Chapter 78 makes a prediction that has no classical counterpart at all. A particle whose energy lies below the top of a potential barrier still appears on the far side of it, with a probability that falls exponentially in the width of the barrier and in the square root of its height. Nothing in Newtonian mechanics permits this: a classical particle turns around at the point where its kinetic energy vanishes, and the region beyond is not merely improbable but inaccessible. The quantum statement is not a small correction to that picture; it contradicts it outright.

This chapter reports the measurements. They are unusually varied for a single prediction. The barriers range from the Coulomb repulsion of a heavy nucleus, a few times $10^{-14}\,\mathrm{m}$ across and tens of megaelectronvolts high, to a vacuum gap of a few tenths of a nanometre and a few electronvolts high; the particles are alpha particles, electrons at a metal surface, electrons in a semiconductor band, and quasiparticles in a superconductor; the observables are half-lives, current–field curves, current–voltage curves, and pictures of individual atoms. Between the shortest and the longest alpha-decay half-life lies a factor of about 10^{24}, and one exponential accounts for it. Two of these experiments, moreover, did not merely confirm the effect: they inverted it into instruments — tunnelling spectroscopy of the superconducting gap and the scanning tunnelling microscope — so that the least intuitive prediction of quantum mechanics is today a routine laboratory tool. The pair tunnelling of Cooper pairs across the same kind of junction is the Josephson effect, measured in Chapter 131.

91.1 The prediction under test

Every experiment in this chapter measures the same quantity in a different guise, so it is worth writing it once. Let a particle of mass m and energy E meet a one-dimensional barrier $V(z) > E$ between the turning points z_1 and z_2. In the forbidden region the Schrödinger equation has no oscillating solution; the wavefunction decays with the local rate

$$\kappa(z) = \frac{\sqrt{2m\,[V(z) - E]}}{\hbar}\,, \tag{91.1}$$

and the semiclassical transmission probability of Chapter 82 is

$$T \simeq \mathrm{e}^{-G}\,, \qquad G = 2\int_{z_1}^{z_2} \kappa(z)\,\mathrm{d}z\,. \tag{91.2}$$

The whole of what follows is the exponent G evaluated for different barriers. Three features of Equation (91.2) make it testable, and each of the five experiments below turns on one or more of them.

First, T is exponential in the barrier area $\int \kappa \, \mathrm{d}z$, so a modest change in the barrier produces an enormous change in the rate. That is what makes the Geiger–Nuttall relation as steep as it is, and what makes the tunnel current a length gauge of picometre resolution.

Second, T contains no temperature. A thermally activated process carries the Arrhenius factor $\mathrm{e}^{-\Delta E/k_{\mathrm{B}}T}$ and dies as the sample is cooled; a tunnelling process does not. Cold emission from a metal and the peak current of a tunnel diode both survive cooling, and that is how they are distinguished from their classical competitors.

Third, the rate depends on the states available on the far side. This is invisible in the one-body formula but decisive in a solid: the current through a junction counts the empty states the particle can arrive in, so a tunnel junction reads out a density of states. Giaever's measurement of the superconducting gap and Esaki's negative differential resistance are both consequences.

91.2 Alpha decay and the Geiger–Nuttall relation (1911, 1928)

The oldest evidence for tunnelling was in hand for seventeen years before anyone could read it. Alpha radioactivity presented two facts that classical mechanics could not hold together: the alpha particle leaves the nucleus with an energy far below the top of the electrostatic barrier it must cross, and the time it takes to do so depends on that energy with a violence that no ordinary rate law approaches.

91.2.1 Apparatus

Two independent measurements are combined, both made with the standard radioactive-source technique of the period. The range of the alpha particles from a thin deposit of a separated activity was measured in air at known temperature and pressure, either by the ionization produced in a shallow chamber as an absorbing gap was widened, or by counting scintillations on a zinc-sulfide screen as the screen was withdrawn from the source; the range in air at standard conditions is a monotone function of the emission energy and was used as its proxy. The decay constant of the same activity was obtained from the decay of its ionization current with time, or, for the long-lived parents, from the equilibrium activity of a known mass. The sources were members of the three natural series — uranium, thorium and actinium — separated by the radiochemistry of the day [372].

The second, independent, apparatus is the alpha-scattering geometry of Chapter 107: a collimated alpha beam from a strong source, a thin metal foil, and a scintillation screen viewed through a microscope on a rotating arm [379]. It does not measure a decay rate at all; it measures the height of the barrier, and it is what turns the decay data into a paradox.

91.2.2 Procedure

For each emitter the range R in air and the decay constant λ were tabulated, and $\log \lambda$ plotted against $\log R$. The claim under test was a statistical one about the family: whether the members of a series, which differ in nuclear charge, mass and structure, follow a single relation between how fast they decay and how energetically.

The scattering measurement runs the process backwards. An alpha particle fired at a heavy nucleus is turned around by Coulomb repulsion at the distance of closest approach d, fixed by

$$E = \frac{1}{4\pi\varepsilon_0}\frac{2Ze^2}{d}\,, \tag{91.3}$$

and the angular distribution follows the Coulomb law exactly, with no sign of the nuclear force, so long as d exceeds the nuclear radius. The barrier top is therefore not a theoretical construct: it is measured by the very nuclei that emit the alpha particles.

91.2.3 Observations and data

Geiger and Nuttall found that the members of each natural series fall on a straight line in the $(\log R, \log \lambda)$ plane, and that the three series give three nearly parallel lines, differing only in intercept [372]. The lines are extraordinarily steep: the observed ranges in air span a factor of about three, from a few centimetres to under a decimetre, while the decay constants span more than twenty powers of ten.

