2 The Schmidt decomposition

[Reserved: every pure bipartite state can be written $\sum_i \sqrt{p_i}\,|a_i\rangle \otimes |b_i\rangle$ with orthonormal local bases, the coefficients being the singular values of the coefficient matrix; the underlying decomposition is Schmidt's [338] and the linear algebra is that of Chapter 5; the Schmidt rank as the first, coarsest measure of entanglement; that the two reduced states share their spectrum, which is why bipartite entanglement entropy is unambiguous.]

84.1.3 Reduced states, purification and steering

[Reserved: the partial trace and the reduced density matrix as the unique object reproducing all local statistics; entanglement as the statement that the parts are mixed while the whole is pure; purification and its essential uniqueness up to a local unitary. Schrödinger's observation that the distant party can steer the local ensemble into any decomposition of the reduced state [759], made precise as the Hughston–Jozsa–Wootters theorem [1868]; that steering changes the ensemble description but not a single measurable local probability, which is the seed of Section 84.4.1.]

84.2 The EPR argument and the replies

84.2.1 Einstein, Podolsky and Rosen

[Reserved: the 1935 argument in its own terms [753]: the sufficient criterion of reality, the locality assumption, the position–momentum correlated two-particle state, and the conclusion that either the description is incomplete or reality depends on what is measured elsewhere; a careful statement of the premises, since almost every later dispute is about which of them a Bell test refutes; Bohr's reply of the same year, which denied the criterion of reality rather than the locality assumption; the reading of the paper Einstein himself preferred, given in his later correspondence, in which the target is separability rather than completeness.]

84.2.2 Verschränkung, the cat, and the amplification argument

[Reserved: Schrödinger's response in Die Naturwissenschaften *[760], which introduced the term* Verschränkung*, framed entanglement as the failure of the whole to be determined by its parts, and used the cat as an* amplification *argument — that nothing in the linear dynamics stops a microscopic superposition from being coupled to a macroscopic degree of freedom; the companion Cambridge paper with the steering theorem [759]; the point, still worth making, that the cat is an argument about the reach of linearity and not a joke about observers, and that its modern quantitative version is the interference of massive molecules and the collapse bounds of Chapter 85.]*

84.2.3 Bohm's spin version

[Reserved: Bohm's replacement of the continuous EPR variables by two spin-$\frac{1}{2}$ particles in the singlet [978], which is what made the argument experimentally tractable: a finite-dimensional Hilbert space, a rotationally invariant state, and the correlation $-\cos\theta$ between spin components along directions at angle θ, with the spin formalism of Chapter 79 and the analyser of Chapter 80. Every subsequent inequality and every experiment uses this version.]

Phenomenon 84.1 (Singlet correlations)**.** Two spin-$\frac{1}{2}$ particles prepared in the singlet state — and the polarization-entangled photon pairs that stand in for them in the laboratory — display two properties at once. Each particle taken by itself is unpolarized: whatever direction $\hat{\boldsymbol{a}}$ its analyser is set to, the outcomes ± 1 occur with equal frequency, so a one-sided

record carries no trace of the setting used on the other side. Taken in pairs the outcomes are correlated, and the correlation depends on nothing but the angle θ between the two analyser directions,

$$E(\hat{\boldsymbol{a}},\hat{\boldsymbol{b}}) = \langle \Psi^- | \, (\boldsymbol{\sigma}\cdot\hat{\boldsymbol{a}}) \otimes (\boldsymbol{\sigma}\cdot\hat{\boldsymbol{b}}) \, | \Psi^- \rangle = -\hat{\boldsymbol{a}}\cdot\hat{\boldsymbol{b}} = -\cos\theta\,, \tag{84.1}$$

so that parallel analysers give opposite results on every single pair while orthogonal analysers give no correlation at all. This is the Einstein–Podolsky–Rosen situation [753] in the two-outcome form that made it experimentally decidable, and Equation (84.1) is the curve against which every measurement of Chapter 89 is read.

Derivation. Write $|\Psi^-\rangle = (|{\uparrow\downarrow}\rangle - |{\downarrow\uparrow}\rangle)/\sqrt{2}$, the unique two-spin state annihilated by the total spin $\boldsymbol{S} = \frac{\hbar}{2}(\boldsymbol{\sigma}_1 + \boldsymbol{\sigma}_2)$. From $(\boldsymbol{\sigma}_1+\boldsymbol{\sigma}_2)^2\,|\Psi^-\rangle = 0$ and $\boldsymbol{\sigma}^2 = 3\,\mathbb{1}$ on each factor, $6 + 2\,\boldsymbol{\sigma}_1\cdot\boldsymbol{\sigma}_2$ annihilates $|\Psi^-\rangle$, so

$$\langle \Psi^- | \, \boldsymbol{\sigma}_1\cdot\boldsymbol{\sigma}_2 \, | \Psi^- \rangle = -3\,. \tag{84.2}$$

The singlet carries zero total angular momentum and is therefore invariant under simultaneous rotations of both factors. Consequently the tensor $T_{ij} = \langle \Psi^- | \, \sigma_1^i \sigma_2^j \, | \Psi^- \rangle$ is an invariant tensor of SO(3) of rank two, and the only such tensor is δ_{ij} up to a factor: $T_{ij} = \lambda\,\delta_{ij}$. Taking the trace and using Equation (84.2) gives $3\lambda = -3$, hence $\lambda = -1$ and

$$E(\hat{\boldsymbol{a}},\hat{\boldsymbol{b}}) = a_i b_j T_{ij} = -\hat{\boldsymbol{a}}\cdot\hat{\boldsymbol{b}}\,,$$

which is Equation (84.1). For the one-sided statistics, the reduced state is $\rho_A = \mathrm{tr}_B\,|\Psi^-\rangle\langle\Psi^-| = \frac{1}{2}\mathbb{1}$, so $\mathrm{tr}(\rho_A\,\boldsymbol{\sigma}\cdot\hat{\boldsymbol{a}}) = 0$ for every $\hat{\boldsymbol{a}}$: each analyser on its own sees a fair coin, which is what makes the correlation invisible until the two records are compared. □

84.3 Bell's theorem

84.3.1 Local hidden variables and the 1964 inequality

[Reserved: the precise hypotheses — a shared variable λ with some distribution, outcome functions $A(a,\lambda)$ and $B(b,\lambda)$ depending only on the local setting (parameter independence) and not on the distant outcome (outcome independence), and settings statistically independent of λ (measurement independence) — and the derivation of Bell's original three-setting inequality on the perfect-anticorrelation singlet [1271]; the quantum prediction $-\cos\theta$ violating it; the fact, essential to the argument's force, that no feature of the quantum formalism is used in deriving the bound.]

84.3.2 CHSH: the form that is actually measured

[Reserved: the four-correlator combination $S = E(a,b) + E(a,b') + E(a',b) - E(a',b')$ with $|S| \le 2$ for any local model, due to Clauser, Horne, Shimony and Holt [1400], which drops the perfect-correlation idealization and so applies to real detectors; the Clauser–Horne form written for detection probabilities rather than correlations [1522]; Fine's theorem, that satisfying the full set of CHSH inequalities is equivalent to the existence of a joint distribution for all four observables [1687], which identifies exactly what a violation refutes; the quantum maximum $2\sqrt{2}$ at the optimal analyser angles; Gisin's theorem that every entangled pure state violates some CHSH inequality [1845].]

Phenomenon 84.2 (Violation of the CHSH bound)**.** Let each station of a two-particle experiment choose between two analyser settings, recording an outcome ± 1, and let $E(a,b)$ be the measured correlation for the setting pair (a,b). The combination

$$S = E(a,b) + E(a,b') + E(a',b) - E(a',b') \tag{84.3}$$

cannot exceed 2 in modulus in any theory in which each outcome is fixed by variables carried by the particles and is unaffected by the setting chosen at the distant station [1271]. Values of S above 2 are what is measured. They were first reported from atomic-cascade photon pairs in the early 1970s, sharpened with two-channel polarizers and with analysers switched while the photons were in flight in the early 1980s, and have since been reproduced with independent sources, analysers and detector technologies; the record, with its uncertainties and its residual assumptions, is Chapter 89. Nature therefore admits no description of the assumed kind.

Derivation. The bound is the whole of the argument, and it uses no quantum mechanics whatever. Suppose the outcomes are functions $A(a,\lambda)$, $A(a',\lambda)$, $B(b,\lambda)$, $B(b',\lambda)$ taking the values ±1, each depending on the setting on its own side and on a variable λ distributed with some density $p(\lambda) \geq 0$, $\int \mathrm{d}\lambda\, p(\lambda) = 1$, so that $E(a,b) = \int \mathrm{d}\lambda\, p(\lambda)\, A(a,\lambda) B(b,\lambda)$. For a fixed λ collect the four products and factor,

$$S(\lambda) = A\big[B + B'\big] + A'\big[B - B'\big]\,, \tag{84.4}$$

suppressing the arguments. Since B and B' each take only the values ±1, either $B = B'$, in which case $B - B' = 0$ and $|B + B'| = 2$, or $B = -B'$, in which case $B + B' = 0$ and $|B - B'| = 2$. In both cases exactly one bracket vanishes and the other has modulus 2; with $|A| = |A'| = 1$ this gives $|S(\lambda)| = 2$ for every λ. Averaging preserves the bound,

$$|S| = \left| \int \mathrm{d}\lambda\, p(\lambda)\, S(\lambda) \right| \leq \int \mathrm{d}\lambda\, p(\lambda)\; |S(\lambda)| = 2\,.$$

Quantum mechanics is not a theory of that form and is not bound by it. Insert the singlet correlation Equation (84.1) with coplanar analyser directions at angles $a = 0$, $a' = \pi/2$, $b = \pi/4$ and $b' = -\pi/4$: then $E(a,b) = E(a,b') = E(a',b) = -1/\sqrt{2}$ while $E(a',b') = -\cos(3\pi/4) = +1/\sqrt{2}$, and Equation (84.3) gives $S = -4/\sqrt{2} = -2\sqrt{2}$. The predicted excess over the local bound is a factor $\sqrt{2}$, not a marginal effect — which is why the question could be settled at all with the photomultipliers of a few percent quantum efficiency available when it was first asked. □

84.3.3 The quantum bound

[Reserved: Tsirelson's proof that quantum mechanics itself caps $|S|$ at $2\sqrt{2}$ [1650], so that the theory is nonlocal in Bell's sense but not maximally so; the Popescu–Rohrlich box, a hypothetical device that reaches the algebraic maximum 4 without permitting signalling [1886], which shows that no-signalling alone does not single out quantum correlations and turns "why $2\sqrt{2}$?" into a live question with several proposed information-theoretic answers; the experimental status, namely that no measured correlation has ever exceeded the Tsirelson bound.]

Phenomenon 84.3 (The data stop at $2\sqrt{2}$)**.** No experiment has produced a CHSH parameter above $2\sqrt{2}$. This is not forced by relativity: the algebraic maximum of Equation (84.3) is 4, and correlation tables reaching 4 can be written down that leave both marginals uniform and so permit no signalling. Nor is it forced by the existence of a violation, which only requires $|S| > 2$. What is observed is that the correlations of Nature stop precisely where the quantum formalism says they stop, so that the measured $|S|$ is bounded above and below by two independent theoretical statements and lies strictly between them [2253, 2254, 2260].

Derivation. Represent the two alternative settings on one side by Hermitian operators A, A' and those on the other side by B, B'. Outcomes ±1 mean $A^2 = A'^2 = B^2 = B'^2 = \mathbb{1}$, hence

$\|A\| = \|A'\| = \|B\| = \|B'\| = 1$; operators belonging to different tensor factors commute. The CHSH observable is $\hat{S} = A \otimes (B + B') + A' \otimes (B - B')$, and $S = \mathrm{tr}(\rho \hat{S})$. Squaring, and using $(B \pm B')^2 = 2\,\mathbb{1} \pm (BB' + B'B)$ together with $(B + B')(B - B') = [B', B]$ and $(B - B')(B + B') = [B, B']$, the anticommutators cancel between the two diagonal terms and the cross terms combine into a single commutator product,

$$\hat{S}^2 = 4\,\mathbb{1} - [A, A'] \otimes [B, B'] \ . \tag{84.5}$$

Each commutator obeys $\|[A, A']\| \leq 2\,\|A\|\,\|A'\| = 2$, so $\left\|\hat{S}^2\right\| \leq 4 + 2 \cdot 2 = 8$ and therefore

$$|S| \leq \left\|\hat{S}\right\| = \sqrt{\left\|\hat{S}^2\right\|} \leq 2\sqrt{2}\,,$$

for every state and every choice of settings. Note where the bound comes from. If the two alternative settings at a station commuted, Equation (84.5) would read $\hat{S}^2 = 4\,\mathbb{1}$ and give back $|S| \leq 2$, the local bound. The whole violation, and its exact size, is therefore the non-commutativity of the two measurements a single station chooses between — not any influence travelling between the stations. □

84.3.4 GHZ: contradiction without inequalities

[Reserved: the three-particle state for which local realism and quantum mechanics disagree on a single *run rather than on an average, so that the refutation is algebraic rather than statistical [1821], in the accessible presentation of [1832]; the sign contradiction obtained from four perfectly correlated measurement settings; the Mermin inequality as its statistical version and its exponentially growing violation with particle number; the experimental realization belongs to Chapter 89.]*

84.3.5 What a violation excludes — and what it does not

[Reserved: the disciplined statement, which this treatise treats as the whole point of the chapter. A measured violation, closing the locality and detection loopholes, refutes the conjunction of the hypotheses of Section 84.3.1. It does not *establish superluminal causation, since Section 84.4.1 forbids it; it does not select any interpretation of Chapter 85; it does not refute determinism as such, only local determinism. The residual assumptions — measurement independence, or "freedom of choice" — are not removable in principle, and the cosmic-Bell experiments of Chapter 89 only push the correlation back in time. The honest summary is that local hidden-variable theories are excluded as a class, which is a statement about theories and is the strongest one the data support.]*

84.4 What entanglement may not do

84.4.1 No-signalling

[Reserved: the theorem that the local statistics at A are independent of the setting chosen at B, because the reduced state is unchanged by any local operation at B — proved directly from the partial trace and the trace-preserving property of local channels; the argument as given by Ghirardi, Rimini and Weber [1653] and the careful analysis of the several distinct locality conditions by Eberhard [1619]; the consequence that entanglement carries no message and that relativistic causality of Chapter 39 is intact; that this is a theorem about quantum mechanics, not a postulate imposed on it.]

Phenomenon 84.4 (No signal accompanies the correlation)**.** In every experiment on entangled pairs, the singles rate recorded at one station is independent, within statistics, of

which setting the distant station chose. The check is made directly in the data of a Bell test as a control on the apparatus [2253, 2254, 2260], and it has never failed. However strongly the two records are correlated, neither party can send the other a message by choosing a setting; the correlation appears only when the two records are brought together and compared, which requires a classical channel and therefore takes at least the light travel time between the stations.

Derivation. Everything one party can measure is computed from the reduced state $\rho_A = \operatorname{tr}_B \rho$. Let the distant party act on their factor alone: the most general such operation is a trace-preserving map $\mathcal{E}_B$, and choosing a setting and performing a measurement whose outcome is not communicated is one instance of it. The joint state becomes $(\mathrm{id}_A \otimes \mathcal{E}_B)\rho$. Then for any observable X of the first factor,

$$\operatorname{tr}\big[(X \otimes \mathbb{1})\,(\mathrm{id}_A \otimes \mathcal{E}_B)\rho\big] = \operatorname{tr}\big[X\ \operatorname{tr}_B \rho\big] = \operatorname{tr}\big[(X \otimes \mathbb{1})\,\rho\big]\,, \tag{84.6}$$

because $\operatorname{tr}_B\big[(\mathrm{id}_A \otimes \mathcal{E}_B)\rho\big] = \operatorname{tr}_B \rho$ whenever $\mathcal{E}_B$ preserves the trace. Hence ρ_A, and with it every local probability, is untouched by anything done at B. The argument uses only linearity and trace preservation, so it holds for every state, every setting and every separation. No-signalling is thus a theorem of the formalism, not a relativistic postulate bolted onto it — which is why Phenomenon 84.2 creates no conflict with the causal structure of Chapter 39. □

84.4.2 No-cloning

[Reserved: the impossibility of a unitary that copies an unknown state, proved in two lines from linearity, given independently by Wootters and Zurek [1708] and by Dieks [1686], both motivated by closing a proposed superluminal-signalling scheme; the no-broadcasting and no-deleting extensions; the constructive consequences — unconditional security of quantum key distribution [1843] and the necessity of teleportation rather than copying in Section 84.6.1; the relation to the distinguishability of non-orthogonal states.]

Phenomenon 84.5 (Unknown states are not copied)**.** No apparatus has ever been built that accepts one system in an unknown state and returns two systems in that same state. The regularity shows itself wherever a quantum signal is amplified: a laser amplifier, an optical repeater or an eavesdropper's tap always adds noise, and the minimum noise it adds is exactly the amount required to stop the output being a faithful pair of copies. It is the reason a key carried by single quanta cannot be intercepted and forwarded undetected, and the reason that the transfer of an unknown state in Section 84.6.1 must destroy the original.

Derivation. Suppose a unitary U on system plus blank register satisfied $U\big(|\psi\rangle \otimes |0\rangle\big) = |\psi\rangle \otimes |\psi\rangle$ for every state $|\psi\rangle$ of the system. Apply it to two states $|\psi\rangle$ and $|\phi\rangle$ and take the inner product of the two results. A unitary preserves inner products, and the inner product of a tensor product is the product of the inner products, so with $z = \langle\psi|\phi\rangle$,

$$z = \langle\psi|\phi\rangle \cdot \langle\psi|\phi\rangle = z^2\,, \tag{84.7}$$

whence $z \in \{0, 1\}$: the only families a single unitary can copy are sets of mutually orthogonal states, which is to say classical alphabets, since a state drawn from an orthogonal set can be measured without disturbance and then rewritten at will. Nothing but linearity and unitarity was used, so the conclusion is exactly as robust as the superposition principle of Chapter 77; in particular it cannot be evaded by a cleverer device. □

84.4.3 Monogamy

[Reserved: entanglement cannot be freely shared. The Coffman–Kundu–Wootters inequality bounds the sum of the squared concurrences of A with B and with C by the squared concurrence

of A with the pair, the deficit defining the three-tangle [1986]; the extreme case, that a maximally entangled pair is uncorrelated with everything else, which is exactly what makes device-independent key distribution possible; the general N-party statement and the role of monogamy in bounding how many parties can jointly violate a Bell inequality.]

84.5 Quantifying entanglement

84.5.1 Separability criteria

[Reserved: the positive-partial-transpose necessary condition of Peres [1928] and the Horodecki proof that it is also sufficient in dimensions 2×2 and 2×3, via the theory of positive but not completely positive maps [1923]; bound entangled states in higher dimensions, which are entangled yet have positive partial transpose and cannot be distilled; entanglement witnesses as the operational form of the criterion, being the observables a laboratory actually measures.]

84.5.2 Entropy of entanglement

[Reserved: for a pure bipartite state, the von Neumann entropy of the reduced state, $S = -\operatorname{tr} \rho_A \log \rho_A$, as the unique measure satisfying the natural axioms; its operational meaning as the asymptotic rate of Bell-pair distillation and of entanglement dilution [1915]; the maximum $\log d$ and the maximally entangled states attaining it; area laws in extended systems and the pointer to Chapter 109 for the field-theoretic case, where the same quantity is ultraviolet divergent and its regularization is a substantive physical question.]

84.5.3 Mixed-state measures

[Reserved: entanglement of formation and distillable entanglement and the gap between them [1915]; Wootters' closed formula for the entanglement of formation of an arbitrary two-qubit state via the concurrence [1964]; the negativity and logarithmic negativity, computable from the partial transpose [2040]; the axioms an entanglement monotone must satisfy — invariance under local unitaries, non-increase under local operations and classical communication — and the fact that no single number orders mixed states completely; the review [2148] as the reference for the full landscape.]

84.6 Entanglement as a resource

84.6.1 Teleportation and entanglement swapping

[Reserved: the protocol of Bennett and co-workers [1860], in which a shared Bell pair plus two classical bits transfer an unknown qubit exactly, destroying the original — and so respecting both Section 84.4.2 and Section 84.4.1, since without the classical message the output is the maximally mixed state; the first photonic realization [1935]; entanglement swapping, which entangles two systems that never interacted and which relies on the two-photon interference of Chapter 83; the resource accounting that makes "one ebit" a physical unit.]

Phenomenon 84.6 (Teleportation of an unknown state)**.** A qubit in a state unknown to everyone involved can be transferred from one system to a second system that never interacted with it, using a previously shared entangled pair and two bits sent over an ordinary classical channel. What is observed is a reconstructed state whose fidelity with the input exceeds 2/3, the highest that any strategy of measuring the input and transmitting a classical description of the result can achieve; the original is destroyed in the process. The protocol has been realized with photon polarization [1935], with trapped ions and atoms,

and with superconducting circuits, and the transfer succeeds only after the classical message arrives.