Table 91.1 restates the same fact in modern terms for six familiar emitters, so that the steepness can be read directly. The energies and half-lives are standard tabulated values [2382] quoted here for orientation, not measurements of this chapter, and are rounded; Geiger and Nuttall themselves worked with ranges rather than energies.

Table 91.1: Alpha energy and half-life for six natural alpha emitters. A factor of 2.2 in energy carries the half-life across some 24 orders of magnitude — the observation that Equation (91.4) has to explain. Values are standard tabulated ones [2382], rounded, and are not drawn from [372], which reports ranges in air.

Emitter	E_α	half-life
^{232}Th	4.01 MeV	1.40×10^{10} yr
^{238}U	4.20 MeV	4.47×10^{9} yr
^{226}Ra	4.78 MeV	1600 yr
^{222}Rn	5.49 MeV	3.30×10^{5} s
^{214}Po	7.69 MeV	1.64×10^{-4} s
^{212}Po	8.78 MeV	3.0×10^{-7} s

The scattering data supply the second number. For a heavy nucleus the Coulomb barrier evaluated at the nuclear surface reaches several times the energy of the alpha particles that the same nucleus emits, and the Coulomb scattering law is observed to hold down to distances of closest approach well inside the classical turning point of an emitted alpha [379].

Phenomenon 91.1 (Emission from below the barrier)**.** An alpha-emitting nucleus emits alpha particles whose energy lies far below the top of its own Coulomb barrier, as that barrier is measured independently by the scattering of alpha particles from the same nuclei [379]. There is no classical trajectory by which the particle can leave, and the nucleus decays regardless [372, 600].

Derivation. The inequality is established without any theory of the decay, by the scattering measurement alone. Fire alpha particles of energy E_s at nuclei of the species in question. If the observed angular distribution follows the Coulomb law, the two charges never came closer than the distance d of Equation (91.3) evaluated at E_s, and no departure from that law is seen for the fastest natural alpha particles on the heaviest nuclei [379]. The nuclear surface therefore lies inside that distance, $R_\mathrm{n} < d$; and since the Coulomb potential decreases monotonically outward,

$$V\left(R_\mathrm{n}\right) > V\left(d\right) = E_\mathrm{s}\,.$$

The barrier top thus exceeds the energy of the fastest alpha particle available for scattering, which in turn exceeds the emission energy of the great majority of the natural emitters of Table 91.1. The classical turning point of an emitted alpha lies outside the nucleus that

emitted it, with a forbidden region in between. That the nucleus decays all the same is the observation; the rate at which it does so is Phenomenon 91.2, and both are accounted for by Equation (91.4). □

Phenomenon 91.2 (The Geiger–Nuttall relation)**.** Within each of the three natural radioactive series the decay constant and the range of the emitted alpha particle satisfy $\log \lambda = A + B \log R$ with a slope B common to the three series and an intercept A characteristic of each [372]. Equivalently, the logarithm of the decay constant is linear in the reciprocal square root of the alpha energy. Across the natural emitters a factor of about two in energy moves the half-life by more than twenty orders of magnitude.

Derivation. Outside the nuclear radius R_{n} the alpha particle of charge $2e$ sees only the Coulomb field of the daughter nucleus of charge Ze,

$$V(r) = \frac{1}{4\pi\varepsilon_0}\frac{2Ze^2}{r}\,,$$

which exceeds the emission energy E everywhere inside the outer turning point b defined by $V(b) = E$. Substituting in Equations (91.1) and (91.2) and writing $b = 2Ze^2/\left(4\pi\varepsilon_0 E\right)$,

$$G = \frac{2}{\hbar}\int_{R_{\mathrm{n}}}^{b}\sqrt{2m\left(\frac{2Ze^2}{4\pi\varepsilon_0 r} - E\right)}\,\mathrm{d}r = \frac{2\sqrt{2mE}}{\hbar}\int_{R_{\mathrm{n}}}^{b}\sqrt{\frac{b}{r} - 1}\,\mathrm{d}r\,.$$

The remaining integral is elementary. With $x = R_{\mathrm{n}}/b$,

$$G = \frac{2b\sqrt{2mE}}{\hbar}\left[\arccos\sqrt{x} - \sqrt{x\,(1-x)}\right]. \tag{91.4}$$

For a barrier much wider than the nucleus, $x \to 0$, the bracket tends to $\pi/2$ and

$$G \longrightarrow 2\pi\eta\,, \qquad \eta = \frac{1}{4\pi\varepsilon_0}\frac{2Ze^2}{\hbar v}\,, \qquad v = \sqrt{\frac{2E}{m}}\,. \tag{91.5}$$

The decay constant is the number of assaults on the barrier per unit time, f, times the probability that one succeeds, so

$$\ln\lambda = \ln f - G\,,$$

and since $\eta \propto Z/\sqrt{E}$ the logarithm of the decay constant is linear in $ZE^{-1/2}$. Within a single series Z varies only slightly, and the statement collapses to the empirical relation of Phenomenon 91.2, the range in air being a monotone function of E. The prefactor f is a nuclear frequency of order $v/2R_{\mathrm{n}}$ and varies by a factor of a few across the whole family; it cannot produce twenty orders of magnitude, and it does not need to, because G does. □

The size of G is what carries the argument. For the alpha decay of $^{238}\mathrm{U}$ the velocity parameter is $v/c \approx 0.047$ and the daughter charge $Z = 90$, so $\eta \approx 28$ and the point-Coulomb exponent $2\pi\eta$ of Equation (91.5) is of order 170; the finite nuclear radius, through the bracket of Equation (91.4), roughly halves it. An exponent of order 10^2 that scales as $E^{-1/2}$ changes by tens when the energy changes by a factor of two, and e^{-G} therefore changes by tens of orders of magnitude. This is the first quantitative success of quantum mechanics inside the nucleus, and it was obtained twice over within months: by Gamow [600] and, independently, by Gurney and Condon [603, 625].