Derivation. Let the unknown state be $|\psi\rangle = a\,|0\rangle + b\,|1\rangle$ on system 1, and let systems 2 and 3 share $|\Phi^+\rangle = (|00\rangle + |11\rangle)/\sqrt{2}$, with 1 and 2 held by the sender and 3 by the receiver. Expand the product $|\psi\rangle_1 \otimes |\Phi^+\rangle_{23}$ in the Bell basis of the pair $(1,2)$, using $|00\rangle = (|\Phi^+\rangle + |\Phi^-\rangle)/\sqrt{2}$ and its three companions. Collecting terms,

$$|\psi\rangle_1 \otimes \left|\Phi^+\right\rangle_{23} = \tfrac{1}{2}\Big[\left|\Phi^+\right\rangle_{12} \otimes (a\,|0\rangle + b\,|1\rangle)_3 + \left|\Phi^-\right\rangle_{12} \otimes (a\,|0\rangle - b\,|1\rangle)_3 + \left|\Psi^+\right\rangle_{12} \otimes (a\,|1\rangle + b\,|0\rangle)_3 + \left|\Psi^-\right\rangle_{12} \otimes (a\,|1\rangle - b\,|0\rangle)_3\Big]. \tag{84.8}$$

The four Bell states are orthonormal and enter with equal weight, so a measurement of $(1,2)$ in that basis yields each of the four outcomes with probability $1/4$ — a distribution independent of a and b, which is why the sender learns nothing about the state and why the outcome, taken alone, is useless. Conditioned on the outcome, system 3 is left in $\mathbb{1}\,|\psi\rangle$, $\sigma_z\,|\psi\rangle$, $\sigma_x\,|\psi\rangle$ or $\sigma_x\sigma_z\,|\psi\rangle$ respectively, each of which the receiver undoes by applying the inverse of that operator once the two bits naming the outcome have arrived. The correction is a fixed unitary chosen from a list of four; no knowledge of a and b enters it.

Three consistency checks close the argument. Before the message arrives, the receiver's state is the average of the four branches, $\frac{1}{4}\sum_k \sigma_k\,|\psi\rangle\langle\psi|\,\sigma_k = \frac{1}{2}\mathbb{1}$, independent of $|\psi\rangle$ — so nothing has been signalled, in accordance with Phenomenon 84.4, and the classical channel really is indispensable. The input system emerges maximally entangled with the sender's half of the pair and no longer carries $|\psi\rangle$, so nothing has been copied, in accordance with Phenomenon 84.5. And the two classical bits are not a disguised description of $|\psi\rangle$, which would need infinitely many bits: they are a description of the sender's measurement outcome, whose distribution Equation (84.8) shows to be uniform. □

84.6.2 Device-independent protocols

[Reserved: the observation that a Bell violation certifies properties of a device without any assumption about its internals — the strongest practical consequence of Section 84.3; certified randomness generation from a measured CHSH value [2163], and device-independent key distribution descending from Ekert's protocol [1843]; self-testing, whereby a maximal violation forces the state and measurements to be the singlet and the optimal analysers up to a local isometry; the honest caveat that the certification assumes no communication between the devices, which is a physical assumption about the laboratory and not a mathematical one.]

84.7 The experimental record

[Reserved: a short bridging section, not a duplicate of Chapter 89, which owns the apparatus, the data tables and the uncertainties. It records only the logical sequence: the first violation with atomic cascade photons by Freedman and Clauser [1471]; the switching experiment that first closed the locality loophole in a time-varying way [1679]; the loophole-free experiments of 2015, the first to close locality and detection simultaneously [2254]; and the resulting status of local realism as an excluded class of theories. Each entry names the loophole it addressed, so that the chapter's logical claim in Section 84.3.5 can be checked against what was actually measured.]

Chapter 85

Interpretations (Evidence-Anchored)

The formalism of Chapter 77 predicts, with no known exception, the outcome statistics of every experiment in this book. What it does not do is say what happens in a single run. The unitary evolution is linear and deterministic; the measurement postulate is nonlinear and probabilistic; and the theory as usually stated does not say which of the two applies when, nor where the boundary between system and apparatus lies. That is the measurement problem, and it is the only reason this chapter exists. It is placed after entanglement (Chapter 84) because the sharpest constraints on the question are Bell-type theorems, and before decoherence (Chapter 87) because decoherence is the piece of the answer that is not interpretation at all but ordinary quantum dynamics of an open system.

This chapter is written under a rule that the rest of the treatise applies silently and that is worth stating aloud here. *What experiment constrains is physics; what it does not constrain is interpretation, and this book will label it as such.* A great deal of the subject is genuinely empirical — Gleason's theorem [1111], Kochen–Specker contextuality [1353], Bell's analysis of von Neumann's impossibility proof [1324], the PBR theorem [2199], Leggett–Garg tests [1759], the whole decoherence programme [1440, 2055], and above all dynamical collapse models [1772], which make numerically different predictions and are being ruled out region by region [2366, 2377]. The remainder — whether the wavefunction is a thing, whether the other branches exist, whether probabilities are credences — has, at present, no experiment attached. Both kinds of statement appear below, and the ledger in Section 85.6 says which is which. Standard references are [1731, 1788, 1872]; for decoherence, [2112]; for collapse models, [2212].

Derivation pending #100

Interpretations (Evidence-Anchored): all derivations of this chapter are pending.

85.1 The measurement problem

85.1.1 The Born rule

[Reserved: Born's probabilistic reading of the wavefunction, introduced in a footnote of the first collision paper [534] and developed in the second [533]; the statement $p = |\langle a|\psi\rangle|^2$ and its generalization to positive operator-valued measures; the fact that this is the only postulate of Chapter 77 that mentions probability, and the question — taken up in Section 85.3 — of whether it can be derived from the others rather than assumed; the experimental tests of the exponent, via three-slit interference bounding higher-order terms in the Born rule, listed with

their bounds.]

85.1.2 The von Neumann chain

[Reserved: von Neumann's model of measurement as a unitary system–apparatus coupling that produces an entangled state, and the separate "process 1" that reduces it [706]; the chain that follows, in which including the next apparatus only moves the cut; the demonstration that the cut may be placed anywhere without changing predictions, which is the reason the problem is hard rather than the reason it is solved; von Neumann's impossibility proof for hidden variables and Bell's identification of the assumption that makes it inapplicable [1324], a case study in Chapter 1 of a theorem being widely believed to say more than it says.]

85.1.3 Three problems, stated separately

[Reserved: the useful decomposition into the problem of outcomes (why one result), the problem of the preferred basis (why this observable is definite), and the problem of statistics (why these probabilities), following Maudlin's separation [1905]; the observation that decoherence solves the second, is silent on the first, and gives at best a circular account of the third; that each proposal in Section 85.3 is best classified by which of the three it addresses and at what cost.]

85.2 What experiment has already settled

85.2.1 Gleason's theorem

[Reserved: that in a Hilbert space of dimension at least three the only probability assignment on the lattice of projections that is additive on orthogonal families is $\mathrm{tr}(\rho P)$ *[1111]; the consequence that the Born rule is not an independent choice once non-contextual additivity is granted, and the equally important consequence that dimension two is exempt; the modern Busch–Caves–Fuchs–Schack strengthening to POVMs, which removes the dimension restriction; the status of this as a mathematical theorem constraining any interpretation, not as an interpretation.]*

85.2.2 Contextuality

[Reserved: the Kochen–Specker theorem, that no assignment of definite values to all observables can reproduce the functional relations among commuting sets [1353]; the original 117*-vector construction and the small modern sets; the distinction from Bell's theorem — contextuality needs no spatial separation and no locality assumption, only compatibility — and the resulting statement that value-definiteness, not merely locality, is what fails; the experimental tests of state-independent contextuality inequalities, and the loopholes (finite precision, compatibility) that keep them weaker than Bell tests.]*

85.2.3 Bell and Leggett–Garg constraints

[Reserved: what the measured Bell violations of Chapters 84 and 89 exclude, restated as a constraint on interpretations rather than on theories: any account must be either non-local, or non-value-definite, or must abandon measurement independence. The temporal analogue of Leggett and Garg [1759], whose assumptions are macroscopic realism and non-invasive measurability, and its violation in superconducting circuits and nuclear spins; the honest caveat that the non-invasiveness assumption is far harder to enforce than spatial separation, so a Leggett–Garg violation is weaker evidence than a Bell violation.]

85.2.4 PBR and the status of the quantum state

[Reserved: the Pusey–Barrett–Rudolph theorem [2199], that if a system has a real physical state determining measurement statistics, and if independently prepared systems have independent physical states, then distinct quantum states cannot correspond to overlapping distributions — so the wavefunction is ontic, not merely a state of knowledge, within that framework; the preparation-independence assumption, which is exactly where epistemic accounts resist; the ontological-models framework of Harrigan and Spekkens in which the statement is formulated; the experimental tests, which bound the degree of overlap rather than settle the question.]

85.2.5 Decoherence

[Reserved: environmental monitoring destroys local coherence on timescales far shorter than any dissipative timescale, as first argued by Zeh [1440], computed for a mass coupled to scattering particles by Joos and Zeh [1757], and developed into einselection and quantum Darwinism by Zurek [2055, 2151]; the derivation belongs to Chapter 87 and is referenced, not repeated, here. The observations: the controlled decay of a mesoscopic cavity superposition [1916], interference of C_{60} molecules [1966], and its controlled destruction by gas collisions [2052]. The crucial negative statement, which this chapter will make plainly: decoherence explains why the interference terms are unobservable and which basis is stable, and it does not *explain why one outcome occurs — the state after decoherence is still an improper mixture.]*

85.3 The interpretive programmes

85.3.1 Copenhagen and complementarity

[Reserved: Bohr's complementarity as announced at Como [593] — that wave and particle descriptions are mutually exclusive and jointly exhaustive, and that the apparatus must be described classically; Heisenberg's uncertainty paper and its microscope argument [576], with the essential correction that the modern inequality is a property of states, proved by Kennard [580] and in general form by Robertson [636], and not a statement about measurement disturbance — a misattribution worth correcting explicitly, since the distinction is measurable and has been measured in weak-measurement experiments; the quantitative wave–particle duality relations that replaced qualitative complementarity; what "Copenhagen" does and does not commit one to, given that Bohr and Heisenberg disagreed.]

85.3.2 Pilot-wave theory

[Reserved: de Broglie's pilot wave as presented at Solvay [567] and Bohm's two-part revival [995, 996]; particles with definite positions guided by the wavefunction through the velocity field of the probability current, with the quantum potential of the polar decomposition already written in Chapter 23; equivariance of the $|\psi|^2$ distribution, so that the theory reproduces every prediction of Chapter 77 exactly and is therefore not distinguishable by experiment; the explicit non-locality of the guidance equation for many particles, which is what Bell's theorem says any such theory must have; the genuine costs — a preferred foliation, and the unsettled relativistic and field-theoretic extension.]

85.3.3 Everett's relative states

[Reserved: Everett's proposal that the unitary evolution is all there is and that measurement outcomes are relative to a branch [1107]; the modern form in which decoherence supplies

the branch structure, so that the preferred-basis problem is answered by Section 85.2.5; the remaining and hardest problem, the status of probability in a theory where every outcome occurs, and the proposed answers — Deutsch's decision-theoretic derivation [1972] and Zurek's envariance argument [2086]; the statement that no experiment currently distinguishes this from any other interpretation, and the fair note that its advocates regard that as its virtue.]

85.3.4 Consistent histories

[Reserved: the reformulation of quantum mechanics in terms of sequences of projections with a decoherence functional whose off-diagonal terms vanish, giving families of histories to which probabilities may consistently be assigned; Griffiths' formulation [1738], Omnès' development [1857], and the Gell-Mann–Hartle decoherent-histories version aimed at closed systems and cosmology [1865]; the set-selection problem — many mutually incompatible consistent families exist and the formalism does not choose — which is where its critics locate the measurement problem in new clothes.]

85.3.5 Epistemic and relational accounts

[Reserved: QBism, in which the quantum state is an agent's personal degree of belief and the Born rule a normative coherence condition, as set out by Fuchs, Mermin and Schack [2233]; Rovelli's relational account, in which state assignments are always relative to a physical system [1929]; the Frauchiger–Renner argument that a set of natural-looking assumptions about agents reasoning about agents is inconsistent [2312], and the several ways different programmes escape it; the treatise's assessment that these are positions on the meaning of probability, on which no experiment discussed in this book bears.]

85.4 Dynamical collapse: interpretation made testable

Collapse models are the reason this chapter is not merely a survey of opinions. They modify the Schrödinger equation itself, so they predict different numbers, and the numbers are being measured.

85.4.1 GRW and continuous spontaneous localization

[Reserved: the Ghirardi–Rimini–Weber model [1772], in which each constituent undergoes spontaneous localization at a rate λ with width r_C, so that an N-particle centre-of-mass superposition collapses N times faster, so that the transition from micro to macro becomes a computed crossover rather than a postulated cut; the parameters originally proposed, a rate λ of $1 \times 10^{-16}/\mathrm{s}$ at a localization length r_C of $1 \times 10^{-7}\,\mathrm{m}$; the continuous stochastic reformulation of Pearle [1825] and its mass-proportional identical-particle version [1831], which is the model actually confronted with data; the unavoidable side effect, that the noise heats matter and makes charged particles radiate, which is what the experiments of Section 85.4.3 exploit; the unresolved problems — energy non-conservation and no relativistic version with a white-noise field.]

85.4.2 Gravitationally induced collapse

[Reserved: Diósi's proposal that the noise is gravitational and the collapse rate therefore fixed by Newton's constant, leaving only a short-distance regulator free [1820], and Penrose's independent argument from the ill-definedness of the time-translation Killing field for a superposition of spacetimes, giving a decay time set by the gravitational self-energy difference

[1926]; the resulting model is parameter-free up to the regulator, which makes it the most falsifiable proposal in the chapter; the relation to Chapter 135, where the question of whether gravity must be quantized at all is examined against evidence.]

85.4.3 The experimental bounds

[Reserved: the section that makes the chapter empirical. The searches use the predicted spontaneous X-ray emission from germanium and the predicted heating of mechanical oscillators. A cantilever-based force sensor at millikelvin temperatures excludes the mass-proportional CSL rate over a wide band of localization lengths [2366]; an underground germanium experiment excludes the parameter-free Diósi–Penrose model outright, requiring a regulator larger than about $5 \times 10^{-11}\,\mathrm{m}$, which is bigger than the size of a nucleus and therefore not a natural choice [2377]; the review [2212] for the full parameter plane. The section will tabulate, in SI, the excluded region of the (λ, r_C) plane with its uncertainties, and state plainly what remains open — which is the point: this is the one part of the subject where a treatise on evidence-based physics has data to report.]

85.5 Adjacent experiments that constrain the discussion

85.5.1 Delayed choice and quantum erasure

[Reserved: Wheeler's delayed-choice gedanken experiment [1629] and its realization with a single-photon interferometer whose output beam splitter is inserted after the photon has entered [2108]; the correct reading — that which-path information and interference are complementary properties of the whole experimental arrangement — and the incorrect reading, that the past is retroactively altered, which the no-signalling theorem of Chapter 84 already excludes; the quantum eraser as the same statement about post-selected subensembles.]

85.5.2 Weak measurement

[Reserved: the weak-value formalism of Aharonov, Albert and Vaidman [1803], in which a weakly coupled pointer, post-selected on a final state, registers a complex quantity outside the eigenvalue spectrum; the reconstruction of average photon trajectories in a two-slit interferometer [2174], which agree with the Bohmian guidance field of Section 85.3.2 — and the careful statement that this confirms a calculation both formalisms share, and selects neither; the use of weak measurements to separate measurement disturbance from the state-intrinsic uncertainty relation of Section 85.3.1.]

85.6 The ledger

[Reserved: the closing section, a two-column table rather than an argument. One column lists the statements this chapter regards as physics because an experiment bears on them — the Born rule and its tested exponent, Gleason, Kochen–Specker, Bell and Leggett–Garg violations, PBR under its stated assumptions, decoherence rates measured against computed ones, and the excluded regions of collapse-model parameter space. The other lists the statements no experiment in this treatise distinguishes: whether an unobserved branch exists, whether the wavefunction is a thing or a credence, whether a particle has a trajectory between measurements. The chapter closes by naming what would move an entry from the second column to the first — an observed deviation from linear evolution, a measured Born-rule violation, or a macroscopic interference experiment beyond the collapse bounds of Section 85.4.3 — and by noting that these are experiments now under construction, not thought experiments.]

Chapter 86

Scattering Theory

Bound states are the exception. Most of what is known about the microscopic world was learned by throwing something at something else and counting what came out at each angle, and scattering theory is the dictionary between that count and the interaction responsible for it. The subject begins with Rutherford's analysis of large-angle alpha deflection [379], which turned a measured angular distribution into the nuclear atom; it acquired its quantum form with Born's collision papers [533, 534], in which the probability interpretation of Chapter 77 and the approximation scheme that still bears his name were introduced in the same breath; and it supplies the language — cross section, phase shift, resonance width, S-matrix — in which nuclear physics (Chapter 107), particle physics (Chapter 116) and cold-atom physics (Chapter 121) all report their results.

The chapter is placed after the approximation methods of Chapter 82, whose time-dependent perturbation theory it uses, and after identical particles (Chapter 83), because the interference between direct and exchange amplitudes is measurable and was measured [663]. It is deliberately nonrelativistic and potential-based; the relativistic S-matrix, its analyticity and its diagrammatic evaluation belong to Chapters 99 and 100, and the formal structure stated here is what those chapters build on. The standard monographs are [1486, 1698]; the elementary treatments are [2287, 2313].

Derivation pending #101

Scattering Theory: all derivations of this chapter are pending.

86.1 What a scattering experiment measures

86.1.1 Cross sections

[Reserved: the differential cross section defined as scattered flux per unit solid angle divided by incident flux per unit area, so that it carries the dimensions of an area per unit solid angle and is quoted in m^2 *per steradian; the integrated and total cross sections; the practical unit of nuclear and particle physics, the barn, defined as exactly* $1 \times 10^{-28}\,\mathrm{m}^2$ *and quoted in this treatise with that conversion given once; luminosity and event rate, connecting the theoretical quantity to what a detector counts; the transport and momentum-transfer cross sections, which are the ones that enter the kinetic theory of Chapter 55 and the transport coefficients of Chapter 124.]*

86.1.2 Kinematics, frames and flux

[Reserved: the reduction of the two-body problem to one body of reduced mass in a fixed potential, as in Chapter 27; the laboratory-to-centre-of-mass transformation of angles and of

the cross section, with the Jacobian written out, since almost every experimental table needs it; elastic, inelastic and reactive channels; the energy variables and the threshold condition; a remark that the relativistic kinematics of Chapter 40 replaces this section wherever the beam energy demands it.]

86.1.3 The scattering amplitude

[Reserved: the asymptotic form $\psi \sim \mathrm{e}^{\mathrm{i}kz} + f(\theta,\phi)\,\mathrm{e}^{\mathrm{i}kr}/r$ *and the identification* $\mathrm{d}\sigma/\mathrm{d}\Omega = |f|^2$ *by computing the probability current of Chapter 77; that the amplitude is complex while the cross section is not, so that a measured angular distribution determines* $|f|$ *and leaves the phase to be inferred — the phase problem that recurs throughout the chapter, and the reason interference experiments such as Section 86.6.2 carry information that a rate measurement cannot.]*

86.2 The stationary formulation

86.2.1 Asymptotic conditions and scattering states

[Reserved: what it means for an interacting state to approach a free state in the far past and far future; the Møller wave operators $\Omega_{\pm}$ *and their isometry [881]; asymptotic completeness — that the ranges of the wave operators together with the bound states exhaust the Hilbert space — stated as the theorem it is and not assumed, with the potentials for which it is proved; the requirement of a potential falling faster than* $1/r$*, which the Coulomb case violates and which is why Section 86.6 is treated separately.]*

86.2.2 Green functions and the Lippmann–Schwinger equation

[Reserved: the outgoing free Green function $-\mathrm{e}^{\mathrm{i}k|\boldsymbol{x}-\boldsymbol{x}'|}/4\pi\,|\boldsymbol{x}-\boldsymbol{x}'|$ *and the* $\mathrm{i}\varepsilon$ *prescription that selects it, with the contour integration of Chapter 8; the integral equation of Lippmann and Schwinger [963] in both wavefunction and operator form, and the transition operator* T *defined by it; the equivalence to the differential equation with a boundary condition, and why the integral form is the useful one; the formal theory of Gell-Mann and Goldberger [1018] relating the stationary and time-dependent pictures, and Dirac's golden rule [572] as the first-order rate that Chapter 82 supplies.]*

86.2.3 The Born series and the Born approximation

[Reserved: iteration of the Lippmann–Schwinger equation; the first Born approximation, in which the amplitude is the Fourier transform of the potential in the momentum transfer $\boldsymbol{q}$ *[533, 534]; the immediate consequences — that a measured angular distribution at high energy is a direct image of the potential, which is the logic of form factors and of Chapter 116; the worked cases, Yukawa and screened Coulomb, with the screened Coulomb limit reproducing the Rutherford formula exactly; the validity criterion, the convergence of the series, and its failure at low energy and for strong potentials, where Section 86.3 takes over.]*

86.3 Partial waves and phase shifts

86.3.1 The partial-wave expansion

[Reserved: expansion of the plane wave and the amplitude in Legendre polynomials for a central potential, with the special functions of Chapter 9; the radial equation, the centrifugal barrier, and the phase shift δ_ℓ *defined by the asymptotic form of the radial function; the amplitude* $f(\theta) = k^{-1}\sum_\ell (2\ell+1)\mathrm{e}^{\mathrm{i}\delta_\ell}\sin\delta_\ell P_\ell(\cos\theta)$*; the systematic use of this expansion for*

slow electrons in gases by Faxén and Holtsmark [575]; the sign of the phase shift as the sign of the potential, and the semiclassical estimate $\ell_{\max} \approx kR$ that says how many partial waves a given energy needs.]

86.3.2 Unitarity and the optical theorem

[Reserved: conservation of probability as unitarity of the partial wave amplitudes, $|S_\ell| = 1$ for purely elastic scattering and $|S_\ell| < 1$ when channels are open; the optical theorem $\sigma_{tot} = (4\pi/k)\,\mathrm{Im}\, f(0)$, derived for potential scattering by Feenberg [697] and stated in the general form covering inelastic channels by Bohr, Peierls and Placzek [829]; the physical reading, that the total removal of flux from the beam is the shadow cast by forward interference; the unitarity bound $\sigma_\ell \le 4\pi(2\ell+1)/k^2$ and its use as a consistency check on measured cross sections.]