91.2.4 Interpretation

The two phenomena above are irreconcilable in classical mechanics and are two readings of one formula in quantum mechanics. Phenomenon 91.1 says the particle is where it cannot be; Phenomenon 91.2 says the rate at which it gets there is exponential in the barrier, which is the signature of Equation (91.2) and of nothing else. No rate law built on a classical escape over the barrier can reproduce the observed steepness with a reasonable nuclear temperature, and the alternative of a barrier low enough to be climbed is excluded by the scattering measurement that fixes its height.

Two consequences reach far beyond this chapter. Run the same penetration factor backwards and it governs the fusion of light nuclei at stellar temperatures, where the thermal energies are likewise far below the Coulomb barrier: this is the Gamow-peak argument of Chapter 52, first drawn by Atkinson and Houtermans within a year of Gamow's paper [622]. And the exponential sensitivity is the reason alpha half-lives are useful chronometers over geological time, since a rate this steep in energy is correspondingly insensitive to everything else, including the chemical and thermal environment.

A caution belongs here about attribution. Gurney and Condon's short note in *Nature* [603] and Gamow's paper [600] appeared within weeks of one another, and the full Gurney–Condon treatment followed the next year [625]. The qualitative insight — that radioactive decay is barrier penetration and needs no trigger — is common to both; the explicit evaluation of Equation (91.4) and its confrontation with the Geiger–Nuttall systematics is Gamow's.

91.2.5 Primary references

[372] for the empirical relation; [379] for the independent measurement of the barrier; [600, 603, 625] for the explanation; [622] for the stellar inverse. The energies and half-lives of Table 91.1 are standard tabulated values quoted at second hand and are not taken from any of these papers.

91.3 Fowler and Nordheim: cold field emission from metals (1928)

A metal emits electrons when it is hot: the thermionic current is the tail of the Fermi distribution spilling over the work function, and it vanishes as the metal is cooled. A metal also emits electrons when it is cold, if the field at its surface is strong enough — and that current does not vanish as the metal is cooled. The two emissions obey different laws, and the difference is the whole of the evidence.

91.3.1 Apparatus

A sharply pointed metal cathode — a wire etched to a tip of radius of order 100 nm, tungsten being the usual choice — facing an anode in a sealed and evacuated tube. The geometry is the point of the apparatus: the field at a tip of radius r held at potential V is of order V/r, so a few kilovolts across a centimetre gap becomes several volts per nanometre at the apex, some four orders of magnitude larger than the mean field in the tube. The emitted current is collected at the anode and measured over several decades with an electrometer; the cathode can be heated independently, so that the emission can be followed as a function of temperature at fixed field.

91.3.2 Procedure

The emitted current I is recorded against the applied voltage, and converted to a current density J and a surface field F through the tip geometry. Two tests are then applied. The first is the shape of the curve: the prediction is that $\ln\left(J/F^2\right)$ is linear in $1/F$, a form now universally called a Fowler–Nordheim plot, with a slope fixed by the work function alone. The second is the temperature dependence at fixed field, which separates the two mechanisms decisively: thermionic emission is exponential in $-1/T$ and field emission is, to first approximation, independent of T.

91.3.3 Observations and data

Cold metals emit copiously once the surface field reaches the order of $10^9\,\mathrm{V/m}$, that is a few volts across a nanometre, at temperatures where thermionic emission is unmeasurably small. Plotted as $\ln\left(J/F^2\right)$ against $1/F$ the measured curves are straight over several decades of current, and the slopes are consistent with work functions of a few electronvolts — the same work functions that the photoelectric threshold of Chapter 69 measures on the same metals. Fowler and Nordheim analysed the existing cold-emission data on exactly this basis and obtained the law from the new wave mechanics [599].

Phenomenon 91.3 (Cold field emission)**.** A metal at room temperature or below emits electrons into vacuum when the field at its surface reaches the order of $10^9\,\mathrm{V/m}$, although no electron in it has the energy to surmount the work function. The emitted current density obeys

$$J = \frac{a\,F^2}{\phi}\exp\left(-\frac{4\sqrt{2m_\mathrm{e}}\,\phi^{3/2}}{3\hbar e F}\right), \tag{91.6}$$

so that $\ln\left(J/F^2\right)$ is linear in $1/F$ with a slope fixed by the work function ϕ alone, and the current is essentially independent of temperature [599].

Derivation. Put the metal surface at $z=0$, the electron gas filled to the Fermi level, and the vacuum level a work function ϕ above it. An applied field F tilts the vacuum potential, so that an electron at the Fermi level sees

$$V(z) - E_\mathrm{F} = \phi - eFz \qquad (z>0)\,,$$

a triangular barrier of height ϕ and base ϕ/eF. The barrier does not have to be surmounted, only crossed, and Equation (91.2) gives

$$G = \frac{2}{\hbar}\int_0^{\phi/eF}\sqrt{2m_\mathrm{e}\left(\phi - eFz\right)}\,\mathrm{d}z = \frac{4\sqrt{2m_\mathrm{e}}}{3\hbar eF}\,\phi^{3/2}\,.$$

Multiplying e^{-G} by the rate at which electrons of the degenerate gas arrive at the surface — an integral over the occupied states which is algebraic, not exponential, in F and contributes the factor F^2/ϕ — gives Equation (91.6). Taking logarithms,

$$\ln\frac{J}{F^2} = \ln\frac{a}{\phi} - \frac{4\sqrt{2m_\mathrm{e}}\,\phi^{3/2}}{3\hbar e}\cdot\frac{1}{F}\,,$$

which is the straight line the experiment plots. Note what is absent: the temperature never entered, because the electrons that cross are those at the Fermi level, not those in the thermal tail. Note also the field required. The exponent falls to order 10 only when F reaches some $10^9\,\mathrm{V/m}$ for a work function of a few electronvolts, which is why cold emission is a phenomenon of sharp points and thin gaps and was never seen from a flat electrode. □