86.3.3 Low energy: scattering length and effective range

[Reserved: the dominance of the s wave as $k \to 0$, the scattering length a defined by $\delta_0 \to -ka$, and the low-energy cross section $4\pi a^2$; the effective-range expansion $k\cot\delta_0 = -1/a + \tfrac{1}{2}r_0k^2 + \cdots$, whose model-independence Bethe established [924]; the neutron–proton system as the worked case, with the triplet and singlet scattering lengths of about $5.4\,\mathrm{fm}$ and $-23.7\,\mathrm{fm}$, the deuteron as the near-threshold bound state the first implies and the virtual state the second implies, and the resulting hugely spin-dependent cross section — a number measured before it was understood (Chapter 107); the Feshbach-resonance tuning of a in cold gases [1956, 2153], which is what makes Chapters 121 and 130 quantitative.]

Phenomenon 86.1 (Low-energy scattering sees only one length)**.** As the collision energy is lowered, elastic scattering becomes isotropic — the measured angular distribution flattens until no direction is preferred — and the total elastic cross section approaches a constant,

$$\sigma \longrightarrow 4\pi a^2 \qquad (k \to 0)\,, \tag{86.1}$$

fixed by a single length a characteristic of the colliding pair. Two potentials of quite different shape that happen to share the value of a cannot be told apart by any low-energy measurement. The length need not resemble the range of the force: it may be many times larger, and it may be negative. Both extremes are observed. The neutron–proton system has scattering lengths of opposite sign and very different magnitude in its two spin channels, which is why the low-energy neutron cross section on hydrogen depends so violently on the relative spin orientation; and in a cold atomic gas a is swept through zero and through infinity by an applied magnetic field tuned across a Feshbach resonance [1956], so that the same atoms behave as an ideal gas or as a strongly interacting fluid on demand.

Derivation. Let the potential have finite range R. For $r > R$ the radial function of angular momentum ℓ is a combination of free solutions, and its amplitude inside the range is suppressed by the centrifugal barrier: the regular free solution behaves as $(kr)^{\ell+1}$ near the origin, so the potential is sampled with weight $(kR)^{2\ell+1}$ and

$$\delta_\ell(k) = O\big((kR)^{2\ell+1}\big) \qquad (k \to 0)\,. \tag{86.2}$$

Only $\ell = 0$ survives the limit. Defining $a := -\lim_{k\to 0}\delta_0(k)/k$, the partial-wave amplitude of Section 86.3.1 gives

$$f(\theta) = \frac{1}{k}\mathrm{e}^{\mathrm{i}\delta_0}\sin\delta_0 + O(k^2) \longrightarrow -a\,,$$

which is independent of θ: the scattering is isotropic, and $\sigma = \int |f|^2\,\mathrm{d}\Omega = 4\pi a^2$, which is Equation (86.1). The geometric meaning of a follows from the same limit. Outside the range

the s-wave radial function is $u \propto \sin(kr + \delta_0) \to k\,(r - a)$, so a is the intercept at which the exterior wave function, extrapolated inwards as a straight line, crosses zero. Everything the interior does to the collision is compressed into that one intercept, and a large $|a|$ signals a bound or virtual state lying close to threshold rather than a large force. □

86.3.4 Levinson's theorem

[Reserved: the relation $\delta_\ell(0) - \delta_\ell(\infty) = n_\ell \pi$ between the total change of a phase shift and the number of bound states of that angular momentum [938], with the half-integer modification for a zero-energy resonance in the s wave; the statement that a scattering measurement therefore counts bound states it cannot produce; the inverse-scattering problem, in which the potential is reconstructed from the phase shifts and the bound-state data, solved by Gel'fand and Levitan [982], together with the non-uniqueness that phase-equivalent potentials exhibit.]

86.4 The S-matrix

86.4.1 The S operator and its symmetries

[Reserved: $S = \Omega_-^\dagger \Omega_+$ as the map from incoming to outgoing asymptotic states, with the name and the resonating-group construction due to Wheeler [806] and its elevation to the primary object of the theory — observable quantities only — by Heisenberg [872]; unitarity from probability conservation, symmetry from time reversal and the resulting reciprocity or detailed-balance relation between forward and reverse reactions, and the constraints from rotational invariance, parity and the discrete symmetries of Chapter 105; the observation that this is where Chapter 109 begins.]

86.4.2 Analyticity, poles and dispersion relations

[Reserved: continuation of the partial-wave amplitude to complex energy or complex momentum; poles on the positive imaginary k axis as bound states, poles on the negative imaginary axis as virtual states, and poles on the second sheet as resonances; the branch cuts and the physical sheet; dispersion relations as Cauchy's theorem (Chapter 8) applied with causality, in the form given for light by Kronig [550] and Kramers [581] and transplanted to scattering amplitudes; complex angular momentum and Regge trajectories [1174], named here because the linear mass-squared–spin trajectories of the observed hadron spectrum are their evidence.]

86.5 Resonances

86.5.1 The Breit–Wigner form

[Reserved: the resonant partial-wave amplitude $\Gamma/2$ over $(E_R - E) - \mathrm{i}\Gamma/2$, giving a Lorentzian peak in the cross section of height set by the unitarity bound and width Γ, first written for slow-neutron capture by Breit and Wigner [771]; the mean life $\tau = \hbar/\Gamma$ and the phase shift sweeping through $\pi/2$; partial widths and branching ratios; the worked examples — neutron resonances in heavy nuclei (Chapter 107), the Δ resonance in pion–nucleon scattering, and the Z line shape whose measured width counts the light neutrino species (Chapter 104).]

Phenomenon 86.2 (Resonances)**.** Cross sections are not smooth functions of energy. Superposed on a slowly varying background are peaks whose shape is, to good accuracy, a Lorentzian of full width Γ at half maximum centred on an energy E_R. Slow neutrons incident on a heavy nucleus show hundreds of them within the first few electronvolts; pion–nucleon scattering shows one dominant peak near the first excited state of the nucleon; and the cross section for electron–positron annihilation into hadrons shows the Z. Wherever the

corresponding unstable state can also be timed independently, its mean life is found to be $\tau = \hbar/\Gamma$, and the widths tabulated for hundreds of such states [2427] are read as lifetimes on exactly that understanding. A resonance is therefore not a new kind of object but a state that lives long enough to be counted and too briefly to be caught.

Derivation. Consider a state that, once formed, decays exponentially: its amplitude is $a(t) = \mathrm{e}^{-\mathrm{i}E_R t/\hbar}\mathrm{e}^{-\Gamma t/2\hbar}$ for $t > 0$ and zero before, so that $|a(t)|^2 = \mathrm{e}^{-\Gamma t/\hbar}$ and the mean life is $\tau = \hbar/\Gamma$. Its energy content is the Fourier transform of Chapter 17,

$$\tilde{a}(E) = \frac{1}{2\pi\hbar}\int_0^\infty \mathrm{d}t\, \mathrm{e}^{\mathrm{i}Et/\hbar} a(t) = \frac{1}{2\pi}\,\frac{\mathrm{i}}{(E - E_R) + \mathrm{i}\Gamma/2}\,, \tag{86.3}$$

the integral converging because of the damping factor. Hence the probability of finding the state at energy E is

$$|\tilde{a}(E)|^2 = \frac{1}{4\pi^2}\,\frac{1}{(E - E_R)^2 + \Gamma^2/4}\,, \tag{86.4}$$

a Lorentzian whose full width at half maximum is exactly Γ. The cross section for forming the state through a given entrance channel is proportional to this same distribution, so the observed line shape and the observed lifetime are two readings of one complex pole at $E = E_R - \mathrm{i}\Gamma/2$; the relation $\tau\Gamma = \hbar$ between them is not an approximation but the statement that the two are Fourier conjugates, the time–energy form of the uncertainty relation of Chapter 77. In partial-wave language the same pole appears as an elastic amplitude proportional to $(\Gamma/2)\big[(E_R - E) - \mathrm{i}\Gamma/2\big]^{-1}$, whose modulus attains the unitarity bound of Section 86.3.2 at $E = E_R$ and whose phase shift sweeps through $\pi/2$ there — which is how a resonance is distinguished from a mere bump in the background. □

86.5.2 Time delay

[Reserved: the Eisenbud–Wigner delay $2\hbar\,\mathrm{d}\delta_\ell/\mathrm{d}E$ as the time a wave packet lingers in the interaction region, with Wigner's lower bound on it — causality forbids arbitrarily large negative delay, that is arbitrarily early emission [1081]; Smith's lifetime matrix generalizing this to many channels [1192]; the equivalence of a long delay and a narrow resonance; the modern measurement of photoionization delays on the attosecond scale as the direct observation of this quantity.]

86.5.3 Fano profiles and Feshbach resonances

[Reserved: interference between a resonant and a direct amplitude producing the asymmetric line shape parametrized by Fano's q [1204], with autoionizing states of helium as the original observation; Feshbach's unified theory of nuclear reactions, in which a closed channel supports a quasi-bound state coupled to an open one [1142]; the optical model, in which the average effect of many open channels is a complex potential [1036], and the absorption cross section it predicts; the same physics used as a control knob in ultracold gases [1956, 2153].]

86.6 Coulomb scattering

86.6.1 Rutherford, classically and quantum mechanically

[Reserved: the classical derivation of the $\csc^4(\theta/2)$ law from the hyperbolic orbits of Chapter 27 [379], and the Geiger–Marsden measurements that tested every one of its dependences [404]; the exact quantum solution in parabolic coordinates by Gordon [602], giving the same cross section but a logarithmically distorted phase and a modified asymptotic form, so that the long range of the Coulomb potential invalidates Section 86.2.1 while leaving the measured

rate unchanged — a coincidence of the inverse-square law that deserves to be flagged rather than passed over; the Mott cross section, which adds the spin of a relativistic projectile [633] and whose deviation from Rutherford at large angle is a measurement of nuclear size.]

Phenomenon 86.3 (Large-angle Coulomb scattering)**.** A beam of alpha particles crossing a thin metal foil is deflected, and a small but perfectly reproducible fraction is deflected through more than a right angle — some of it back towards the source [354]. The number counted per unit solid angle at a scattering angle θ obeys

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \left(\frac{Z_1 Z_2 e^2}{16\pi\epsilon_0 E}\right)^2 \frac{1}{\sin^4(\theta/2)}\,, \tag{86.5}$$

with E the kinetic energy in the centre-of-mass frame. Four dependences are asserted here and all four were measured separately: the fourth power of the sine of the half angle, the inverse square of the energy, the square of the charge number of the target, and — for a foil thin enough that a particle meets at most one scatterer — strict proportionality to the foil thickness [404]. Together they establish that the positive charge of an atom is not spread through it but concentrated in a region small enough to permit the close approaches that large angles require.

Derivation. Let the projectile of charge $Z_1 e$ approach a fixed charge $Z_2 e$ with reduced mass μ, asymptotic speed v, energy $E = \tfrac{1}{2}\mu v^2$ and impact parameter b, and write $\kappa = Z_1 Z_2 e^2/4\pi\epsilon_0$ so that the potential is κ/r. The orbit is the repulsive hyperbola of Chapter 27, whose asymptotes make the deflection angle θ given by

$$b = \frac{\kappa}{2E}\cot\frac{\theta}{2}\,. \tag{86.6}$$

The map $b \mapsto \theta$ is monotone, so particles entering the annulus between b and $b + \mathrm{d}b$ leave between θ and $\theta + \mathrm{d}\theta$, and equating the two fluxes, $2\pi b\,|\mathrm{d}b| = (\mathrm{d}\sigma/\mathrm{d}\Omega)\,2\pi\sin\theta\,|\mathrm{d}\theta|$, gives the classical cross-section formula

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{b}{\sin\theta}\left|\frac{\mathrm{d}b}{\mathrm{d}\theta}\right|\,. \tag{86.7}$$

Differentiating Equation (86.6) gives $|\mathrm{d}b/\mathrm{d}\theta| = (\kappa/4E)\sin^{-2}(\theta/2)$, while $\sin\theta = 2\sin(\theta/2)\cos(\theta/2)$ turns the first factor into $b/\sin\theta = (\kappa/4E)\sin^{-2}(\theta/2)$ as well. Their product is

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \left(\frac{\kappa}{4E}\right)^2 \frac{1}{\sin^4(\theta/2)}\,,$$

which is Equation (86.5). The thickness dependence follows from counting: with n scatterers per unit volume in a foil of thickness t, the fraction of the beam deflected into $\mathrm{d}\Omega$ is $nt\,(\mathrm{d}\sigma/\mathrm{d}\Omega)\mathrm{d}\Omega$, linear in t so long as $nt\sigma \ll 1$.

Two remarks belong with the result rather than after it. First, nothing in the derivation refers to $\hbar$, and yet the first Born approximation of Section 86.2.3 and the exact quantum solution in parabolic coordinates both return Equation (86.5) unchanged. That agreement is a peculiarity of the inverse-square law and must not be read as a general licence to compute cross sections classically. Second, the total cross section obtained by integrating Equation (86.5) diverges, because $\sin^{-4}(\theta/2)$ is not integrable at $\theta = 0$: an unscreened Coulomb potential deflects every particle, however distant. Real targets are screened by their own electrons, which cuts the divergence off at an angle of order the inverse of the screening length times the momentum, and it is that screening — not the formula — that makes a total cross section finite. □

86.6.2 Identical particles: Mott scattering

[Reserved: when projectile and target are identical, the direct and exchange amplitudes must be added with the exchange parity of Chapter 83 before squaring, giving an interference term with no classical analogue and a cross section symmetric about 90 *degrees in the centre-of-mass frame; Mott's calculation for two electrons [663] — customarily cited to his 1929 paper, which is a different result — and its confirmation in alpha-on-helium scattering [645], where the interference maximum is a factor of two above the classical sum; the spin-averaged version, weighting singlet and triplet, as the cleanest laboratory demonstration that exchange symmetry is a measurable property of nature and not a bookkeeping convention.]*

Phenomenon 86.4 (Interference between identical colliding particles)**.** When projectile and target are identical, the measured centre-of-mass angular distribution is symmetric about 90° — as it must be, since the two particles arriving at the detectors cannot be told apart — and it is not the sum of the two contributions that a trajectory picture would add. For identical spinless particles, such as an alpha particle scattering on helium, the counting rate at exactly 90° is twice the classical sum, with oscillations on either side of it [645]. For unpolarized identical spin-half particles the interference enters with the opposite sign in the triplet, which has three times the weight of the singlet, and the measured rate at 90° is instead *half* the classical sum. The sign of a term in a cross section is thus a directly measurable consequence of the exchange symmetry postulated in Chapter 83.

Derivation. Detecting a particle at angle θ in the centre-of-mass frame can happen in two ways: the projectile was deflected by θ, amplitude $f(\theta)$, or the projectile was deflected by $\pi-\theta$ and the recoiling target reached the detector, amplitude $f(\pi-\theta)$. The two possibilities end in the same final configuration and are indistinguishable in principle, so the amplitudes are added before squaring, with the relative sign fixed by the required symmetry of the spatial state:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = |f(\theta) \pm f(\pi-\theta)|^2 = |f(\theta)|^2 + |f(\pi-\theta)|^2 \pm 2\,\mathrm{Re}\big[f(\theta) f^*(\pi-\theta)\big]\,, \tag{86.8}$$

the upper sign for a symmetric spatial state — identical spinless bosons, or spin-half particles in the spin singlet — and the lower sign for an antisymmetric one. The classical prediction is the first two terms alone; the third has no classical counterpart, and both expressions are manifestly symmetric under $\theta \mapsto \pi-\theta$.

At $\theta = \pi/2$ the two amplitudes coincide, $f(\theta) = f(\pi-\theta)$, and the arithmetic is immediate. The symmetric case gives $|2f|^2 = 4\,|f|^2$ against a classical $2\,|f|^2$: a factor of two. The antisymmetric case gives exactly zero, however strong the interaction. For unpolarized spin-half particles the four spin states are equally likely, so the singlet carries weight $\frac{1}{4}$ and the triplet $\frac{3}{4}$; since a symmetric spin state (triplet) forces an antisymmetric spatial state and conversely, the spin-averaged rate at 90° is

$$\tfrac{1}{4}\cdot 4\,|f|^2 + \tfrac{3}{4}\cdot 0 = |f|^2\,,$$

one half of the classical $2\,|f|^2$. The measured ratio at 90° therefore distinguishes bosons from fermions with no adjustable parameter, and it does so through the value of the cross section and not through any spin-dependent force. □

86.7 Observed effects the formalism must reproduce

86.7.1 The Ramsauer–Townsend effect

[Reserved: the near-vanishing of the cross section for slow electrons in argon, krypton and xenon near 0.7 eV*, reported independently by Ramsauer [480] and by Townsend and Bailey*

[495]; its explanation as an s-wave phase shift passing through π, so that the leading partial wave contributes nothing — a purely quantum result with no classical counterpart, and historically one of the earliest; the corresponding transparency window and its consequence for electron transport in noble gases; the analogous zero-crossing of the scattering length used to make non-interacting Fermi gases.]

86.7.2 Threshold behaviour

[Reserved: Wigner's threshold laws, giving the energy dependence of a cross section just above the opening of a channel as a power fixed by the angular momentum and the range of the interaction [922]; the $1/v$ law for exothermic reactions on which slow-neutron absorption and the operation of every thermal reactor rest (Chapter 107); cusps at thresholds as a unitarity consequence rather than a dynamical one; the modification for long-range potentials.]

Phenomenon 86.5 (The inverse-velocity absorption law)**.** For an exothermic reaction — one whose outgoing channel is open with a large energy release, radiative neutron capture being the standard case — the cross section measured at low incident energy rises as the inverse of the incident speed over several decades, so that the product σv is constant. Absorption of slow neutrons in boron, in cadmium and in most heavy nuclei follows this law from thermal energies downwards, interrupted only by the resonances of Phenomenon 86.2. The law is why a reactor moderates its neutrons before it asks them to be absorbed: slowing a neutron buys cross section in exact proportion to the slowing (Chapter 107).

Derivation. At low incident energy only the $\ell = 0$ wave reaches the target, by Equation (86.2), so the reaction cross section is

$$\sigma_{\mathrm{r}} = \frac{\pi}{k^2}\left(1 - |S_0|^2\right). \tag{86.9}$$

Write the exterior s-wave radial function as $u(r) = \mathrm{e}^{-\mathrm{i}kr} - S_0\mathrm{e}^{\mathrm{i}kr}$ and let $f = R\,u'(R)/u(R)$ be its logarithmic derivative at the surface $r = R$ of the interacting region. Matching to the interior solution makes f complex — its imaginary part is the flux disappearing into the reaction channel — and, crucially, the reaction channel is open by an energy of nuclear size, so f is insensitive to the tiny incident energy and may be treated as a constant $f = f_1 + \mathrm{i}f_2$ with $f_2 < 0$. Solving the matching condition for S_0,

$$S_0 = \mathrm{e}^{-2\mathrm{i}kR}\,\frac{f + \mathrm{i}kR}{f - \mathrm{i}kR}, \tag{86.10}$$

so that

$$1 - |S_0|^2 = \frac{(f_2 - kR)^2 - (f_2 + kR)^2}{f_1^2 + (f_2 - kR)^2} = \frac{-4f_2\,kR}{f_1^2 + (f_2 - kR)^2},$$

which is positive and, as $kR \to 0$, proportional to k. Substituting into Equation (86.9),

$$\sigma_{\mathrm{r}} \longrightarrow \frac{\pi}{k^2}\cdot\frac{-4f_2R}{f_1^2 + f_2^2}\,k = \frac{\text{constant}}{k} \propto \frac{1}{v}, \tag{86.11}$$

the constant being fixed by the interior alone. The physical content is worth separating from the algebra: the two powers of $1/k$ in Equation (86.9) are the geometric size of the incident s wave, which grows without limit as the wavelength does, while the single factor of k is the small amplitude that wave has at the target. An endothermic reaction behaves quite differently, because there the outgoing momentum vanishes at threshold and supplies its own energy dependence. □

86.7.3 High energy: the eikonal and Glauber regime

[Reserved: the eikonal approximation, in which the phase accumulated along a straight-line path replaces the full solution — the same short-wavelength limit as the optical–mechanical analogy of Chapter 23, here applied to the quantum amplitude; the profile function and the impact-parameter representation; Glauber's multiple-scattering theory for composite targets [1068], which is how the deuteron and then nuclei are treated as collections of scatterers; the black-disc limit and the factor-of-two total cross section, whose shadow term is the optical theorem of Section 86.3.2 in its most physical form; the pointer to the relativistic treatment in Chapters 100 and 102.]

Phenomenon 86.6 (An opaque target removes twice its own area)**.** At wavelengths short compared with the target, and for a target that absorbs nearly everything striking it, the measured total cross section is not the geometric area πR^2 but twice it. One half is accounted for by the absorption itself; the other half is elastic scattering confined to a narrow forward cone of angular width of order $1/kR$ and carrying diffraction minima, from whose spacing R can be read off. The pattern is standard in fast-neutron scattering from nuclei and in high-energy hadron collisions. It has no classical counterpart whatever: a classical opaque disc removes πR^2 of flux, and nothing more.