91.3.4 Interpretation

This is the first tunnelling experiment in which the barrier is under the experimenter's control. In alpha decay the barrier is whatever the nucleus provides; here the height is chosen by choosing the metal and the width is set by turning a voltage knob, and the predicted functional form in both variables can be checked. The straightness of the Fowler–Nordheim plot tests the exponent's dependence on F; the slope tests its dependence on $\phi^{3/2}$ against an independent photoelectric measurement of ϕ; and the absence of temperature dependence excludes the thermionic alternative outright.

The historical position of [599] is worth stating plainly. It is one of the earliest quantitative applications of the new quantum mechanics to a solid, and it rests on Sommerfeld's Fermi-statistics treatment of the electron gas [620], published the same year. The pre-quantum theories of cold emission, which sought to lower the barrier until classical escape became possible, could not survive a measurement of ϕ by any other route.

Two long descendants follow. The field-emission electron source, being cold, bright and small, became the standard gun of high-resolution electron microscopy; and the recognition that a vacuum gap is simply a barrier whose width can be varied continuously is the seed of Section 91.6.

91.3.5 Primary references

[599]; the underlying electron-gas statistics [620]. The empirical finding that the logarithm of the cold-emission current is linear in the reciprocal field predates the theory and is due to Millikan and his collaborators [612]; it is quoted here at second hand through [599], which analyses that data.

91.4 Esaki: the tunnel diode and negative differential resistance (1958)

Tunnelling in a solid need not cross a vacuum gap. In a semiconductor the forbidden energy gap is itself a barrier, and a p–n junction narrow enough turns it into one a carrier can cross. What Esaki found in doing so was a current that *falls* as the voltage rises — a negative differential resistance, impossible for any junction whose carriers move by drift and diffusion.

91.4.1 Apparatus

Germanium p–n junctions doped degenerately on both sides, so that the Fermi level lies inside the conduction band on the n-side and inside the valence band on the p-side. Degenerate doping is what makes the experiment: the depletion layer of a junction narrows as the doping rises, and at the impurity concentrations used the junction is of order 10 nm wide — thin enough for Equation (91.2) to give an appreciable transmission across the forbidden gap. The junctions were made by alloying, contacted for four-terminal measurement, and mounted in a cryostat so that the characteristic could be taken at several temperatures [1141].

91.4.2 Procedure

The current–voltage characteristic is recorded through forward and reverse bias, at room temperature and on cooling. Three features are looked for. In forward bias, the ordinary junction current is thermal injection over the built-in barrier and rises monotonically and exponentially; any departure from monotonicity is disqualifying for that mechanism. In reverse bias, an ordinary junction passes only a small saturation current until avalanche

breakdown; a tunnelling junction conducts freely from the smallest reverse bias. And on cooling, the thermal current must collapse while a tunnel current must not.

91.4.3 Observations and data

In forward bias the current rises steeply from zero to a peak at a bias of a few tens of millivolts, then *falls* with increasing voltage to a valley at a few hundred millivolts, and only then resumes the ordinary exponential climb of a diode. Between peak and valley the differential resistance $\frac{\mathrm{d}V}{\mathrm{d}I}$ is negative. In reverse bias the junction conducts immediately, with no threshold. The peak current is weakly dependent on temperature while the current beyond the valley follows the strongly temperature-dependent thermal law, so that cooling the sample makes the negative-resistance region more pronounced rather than less [1141].

Phenomenon 91.4 (Negative differential resistance in a degenerate junction)**.** A p–n junction degenerate on both sides and of order 10 nm wide passes, in forward bias, a current that rises to a peak at a bias of a few tens of millivolts and then decreases with increasing voltage before rising again: over a finite range of bias the differential resistance is negative. The effect is weakly temperature-dependent, unlike the thermal injection current that dominates beyond the valley [1141].

Derivation. Elastic tunnelling conserves energy, so a carrier crosses only into an empty state at its own energy; the current is therefore proportional to the overlap, in energy, between occupied states on one side and empty states on the other, weighted by the transmission e^{-G} of the junction.

Degeneracy on both sides is what creates such an overlap. On the n-side the conduction band is occupied up to a Fermi level lying above its edge; on the p-side the valence band is empty down to a Fermi level lying below its edge. At zero bias the two Fermi levels coincide, the forward and reverse flows cancel, and no net current flows. A forward bias V raises the whole n-side ladder by eV, opening a window of width eV in which occupied conduction states on the n-side face empty valence states on the p-side at the same energy: the tunnel current grows with V.

It cannot grow indefinitely. As the n-side rises further, its conduction-band edge is lifted past the p-side valence-band edge, and an electron in the window then faces the forbidden gap of the p-side, where there are no states at its energy at all. The overlap shrinks to zero, and with it the tunnel current. A current that rises from zero, is positive in between, and returns to zero must pass through a maximum and then decrease — and a decreasing current at increasing voltage is negative differential resistance. Beyond the cut-off, only the ordinary thermal injection current of a p–n junction remains, and its exponential climb produces the valley and the recovery.