Derivation. Model the target as a black disc: in the partial-wave expansion of Section 86.3.1 set $S_\ell = 0$ for $\ell \le L$, with $L = kR$, and $S_\ell = 1$ for $\ell > L$. The two standard sums of Section 86.3.2 then read

$$\sigma_{\mathrm{el}} = \frac{\pi}{k^2}\sum_{\ell}(2\ell+1)\,|1-S_\ell|^2 = \frac{\pi}{k^2}\sum_{\ell=0}^{L}(2\ell+1) = \frac{\pi}{k^2}(L+1)^2 \approx \pi R^2\,, \tag{86.12}$$

$$\sigma_{\mathrm{abs}} = \frac{\pi}{k^2}\sum_{\ell}(2\ell+1)(1-|S_\ell|^2) = \frac{\pi}{k^2}(L+1)^2 \approx \pi R^2\,, \tag{86.13}$$

using $\sum_{\ell=0}^{L}(2\ell+1) = (L+1)^2$ and $L = kR \gg 1$. Their sum is $\sigma_{\mathrm{tot}} = 2\pi R^2$. The same answer follows from the optical theorem: the forward amplitude is $f(0) = (2\mathrm{i}k)^{-1}\sum_\ell(2\ell{+}1)(S_\ell{-}1) = \mathrm{i}(L{+}1)^2/2k \approx \mathrm{i}kR^2/2$, so $\sigma_{\mathrm{tot}} = (4\pi/k)\,\mathrm{Im}\,f(0) = 2\pi R^2$, in agreement with Equations (86.12) and (86.13).

The physical reading is the one worth keeping. Behind an absorbing target there is a shadow, and a shadow is not an absence of wave but the superposition of the incident wave with a second wave that cancels it there. That cancelling wave must be produced by the target, and it carries as much flux as the absorbed wave removed. Far downstream the shadow wave spreads out of the forward direction — by the diffraction angle $1/kR$ — and is then counted by a detector at finite angle as elastic scattering. The elastic half of the cross section is thus not an independent process but the necessary accompaniment of absorption, which is why σ_{el} cannot be made smaller than σ_{abs} for a fully absorbing target however the interaction is arranged. □

Chapter 87

Open Quantum Systems and Decoherence

Every system treated so far in this part has been closed: a state vector, a Hamiltonian, and unitary evolution for all time. No system in a laboratory is closed. A trapped ion radiates, a superconducting circuit shares its substrate with two-level defects, a molecule in flight scatters background gas and emits thermal photons, and an apparatus is by construction coupled to whatever will record its reading. This chapter is the systematic theory of what remains when the rest of the world is traced away: the density operator [582, 585], the completely positive maps that carry it forward [1080, 1450, 1541], the master equations that generate those maps in continuous time [1579, 1586], and the loss of interference — decoherence — that they describe [1440, 1676].

Its place in the book is fixed by what it explains. The entanglement of Chapter 84 is here turned from a resource into a nuisance: coupling to an environment entangles a system with degrees of freedom nobody monitors, and the interference terms that make quantum mechanics quantum are not destroyed but exported, becoming inaccessible to any local measurement. That process is fast, and it is quantitative — the measured decay of a mesoscopic superposition in a microwave cavity [1916] and of interference fringes of hot molecules [2060] are the two cleanest instances, and this chapter states what will be derived and what was measured in each. Decoherence explains why the classical world of Chapter 22 looks classical, and this treatise records plainly what it does not do: it does not select an outcome, and the residual question belongs to Chapter 85. The standard monographs are [2023, 2112].

Derivation pending #102

Open Quantum Systems and Decoherence: all derivations of this chapter are pending.

87.1 States of an open system

87.1.1 The density operator

[Reserved: the density operator introduced independently by Landau, from the damping problem in wave mechanics [582], and by von Neumann in his probabilistic reconstruction of quantum mechanics [585, 706]; its defining properties $\rho = \rho^\dagger$, $\rho \geq 0$, $\operatorname{tr}\rho = 1$; expectation values as $\langle A\rangle = \operatorname{tr}(\rho A)$; the von Neumann equation $\mathrm{i}\hbar\,\mathrm{d}\rho/\mathrm{d}t = [H,\rho]$ as the state-operator form of the Schrödinger evolution of Chapter 77; pure states as the projectors $\rho^2 = \rho$ and the purity $\operatorname{tr}\rho^2$ as the scalar that measures departure from them.]

87.1.2 Reduced states and the partial trace

[Reserved: the partial trace as the unique map reproducing the statistics of every observable of the subsystem; the Schmidt decomposition of a bipartite pure state [338] and the equality of the two reduced spectra; purification, so that every mixed state is the restriction of a pure state on a larger space, which is the state-space face of Stinespring's dilation theorem [1080]; the bipartite machinery of Chapter 84 reused here with the roles reversed.]

87.1.3 Proper and improper mixtures

[Reserved: the distinction, due in its sharp form to d'Espagnat [1577], between a statistical mixture prepared by a classical randomizer and the reduced state of one half of an entangled pair; the two are described by the same operator and are indistinguishable by any measurement on the subsystem alone, and they are not the same physical situation — the second can be undone by recohering the environment, as the spin echo of Section 87.7.2 demonstrates. Why this is the point at which decoherence stops short of solving the measurement problem (Section 87.4.6).]

87.1.4 Entropy and mixedness

[Reserved: the von Neumann entropy $S = -\operatorname{tr}(\rho \ln \rho)$ [706], its vanishing exactly on pure states, its invariance under unitary evolution — hence the impossibility of a closed system's entropy growing, which is why an environment is mandatory; subadditivity and the strong subadditivity inequality of Lieb and Ruskai [1508]; entanglement entropy of a bipartition as the reduced-state entropy; the relation to the thermodynamic entropy of Chapter 118.]

87.2 Quantum channels

87.2.1 Complete positivity

[Reserved: why positivity of a map is not enough — the transpose is positive and its extension to half of an entangled pair is not, so a physical map must be completely positive; Stinespring's dilation theorem for completely positive maps on operator algebras [1080]; Choi's finite-dimensional criterion, that a map is completely positive if and only if its Choi matrix is positive semidefinite [1541]; trace preservation, and the CPTP maps as exactly the reduced dynamics obtainable from a unitary evolution on system plus environment in a product initial state.]

87.2.2 The Kraus representation

[Reserved: Kraus's operator-sum form $\rho \mapsto \sum_k K_k \rho K_k^\dagger$ with $\sum_k K_k^\dagger K_k = \mathbb{1}$ [1450]; the non-uniqueness of the operator set up to an isometry, and what is therefore physical about it; the reading of the K_k as measurement outcomes on the environment, which connects the formalism to the generalized measurements of Chapter 77; the number of Kraus operators bounded by the square of the dimension.]

87.2.3 The standard channels

[Reserved: the qubit channels that every later section uses — dephasing, which destroys coherences in a fixed basis while leaving populations untouched; amplitude damping, the channel of spontaneous emission (Chapter 122); the depolarizing channel; and the two relaxation times T_1 and T_2 they define, with the inequality $T_2 \le 2T_1$ that separates energy relaxation from pure dephasing [2161].]

87.2.4 Process tomography

[Reserved: reconstruction of an unknown channel from the states it produces on a tomographically complete input set, the prescription of Chuang and Nielsen [1936]; its first full application to a two-qubit gate [2064]; the scaling of the required number of settings, and randomized benchmarking as the practical substitute; a measured process matrix is what makes "decoherence" a number rather than a word.]

87.3 Master equations

87.3.1 Projection-operator derivations

[Reserved: the exact Nakajima–Zwanzig equation obtained by projecting the total von Neumann equation onto the relevant part of the state [1155, 1197], with its memory kernel and inhomogeneous initial term; Redfield's earlier relaxation theory for magnetic resonance [1128]; the Born and Markov approximations, weak coupling and short environment correlation time, stated as inequalities on time scales rather than as slogans; the secular (rotating-wave) approximation, without which the resulting equation can produce negative probabilities.]

87.3.2 The Lindblad–Gorini–Kossakowski–Sudarshan generator

[Reserved: the theorem fixing the most general generator of a completely positive trace-preserving semigroup, proved for bounded generators by Lindblad [1586] and, in N-level systems, by Gorini, Kossakowski and Sudarshan [1579]: a Hamiltonian commutator plus a dissipator built from jump operators L_k with non-negative rates. Davies's derivation of the semigroup as the weak coupling limit [1523], which is what ties the abstract theorem to a physical bath; the detailed-balance condition that makes the Gibbs state stationary; why no Markovian generator can be exact.]

87.3.3 Quantum Brownian motion

[Reserved: the influence functional of Feynman and Vernon [1251], integrating out a linear bath exactly; the Caldeira–Leggett model of a particle bilinearly coupled to a continuum of oscillators, its Ohmic spectral density and its high-temperature master equation [1716], together with the demonstration that dissipation suppresses macroscopic tunnelling [1666]; the position-diffusion term whose coefficient sets the decoherence rate of a spatial superposition; the spin–boson problem and its phase diagram [1795]; the classical limit returning the Langevin equation of Chapter 119 and the transport coefficients of Chapter 124.]

87.3.4 Unravellings and quantum trajectories

[Reserved: the Monte Carlo wave-function method, in which the Lindblad evolution is recovered as the average over stochastic pure state trajectories punctuated by jumps [1851], and the diffusive alternative of quantum-state diffusion [1854]; that the unravelling is not unique but is fixed by what the environment is actually measured with; the observation of individual quantum jumps in a single trapped ion by electron shelving [1780], which turned an ensemble formalism into a record of single events.]

Phenomenon 87.1 (Individual quantum jumps)**.** The fluorescence of a single trapped ion driven hard on a strong transition, and coupled weakly to a long-lived third level, is not a smoothly decaying signal. It is a random telegraph: the ion is either fully bright or completely dark, it switches between the two abruptly on the time scale of the detector, and the intervals it spends in each are distributed exponentially [1780]. Averaged over many

such records the signal reproduces the smooth exponential relaxation of ensemble theory exactly. The measurement therefore establishes something an ensemble experiment cannot: that the exponential decay law of an ensemble carries no information about whether the individual system changes gradually or in a single event, and that here it does the latter.

Derivation. Let the ion have a bright configuration B, cycling on the strong transition and scattering photons at a rate the detector resolves, and a dark configuration D, shelved in the metastable level and scattering none; let $\Gamma_\uparrow$ be the rate of the transition $B \to D$ and $\Gamma_\downarrow$ that of $D \to B$. Markovian dynamics — the environment forgetting between events, which is the approximation stated as an inequality on time scales in Section 87.3.1 — means the switching probability per unit time is constant, so the probability of still being bright after a time t obeys $\mathrm{d}P/\mathrm{d}t = -\Gamma_\uparrow P$ and

$$P_{\text{no jump}}(t) = \mathrm{e}^{-\Gamma_\uparrow t}\,, \tag{87.1}$$

an exponential distribution of bright intervals with mean $1/\Gamma_\uparrow$, and likewise for the dark ones with $\Gamma_\downarrow$. Every individual record is therefore a two-valued telegraph with exponentially distributed dwell times, which is what is seen. The ensemble probability $p(t)$ of being dark obeys the rate equation

$$\dot{p} = \Gamma_\uparrow(1-p) - \Gamma_\downarrow p\,, \tag{87.2}$$

whose solution relaxes smoothly and exponentially to $\Gamma_\uparrow/(\Gamma_\uparrow+\Gamma_\downarrow)$. The smooth ensemble curve and the discontinuous single record are thus not in conflict — the first is the mean of the second — and no measurement of the first could have decided between them. That is the general content of an unravelling: a stochastic pure-state trajectory whose average is the Lindblad evolution of Section 87.3.2. It is also why the unravelling is not unique. Which trajectories are realized is fixed by what the environment is monitored with, and here it is fixed by the fact that the experiment counts photons. □

87.3.5 Beyond Markov

[Reserved: structured environments in which the memory kernel cannot be collapsed — solid-state qubits with $1/f$ noise, photonic band gaps, strongly coupled molecular aggregates; measures of non-Markovianity based on the backflow of distinguishability [2143] and on divisibility of the dynamical map [2165], and the fact that the two do not agree; why non-Markovian dynamics is not merely a correction but changes what the coherence time means.]

87.4 Decoherence

87.4.1 Environment-induced superselection

[Reserved: Zeh's argument that macroscopic systems are never isolated and that this, not any modification of the theory, is what makes their superpositions unobservable [1440]; Zurek's pointer-basis analysis [1676] and environment-induced superselection [1709], in which the interaction with the environment singles out a preferred basis and forbids superpositions across it; the review that consolidated the programme [2055]; the honest statement that einselection derives a superselection rule from ordinary unitary dynamics and postulates nothing new.]

87.4.2 Pointer states

[Reserved: the pointer states as those least perturbed by the system–environment coupling — exact eigenstates of the interaction in the ideal case, and predictability-sieve selected states in general [1676, 2055]; why position is the pointer observable for a particle scattering photons

and air molecules while energy eigenstates are pointer states for a weakly damped oscillator; coherent states as the pointer states of the harmonic oscillator, the classical limit already met in Chapters 23 and 78.]

87.4.3 Decoherence rates

[Reserved: the scattering formula of Joos and Zeh [1757] for the decay of spatial coherence, linear in the scattering rate and quadratic in the separation for small separations; the resulting estimates, which give decoherence times shorter than relaxation times by enormous factors — a dust grain in air loses spatial coherence over micrometre separations in far less than a nanosecond, while a single atom in ultrahigh vacuum stays coherent for seconds; the collisional, thermal-photon and gravitational channels compared; why the numbers, not the mechanism, are what make classicality inevitable.]

87.4.4 Quantum Darwinism

[Reserved: Zurek's account of objectivity as redundancy — the pointer observable is the one whose record is imprinted many times over in disjoint fragments of the environment, so that many observers can learn it independently without disturbing it [2151]; the redundancy plateau in the partial information plot as the signature; the first laboratory signatures of the plateau in photonic cluster states [2304]; the claim's status as a consequence of unitary dynamics plus a factorized environment, not a new postulate.]

87.4.5 Thermalization of an isolated system

[Reserved: the complementary route to classical statistics, in which the "bath" is the rest of the same closed system — Deutsch's random-matrix argument [1842] and Srednicki's eigenstate thermalization hypothesis [1887], under which each individual energy eigenstate already encodes thermal expectation values; its direct test in an isolated ultracold Bose gas, where the growth of entanglement entropy was measured while the global state stayed pure [2272]; the link forward to the statistical mechanics of Chapter 118 and back to the scattering description of Chapter 86.]

Phenomenon 87.2 (An isolated system thermalizes while staying pure)**.** A small, completely isolated quantum system — an ultracold gas of a few atoms in an optical lattice, prepared in a pure state and shielded from every bath — relaxes so that each local observable takes the value a thermal ensemble would assign it, while the global state remains pure and its evolution remains unitary. What grows during the relaxation is the entanglement entropy of a subregion, measured by interfering two identical copies of the system; it rises and saturates at the value the thermodynamic entropy of that subregion would have, while the entropy of the whole stays zero throughout [2272]. Thermalization therefore needs no external environment: a system large enough to contain its own complement is its own bath, and the environment of Section 87.2 may be internal.

Derivation pending #103

Eigenstate thermalization: that the expectation of a local observable in an individual many-body energy eigenstate is a smooth function of the energy density alone, so that any superposition confined to a narrow energy window relaxes to the microcanonical value of every local observable; and that the entanglement entropy of a small subregion then grows to the thermodynamic entropy that subregion would carry at the corresponding temperature

87.4.6 What decoherence does not settle

[Reserved: the precise statement of the limit — decoherence converts an improper mixture in a preferred basis into a state operationally indistinguishable from a classical ensemble, and does not select which member is realized; the circularity objection, that the interference terms are still present in the global state; why this leaves the measurement problem exactly where Chapter 85 takes it up, and why no experiment in this treatise distinguishes the readings. The section is to say this plainly rather than allow the formalism to suggest more than it proves.]

87.5 Decoherence observed

87.5.1 Cavity quantum electrodynamics

[Reserved: the Paris experiment in which a mesoscopic superposition of two coherent states of a microwave field, separated by a few photons in phase space, was created with a circular Rydberg atom and its decoherence followed in real time with a second atom [1916]; the observed scaling of the decoherence rate with the square of the separation, the first direct measurement of the rate rather than of its consequences; later reconstruction of the full Wigner function of such a state and of its decay [2121]; the apparatus belongs with Chapter 122.]

Phenomenon 87.3 (Decoherence outruns dissipation by the square of the separation)**.** A superposition of two coherent states of a microwave cavity field, separated by a few photons in phase space, loses its interference much faster than the field loses its energy, and the ratio of the two rates is the square of the phase-space separation. In the Paris experiment a circular Rydberg atom prepared such a superposition and a second atom, sent after a controlled delay, read out the coherence that survived [1916]; the coherence decayed exponentially in the delay, with a time constant shorter than the cavity's own energy damping time by the measured factor, and the dependence on the separation was measured by varying it. The observation is a direct one — the rate itself, read against a delay — and not classicality inferred after the fact from an outcome that looks classical.

Derivation. Grant the generator of Section 87.3.2 for a cavity losing photons to a zero-temperature environment at rate κ, with the single jump operator $L = \sqrt{\kappa}\, a$:

$$\dot\rho = \kappa\Big(a\rho a^\dagger - \tfrac{1}{2}a^\dagger a\rho - \tfrac{1}{2}\rho\, a^\dagger a\Big)\,. \tag{87.3}$$

Coherent states are eigenstates of the annihilation operator, $a\,|\alpha\rangle = \alpha\,|\alpha\rangle$ and $\langle\beta|\,a^\dagger = \beta^*\,\langle\beta|$, so on the coherence $\rho = |\alpha\rangle\,\langle\beta|$ every term of Equation (87.3) acts by multiplication:

$$\dot\rho = \kappa\Big(\alpha\beta^* - \tfrac{1}{2}\,|\alpha|^2 - \tfrac{1}{2}\,|\beta|^2\Big)\rho\,. \tag{87.4}$$

The imaginary part of the bracket only turns the phase. Its real part is $\mathrm{Re}(\alpha\beta^*) - \frac{1}{2}\,|\alpha|^2 - \frac{1}{2}\,|\beta|^2 = -\frac{1}{2}\,|\alpha-\beta|^2$, so the modulus of the coherence decays at the rate

$$\Gamma_{\mathrm{dec}} = \tfrac{1}{2}\kappa\;|\alpha-\beta|^2\;, \tag{87.5}$$

whereas the mean photon number obeys $\mathrm{d}\langle n\rangle/\mathrm{d}t = -\kappa\langle n\rangle$ and so relaxes at the rate κ. The ratio is

$$\frac{\Gamma_{\mathrm{dec}}}{\kappa} = \tfrac{1}{2}\,|\alpha-\beta|^2\;, \tag{87.6}$$

the square of the phase-space separation. At a separation of ten photon amplitudes the interference is gone fifty times faster than the energy; for a separation of macroscopic size,

where $|\alpha-\beta|^2$ counts the quanta by which the two branches differ, the factor is astronomical. This is the quantitative content of the claim that large objects look classical: nothing in Equation (87.3) changes with size except one number in an exponent, and no new physics is invoked at any size. □

87.5.2 Engineered reservoirs in ion traps

[Reserved: superpositions of motional states of a single trapped ion exposed to a deliberately applied, characterized noise, so that the environment is a control parameter rather than a nuisance [2001, 2003]; the measured decay of coherence against the amplitude of the applied noise and against the size of the superposition, confirming the predicted scaling over an order of magnitude; why an engineered reservoir is the cleanest possible test of the Lindblad form of Section 87.3.2.]

87.5.3 Matter-wave interferometry

[Reserved: interference of large molecules [1966] as the platform (theory in Chapter 71); controlled collisional decoherence, in which fringe contrast decays exponentially with background gas pressure exactly as predicted [2052]; thermal decoherence, in which the molecules are heated until they emit their own blackbody photons and destroy their own interference [2060] — decoherence with no external environment at all, the environment being the internal vibrational degrees of freedom; both are quantitative confirmations of the Joos–Zeh formula [1757].]

Phenomenon 87.4 (Interference destroyed by a record kept elsewhere)**.** A beam of large molecules crossing a grating interferometer produces fringes whose contrast can be read directly. Admitting background gas reduces that contrast exponentially in the gas pressure, with no shift of the fringe positions and no loss of molecules beyond ordinary attenuation [2052]. Heating the molecules until they emit their own thermal photons reduces it in the same way, the environment in that case being the molecule's own internal vibrational degrees of freedom, with nothing external involved at all [2060]. In both cases the contrast returns when the disturbance is removed, and in neither does anything about the molecule's own dynamics change. What is measured is therefore the export of coherence into a record kept somewhere else, not a modification of the Schrödinger equation of Chapter 77.

Derivation. Let the interferometer put the molecule in a superposition of two paths separated by Δx, and let a single environment particle scatter from it. Write the environment state after the scattering as $|\chi_1\rangle$ or $|\chi_2\rangle$ according to which path the molecule took. Linearity of the joint evolution gives

$$\tfrac{1}{\sqrt{2}}\big(|1\rangle+|2\rangle\big)\otimes|\chi_0\rangle \longmapsto \tfrac{1}{\sqrt{2}}\big(|1\rangle\otimes|\chi_1\rangle+|2\rangle\otimes|\chi_2\rangle\big)\,, \tag{87.7}$$

and tracing out the environment multiplies the molecule's off-diagonal element by $\langle\chi_1|\chi_2\rangle$. Nothing has been done to the molecule — its two path amplitudes are untouched, and its momentum is barely changed — yet the fringe contrast is now $|\langle\chi_1|\chi_2\rangle|$. When the scattered particle's wavelength is short compared with Δx the two environment states are essentially orthogonal, that overlap is essentially zero, and a single event suffices. The visibility after a time t is then simply the probability that no such event has occurred,

$$V(t)=\mathrm{e}^{-\Gamma t}\,, \qquad \Gamma = n\sigma v_{\mathrm{rel}}\,, \tag{87.8}$$

with n the number density of the gas, proportional to its pressure at fixed temperature, σ the collision cross section of Chapter 86 and v_{rel} the mean relative speed. Hence the observed exponential in pressure, with a decay constant that is an ordinary collision rate

and contains no new parameter. Two features deserve marking. This is not attenuation: the molecule is deflected by a negligible angle and still arrives, but arrives without its fringe. And the total state in Equation (87.7) stays pure throughout, so the coherence has been relocated rather than destroyed — which is the distinction of Section 87.1.3, and the reason the refocusing of Section 87.7.2 can sometimes retrieve it. □

87.5.4 Solid-state qubits

[Reserved: coherent oscillations in a single-Cooper-pair box [1980] and the coherence times of superconducting and spin qubits since — from nanoseconds to hundreds of microseconds, an improvement of five orders of magnitude achieved by removing environments one at a time; $1/f$ charge and flux noise and two-level defects as the dominant channels; why this is the branch of physics in which decoherence theory is used as an engineering tool.]

87.6 The quantum Zeno effect

87.6.1 The Misra–Sudarshan theorem

[Reserved: the theorem that for a state with a Hamiltonian of bounded second moment the short-time survival probability is quadratic in the elapsed time, $1-(\Delta E\,t/\hbar)^2$, so that N ideal projective measurements in a fixed interval leave a survival probability tending to one as $N\to\infty$ — a continuously observed unstable system never decays [1606]; the conditions under which the quadratic regime is destroyed, and the anti-Zeno regime in which measurement accelerates decay; the relation to the projection postulate of Chapter 77.]

87.6.2 Observations

[Reserved: the trapped-ion demonstration of Itano and collaborators, in which the induced transition between two hyperfine levels was progressively suppressed as the number of interrogating optical pulses grew [1833]; the objection that the result follows from ordinary unitary dynamics of the three-level system and requires no collapse postulate [1841], which this treatise states as part of the result rather than as a footnote; observation of both the Zeno and the anti-Zeno regime in the tunnelling decay of atoms from an accelerating optical lattice [2012], where the crossover between them was measured.]

Phenomenon 87.5 (Frequent interrogation suppresses a transition)**.** A driven transition between two levels of a trapped ion, which transfers the whole population in a fixed time when left alone, is progressively suppressed as the number of interrogating pulses applied during that time is increased: the population surviving in the initial level rises monotonically towards unity with the number of pulses [1833]. The effect is real and reproducible. Its interpretation is not settled by the observation, and this treatise says so as part of the result rather than in a footnote: the same numbers follow from the ordinary unitary dynamics of the three-level system with its driving and probe fields, so the experiment does not by itself demonstrate a collapse of the state, and what it does and does not decide belongs with Chapter 85.

Derivation. Let $|\psi\rangle$ be the initial state and H the generator of its evolution. Expanding $|\psi(t)\rangle = \mathrm{e}^{-\mathrm{i}Ht/\hbar}\,|\psi\rangle$ to second order in t and taking the overlap with $|\psi\rangle$, the terms linear in t cancel between the amplitude and its conjugate and there remains

$$P(t) = |\langle\psi|\psi(t)\rangle|^2 = 1 - \frac{(\Delta E)^2 t^2}{\hbar^2} + O(t^4)\,, \qquad (\Delta E)^2 = \langle H^2\rangle - \langle H\rangle^2\,. \tag{87.9}$$

The initial decay is quadratic, not linear, and that is the whole of the effect: a genuine rate would give $P(t)=1-\lambda t$, for which the argument below does nothing at all. Divide a fixed

interval T into N equal parts and project onto $|\psi\rangle$ after each. If each projection resets the state, the survival probability is the product of N independent factors,

$$P_N(T) = \left[1 - \frac{(\Delta E\, T/N)^2}{\hbar^2}\right]^N \longrightarrow \exp\left[-\frac{(\Delta E\, T)^2}{N\hbar^2}\right] \longrightarrow 1 \qquad (N \to \infty)\,, \tag{87.10}$$

so a continuously watched system never leaves its initial state. The hypotheses carry the result and must be stated with it. The second moment ΔE must be finite, which fails for a Hamiltonian unbounded in the relevant sense and is exactly the case of a decay that is exponential at all times; and the interval T/N must still lie inside the quadratic regime of Equation (87.9), which for a decay into a broad continuum is extremely short. When the second condition fails and the probe instead broadens the level into the continuum, the same analysis gives an *increase* of the decay rate — the anti-Zeno regime, which is measured in the same systems. □

87.7 Fighting decoherence

87.7.1 Decoherence-free subspaces

[Reserved: symmetry of the system–environment coupling leaving a subspace on which the dissipator acts trivially [1957]; the singlet of two qubits under collective dephasing as the minimal example; its realization as a memory in two trapped ions, with a measured coherence time an order of magnitude longer than that of a bare qubit [2015].]

87.7.2 Dynamical decoupling

[Reserved: Hahn's spin echo [959], in which a refocusing pulse recovers coherence lost to static inhomogeneity — the direct demonstration that such loss is not irreversible, and the sharpest illustration of Section 87.1.3; the generalization to pulse sequences that average an arbitrary slow environment to zero [1983]; the filter-function picture relating a sequence to the noise spectrum it suppresses, which turns a qubit into a spectrometer of its own environment.]

Phenomenon 87.6 (Coherence recovered by a refocusing pulse)**.** An ensemble of spins precessing in a slightly inhomogeneous static field loses its transverse magnetization in a time T_2^* fixed by the spread of the field. A single π pulse applied at time τ makes the magnetization reappear at time 2τ, essentially undiminished [959]. The echo can be repeated many times, and the envelope of successive echoes decays on a much longer time T_2. The disappearance of the signal is therefore not by itself irreversible — only the residual envelope is — and the two time scales measure two different things: the inhomogeneity of the field, and the rate at which that inhomogeneity itself fluctuates.

Derivation. Give each spin of the ensemble a detuning δ from the mean Larmor frequency, constant in time but differing from spin to spin with some distribution $p(\delta)$. In the frame rotating at the mean frequency its transverse component acquires the phase $\phi(t) = \delta t$, so the ensemble-averaged transverse magnetization at time τ is

$$\int \mathrm{d}\delta\, p(\delta)\, \mathrm{e}^{\mathrm{i}\delta\tau}\,, \tag{87.11}$$

the Fourier transform of the detuning distribution, which decays on the time T_2^* set by the reciprocal of its width. No individual spin has lost anything at that point; their phases have merely fanned out. A π pulse about an axis in the transverse plane conjugates the

accumulated phase, $\phi \mapsto -\phi$. Evolving for a further time t gives the total phase $-\delta\tau + \delta t$, and

$$\phi_{\text{total}}(2\tau) = 0 \qquad \text{for every } \delta\,, \tag{87.12}$$

simultaneously and whatever $p(\delta)$ may be, so the whole ensemble rephases and Equation (87.11) returns to its initial value. The only property of δ used is that it is the same before and after the pulse. Whatever part of δ fluctuates on the time scale τ accumulates different phases in the two halves of the interval, and for that part the cancellation is incomplete — which is precisely the separation between T_2^* and T_2, and the reason a longer τ recovers less. The echo is the sharpest available demonstration of Section 87.1.3: a state operationally indistinguishable from a classical ensemble can nevertheless be brought back, so looking like a mixture is not the same as being one. □

87.7.3 Quantum error correction

[Reserved: Shor's nine-qubit code [1909] and Steane's seven-qubit code [1931], which encode one logical qubit so that the syndrome of an error can be measured without measuring the state; the discretization of errors, whereby correcting a finite set of Pauli errors corrects a continuum; the threshold theorem as a statement about rates rather than about principles; the experimental demonstration that a logical qubit's error rate falls as the code distance grows [2415], which is the point at which the theory of this chapter became a construction rather than a limit.]

Chapter 88

Atoms and Molecules

The hydrogen atom of Chapter 81 is the last atom that can be solved exactly. Adding a single electron adds an interaction term that couples all coordinates and destroys separability, and with it the closed-form spectrum; everything beyond helium is approximation plus computation. What is remarkable is how much survives. The shell structure that the exclusion principle imposes on the one-electron orbitals [529] reproduces the periodic table — the largest single body of chemical regularity ever assembled — from counting alone, and the self-consistent field of Hartree and Fock [604, 653] turns the counting into numbers that match measured ionization energies. This chapter is where the quantum mechanics of Parts VIII and IX meets the evidence of chemistry.

Its second half joins nuclei to electrons. The Born–Oppenheimer separation [564] exploits the mass ratio to define a potential energy surface on which nuclei move, and that surface is what a chemical bond is: the electronic ground-state energy of H_2^+ as a function of internuclear distance [568], or of H_2 in the exchange treatment of Heitler and London [577]. Rotations, vibrations and electronic transitions on that surface are the molecular spectra [961], and the residual attraction between closed-shell atoms with no bond at all is London's dispersion force [661], whose retarded form [910] is the bridge to the vacuum of Part XI. The chapter is placed after Chapter 83, whose antisymmetry postulate it uses on every page, and before the precision spectroscopy of Chapter 90, which measures what is computed here.

Derivation pending #104

Atoms and Molecules: all derivations of this chapter are pending.

88.1 The many-electron problem

88.1.1 The Coulomb Hamiltonian

[Reserved: the nonrelativistic Hamiltonian of Z electrons and a nucleus, with its one-body Coulomb attraction and its pairwise repulsion $\sum_{i<j} e^2/4\pi\epsilon_0\,|\boldsymbol{r}_i-\boldsymbol{r}_j|$; why the repulsion term forbids separation of variables and hence any closed-form solution; the infinite-nuclear-mass approximation and the reduced-mass correction; the atomic units in which the literature is written, with the statement of their SI conversion required by the units axiom (Chapter 2).]

88.1.2 Antisymmetry and Slater determinants

[Reserved: the exclusion principle in its original spectroscopic formulation [529] and its restatement as antisymmetry of the total state (Chapter 83); the Slater determinant as the antisymmetric product built from one-electron spin-orbitals [637], and the Slater–Condon

rules for matrix elements of one- and two-body operators between determinants; the exchange term as a consequence of antisymmetry rather than of any force.]

88.1.3 Helium: exchange and the ortho–para splitting

[Reserved: helium as the smallest instance of everything — Heisenberg's resonance treatment, which identified the singlet–triplet splitting as the exchange integral and explained why ortho-helium and parahelium behave as two non-combining species [545]; first-order perturbation theory and the variational estimate of the ground-state energy (Chapter 82); Hylleraas's explicitly correlated wave function [628], the first calculation to reach spectroscopic accuracy and still the template for benchmark work; the measured ionization energy 24.587 eV *as the number to be reproduced.]*

88.2 Self-consistent field theory

88.2.1 The Hartree method

[Reserved: Hartree's non-Coulomb central field, in which each electron moves in the spherically averaged field of the nucleus and of all the others, solved by iteration to self-consistency [604]; the resulting effective potential interpolating between $-Ze^2/r$ near the nucleus and $-e^2/r$ far away, which is what lifts the ℓ-degeneracy of hydrogen and orders the subshells; the Hartree product's failure to be antisymmetric, and what that costs.]

Phenomenon 88.1 (The accidental degeneracy of hydrogen does not survive)**.** In hydrogen the energy depends on n alone. In every other atom it depends on n and ℓ separately, and always in the same direction: for fixed n, $E_{ns} < E_{np} < E_{nd} < E_{nf}$. The alkali spectra display this with no interpretation required [248]. Their terms are described to high accuracy by

$$E_{n\ell} = -\frac{hcR}{(n-\mu_\ell)^2}\,, \tag{88.1}$$

with a quantum defect μ_ℓ that is nearly independent of n along a series, decreases rapidly with ℓ, and is essentially zero for the highest ℓ: in sodium the s terms are displaced by more than one whole unit of n, while the d and f terms lie almost exactly on the hydrogen values. The ordering is severe enough to reorder shells — the $4s$ level lies below $3d$ — which is why the fourth period of the table is eighteen elements long and not eight.

Derivation. Model the field seen by one outer electron as a central potential $V(r)$ tending to $-Ze^2/4\pi\epsilon_0 r$ as $r \to 0$, where the nucleus is unscreened, and to $-e^2/4\pi\epsilon_0 r$ as $r \to \infty$, where the other $Z-1$ electrons screen all but one unit of charge. Interpolating between those two limits is the whole content of the self-consistent field. Write

$$\delta V(r) = V(r) + \frac{e^2}{4\pi\epsilon_0 r} \tag{88.2}$$

for the departure from a hydrogenic problem of unit effective charge. Since V is more attractive than the fully screened form everywhere and equals it only asymptotically, $\delta V(r) < 0$ at every finite r, and it is concentrated at small r, falling off with the density of the core.

First-order perturbation theory (Chapter 82) gives $\Delta E_{n\ell} = \int_0^\infty \mathrm{d}r\; |u_{n\ell}(r)|^2\, \delta V(r)$, negative for every $n\ell$. The dependence on ℓ follows from one fact about the radial functions: near the origin the regular solution behaves as $u_{n\ell}(r) \propto r^{\ell+1}$, because the centrifugal term $\hbar^2\ell(\ell+1)/2mr^2$ dominates there. So for fixed n the weight $|u_{n\ell}|^2$ carried into the region where δV lives falls monotonically as ℓ grows, and with it the size of the shift,

$$\Delta E_{ns} < \Delta E_{np} < \Delta E_{nd} < \cdots < 0\,,$$

which is the observed ordering. Rewriting the shifted level in Rydberg form gives Equation (88.1) with $\mu_\ell > 0$ decreasing in ℓ; and μ_ℓ is nearly independent of n because the small-r amplitude of $u_{n\ell}$ scales as $n^{-3/2}$ along a series, so that the shift and the level spacing scale together.

What this does *not* give is the order in which subshells fill across the table, which requires comparing different n as well as different ℓ; that ordering remains the empirical rule of Section 88.4.2, and the chapter says so there rather than pretending otherwise. □

88.2.2 Hartree–Fock

[Reserved: Fock's variational derivation from an antisymmetrized trial state [653], independently obtained by Slater [671], giving the Hartree–Fock equations with their nonlocal exchange operator; the self-consistency loop; Koopmans' theorem identifying the orbital energy with minus the ionization energy at frozen orbitals [743], and its direct test in photoelectron spectroscopy; restricted and unrestricted forms, and the basis-set expansions that make the equations a matrix problem.]

88.2.3 Correlation energy

[Reserved: the correlation energy defined as the difference between the exact nonrelativistic energy and the Hartree–Fock limit [1075]; its magnitude — a fraction of a percent of the total energy, and of the same order as the chemical bond energies that must be predicted, which is why the definition matters; configuration interaction, and the systematic hierarchies that converge to the exact answer at a computational cost growing factorially.]

88.2.4 Density functional theory

[Reserved: the Hohenberg–Kohn theorems, that the ground-state density determines the external potential up to a constant and that a universal functional of the density is minimized by it [1284]; the Kohn–Sham construction, which restores an orbital picture by mapping onto a fictitious non-interacting system with the same density [1314]; the exchange–correlation functional as the one unknown, and the honest statement that its approximations are calibrated against experiment and computation rather than derived; the direct descent of this line from the Thomas–Fermi model of Section 88.3.]

88.3 The Thomas–Fermi model

[Reserved: the statistical treatment of the electron cloud as a degenerate Fermi gas at each point, due to Thomas [588] and Fermi [598], with the local relation between density and Fermi momentum taken from Chapter 120; the resulting nonlinear equation for the screened potential and its universal dimensionless solution; the predicted total energy scaling as $Z^{7/3}$, which the exact atomic energies do follow; the proof by Lieb and Simon that the model is the exact large-Z limit [1604]; and Teller's theorem that it cannot bind molecules [1243] — a model that is asymptotically exact for atoms and predicts no chemistry at all, which is the cleanest available lesson about the reach of a limit theorem.]

Phenomenon 88.2 (Atomic binding energies grow as $Z^{7/3}$)**.** The energy required to strip a neutral atom completely — the sum of all its ionization energies — is not proportional to Z, nor to Z^2 as a naive hydrogenic count of Z electrons each bound by an energy of order Z^2 would suggest, but grows very nearly as $Z^{7/3}$ across the whole periodic table [2420]. Equivalently, the bulk of the electron cloud contracts: the radius containing a fixed fraction of the charge falls as $Z^{-1/3}$. This is why atomic volumes vary by less than one order of

magnitude from hydrogen to uranium while Z varies by ninety, and hence why chemistry takes place on a shell whose radius is almost independent of the element.

Derivation. The Thomas–Fermi energy functional has three terms: the kinetic energy of a locally degenerate Fermi gas (Chapter 120), the attraction to the nucleus, and the electrostatic self-repulsion of the cloud,

$$E[n] = C_{\mathrm{F}} \int n^{5/3} \mathrm{d}^3 r - \frac{Z e^2}{4\pi\epsilon_0} \int \frac{n(\boldsymbol{r})}{r} \mathrm{d}^3 r + \frac{e^2}{8\pi\epsilon_0} \iint \frac{n(\boldsymbol{r})\, n(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|} \mathrm{d}^3 r\, \mathrm{d}^3 r' \,, \tag{88.3}$$

C_{F} being a pure number times $\hbar^2/m$. Try the scaling

$$n(\boldsymbol{r}) = Z^2\, \nu(Z^{1/3} \boldsymbol{r}) \,, \tag{88.4}$$

which is the unique power-law choice preserving the electron count: substituting $\boldsymbol{u} = Z^{1/3}\boldsymbol{r}$ gives $\int n\, \mathrm{d}^3 r = Z \int \nu\, \mathrm{d}^3 u$, so ν is normalized once and for all. Each of the three terms then carries the same power of Z. The kinetic term collects $Z^{10/3}$ from $n^{5/3}$ and Z^{-1} from the volume element: $Z^{7/3}$. The nuclear term collects Z explicitly, Z^2 from n, $Z^{1/3}$ from $1/r$ and Z^{-1} from the volume element: $Z^{7/3}$. The repulsion collects Z^4 from the two densities, $Z^{1/3}$ from the kernel and Z^{-2} from the two volume elements: $Z^{7/3}$ again. Hence

$$E[n] = Z^{7/3}\, \mathcal{E}[\nu] \,, \tag{88.5}$$

with $\mathcal{E}$ carrying no Z at all: minimizing over ν once settles every atom, and the ground-state energy is a negative constant times $Z^{7/3}$. The same substitution makes the length scale $Z^{-1/3}$, which is the contraction stated above.

Two limits bound how far this may be pressed. It is not a fit but the exact leading behaviour of the true nonrelativistic Coulomb ground-state energy as $Z \to \infty$, which Lieb and Simon later proved as a theorem. And the same model, exact in that limit, cannot bind two atoms into a molecule at any Z — Teller's theorem — so that a description asymptotically correct for atomic energies predicts no chemistry whatever. The pair of statements is the cleanest available warning that an asymptotic theorem constrains the quantity it is about and nothing else. □

88.4 The periodic table

88.4.1 The building-up principle

[Reserved: Bohr's building-up principle, in which the elements are constructed by adding electrons to successive orbits and the periodicity of chemical behaviour is read off the closing of groups [498]; Pauli's exclusion principle supplying the missing reason why a group closes at all [529], with the counting $2(2\ell+1)$ per subshell; the shell capacities 2, 8, 18, 32 and the observed period lengths; the noble gases and the alkali metals as the extreme cases of the same count.]

88.4.2 The Madelung rule and its exceptions

[Reserved: the empirical ordering of subshell filling by increasing $n+\ell$, and by increasing n within equal $n+\ell$, stated by Madelung [780]; the partial rationalizations in terms of the effective potential of Section 88.2.1 [1649]; the roughly twenty elements that violate it, chromium and copper among them, and the fact that no derivation of the rule from the Schrödinger equation exists — stated here as an open item rather than glossed [2111].]

88.4.3 Periodic trends and their evidence

[Reserved: first ionization energies across a period and down a group, with their sawtooth at the half-filled subshells; electron affinities; atomic and ionic radii; electronegativity as a derived rather than a primitive quantity [1188]; Moseley's X-ray law, which established the atomic number as the ordering principle and closed the gaps in the table [408], with the pointer to Chapter 70 where the measurement sits. Each trend is to be given as measured data with uncertainties, not as a schematic arrow.]

88.5 Angular-momentum coupling

88.5.1 LS coupling and atomic terms

[Reserved: Russell–Saunders coupling, in which the orbital and spin angular momenta separately couple to L and S before spin–orbit combines them into J [530]; the term symbol $^{2S+1}L_J$; the addition of angular momenta of Chapter 79 applied to equivalent electrons, where antisymmetry eliminates most of the naive terms; the fine-structure interval rule and its measured departures; the alkali doublets as the simplest observed case.]

88.5.2 Hund's rules

[Reserved: Hund's empirical ordering of the terms of a configuration — maximum S, then maximum L, then minimum J for a less-than-half-filled shell [524]; their validity range, which is the ground configuration and not the excited ones; and the honest correction to the standard textbook explanation, since the detailed calculations show the first rule to be driven by reduced screening and increased electron–nucleus attraction rather than by reduced electron–electron repulsion [1736].]

88.5.3 jj coupling and the intermediate regime

[Reserved: the opposite limit, in which the spin–orbit coupling — growing roughly as Z^4 for the inner electrons — dominates the residual electrostatic interaction, so that each electron's j is good and the j values couple to J; the intermediate coupling that describes most heavy atoms, with term mixing making L and S approximate labels; the observable consequence, namely intercombination lines that are strictly forbidden in pure LS coupling and are nonetheless measured, including the clock transitions used in Chapter 90.]

88.5.4 Atoms in external fields

[Reserved: the Zeeman effect in a many-electron atom, with the Landé g-factor derived from the LS coupling scheme [478]; the Paschen–Back regime in which a strong field decouples L and S and the anomalous pattern reverts to the normal one [391]; the quadratic Stark effect for non-degenerate levels and the linear one for hydrogenic degeneracies (Chapter 81); the light shift, which is the same physics at optical frequency and is the systematic that dominates the error budgets of Chapter 90.]