The reverse-bias behaviour is the same argument with the roles exchanged: reverse bias always increases the overlap between occupied valence states and empty conduction states, so the current rises monotonically from zero bias with no threshold, which is what distinguishes this junction from an ordinary rectifier. □

Derivation pending #109

Magnitude of the interband tunnel current: the transmission of a carrier across the forbidden gap of a uniformly biased semiconductor, the imaginary wavevector inside the gap obtained by continuing the two-band dispersion relation, and the resulting exponential dependence of the peak current on the gap, the effective mass and the junction field

91.4.4 Interpretation

The observation of Phenomenon 91.4 is decisive because negative differential resistance is not a quantitative anomaly but a qualitative impossibility for transport by drift and diffusion, in which carrier flow increases with the driving field by construction. Its appearance requires a mechanism in which raising the bias can *remove* the final states, and interband tunnelling is such a mechanism because it is elastic and the semiconductor gap is empty of states. The temperature behaviour closes the argument: a thermally activated process cannot become more prominent on cooling.

The mechanism itself was not new in 1958 — Zener had proposed interband tunnelling as the cause of dielectric breakdown a quarter of a century earlier [750] — but the breakdown context gave no clean signature, since a runaway current can be produced in several ways. Esaki's contribution was to make a junction narrow enough that tunnelling dominates at low bias, where its consequences are unmistakable, and to read off from the shape of the characteristic that the current is a density-of-states overlap.

The device consequences were immediate and are treated with the band theory of Chapter 126 and the junction physics of Chapter 127: a tunnel current involves no storage of minority carriers and no transit time across a drift region, so the tunnel diode responds far faster than a conventional junction, and a negative resistance is an amplifier and an oscillator. For this chapter its importance is evidential — it is tunnelling observed in a solid, at millivolt energies, with the density of states of the far side written into the shape of the curve.

[1141]; the interband tunnelling mechanism [750].

91.5 Giaever: tunnelling spectroscopy of the superconducting gap (1960)

Esaki's junction reads out the states available on the far side of a barrier. Giaever turned that incidental feature into the measurement itself: if the tunnel current counts final states, then a junction with a superconductor on one side is a spectrometer for the superconducting energy gap — a quantity of order a millielectronvolt, far below anything optical spectroscopy could then reach.

91.5.1 Apparatus

A thin-film sandwich junction evaporated on a glass substrate. An aluminium strip is deposited first and its surface oxidized in air or in an oxygen glow discharge to grow an insulating film of aluminium oxide a few nanometres thick; a lead strip is then evaporated across it, the crossing defining the junction area. The oxide is the barrier; its thickness is what sets the junction resistance, and it must be thin enough to pass a measurable current and free enough of pinholes to pass it by tunnelling rather than through metallic shorts. Contacts at the four ends of the two strips allow a four-terminal measurement, which keeps the lead resistances out of the answer. The assembly sits in a liquid-helium cryostat, and a solenoid supplies a magnetic field large enough to drive the lead film normal [1180].

The choice of metals is deliberate. Lead becomes superconducting at about 7.2 K, aluminium at about 1.2 K. At 4.2 K the lead is superconducting and the aluminium is not, so the junction has one superconducting and one normal electrode; and the superconductivity can be switched off in place, without changing the junction, by applying the magnetic field.

91.5.2 Procedure

The current–voltage characteristic of the junction is recorded in two states of the same sample: with the lead film normal, and with it superconducting. The comparison is the experiment. Any feature that appears in the second curve and not in the first belongs to the superconducting state and not to the barrier, the geometry or the contacts — an internal control of exactly the kind an oxide barrier demands, since a pinhole or a thermal effect would show in both. The measurement is then repeated at several temperatures between the base temperature and the transition, so that the temperature dependence of any threshold can be followed.

91.5.3 Observations and data

With both films normal the junction is ohmic: current proportional to voltage over the range of interest, which is itself the signature of tunnelling through a thin barrier rather than conduction through metal bridges. With the lead superconducting the characteristic changes completely at low bias. The current is strongly suppressed — reduced to a small residual set by the temperature — until the bias exceeds a threshold, above which the curve rises steeply and rejoins the normal line, displaced from it by roughly the threshold voltage. The threshold is of order a millivolt, corresponding to an energy of order 1 meV. On warming, the threshold shrinks and vanishes at the transition temperature of the lead film [1180].

Phenomenon 91.5 (A tunnel junction measures the superconducting gap)**.** In a normal-metal–insulator–superconductor tunnel junction the current is suppressed below a threshold bias and the differential conductance above it maps out the excitation spectrum of the superconductor. The threshold measures the energy gap directly; for lead it corresponds to an energy of the order of a millielectronvolt, and it closes continuously as the temperature approaches the transition temperature [1180].

Derivation pending #110

The tunnel current between a normal metal and a superconductor: the elastic-tunnelling current as the convolution of the two densities of states with the difference of the two Fermi functions [1198], the BCS quasiparticle density of states with its square-root edge at the gap, and the consequence that the differential conductance at low temperature is proportional to that density of states evaluated at the bias energy

The scale is set independently by the theory of Chapter 130. The weak-coupling BCS relation between the gap and the transition temperature, $2\Delta(0) = 3.53\,k_{\mathrm{B}}T_{\mathrm{c}}$, gives about 2.2 meV for a transition temperature of 7.2 K; lead is a strong-coupling superconductor and its actual gap lies somewhat above the weak-coupling value. The measured threshold is of that order, which is the point: a prediction of the theory published three years earlier [1102] was confronted with a direct measurement of the quantity it predicts.

91.5.4 Interpretation

Two results are obtained at once, and they support each other. The first is about tunnelling: the current through the junction is not a property of the barrier alone but of the states on either side of it, because switching the far electrode between two states of the same metal — with the barrier untouched — changes the characteristic qualitatively. The second is about superconductivity: the excitation spectrum has a gap, of the predicted size, closing at the transition temperature.