88.5.5 Hyperfine structure

[Reserved: the nuclear-spin hypothesis introduced to explain the observed line satellites [516]; Fermi's contact interaction between the nuclear magnetic moment and the s-electron density at the nucleus [652], with the resulting splitting and the interval rule; the hydrogen ground-state splitting of 1420.4 MHz *and its astronomical detection as the 21-centimetre line [981], which is the survey tool of Chapter 48; isotope shifts, both mass and field, as a probe of nuclear size, feeding Chapter 90.]*

88.6 The Born–Oppenheimer separation

88.6.1 The adiabatic approximation

[Reserved: Born and Oppenheimer's expansion in the fourth root of the electron-to-nucleus mass ratio [564], giving the electronic problem at clamped nuclei, the potential energy surface as its eigenvalue, and the nuclear Schrödinger equation on that surface; the ordering of electronic, vibrational and rotational energy scales in the ratio $1 : \sqrt{m/M} : m/M$*, which is what makes a molecular spectrum look the way it does; the adiabatic theorem underlying it (Chapter 82).]*

Phenomenon 88.3 (Three separated spectral scales)**.** The spectrum of a molecule is not one ladder but three, cleanly separated: electronic transitions in the visible and ultraviolet, vibrational transitions in the infrared, rotational transitions in the microwave. Their spacings stand in the ratios

$$E_{\mathrm{el}} : E_{\mathrm{vib}} : E_{\mathrm{rot}} \approx 1 : \sqrt{m/M} : m/M \,, \tag{88.6}$$

with m the electron mass and M a nuclear mass, so that each scale is smaller than the one above it by a factor of order forty for a light molecule and more for a heavy one. This separation is the reason an electronic band carries a vibrational progression, why each vibrational band carries rotational fine structure, and why the three regions of a molecular spectrum are recorded with three different kinds of apparatus and were historically three different subjects.

Derivation. Let a be the size of the molecule. An electron confined to that size has momentum of order $\hbar/a$ by the uncertainty relation of Chapter 77, hence an energy scale

$$E_{\mathrm{el}} \sim \frac{\hbar^2}{m a^2} \,, \tag{88.7}$$

which fixes both the depth and the width of the potential energy surface, since both are electronic quantities. Displacing the nuclei by an amount of order a therefore changes the electronic energy by an amount of order E_{el}, so the curvature of the surface at its minimum is $k \sim E_{\mathrm{el}}/a^2$. Nuclei of mass M vibrating in that curvature have

$$E_{\mathrm{vib}} = \hbar\omega \sim \hbar\sqrt{\frac{k}{M}} \sim \hbar\sqrt{\frac{E_{\mathrm{el}}}{M a^2}} = E_{\mathrm{el}}\sqrt{\frac{\hbar^2}{M a^2 E_{\mathrm{el}}}} = E_{\mathrm{el}}\sqrt{\frac{m}{M}} \,, \tag{88.8}$$

the last step by Equation (88.7). Rotation of the whole molecule about its centre of mass has moment of inertia $I \sim M a^2$ and level spacing

$$E_{\mathrm{rot}} \sim \frac{\hbar^2}{M a^2} = E_{\mathrm{el}}\,\frac{m}{M} \,, \tag{88.9}$$

again by Equation (88.7). Together these are Equation (88.6).

The same small parameter justifies the separation that produced the surface in the first place. The nuclear zero-point amplitude is $x_0 = \sqrt{\hbar/M\omega}$, and dividing by a and using Equations (88.7) and (88.8) gives $x_0/a \sim (m/M)^{1/4}$. That is why the Born–Oppenheimer expansion proceeds in the *fourth* root of the mass ratio and not in the ratio itself: what must be small is the excursion of the nuclei measured against the scale on which the electronic state changes. □

88.6.2 Where the surface fails

[Reserved: the Jahn–Teller theorem, that any non-linear molecule in an orbitally degenerate electronic state distorts to remove the degeneracy [794], with its observed signatures in the

spectra of octahedral complexes; conical intersections, where two surfaces touch and the separation breaks down entirely, controlling radiationless transitions and photochemistry; the geometric phase acquired on a circuit around such an intersection, and its relation to the general Berry phase of Chapter 82.]

88.7 The chemical bond

88.7.1 The one-electron bond

[Reserved: H_2^+*, the only molecule whose electronic problem separates exactly, in prolate spheroidal coordinates; Burrau's numerical solution [568], giving the bonding and antibonding curves, the equilibrium separation* 106 pm *and the dissociation energy* 2.79 eV*; the bonding mechanism read off the exact solution — accumulation of electron density between the nuclei — with the virial analysis that attributes it correctly.]*

88.7.2 Valence bond theory

[Reserved: Heitler and London's treatment of H_2 *[577], in which a symmetrized product of atomic orbitals binds and an antisymmetrized one does not, so that the covalent bond is exchange plus spin pairing and the singlet–triplet splitting is the bond; the resulting binding energy compared with the measured* 4.478 eV*; Pauling's hybridization and resonance [686], and the systematization of directed valence [1188].]*

Phenomenon 88.4 (The covalent bond is spin-selected electrostatics)**.** Two hydrogen atoms in their ground states attract and form a stable molecule when their electron spins are opposed, and do not bind at all when the spins are parallel: the singlet potential curve has a deep minimum near an internuclear separation of 74 pm, while the triplet curve is repulsive at every distance. The difference cannot be magnetic. The bond energy is several electronvolts, whereas the magnetic interaction of two electron moments that far apart is of order 1×10^{-4} eV, four to five orders of magnitude too small. The spin therefore does not act on anything; it selects, through the antisymmetry requirement of Chapter 83, which spatial state is permitted, and the two permitted spatial states have very different electrostatic energies.

Derivation pending #105

The Heitler–London calculation: that the symmetrized and the antisymmetrized products of two hydrogenic ground-state orbitals have expectation energies differing by twice an exchange integral; that this integral has the sign, over the relevant range of internuclear distance, which puts the singlet below the separated atoms and the triplet above them; and the size of the discrepancy that remains between so simple a variational estimate and the measured dissociation energy

88.7.3 Molecular orbitals and LCAO

[Reserved: the alternative in which electrons occupy orbitals delocalized over the whole nuclear framework, developed independently by Hund [607] and Mulliken [613], with the linear-combination-of-atomic-orbitals approximation and the secular equations set out by Lennard-Jones [631]; bonding and antibonding combinations, symmetry labels, correlation diagrams, and bond order; the prediction that O_2 *has a triplet ground state — confirmed by its paramagnetism — which valence bond theory in its simple form gets wrong.]*

Phenomenon 88.5 (Molecular oxygen is paramagnetic)**.** Liquid oxygen poured between the poles of a magnet is held there. Gaseous oxygen has a magnetic susceptibility of the size characteristic of two unpaired electron spins per molecule [264], and its microwave spectrum shows the fine structure of a triplet. Every straightforward pairing of the sixteen electrons of O_2 into a closed-shell structure with a double bond predicts a diamagnetic singlet, and is wrong. This is one of the few questions on which two descriptions usually called equivalent give different answers — the simple valence-bond structure fails and the molecular-orbital picture succeeds — and it is settled by a magnet.

Derivation. Grant the molecular-orbital ordering, which puts the last two electrons of O_2 into the antibonding π_g pair. Those two orbitals are degenerate by the cylindrical symmetry of the molecule: they differ only by a rotation about the internuclear axis, so no electrostatic term can separate them. Call them ϕ_1 and ϕ_2. Two electrons in two degenerate orbitals, with the total state obliged to be antisymmetric, have exactly two possibilities: the symmetric spatial combination $\phi_1(1)\phi_2(2) + \phi_2(1)\phi_1(2)$ paired with the spin singlet, or the antisymmetric combination $\phi_1(1)\phi_2(2) - \phi_2(1)\phi_1(2)$ paired with the spin triplet. Their Coulomb expectations are $J \pm K$ with

$$K = \frac{e^2}{4\pi\epsilon_0} \iint \frac{\phi_1^*(\boldsymbol{r}_1)\phi_2^*(\boldsymbol{r}_2)\,\phi_2(\boldsymbol{r}_1)\phi_1(\boldsymbol{r}_2)}{|\boldsymbol{r}_1 - \boldsymbol{r}_2|} \mathrm{d}^3 r_1\, \mathrm{d}^3 r_2\,, \tag{88.10}$$

the symmetric state at $J + K$ and the antisymmetric at $J - K$. The antisymmetric spatial function vanishes identically whenever $\boldsymbol{r}_1 = \boldsymbol{r}_2$, so two electrons in it are never found at the same point, their mutual repulsion is the smaller, and $K > 0$. The triplet therefore lies lower, O_2 has $S = 1$, and it is paramagnetic. Nothing magnetic entered the argument: the splitting is electrostatic, and the spin only labels which spatial state is allowed.

One qualification belongs with the result. The argument holds the orbitals fixed, and at that level it is exact. When the orbitals are allowed to relax the ordering survives, but its accounting changes — the dominant gain is then in the electron–nucleus attraction rather than in the electron–electron repulsion, which is the correction recorded in Section 88.5.2. The conclusion is robust; the usual one-line explanation of it is not. □

88.7.4 What the two pictures agree on

[Reserved: the demonstration that valence bond and molecular orbital descriptions of H_2 *are the same wave function in different bases once ionic and covalent terms are treated on an equal footing, and that they differ only in what they get right first — molecular orbital theory at equilibrium, valence bond theory at dissociation; the practical consequence for how molecular calculations are set up, and the standing reminder that a picture is a basis choice, not a physical claim [961, 1188].]*

88.8 Molecular spectra

88.8.1 Rotational spectra

[Reserved: the rigid rotor, its $BJ(J+1)$ *ladder and the equally spaced lines of a pure rotational spectrum in the microwave region, with centrifugal distortion as the first correction [961]; the selection rule* $\Delta J = \pm 1$ *and the requirement of a permanent dipole moment; bond lengths determined to four significant figures from measured rotational constants; the ammonia inversion doublet as the transition that ran the first maser [1070] and opened the road to Chapter 90.]*

88.8.2 Vibrational spectra

[Reserved: the harmonic approximation about the minimum of the potential energy surface, giving the normal modes of Chapter 28 applied to a molecule; the Morse potential and its exactly solvable anharmonic spectrum [632], with the convergence of levels to the dissociation limit and the Birge–Sponer extrapolation; overtones and combination bands; rotational fine structure and the P, Q and R branches of a vibration–rotation band [961]; the greenhouse-active modes of CO_2 *and* H_2O *as the worked case with the largest external stakes.]*

88.8.3 Electronic transitions

[Reserved: band systems and their vibrational progressions; the Franck–Condon principle, argued classically from the slowness of nuclear motion [542] and given its quantum form as the overlap of vibrational wave functions on the two surfaces [536], with the observed intensity distributions as its test; predissociation and photodissociation; molecular electronic spectra as the identification tool of interstellar chemistry (Chapter 52).]

88.8.4 Raman scattering

[Reserved: Smekal's prediction of inelastic light scattering with shifted frequencies [504]; its observation in liquids by Raman and Krishnan [618] and, independently and almost simultaneously, in quartz by Landsberg and Mandelstam [610] — an attribution this treatise states in full; Stokes and anti-Stokes lines and the intensity ratio as a thermometer; the polarizability selection rule, complementary to the dipole rule, so that Raman and infrared spectroscopy see different modes of a centrosymmetric molecule; the scattering formalism itself belongs to Chapter 65.]

Phenomenon 88.6 (Light scattered with a molecular frequency shift)**.** Light scattered by a transparent liquid, gas or crystal contains, besides the unshifted Rayleigh line, weak lines displaced from it by fixed frequency intervals characteristic of the scattering substance and independent of the frequency of the illumination [610, 618]. The displacements coincide with vibrational and rotational intervals of the molecule — which is what distinguishes the effect from fluorescence, whose emitted frequency is fixed rather than its shift. The lines appear in pairs, one on each side of the exciting line, and the pair is not symmetric in intensity: the line displaced to lower frequency is much the stronger, and the ratio of the two intensities depends on the temperature alone, so that the two lines together are a thermometer requiring no calibration.

Derivation. The shift itself is conservation of energy. The scattering event leaves the molecule in a different vibrational or rotational state, so $h\nu_{\text{in}} = h\nu_{\text{out}} + \Delta E$ and the displacement $\nu_{\text{in}} - \nu_{\text{out}} = \Delta E/h$ is a property of the molecule, not of the illumination. A displacement downwards — the Stokes line — requires only that the molecule start in the lower state; a displacement upwards — the anti-Stokes line — requires that it already be in the upper one.

The intensity ratio follows from that asymmetry. By microscopic reversibility the two processes have the same squared matrix element, so their rates differ only through the populations of the initial states and through the frequency dependence of dipole radiation (Chapter 65), which supplies a factor ν_{out}^4. In thermal equilibrium (Chapter 118) the population ratio is the Boltzmann factor, so

$$\frac{I_{\text{anti-Stokes}}}{I_{\text{Stokes}}} = \left(\frac{\nu_{\text{in}} + \Delta E/h}{\nu_{\text{in}} - \Delta E/h}\right)^4 \mathrm{e}^{-\Delta E/k_{\text{B}}T}\,. \tag{88.11}$$

At room temperature and a vibrational interval of a few hundred reciprocal centimetres the exponential is small, which is why the anti-Stokes lines are the weak ones and why they

vanish altogether in a cold sample. Inverting Equation (88.11) gives T; and because the two lines are recorded in one spectrum through one optical path, the detector response and the collection efficiency cancel from the ratio, which is what makes the thermometer self-calibrating. □

88.9 Intermolecular forces

88.9.1 London dispersion

[Reserved: second-order perturbation theory in the dipole–dipole interaction between two neutral, non-polar atoms, giving an attraction falling as R^{-6} with a coefficient fixed by the atomic polarizabilities [650, 661]; that the force exists between closed shells with no bond, no permanent moments and no overlap, and that it is a correlation effect invisible to Hartree–Fock; the Lennard-Jones form combining it with exchange repulsion, and the van der Waals equation of state of Chapter 54 as its macroscopic signature.]

Phenomenon 88.7 (Closed-shell atoms attract)**.** Two neutral atoms with no permanent electric moments, no unpaired electrons and no chemical affinity for one another nevertheless attract at distances well beyond the reach of their electron clouds, with an interaction energy falling as the inverse sixth power of the separation. The evidence is everywhere: the noble gases liquefy, the second virial coefficient of every real gas is negative at low temperature (Chapter 54), and even helium — the least polarizable atom there is — forms a dimer [1990]. The force is absent from any description in which each electron moves in the average field of the others, so the Hartree–Fock method of Section 88.2.2 returns exactly zero for it by construction. It is a correlation effect: an interaction between the fluctuations of two charge distributions, not between their means.

Derivation. Place the atoms at a separation R large compared with their radii, so that the charge distributions do not overlap and the interaction may be expanded in multipoles. The leading term is dipole–dipole,

$$W = \frac{1}{4\pi\epsilon_0 R^3}\Big[\boldsymbol{d}_1\cdot\boldsymbol{d}_2 - 3(\boldsymbol{d}_1\cdot\hat{\boldsymbol{R}})(\boldsymbol{d}_2\cdot\hat{\boldsymbol{R}})\Big]\,, \tag{88.12}$$

with $\boldsymbol{d}_i$ the dipole operators of the two atoms. Each atom in its ground state is spherically symmetric, so $\langle \boldsymbol{d}_i\rangle = 0$ and the first-order energy $\langle W\rangle$ vanishes identically: on the average there is nothing there to interact. Second-order perturbation theory (Chapter 82) does not vanish, and for the ground state it is negative term by term,

$$\Delta E = -\sum_{k\neq 0}\frac{|\langle k|W|0\rangle|^2}{E_k - E_0} = -\frac{C_6}{R^6}\,, \qquad C_6 > 0\,, \tag{88.13}$$

the sixth power following immediately because $W \propto R^{-3}$ and the energy is quadratic in W, and C_6 being a double sum over the dipole transitions of the two atoms — that is, an integral over their polarizabilities. Every step used only that an atom has transitions with nonvanishing dipole matrix elements, which every atom has: the attraction is universal, and it is attractive for every pair.

Two consequences are worth recording. Being second order, the process excites both atoms virtually at once, which is precisely what a one-electron mean field cannot represent, and is why the effect is invisible to Hartree–Fock and is the standard benchmark for anything claiming to include correlation. And the derivation assumed the interaction to be instantaneous. Once R exceeds the wavelength of the transitions doing the work, the light-crossing time is no longer negligible against the period of the fluctuation, the correlation is partly lost, and the attraction weakens to R^{-7} — the retarded regime of Section 88.9.2, and the point at which the electromagnetic vacuum has to enter the account. □

88.9.2 Retardation and the Casimir–Polder force

[Reserved: Casimir and Polder's result that beyond a distance of order the transition wavelength, the finite speed of light weakens the interaction to R^{-7} between two atoms and to z^{-4} between an atom and a conducting wall [910]; the direct measurement of the atom–surface potential in the retarded regime by deflection of a sodium beam through a micrometre-scale cavity [1875]; the pointer forward to the field-theoretic reading of the same result in Chapter 99.]

88.9.3 Weakly bound dimers

[Reserved: the helium dimer as the extreme test case — a molecule bound by dispersion alone, with a binding energy of order $100\,\mathrm{neV}$ *and a mean internuclear separation of about* $5\,\mathrm{nm}$*, larger than the classical turning point, measured by diffraction of a helium beam from a transmission grating [1990]; why so weakly bound an object is the sharpest available check on a computed dispersion coefficient; Efimov states and the three-body physics that follows, noted here and left to the few-body literature.]*

Chapter 89

Experiment: Bell Tests

Bell's theorem [1271] converted a philosophical dispute about the completeness of quantum mechanics [753] into an inequality between measurable correlation rates, and thereby into an experiment. This chapter is the record of that experiment: the cascade-photon tests of the 1970s [1471, 1663], the switched-analyzer measurement that first enforced relativistic separation between the choice of setting at one station and the detection at the other [1679], the two experiments that closed the locality and detection loopholes one at a time [1963, 2019], and the three independent 2015 experiments that closed them simultaneously [2253, 2254, 2260]. The theory that the data test — the derivation of the inequality, the meaning of a violation, and what is and is not entailed — is developed in Chapter 84; this chapter supplies the apparatus, the numbers and the error budgets, and states the residual assumptions without softening them.

When written the chapter will use the structured *experiment* environment, with apparatus, procedure, observations, interpretation and references as separate fields, and the tabulated CHSH parameters with their uncertainties lodged as a dataset in the evidence store. Three features distinguish a Bell test from every other experiment in this treatise and shape the sections below. Its result is a bound rather than a value, so the figure of merit is a p-value under an explicitly stated null hypothesis, not an agreement with a predicted number. Its validity rests on the spacetime layout of the apparatus, so the timing diagram is part of the physics and not part of the engineering. And one assumption — that the setting choices are not themselves correlated with the hidden variables — cannot be removed by any experiment, only pushed back in time, which is what the cosmic Bell tests do [2283, 2318]. The 2022 Nobel Prize recognized this line of work [2408]; the reviews are [2232, 2235].

Derivation pending #106

Experiment: Bell Tests: all derivations of this chapter are pending.

89.1 Historical context and the prediction under test

89.1.1 From EPR to a testable inequality

[Reserved: the Einstein–Podolsky–Rosen argument that quantum mechanics is either incomplete or non-local [753]; Bohm's reformulation with two spin-half particles in a singlet, which replaced continuous variables by a two-outcome measurement and made the problem experimental in principle [978]; Bell's derivation of an inequality obeyed by every local hidden-variable model and violated by quantum mechanics [1271], with his own later commentary on what the assumptions mean [1788]; the reduction of the whole dispute to a counting experiment.]

Phenomenon 89.1 (Perfect anticorrelation at aligned analysers)**.** When the two analysers of a Bell apparatus are set to the same direction, the two recorded outcomes are found to be opposite on every detected pair, up to the imperfections of source and detectors, while each outcome taken alone is a fair coin. This is the observation on which the Einstein–Podolsky–Rosen argument rests [753]: the result at one station can be predicted with certainty from the result at the other, at any separation, without the second particle having been touched. It is also the observation a Bell test must reproduce as a calibration before its inequality means anything, and it is measured as a matter of routine in every experiment of this chapter.

Derivation. Write the singlet $|\Psi^-\rangle = (|{\uparrow\downarrow}\rangle - |{\downarrow\uparrow}\rangle)/\sqrt{2}$ in the eigenbasis of the spin component along the common analyser direction $\hat{\boldsymbol{a}}$. Both surviving terms have the two spins opposite and no term with them parallel appears at all, so a joint measurement of that component returns $(+,-)$ or $(-,+)$ and never $(+,+)$ or $(-,-)$: the outcomes are opposite on every pair, and $E(\hat{\boldsymbol{a}},\hat{\boldsymbol{a}}) = -1$. The two terms carry equal amplitude, so each occurs with probability $\frac{1}{2}$ and the marginal recorded at either station is uniform, carrying no information about which direction was chosen. Finally, the singlet is the unique two-spin state of zero total angular momentum and is therefore invariant under simultaneous rotations of both spins, so the same expansion holds in the eigenbasis of *any* direction: the anticorrelation is not a property of a preferred axis.

Note what this does not establish. Nothing in the argument is inconsistent with local hidden variables — a pair of particles carrying opposite predetermined values reproduces every statement above exactly. That is why the settings in Section 89.1.2 must be unequal, and why the dispute could not be decided until Bell found an inequality that unequal settings violate. □

89.1.2 CHSH: the inequality that is measured

[Reserved: the Clauser–Horne–Shimony–Holt inequality $|S| \le 2$, built from four correlation measurements at two settings per side and requiring no perfect anticorrelation [1400]; the Clauser–Horne form, which uses only singles and coincidence rates and so needs no auxiliary no-enhancement assumption [1522]; Eberhard's inequality, optimized for low detection efficiency and used in the 2015 photonic experiments [1862]; the quantum maximum $S = 2\sqrt{2} \approx 2.828$ and Tsirelson's proof that no quantum state exceeds it [1650], which fixes the scale against which every measured S is read.]

89.1.3 The three loopholes

[Reserved: the detection or fair-sampling loophole, exhibited constructively by Pearle, who built a local model reproducing the quantum correlations when undetected pairs are discarded [1430], with the efficiency thresholds — about 83 % for CHSH with a maximally entangled state, about 67 % for the Eberhard inequality with a partially entangled one [1862]; the locality loophole, closed only when the setting choice at one station is spacelike separated from the detection at the other; the freedom-of-choice loophole, and the honest statement that superdeterminism is not testable and that the experiments therefore constrain, and never eliminate, it [2235].]

89.1.4 The first tests

[Reserved: Kocher and Commins's measurement of the polarization correlation of the calcium cascade photons, made for other reasons and later recognized as the first relevant data [1354]; Freedman and Clauser's dedicated test [1471], which measured $\delta = 0.050 \pm 0.008$ against the local bound $\delta \le 0$ — the first reported violation; the conflicting null result of Holt and Pipkin

and its resolution, together with Clauser's own re-measurement that traced the anomaly to the source [1576] and Fry and Thompson's fast confirmation with an isotopically selected mercury cascade [1578]. The episode is kept because a disagreement resolved by finding a systematic is better evidence than unanimity.]

89.2 Apparatus

89.2.1 Atomic cascade sources

[Reserved: the two-photon radiative cascade in calcium $4p^2\,{}^1S_0 \to 4s4p\,{}^1P_1 \to 4s^2\,{}^1S_0$, whose angular-momentum selection rules correlate the polarizations of the two emitted photons; the resonant two-photon laser excitation that raised the rate by orders of magnitude in Aspect's apparatus [1663]; the intrinsic limitation of the geometry — the correlation is degraded by the finite solid angle, since the photons are not emitted back to back — and why this made the detection loophole unclosable with cascade sources.]

89.2.2 Parametric down-conversion

[Reserved: spontaneous parametric down-conversion in a noncentrosymmetric crystal, in which one pump photon splits into a correlated pair; the type-II geometry with its two intersecting cones, which produces polarization-entangled pairs directly and brightly [1902]; phase matching, spectral filtering, and the collection optics that determine the heralding efficiency — the single parameter on which the detection loophole turns; the source used in Section 89.6.1 and, with far higher collection efficiency, in the 2015 experiments.]

89.2.3 Detectors

[Reserved: photomultipliers with quantum efficiencies of a few percent in the cascade era, which is why every experiment before 2001 assumed fair sampling; avalanche photodiodes; transition-edge sensors operating at millikelvin temperatures, which reach detection efficiencies above $90\,\%$ in the near infrared [2131] and are what made the photonic loophole-free experiments possible; state readout by resonance fluorescence in trapped ions and nitrogen–vacancy centres, which is essentially deterministic and closes the detection loophole by construction [2019, 2254].]

89.2.4 Entangled matter systems

[Reserved: entanglement between two trapped ions in the same trap [2019]; entanglement swapping through a Bell-state measurement on photons emitted by remote emitters, the event-ready scheme proposed by Żukowski and collaborators [1878] and used to entangle nitrogen–vacancy centres $1.3\,\mathrm{km}$ apart [2254]; entangled atoms in separate laboratories [2285]; superconducting circuits entangled through a cryogenic waveguide over $30\,\mathrm{m}$ [2422], where the whole spacelike-separation budget is metres rather than kilometres because the readout is nanoseconds rather than microseconds.]

89.2.5 Setting generators

[Reserved: the progression of setting choices — fixed orientations in the earliest tests; the acousto-optic switches of Aspect, Dalibard and Roger, which redirected the light periodically rather than randomly [1679]; physical random-number generators driven by a beam splitter [1963]; photons from Milky Way stars, whose emission moved the last possible common cause back centuries [2283]; high-redshift quasars, moving it back billions of years [2318]; and the

choices of about one hundred thousand human participants [2307]. Each is a statement about when *the setting was fixed, which is the only thing that matters.]*

89.3 Procedure

[Reserved: the spacetime layout, drawn as a diagram with the two stations' light cones — setting choice, analyzer setting completed, detection, and the requirement that each station's setting event be spacelike separated from the other's detection event; the coincidence window and the pitfalls of defining coincidences by post-selection on arrival times; the run structure, with the number of trials fixed in advance; the pre-registered analysis and the martingale-based hypothesis test that avoids assuming independent and identically distributed trials; how the p-value is computed and why it, and not a number of standard deviations, is the honest statistic [2253, 2260].]

89.4 Observations

[Reserved: the quantities to be tabulated for each experiment, in SI with uncertainties per [2129] — source type, station separation, detection and heralding efficiencies, trial count, the measured CHSH parameter and its uncertainty, and the p-value under local realism. The series to be given: Freedman and Clauser's $\delta = 0.050 \pm 0.008$ *[1471]; Aspect's* $S = 2.697 \pm 0.015$ *with two-channel polarizers [1680] and* $S = 2.404 \pm 0.080$ *with time-varying analyzers [1679]; Weihs's* $S = 2.73 \pm 0.02$ *under strict Einstein locality [1963]; Rowe's* $S = 2.25 \pm 0.03$ *with unit detection efficiency [2019]; the 2015 results,* $S = 2.42 \pm 0.20$ *with* $p = 0.039$ *over* $1.3\,\mathrm{km}$ *[2254],* $p \leq 3.74 \times 10^{-31}$ *[2253] and* $p \leq 2.3 \times 10^{-7}$ *[2260]. Every entry is to be read against the quantum bound* $2\sqrt{2}$ *of Section 89.1.2.]*

Phenomenon 89.2 (The measured CHSH parameter exceeds the local bound)**.** Coincidence counting on entangled pairs, with two alternative analyser settings at each station, yields values of

$$S = E(a,b) + E(a,b') + E(a',b) - E(a',b') \tag{89.1}$$

exceeding 2 in modulus — which no local hidden-variable model can produce — and consistent with the quantum prediction, whose maximum is $2\sqrt{2}$. The result has been obtained with atomic cascade photons [1471, 1680], with parametric down-conversion [1963, 2253, 2260], with trapped ions [2019], with nitrogen–vacancy centres [2254] and with superconducting circuits [2422]; at station separations from micrometres to kilometres; and with settings fixed by hand, by periodic switches, by physical random-number generators, by starlight, by quasar light and by human choices. The excess over 2 is therefore not one number from one apparatus but a stable feature of Nature reproduced on every platform on which it has been sought.

Derivation. Both numbers being compared are short to obtain. For the local bound, suppose the outcomes are functions $A(a,\lambda), A(a',\lambda), B(b,\lambda), B(b',\lambda) \in \{-1,+1\}$ of the setting on their own side and of a shared variable λ with density $p(\lambda)$, so that $E(a,b) = \int \mathrm{d}\lambda\, p(\lambda) A(a,\lambda) B(b,\lambda)$. At fixed λ, group the four terms as $S(\lambda) = A[B + B'] + A'[B - B']$. Since $B, B' \in \{-1,+1\}$, one bracket vanishes and the other has modulus 2, so $|S(\lambda)| = 2$ for every λ, and averaging gives $|S| \leq 2$. No quantum mechanics is used, which is what gives the bound its force; the same argument is set out at greater length in Chapter 84.

For the quantum value, take the singlet, whose correlation between analyser directions at angle θ is $-\cos\theta$, and choose coplanar directions $a = 0$, $a' = \pi/2$, $b = \pi/4$, $b' = -\pi/4$. Then $E(a,b) = E(a,b') = E(a',b) = -1/\sqrt{2}$ while $E(a',b') = -\cos(3\pi/4) = +1/\sqrt{2}$, so Equation (89.1) gives $S = -4/\sqrt{2} = -2\sqrt{2}$. The two statements are the whole experiment:

the apparatus is asked to produce a number, and the number it produces must fall on one side or the other of 2. Because the predicted excess is a factor $\sqrt{2}$ rather than a marginal effect, the question was answerable with the detectors of the 1970s once fair sampling was granted, and the fifty years since have gone into removing that grant rather than into improving the statistics. □

89.5 Interpretation

89.5.1 What the violations exclude

[Reserved: the exact statement — no theory in which each outcome is determined by variables carried by the particles and unaffected by the distant setting can reproduce the observed rates; that this is a constraint on explanations*, not the observation of a signal, since the marginal distributions are uniform and no information is transmitted; the no-signalling property checked directly in the data as a control; and the standing warning that "non-locality" names the failure of an assumption, not a mechanism [2232].]*

Phenomenon 89.3 (The marginals carry no message)**.** In every Bell experiment the singles rate recorded at one station is compatible, within its statistical uncertainty, with being independent of the setting chosen at the other. The comparison is made directly on the recorded data and reported as a control, so this is an experimental result and not only a theorem. Consequently a violation of Equation (89.1) is not the observation of a signal: nothing detectable at one station changes when the distant setting changes, and the correlation becomes visible only once the two records are brought together, which needs a classical channel and therefore takes at least the light travel time between the stations. The word "non-locality" in this subject names the failure of an assumption, not the discovery of an influence.

Derivation. Everything one station can record is computed from its reduced state $\rho_A = \operatorname{tr}_B \rho$. The most general thing the distant station can do to its own factor is a trace-preserving map $\mathcal{E}_B$, of which "set the analyser to b and measure, without telling anyone the result" is one instance. Since $\operatorname{tr}_B\big[(\mathrm{id}_A \otimes \mathcal{E}_B)\rho\big] = \operatorname{tr}_B \rho$ whenever $\mathcal{E}_B$ preserves the trace, the reduced state ρ_A is unchanged, and with it

$$\operatorname{tr}\big[(X \otimes \mathbb{1})\,(\mathrm{id}_A \otimes \mathcal{E}_B)\rho\big] = \operatorname{tr}\big[(X \otimes \mathbb{1})\,\rho\big] \tag{89.2}$$

for every local observable X. Only linearity and trace preservation were used, so the conclusion holds for any state and any separation. The reason the check is nonetheless performed on the data is that the *apparatus* might signal even though the physics does not — through cross-talk between the two arms, a shared clock, or a setting generator that drifts in step with a detector. A measured dependence of the marginals on the distant setting would therefore indicate a fault, and finding none is a statement about the experiment. □

89.5.2 What remains open

[Reserved: the alternatives that survive — explicitly nonlocal hidden-variable theories, retrocausal accounts, and superdeterministic models in which the setting choices are correlated with the state at preparation; the honest observation that the cosmic Bell tests constrain the last of these only by pushing the required conspiracy back in time [2283, 2318], and that no experiment can close it. The interpretive consequences belong to Chapter 85; what this chapter contributes there is the datum that any interpretation must accommodate.]

89.5.3 Why a violation is not fragile

[Reserved: the quantitative role of decoherence (Chapter 87) — entanglement degrades with photon loss, mode mismatch and dephasing, so a measured S below the Tsirelson bound is an apparatus statement rather than a physics statement; the visibility threshold $1/\sqrt{2}$ below which CHSH cannot be violated at all; why every reported violation is therefore also a bound on the imperfection of the source and detectors, and how the two are separated in the error budget.]

Phenomenon 89.4 (A violation requires a threshold quality)**.** The measured S falls below $2\sqrt{2}$ in every real apparatus, and it falls monotonically with the interference visibility of the source. No violation at all is seen once that visibility drops below $1/\sqrt{2}$, about 71 %. Photon loss, mode mismatch, dark counts, dephasing and drift all act through this one parameter, and a reported S is therefore two statements at once: one about Nature and one about the apparatus. Separating them is what the error budget of a Bell test is for, and it is the reason a value of S short of $2\sqrt{2}$ is a statement about the equipment rather than a discrepancy with the theory.

Derivation. Model the imperfection by mixing the intended singlet with unpolarized noise,

$$\rho = V\,\left|\Psi^-\right\rangle\left\langle\Psi^-\right| + (1-V)\,\tfrac{1}{4}\mathbb{1}\,, \tag{89.3}$$

where V is the visibility read off the correlation fringe. The maximally mixed part contributes nothing to any correlator, since $\operatorname{tr}\big[\mathbb{1}\,(\boldsymbol{\sigma}\cdot\hat{\boldsymbol{a}})\otimes(\boldsymbol{\sigma}\cdot\hat{\boldsymbol{b}})\big] = \operatorname{tr}(\boldsymbol{\sigma}\cdot\hat{\boldsymbol{a}})\,\operatorname{tr}(\boldsymbol{\sigma}\cdot\hat{\boldsymbol{b}}) = 0$, so every correlator is simply scaled: $E(\hat{\boldsymbol{a}},\hat{\boldsymbol{b}}) = -V\cos\theta$. Substituting into Equation (89.1) at the optimal angles multiplies the ideal value by V,

$$S_{\max}(V) = 2\sqrt{2}\,V\,, \tag{89.4}$$

so $|S|>2$ demands $V > 1/\sqrt{2}\approx 0.707$. Below that visibility no choice of settings violates the inequality, however many pairs are counted — the deficiency cannot be bought off with statistics — and for $V \le \tfrac{1}{2}$ there is in addition an explicit local hidden-variable model reproducing every projective measurement on Equation (89.3), so the state is then provably useless for the purpose. Above the threshold the number of pairs required grows only as the inverse square of the excess of S over 2, which is why the loophole-free experiments could afford to trade brightness for efficiency. □

89.5.4 The 2022 Nobel citation

[Reserved: the award to Clauser, Aspect and Zeilinger for experiments with entangled photons establishing the violation of Bell inequalities and pioneering quantum information science [2408]; the scientific background document as a compact history of the fifty years covered by this chapter; the observation, worth stating, that the prize was given for closing loopholes rather than for a discovery of a new effect — the discipline of eliminating alternatives is itself the achievement.]

89.6 Modern repetitions and precision

89.6.1 Closing the locality loophole

[Reserved: the Innsbruck experiment, with independent quantum random-number generators, fast electro-optic modulators and a 400 m fibre separation, in which every setting choice was spacelike separated from the distant detection [1963]; the timing budget that makes the claim, given as numbers; the extension to 144 km between the Canary Islands, which also addressed the freedom-of-choice loophole [2166].]

89.6.2 Closing the detection loophole

[Reserved: the trapped-ion experiment in which every prepared pair was detected, so that no fair-sampling assumption was needed [2019] — at the cost of a separation of a few micrometres, which leaves the locality loophole wide open; why the two loopholes pulled the design in opposite directions for fourteen years, and what had to improve in detector efficiency [2131] and in entanglement distribution before both could be closed at once.]

89.6.3 The loophole-free experiments

[Reserved: the three independent 2015 experiments — Delft, with nitrogen–vacancy centres 1.3 km *apart and event-ready entanglement swapping, 245 trials and* $p = 0.039$ *[2254]; Vienna, with a high-efficiency photonic source and the Eberhard inequality [2253]; and Boulder, with transition-edge sensors and a fully pre-registered analysis [2260]; the differences in their residual assumptions, and why three experiments with different systematics are worth more than any one of them repeated.]*

Phenomenon 89.5 (Locality and detection closed at the same time)**.** In 2015 three independent experiments [2253, 2254, 2260] observed violations of Equation (89.1) while enforcing together the two conditions that had previously been met only one at a time: each station's setting was chosen and its measurement completed in a region spacelike separated from the distant station's detection event, and essentially every prepared pair yielded a recorded outcome, so that no assumption of fair sampling was needed. The three used different physical systems — nitrogen–vacancy centres on a kilometre-scale baseline with event-ready entanglement swapping at Delft, and two high-efficiency photonic sources with pre-registered analyses at Vienna and at Boulder — and therefore different systematics, so that no single misunderstood effect can account for all three. Their combined conclusion is a statement about a class of theories, and it is the strongest statement the data support: no local hidden-variable theory reproduces the observed rates. The one assumption that remains, that the setting choices are not themselves correlated with the pair at preparation, cannot be removed by any experiment and can only be pushed back in time (Section 89.6.4).

Derivation pending #107

The detection-efficiency threshold: the least heralding efficiency at which the observed coincidence and singles rates cannot be reproduced by any local model free to decide which pairs go undetected, worked out both for the CHSH inequality with a maximally entangled state and for the Eberhard inequality with a partially entangled one, the latter threshold being the lower and being the reason the photonic experiments deliberately used a non-maximally entangled state

89.6.4 Pushing back the setting choice

[Reserved: cosmic Bell tests using the colour of photons from Milky Way stars [2283] and from quasars at redshifts above 3 [2318] to choose the settings; the BIG Bell Test, in which about one hundred thousand people supplied the setting bits for thirteen experiments on five continents in a single day [2307]; what each achieves precisely — an upper bound on the time available for a common cause — and what none of them can achieve.]

89.6.5 Other platforms and longer baselines

[Reserved: atoms in separate buildings [2285]; superconducting circuits in a cryogenic link [2422], the first loophole-free test with massive solid-state systems; satellite-distributed

entanglement over 1200 km*, which extends the correlations to space without closing the loopholes [2290]; multipartite tests, where the Greenberger–Horne–Zeilinger argument turns the statistical contradiction into an all-or-nothing one [1821] and its three-photon realization confirms the prediction [2002].]*

89.6.6 From test to instrument

[Reserved: the inversion of the logic, in which a measured violation certifies rather than tests — Ekert's entanglement-based key distribution [1843]; device-independent randomness generation, certified by the impossibility of superluminal signalling [2303]; the first device-independent quantum key distribution between two trapped-ion nodes [2404]; and the point that a violation used as an instrument must be loophole-free for exactly the reasons catalogued in Section 89.1.3.]

Chapter 90

Experiment: Precision Spectroscopy and Atomic Clocks

Frequency is the quantity physics measures best. Nothing else is known to eighteen significant figures, and the reason is structural: a frequency is a count of cycles against a clock, so its uncertainty falls with averaging time rather than being set by the resolution of an instrument. This chapter is the experimental record of that advantage. It begins with the microwave measurement by Lamb and Retherford of a splitting the Dirac equation of Chapter 93 forbids [901], whose explanation by Bethe [897] started renormalized quantum electrodynamics (Chapter 100). It continues through the hydrogen $1S$–$2S$ two-photon transition, whose natural linewidth of about 1.3 Hz on a carrier of 2.5×10^{15} Hz makes it the sharpest transition in the simplest atom [2179, 2221], and through the femtosecond frequency comb [1987, 1993, 2039], which replaced building-sized frequency chains with a single laser and made optical clocks possible. It ends with clocks whose systematic uncertainty is below 10^{-18} [2315, 2332, 2401].

When written the chapter will use the structured *experiment* environment, with apparatus, procedure, observations, interpretation and references as separate fields, and the measured frequencies with their uncertainty budgets lodged as a dataset in the evidence store. Its place in the book is as the quantitative test bench for Chapters 81 and 88: the atomic theory of those chapters is where the numbers come from, and the disagreements recorded here — above all the proton-radius puzzle [2164, 2210], which moved the accepted proton charge radius by seven standard deviations — are what a 10^{-15} measurement can do to a theory. The chapter also supplies evidence used elsewhere: the constancy of the fundamental constants (Chapter 2) [2134], the gravitational redshift of Chapter 42 measured across a millimetre [2401], and the CPT test of Chapter 105 in antihydrogen [2299]. The review is [2256].

Derivation pending #108

Experiment: Precision Spectroscopy and Atomic Clocks: all derivations of this chapter are pending.

90.1 Historical context and the prediction under test

90.1.1 The degeneracy the Dirac equation predicts

[Reserved: the Dirac spectrum of hydrogen (Chapter 93), in which the energy depends only on n and j, so that $2S_{1/2}$ and $2P_{1/2}$ are exactly degenerate; the pre-war optical evidence, which was consistent with the degeneracy to within its resolution; why an optical measurement

could not settle it and a radio-frequency measurement between the two levels could.]

90.1.2 The Lamb shift

[Reserved: the Lamb–Retherford experiment, in which a beam of metastable $2S_{1/2}$ hydrogen atoms was driven to $2P$ by a microwave field and the quenching detected as a drop in the beam current, giving a splitting of about 1000 MHz *where theory predicted zero [901]; Bethe's nonrelativistic estimate, made within weeks, which located the effect in the electron's interaction with its own radiation field and got the number essentially right by a mass subtraction [897]; the modern value near* 1057.8 MHz*, and the pointer to Chapters 100 and 112.]*

90.1.3 What a frequency measures

[Reserved: the chain from a measured transition frequency to a constant of nature — the Rydberg constant $R_\infty = (10\,973\,731.568\,157 \pm 0.000\,012)/\mathrm{m}$ as the most precisely known of the CODATA inputs [2392, 2431], the proton charge radius entering through the finite-size shift of the S levels, and the fine-structure constant entering through the QED terms; that a single transition determines a combination and not a constant, so at least two independent measurements are always needed; the definition of the second in the SI [2333] as the fixed point of the whole construction.]

Phenomenon 90.1 (Frequency uncertainty falls as the inverse square root of the averaging time)**.** The fractional frequency instability of an atomic clock — the deviation between successive averages of its output — falls as $\tau^{-1/2}$ with the averaging time τ, over many decades, before flattening on to a floor set by systematic effects [2315, 2332]. Nothing else in physics is measured this way. The resolution of the instrument is not the limit; a longer measurement buys precision at a known and verifiable rate, and the rate itself is checked by plotting the deviation against τ and reading off the slope. This is why frequency is the best-measured quantity there is, and why a precision spectroscopy paper is mostly about its systematic budget rather than about its statistics.