The methodological gain is larger than either. A tunnel junction whose differential conductance is proportional to a density of states is a spectrometer of resolution set by temperature, and at a few kelvin that resolution is a fraction of a millielectronvolt — three orders of magnitude finer than optical spectroscopy of the period. Tunnelling spectroscopy went on to measure the phonon structure imprinted on the superconducting gap, and so to confirm that the pairing interaction is the lattice one.

This experiment also sets the stage for the next step in the same apparatus. Replace the normal electrode with a second superconductor and the single-particle current acquires a larger threshold [1179]; but a second current, carried by pairs and flowing at zero bias, appears alongside it. That is the Josephson effect, predicted in [1231] and observed in [1246], and it is measured in Chapter 131 rather than here, because its content is the macroscopic phase rather than barrier penetration as such.

91.5.5 Primary references

[1180]; the gap prediction [1102]; the pair tunnelling that follows from the same junction [1231, 1246].

91.6 Binnig and Rohrer: the scanning tunnelling microscope (1982)

The last experiment in this chapter is the one in which tunnelling stops being the thing measured and becomes the thing measuring. The transmission through a vacuum gap falls by about an order of magnitude for every 0.1 nm of extra width. Read forwards, that is a prediction to be tested; read backwards, it is a displacement transducer of picometre sensitivity, and holding the current constant while a tip is scanned holds the gap constant to the same precision.

91.6.1 Apparatus

A sharp metal tip mounted on a piezoelectric tripod, which translates it in three orthogonal directions with sub-picometre response to an applied voltage, facing the sample across a vacuum gap of a few tenths of a nanometre. A coarse approach mechanism — in the original instrument a piezoelectric walker, since the gap must be closed from millimetres to angstroms without collision — brings the tip within tunnelling range. A bias of order a volt is applied between tip and sample and the tunnel current, of order a nanoampere, is amplified and compared with a set point; the error signal drives the vertical piezo through a feedback loop. The whole assembly is in ultra-high vacuum and, critically, isolated from vibration: the first instrument floated its stage magnetically above a superconducting bowl, and later designs used stacked springs with eddy-current damping [1682].

The vibration requirement follows from the very sensitivity that makes the instrument work. If the current is to be held to a few percent, the gap must be held to a few picometres, and a building vibrates by far more than that.

91.6.2 Procedure

Two measurements are made with the same hardware. The first tests the prediction: with the feedback loop open, the tunnel current is recorded as the tip is advanced or retracted by a known piezoelectric displacement, and $\ln I$ is plotted against the displacement. The slope gives 2κ of Equation (91.1), and hence an apparent barrier height that can be compared with the work functions of the two electrodes — a control that also detects contamination, since an adsorbed layer lowers the apparent barrier far below the clean-surface value.

The second is imaging. The feedback loop is closed, holding the current and therefore the gap constant, and the tip is raster-scanned across the surface. The voltage applied to the vertical piezo, recorded as a function of the lateral position, is the image: a contour of constant tunnel current, which is a contour of constant gap over a homogeneous surface.

91.6.3 Observations and data

The tunnel current across a vacuum gap is measurable and reproducible, and it varies exponentially with the gap width at a rate corresponding to an apparent barrier height of a few electronvolts — the order of a metal work function, as Equation (91.1) requires. Scanned images resolve monatomic steps, a few tenths of a nanometre in height, as clean terraces, and resolve surface reconstructions on the metal and intermetallic surfaces examined [1682]. Within a year the same instrument resolved the seven-by-seven reconstruction of the silicon (111) surface in real space [1715], ending a long-standing crystallographic controversy.

Phenomenon 91.6 (Vacuum tunnelling made an instrument)**.** A current flows between two electrodes separated by a vacuum gap that no electron of the available energy can cross classically, and its logarithm is linear in the gap width with a slope corresponding to a barrier of the order of the work function. Holding that current constant while a tip is scanned therefore holds the gap constant to a few picometres, which is sufficient to image the topography of a surface at the atomic scale [1682].

Derivation. The gap is a barrier of height equal to the work function ϕ and width equal to the separation d, so Equation (91.1) gives a decay rate $\kappa = \sqrt{2m_{\mathrm{e}}\phi}/\hbar$ that does not depend on d at all, and Equation (91.2) gives $I \propto \mathrm{e}^{-2\kappa d}$: the whole width dependence of the current is that of the squared amplitude of the decaying solution at the far electrode. This is the calculation carried out in Chapter 78, and its numerical content is what the instrument exploits. For a clean metal of work function about $4\,\mathrm{eV}$ the rate is $\kappa \approx 10^{10}/\mathrm{m}$, so that $2\kappa d \approx 2$ for $d = 0.1\,\mathrm{nm}$ and the current changes by roughly a factor e^{-2} per tenth of a nanometre. Inverting the relation gives the instrument: holding I to $1\,\%$ holds d to $\delta d = \delta I/(2\kappa I)$, which is about half a picometre. What this one-dimensional argument does *not* supply is the relation between the current and the surface it is imaging, and that is what the image requires. □

Derivation pending #111

The tunnel current as a probe of the local density of states: the transfer-Hamiltonian expression for the current between two weakly coupled electrodes in terms of the overlap of their surface wavefunctions [1198], and its reduction, for a tip modelled by a single spherically symmetric orbital, to the local density of states of the sample at the position of the tip and at the bias energy [1765]

91.6.4 Interpretation

The measurement of the apparent barrier height is the physics; the images are its proof by demonstration. An exponential current–distance relation with a decay rate matching the work function establishes that the transport is vacuum tunnelling and not field emission, contact conduction, or an adsorbate bridge — each of which would give a different slope or no exponential at all. That the same relation, once established, yields atomic-scale images is a much stronger statement than any single I–d curve, because it requires the exponential to hold locally, reproducibly, and over a whole surface.

It is worth stating what has happened here in the terms of Section 91.1. The exponential sensitivity that made tunnelling seem an exotic curiosity in alpha decay — a rate too small

to matter, too steep to control — is the same property that makes the scanning tunnelling microscope work. Steepness is precision when the exponent is a length you wish to measure. The most counterintuitive prediction in Chapter 78 became, within sixty years of being written down, the finest length gauge in surface physics and the basis of an entire family of scanned-probe instruments.

91.7 Summary of the evidence

Table 91.2: Tests of barrier penetration reported in this chapter. The barrier column gives its physical origin and rough scale; the last column gives the observable that no classical mechanism reproduces. The five span some seven orders of magnitude in barrier height and five in barrier width, and one exponential describes all of them.

Experiment	Barrier	Decisive observation
Geiger–Nuttall 1911, explained by Gamow and by Gurney and Condon 1928	Coulomb repulsion of the daughter nucleus; tens of MeV high, a few times 10^{-14} m wide	half-life exponential in $ZE^{-1/2}$, spanning some 24 orders of magnitude while the energy changes by a factor of two
Fowler–Nordheim 1928	work function of a metal surface tilted by an applied field; a few eV high, of order 10^{-9} m wide	$\ln(J/F^2)$ linear in $1/F$ with slope fixed by $\phi^{3/2}$, and no temperature dependence
Esaki 1958	forbidden gap of a degenerate germanium junction; of order 1 eV high, of order 10^{-8} m wide	negative differential resistance in forward bias, impossible for drift-diffusion transport
Giaever 1960	aluminium-oxide film a few nanometres thick	current suppressed below a threshold of order 1 meV that closes at the transition temperature of the lead film
Binnig–Rohrer 1982	vacuum gap of a few tenths of a nanometre; a few eV high	current exponential in the gap at the work-function rate; constant-current scanning images monatomic steps

The entries in Table 91.2 have almost nothing in common at the level of the apparatus. They were performed seventy years apart, by nuclear physicists, vacuum physicists, semiconductor engineers, low-temperature physicists and surface scientists, on barriers differing by seven orders of magnitude in height. What they share is Equation (91.2): in every case the measured quantity is exponential in $\int \kappa \, \mathrm{d}z$ across a region the particle classically cannot enter, with the mass, the height and the width entering exactly as Equation (91.1) prescribes and the temperature not entering at all.

That last point deserves the final word, because it is what makes the case unavoidable. Every classical account of these observations has to supply the particle with the missing energy from somewhere, and the only available reservoir is thermal. But the alpha half-life

of a nucleus is insensitive to the temperature of the sample; cold field emission persists at temperatures where thermionic emission is unmeasurable; the tunnel diode's peak current strengthens relative to its surroundings on cooling; Giaever's threshold and Binnig and Rohrer's images are obtained at liquid-helium temperatures and below. The classically forbidden region is entered, and it is not entered by borrowing heat. It is entered because the wavefunction of Chapter 77 does not vanish there, and Equation (91.2) says by how much.

Part X

Relativistic Quantum Mechanics

Chapter 92

The Klein–Gordon Equation

The first relativistic wave equation of quantum mechanics was written down before the nonrelativistic one, and discarded. Schrödinger set up the wave equation of a Coulomb-bound electron in relativistic form, found that it gave the wrong fine structure of hydrogen — the term Sommerfeld's old-quantum formula [441] had already fitted — and published instead the nonrelativistic limit that carries his name [557, 1692], returning to the relativistic form only in his fourth communication [559]. Within months the same equation was published by Klein [547] and, in its minimally coupled form and applied to the Compton effect, by Gordon [544]; it has carried their two names ever since. This chapter opens Part X because the equation is the simplest possible marriage of Part IX with Part IV: it is nothing but the mass-shell relation $E^2 = |\boldsymbol{p}|^2 c^2 + m^2 c^4$ of Chapter 40 with the operator substitutions of Chapter 77, and equivalently the eigenvalue equation of the first Poincaré Casimir $\hat{P}^2 = m^2 c^2$ of Chapter 94 at spin zero.

It is also where that marriage fails. Being second order in time, the equation admits both signs of the energy, and the density built from its conserved current is not positive: neither object can be read as a probability, so the equation is not a one-particle quantum mechanics. Dirac's response was a different equation (Chapter 93); the correct response, given by Pauli and Weisskopf in 1934 [748], was to keep this one and change what it describes — not a wavefunction but a *field*, whose quanta are particles and antiparticles and whose conserved density is charge rather than probability. Read that way the equation is exact and is used everywhere: it is the free part of every scalar field in Part XI, its static source solution is the Yukawa potential of nuclear physics [765], and its observed quanta are the pion [902] and the Higgs boson [2186, 2192]. Standard treatments are [1273, 1912, 2287].

Derivation pending #112

The Klein–Gordon Equation: all derivations of this chapter are pending.

92.1 The equation

92.1.1 Schrödinger's discarded first attempt

[Reserved: the historical order of events, which matters because it explains why a correct equation was abandoned — Schrödinger's relativistic Coulomb calculation of late 1925, its disagreement with the measured fine structure of hydrogen, and the nonrelativistic retreat published as the first communication [557], documented in detail by Kragh [1692]; the relativistic equation with electromagnetic coupling restored in the fourth communication [559]. The disagreement was real and its cause was spin, not relativity, as Chapter 93 shows.]