Derivation. Interrogate N uncorrelated atoms with a Ramsey sequence of free-evolution time T inside a cycle of total duration $T_\mathrm{c} \geq T$, and steer the oscillator to the centre of the resulting fringe. Each atom yields one of two outcomes, so the transition probability is estimated with the binomial uncertainty $1/(2\sqrt{N})$ at the half-height point of the fringe, where its slope is steepest. By Phenomenon 90.2 that slope is πT per unit frequency, so one cycle determines the frequency to

$$\delta\nu \sim \frac{1}{2\pi T\sqrt{N}}\,. \tag{90.1}$$

Successive cycles are statistically independent, so after a time τ containing $M = \tau/T_\mathrm{c}$ of them the error falls as $M^{-1/2}$ and the fractional instability is

$$\sigma_y(\tau) \sim \frac{1}{2\pi\nu_0 T\sqrt{N}}\sqrt{\frac{T_\mathrm{c}}{\tau}}\,, \tag{90.2}$$

with ν_0 the transition frequency. Three readings of Equation (90.2) between them account for the shape of the whole field. The $\tau^{-1/2}$ law is nothing but the independence of the cycles, so it persists exactly until some drift correlates them, and the τ at which the measured curve departs from the slope is therefore a diagnostic. The instability is inversely proportional to ν_0, so replacing a microwave transition near 1×10^{10} Hz by an optical one near 1×10^{15} Hz buys five orders of magnitude at equal T and N — which is the entire case for optical clocks,

and the reason the counting problem of Section 90.2.5 had to be solved before they could be used at all. And T is in practice limited by the coherence of the interrogating laser rather than of the atom, which is why Section 90.2.4 is a section about lasers in a chapter about atoms. □

90.2 Apparatus

90.2.1 Resonance methods

[Reserved: Rabi's molecular-beam magnetic resonance, which turned a frequency into a deflection and a null [819]; Ramsey's method of separated oscillatory fields, whose interference fringe is narrower than the transit-time limit of a single interaction region and which is the operating principle of every atomic clock since [968]; the hydrogen maser as an active oscillator on the ground-state hyperfine transition [1182]; the microwave method of [901] as the same idea applied to an excited state.]

Phenomenon 90.2 (Separated fields give a fringe narrower than the interaction)**.** Splitting the interrogation into two short pulses separated by a free interval T, instead of applying one continuous pulse, produces a transition probability that oscillates with the detuning with period $1/T$. The central fringe of that pattern is narrower than the resonance obtained from a single interaction of the same total duration, and narrower than the transit-time width of either pulse taken alone: the width is fixed by the time the atom spends *undisturbed* between the pulses, not by the time it spends interacting. Every atomic clock built since 1950 rests on this, and the SI second [2333] is realized with it.

Derivation. Treat the two levels as a spin one-half in the frame rotating at the drive frequency, where a detuning δ in angular measure appears as a field along the polar axis and the drive as a field in the equatorial plane. A pulse of area $\pi/2$, short enough that δ may be neglected during it, carries the initial state from the pole to the equator, $|0\rangle \mapsto (|0\rangle + |1\rangle)/\sqrt{2}$. During the free interval the two components acquire a relative phase δT,

$$\tfrac{1}{\sqrt{2}}\big(|0\rangle + |1\rangle\big) \longmapsto \tfrac{1}{\sqrt{2}}\big(|0\rangle + \mathrm{e}^{\mathrm{i}\delta T}\,|1\rangle\big)\,, \tag{90.3}$$

and a second identical pulse converts that phase back into a population,

$$P_1(\delta) = \tfrac{1}{2}\big[1 + \cos(\delta T)\big]\,. \tag{90.4}$$

The fringes are periodic in δ with period $2\pi/T$, that is $1/T$ in ordinary frequency; the central fringe has full width at half maximum $1/2T$; and the steepest slope, at the half-height point, is πT per unit frequency, which is the number Phenomenon 90.1 needs. Nothing in Equation (90.4) refers to the pulse duration at all.

Two consequences constrain the apparatus. The pattern is periodic, so the resonance must first be located to better than $1/T$ before the central fringe can be identified, which is why an interrogation is stepped down in T from a broad line. And any phase acquired between the pulses that is not δT — from a stray field, a residual motion, or an imperfect drive — is indistinguishable from a frequency offset. That is the reason the systematic budget of Section 90.3 is, item for item, a list of phases. □

90.2.2 Doppler-free laser spectroscopy

[Reserved: the first-order Doppler width, which at room temperature exceeds the natural width of an optical transition by four orders of magnitude and is the obstacle every technique here addresses; saturated-absorption spectroscopy; Doppler-free two-photon excitation, in which counter-propagating beams cancel the linear shift for every velocity class at once — applied to hydrogen $1S$–$2S$ by Hänsch and collaborators [1546]; the residual second-order (time-dilation) shift, which is not *cancelled and which is why the atoms must also be slowed.]*

90.2.3 Cooling and trapping

[Reserved: the proposal to cool a gas by resonant radiation pressure [1547]; deceleration of an atomic beam by frequency-chirped light [1700]; three-dimensional optical molasses [1750]; the magneto-optical trap; the optical lattice at the magic wavelength, at which the light shifts of the two clock levels are equal so that trapping does not move the clock transition [2053]; cryogenic hydrogen beams and the nozzle temperature that sets the residual second-order Doppler shift in [2179].]

Phenomenon 90.3 (A trap that does not move the clock)**.** Atoms held in an optical lattice have both clock levels displaced by the trapping light, and at a general trap wavelength the two displacements differ, so a trapped atom does not have the transition frequency of a free one. At one particular wavelength, different for each species and found by measurement, the two displacements are equal [2053, 2084]: the transition frequency of the trapped sample then agrees with the free-atom value, and what residual dependence on the trap depth remains is small enough to be extrapolated to zero. This is what permits some 10^4 atoms to be interrogated simultaneously while confined tightly enough that the recoil and the first-order Doppler shift both vanish, without the confinement itself displacing the clock.

Derivation. A non-resonant field of amplitude E_0 and angular frequency ω displaces a level i by the second-order energy

$$U_i(\omega) = -\tfrac{1}{4}\alpha_i(\omega)\,E_0^2\,, \tag{90.5}$$

where α_i is the dynamic polarizability, a sum over the dipole transitions out of level i weighted by $(\omega_{ki}^2 - \omega^2)^{-1}$. The displacement of the clock transition is the difference,

$$\Delta U(\omega) = -\tfrac{1}{4}\big[\alpha_e(\omega) - \alpha_g(\omega)\big]E_0^2\,, \tag{90.6}$$

which vanishes wherever the two polarizability curves cross, and does so at every intensity: the condition $\alpha_e = \alpha_g$ fixes a wavelength and says nothing whatever about the trap depth. Such a crossing exists because the two levels are connected by dipole transitions to different sets of states, so their polarizabilities have poles at different frequencies and their difference must change sign between consecutive poles; a usable magic wavelength is a zero of that difference lying far enough from every pole that the induced scattering loss is tolerable.

The distinction that makes this an instrument rather than a trick is worth stating. A cancellation arranged by tuning an intensity would have to be maintained, and every fluctuation of the intensity would reappear as a frequency shift. Here the cancellation is a property of the frequency of the light alone — a quantity that can itself be stabilized to the precision of the clock — so the residual sensitivity to depth is second order and the leading systematic disappears from Section 90.3 rather than being corrected for. □

90.2.4 Stable lasers and optical cavities

[Reserved: the Pound–Drever–Hall scheme for locking a laser to a reference cavity [1718], the same technique that holds the interferometers of Chapter 47 on resonance; the thermal noise floor of the mirror coatings, and the cryogenic single-crystal silicon cavity that reached a linewidth below 40 mHz *[2195]; why the interrogation laser, not the atom, has been the limiting element of optical clocks.]*

90.2.5 The frequency comb

[Reserved: the spectrum of a mode-locked femtosecond laser as a comb of lines at $f_n = n f_{rep} + f_{ceo}$, so that an optical frequency is measured by counting two radio frequencies; self-referencing by octave-spanning supercontinuum, which measures f_{ceo} directly [1993]; the first direct microwave-to-optical link [1987]; the review that established the method [2039];

comb transfer over a 920 km *fibre link between Garching and Braunschweig, which let the hydrogen transition be compared with a primary caesium standard without moving either [2221].]*

Phenomenon 90.4 (A pulse train is a comb of exactly equidistant optical lines)**.** The spectrum of a mode-locked femtosecond laser consists of hundreds of thousands of sharp lines spanning hundreds of terahertz, and their spacing is uniform across the whole span to the precision with which it can be compared. Each line sits at

$$f_n = n\, f_{\mathrm{rep}} + f_{\mathrm{ceo}}\,, \tag{90.7}$$

with n an integer of order 10^6 and f_{rep} and f_{ceo} both radio frequencies that an ordinary counter measures directly. An optical frequency is therefore determined by counting two radio frequencies and one integer [1987, 1993]. Before this, the gap between a caesium standard and an optical transition had to be bridged by a chain of phase-locked oscillators that filled a building and was operated by a team; the comb replaced it with one laser, and that is what made optical clocks usable rather than merely conceivable.

Derivation. Let $A(t)$ be the complex field of a single pulse — envelope times carrier — and let the train repeat with period $T = 1/f_{\mathrm{rep}}$. The carrier is not locked to the envelope: group and phase velocities in the laser cavity differ, so the carrier slips under the envelope by a fixed phase φ from one pulse to the next, and

$$E(t) = \sum_{m} A(t - mT)\, \mathrm{e}^{\mathrm{i}m\varphi}\,. \tag{90.8}$$

Taking the Fourier transform of Chapter 17,

$$\tilde{E}(\omega) = \tilde{A}(\omega) \sum_{m} \mathrm{e}^{\mathrm{i}m(\varphi - \omega T)}\,, \tag{90.9}$$

and the sum is a periodic comb of delta functions: it vanishes unless $\omega T - \varphi$ is an integer multiple of 2π, that is unless $\omega_n = (2\pi n + \varphi)/T$. In ordinary frequency this is Equation (90.7), with

$$f_{\mathrm{rep}} = \frac{1}{T}\,, \qquad f_{\mathrm{ceo}} = \frac{\varphi}{2\pi}\, f_{\mathrm{rep}}\,. \tag{90.10}$$

The pulse shape enters only through $\tilde{A}(\omega)$, which decides which lines carry appreciable amplitude and never where a line sits. The spacing is therefore exactly f_{rep} everywhere in the spectrum, with no error accumulating across the span, because it descends from a repetition period rather than from a dispersion relation.

Measuring f_{rep} is trivial. Measuring the offset is not, and the trick that makes it possible requires the comb to span an octave: frequency-double the line n and beat it against the line $2n$. Their difference is $2(n f_{\mathrm{rep}} + f_{\mathrm{ceo}}) - (2n f_{\mathrm{rep}} + f_{\mathrm{ceo}}) = f_{\mathrm{ceo}}$, in which the unknown integer has cancelled identically. That self-referencing is why an octave-spanning supercontinuum is not a convenience but the enabling step. □

90.3 Procedure

[Reserved: the measurement cycle — prepare, interrogate with a Ramsey sequence, read out, steer the laser to the line centre, repeat; line-centre determination and the statistical uncertainty falling as the inverse square root of averaging time; the systematic budget, which is the real content of a precision measurement and is to be tabulated in full: second-order Doppler, recoil, DC and AC Stark, Zeeman, blackbody radiation, collisional, servo and gravitational shifts, each with its measured or bounded size [2179, 2256]; extrapolation to zero density and to zero light intensity; the practice of splitting the analysis between groups and of publishing the budget before the value.]

90.4 Observations

[Reserved: the quantities to be tabulated in SI with uncertainties per [2129]. The hydrogen $1S$–$2S$ centroid frequency $(2\,466\,061\,413\,187\,035 \pm 10)$ Hz, a fractional uncertainty of 4.2×10^{-15} [2179], and its confirmation through the fibre link [2221]; the $2S$–$4P$ and $1S$–$3S$ transitions as the second input needed to separate R_∞ from the proton radius [2281, 2311]; the $2S$–$2P$ Lamb shift measured in electronic hydrogen [2331] and in muonic hydrogen [2164, 2210]; the derived root-mean-square charge radius, $(0.841\,84 \pm 0.000\,67)$ fm from muonic hydrogen against the then-accepted (0.8768 ± 0.0069) fm from electronic hydrogen and electron scattering; clock fractional uncertainties — caesium fountains at a few parts in 10^{16} [2321], Al^+ at 9.4×10^{-19} [2332], ytterbium at 1.4×10^{-18} [2315].]

90.5 Interpretation

90.5.1 Tests of quantum electrodynamics

[Reserved: hydrogen as the system in which a bound-state QED calculation and a measurement meet with no adjustable parameters beyond R_∞ and the proton radius; the hierarchy of contributions — self-energy, vacuum polarization, recoil, two-loop terms — and the order at which theory rather than experiment currently limits the comparison; the complementary tests in the electron anomalous moment [2256] and in Chapter 112, and in helium (Section 90.6.3).]

90.5.2 The proton-radius puzzle

[Reserved: the discrepancy as it arose — muonic hydrogen giving a radius smaller by about 4 %, some seven standard deviations from the CODATA value, with the muon's larger overlap with the nucleus amplifying the finite-size shift by roughly $(m_\mu/m_e)^3$ [2164, 2210]; the subsequent electronic measurements that moved toward the small radius [2281, 2331, 2358], the low-momentum-transfer scattering experiment that agreed with them [2344], and the $1S$–$3S$ result that did not [2311]; the CODATA adjustment that followed [2431]; the honest verdict, that the puzzle is largely resolved in favour of the small radius and that the remaining tension is a datum, not an embarrassment to be smoothed.]

90.5.3 Constants, and whether they are constant

[Reserved: the comparison of two optical clocks with different sensitivity to the fine-structure constant as a null test of its variation, and the aluminium–mercury ratio measurement that bounded $\dot\alpha/\alpha$ at the 10^{-17} level per year [2134]; the improved bounds from clock networks and the associated limits on violations of local position invariance [2385]; the relation to the astrophysical claims and to the Oklo bound already assessed in [2183]; why a laboratory null result at this precision is the strongest available statement.]

Phenomenon 90.5 (The fine-structure constant does not measurably change)**.** Two optical clocks whose transition frequencies depend differently on the fine-structure constant have been compared over long periods, and their ratio is found not to drift. The comparison of an aluminium-ion clock with a mercury-ion clock bounds the fractional rate of change of α at the level of parts in 10^{17} per year [2134], and it is consistent with the geological and astrophysical bounds assessed in [2183]. What is measured is a ratio of two frequencies in one laboratory, so no assumption about the constancy of any unit enters anywhere — which is the point, since a dimensional constant has no observer-independent rate of change at all and only a dimensionless one can be said to drift.

Derivation. Any atomic transition frequency may be written

$$\nu_i = c\,R_\infty\,A_i\,F_i(\alpha)\,, \tag{90.11}$$

with A_i a pure number fixed by the level structure and F_i collecting the relativistic and radiative corrections, which are the only place α enters once cR_∞ has been factored out. Define the sensitivity $K_i = \partial \ln F_i / \partial \ln \alpha$, computed once per species and large for heavy atoms, where the relativistic corrections grow steeply with nuclear charge. In the ratio of two such frequencies the factor cR_∞ cancels, and with it every dimensional quantity in the problem, leaving

$$\frac{\mathrm{d}}{\mathrm{d}t} \ln \frac{\nu_1}{\nu_2} = (K_1 - K_2)\,\frac{\dot\alpha}{\alpha}\,. \tag{90.12}$$

A bound on the drift of the measured ratio therefore converts directly into a bound on $\dot\alpha/\alpha$, divided by the difference of the two sensitivities — which is why the experiment pairs species chosen to make $K_1 - K_2$ as large as possible rather than to make either clock individually best.

Two features of Equation (90.12) carry the argument. Because it is a ratio it is a dimensionless statement, immune to the objection that the second might be drifting along with everything else. And because it is tested against zero rather than against a predicted value, its reach improves twice over: through the statistical uncertainty of each comparison, which falls by Phenomenon 90.1, and through the span of time over which the comparisons are separated, which enters the slope directly. □

90.5.4 Relativity measured with clocks

[Reserved: the Gravity Probe A hydrogen-maser rocket flight, confirming the gravitational redshift to about $0.007\,\%$ *[1660]; the demonstration of both the velocity and the height effect with optical clocks at everyday scales — speeds of* $10\,\mathrm{m/s}$ *and height differences of* $0.33\,\mathrm{m}$ *[2154]; the resolution of the redshift across a single millimetre of a strontium sample [2401]; the consequence that relativistic geodesy is now a measurement technique (Chapters 41 and 42), and that a clock comparison at* 10^{-18} *requires the geoid height of each clock to a centimetre.]*

Phenomenon 90.6 (Two clocks one metre apart run at different rates)**.** Two clocks of identical construction, at rest in the laboratory and separated vertically, do not keep the same time: the higher runs faster, by the fractional amount

$$\frac{\Delta\nu}{\nu} = \frac{g\,\Delta h}{c^2}\,, \qquad \frac{g_0}{c^2} = 1.09 \times 10^{-16}/\mathrm{m}\,, \tag{90.13}$$

and the effect has been resolved at height differences of a fraction of a metre and, most recently, across a single millimetre of one trapped atomic sample [2154, 2401]. It is not a correction to be applied at the end of an analysis. At the 10^{-18} level of the best clocks the height of each clock above the geoid must be known to about a centimetre before two of them can be compared at all, so that a clock comparison has become a way of measuring that height (Chapter 42).

Derivation. Compare a clock at height h with one at the floor, in a field treated as uniform over that height, and use the equivalence principle: the laboratory is locally indistinguishable from a frame accelerating upwards with acceleration g. A signal of frequency ν emitted downwards takes a time h/c to arrive, and during that time the receiver has acquired an upward speed $v = gh/c$ relative to the frame in which the emitter was at rest at the moment of emission. The first-order Doppler shift then makes the received frequency higher by

$$\frac{\Delta\nu}{\nu} = \frac{v}{c} = \frac{gh}{c^2}\,, \tag{90.14}$$

which is Equation (90.13). Inserting the conventional standard value $g_0 = 9.806\,65\,\mathrm{m/s^2}$ and the exactly defined $c = 299\,792\,458\,\mathrm{m/s}$ [2333] gives $g_0/c^2 = 1.09 \times 10^{-16}/\mathrm{m}$, the number quoted — a shift that the best clocks resolve in seconds and that was, within living memory, at the edge of what a Mössbauer experiment could reach over the height of a tower.

Two limits on the reading. The derivation is first order in gh/c^2 and uses only the equivalence principle together with special relativity, so what it tests is the universality of free fall and not any field equation; the general-relativistic treatment, and what a measured violation would mean, belong to Chapter 42. And the comparison is one of *rates*, not of readings, so it is unaffected by the arbitrary epoch at which either clock was started — which is exactly why an atomic transition, whose frequency is fixed by physics rather than by a convention, is the right instrument for the measurement. □

90.6 Modern repetitions and precision

90.6.1 Optical clocks

[Reserved: the two families — single trapped ions, with essentially no collisional shift but a small signal [2134, 2332], and neutral atoms in a magic wavelength lattice, with 10^4 atoms interrogated at once [2053, 2084, 2315, 2401]; quantum logic spectroscopy, which reads out a clock ion through a co-trapped logic ion [2332]; the blackbody shift as the dominant systematic for most species and the cryogenic environments that suppress it; the stability–accuracy distinction, which is routinely conflated and must not be here [2256].]

90.6.2 Redefining the second

[Reserved: Essen and Parry's caesium standard [1064] and the 1967 definition it enabled [2333]; the accuracy of present primary fountains [2321], now two orders of magnitude behind the best optical clocks; the recommended frequency values for secondary representations of the second [2319] and the criteria a redefinition must satisfy; the practical obstacle, which is not clock performance but the comparison links between national laboratories.]

90.6.3 Two-electron and exotic atoms

[Reserved: helium as the two-electron benchmark, with the $2\,^3S_1 \to 2\,^1S_0$ transition measured in a quantum degenerate gas [2182] and the $2\,^3S$–$2\,^3P$ interval as a route to the fine-structure constant [2291]; muonic helium, giving the alpha-particle charge radius [2384]; positronium, a purely leptonic atom with no nuclear structure at all, in the $1\,^3S$–$2\,^3S$ interval [1864] and in the $n = 2$ fine structure [2359]; muonium, in the ground-state hyperfine interval [1978] and in the $1S$–$2S$ transition [1999]. Each removes one source of theoretical uncertainty that hydrogen carries.]

90.6.4 Antihydrogen

[Reserved: trapped antihydrogen and the measurement of its $1S$–$2S$ transition, consistent with hydrogen at the level of 2×10^{-12} [2299] — the sharpest existing test of CPT symmetry in a bound system (Chapter 105); the production, trapping and laser-cooling chain that makes a spectroscopy experiment out of a few thousand atoms per run; the gravitational free-fall measurement as the complementary programme.]

90.6.5 Toward a nuclear clock

[Reserved: the anomalously low-lying isomeric state of $^{229}\mathrm{Th}$, at about $8.4\,\mathrm{eV}$, the only nuclear transition within reach of a laser; its direct laser excitation [2428] and the measurement

of its frequency ratio against a strontium optical clock [2429]; why a nuclear transition is expected to be far less sensitive to external fields and far more sensitive to a variation of the constants of Section 90.5.3 than any electronic one; the status, which is a demonstrated transition and not yet a clock.]

Chapter 91

Experiment: Quantum Tunnelling Observed