92.1.2 Klein, Gordon, and the equation itself

[Reserved: the equation $(\Box + m^2c^2/\hbar^2)\,\varphi = 0$ with $\Box = \partial_\mu\partial^\mu$, as published by Klein [547] — whose five-dimensional framing is a unification programme without evidence and is treated as such in Part XIII — and by Gordon [544]; the canonical substitutions $E \mapsto \mathrm{i}\hbar\partial_t$, $\boldsymbol{p} \mapsto -\mathrm{i}\hbar\boldsymbol{\nabla}$ applied to the squared mass-shell relation, and why squaring is the step that costs the probability interpretation; the Compton wavelength $\hbar/mc$ as the length scale the mass term introduces.]

92.1.3 The mass shell and the Poincaré Casimir

[Reserved: the equation restated group-theoretically. Every irreducible unitary representation of the Poincaré group carries $\hat{P}^2 = m^2c^2$ [849], so every *relativistic field of any spin satisfies the Klein–Gordon equation component by component; what distinguishes spin 0 is that this is the* only *condition. The classification is carried out in Chapter 94 and instantiated for spin $\frac{1}{2}$ in Chapter 93 and for higher spin in Chapter 97.]*

Phenomenon 92.1 (The relativistic mass shell)**.** Every free particle observed in Nature, of whatever spin, carries an energy and a momentum related by

$$E^2 = |\boldsymbol{p}|^2 c^2 + m^2c^4\,, \tag{92.1}$$

with a single constant m — its mass — that is the same for every particle of the species and the same in every inertial frame. The relation holds across the whole range of momenta accessible to experiment, and the masses it defines are tabulated for every known species in [2427]; its most direct laboratory face, the saturation of a charged particle's speed at c however much kinetic energy is supplied to it, was measured by Bertozzi [1272].

Derivation. Insert the plane wave $\varphi(x) = A\,\mathrm{e}^{-\mathrm{i}p\cdot x/\hbar}$, with $p\cdot x = \eta_{\mu\nu}p^\mu x^\nu = Et - \boldsymbol{p}\cdot\boldsymbol{x}$, into the Klein–Gordon equation $(\Box + m^2c^2/\hbar^2)\,\varphi = 0$ of Section 92.1.2, where $\Box = \partial_\mu\partial^\mu$. Each derivative brings down a factor, $\partial_\mu\varphi = -\mathrm{i}p_\mu\varphi/\hbar$, so that $\Box\varphi = -p_\mu p^\mu\varphi/\hbar^2$ and

$$\left(\Box + \frac{m^2c^2}{\hbar^2}\right)\varphi = \frac{1}{\hbar^2}\left(m^2c^2 - p_\mu p^\mu\right)\varphi\,.$$

A nonzero solution therefore requires $p_\mu p^\mu = m^2c^2$, which written out is $E^2/c^2 - |\boldsymbol{p}|^2 = m^2c^2$ and hence Equation (92.1). Both sides are Lorentz scalars, so every frame returns the same m. The universality is a group-theoretic fact rather than a property of spin zero: every irreducible unitary representation of the Poincaré group is labelled by the eigenvalue of the Casimir $\hat{P}^2$ [849], so a field of any spin satisfies this same equation component by component, and what singles out spin zero is only that no further condition is imposed. □

92.1.4 Lorentz covariance and the scalar transformation law

[Reserved: $\varphi'(x') = \varphi(x)$ as the defining transformation law of a scalar; invariance of the d'Alembertian under the transformations of Chapter 38; the Lagrangian density $\mathcal{L} = \frac{1}{2}\partial_\mu\varphi\,\partial^\mu\varphi - \frac{1}{2}(mc/\hbar)^2\varphi^2$ whose Euler–Lagrange equation this is, connecting to the field-theoretic variational formalism of Chapter 64; the distinction between a scalar and a pseudoscalar under parity, which is what the observed pion turns out to be (Chapter 105).]

92.2 Negative energies and the indefinite density

The two defects of the equation as a one-particle theory are usually listed separately. They are the same defect.

92.2.1 Both branches of the dispersion relation

[Reserved: plane-wave solutions $\mathrm{e}^{-\mathrm{i}p\cdot x/\hbar}$ *with* $p^0 = \pm\sqrt{|\boldsymbol{p}|^2 + m^2c^2}$*; the negative-energy branch cannot be discarded because the positive-energy solutions alone are not complete — any localized initial datum excites both — and because a Lorentz transformation cannot remove it, the two branches being separate orbits in Chapter 94; the resulting instability of any system coupled to such a spectrum, and Dirac's statement of the difficulty as the motivation for a first-order equation [596].]*

92.2.2 The conserved current and why its density changes sign

[Reserved: the current $j^\mu = \frac{\mathrm{i}\hbar}{2m}\left(\varphi^*\partial^\mu\varphi - \varphi\,\partial^\mu\varphi^*\right)$ *conserved by* $\partial_\mu j^\mu = 0$*; the density* j^0 *containing a time derivative because the equation is second order, so that* φ *and* $\partial_t\varphi$ *are independent initial data and* j^0 *takes either sign; the contrast with the positive-definite* $|\psi|^2$ *of Chapter 77 and with the Dirac current of Chapter 93 [596].]*

Phenomenon 92.2 (What is conserved is charge, not particle number)**.** The quantity conserved in the processes that spin-0 particles undergo is electric charge, which takes both signs, and not the number of particles, which does not survive: charged pions are created singly in weak decays, in pairs of opposite charge in strong collisions, and the neutral pion disappears entirely into two photons. Every charged spin-0 species observed comes with a partner of equal mass and opposite charge, while the neutral pion is its own antiparticle [2427]. No experiment counts a conserved number of spin-0 quanta; every experiment finds the total charge unchanged.

Derivation. That the equation cannot supply a conserved *probability* is immediate. Evaluate the current of Section 92.2.2 on the plane wave $\varphi = A\,\mathrm{e}^{-\mathrm{i}p\cdot x/\hbar}$ of Phenomenon 92.1. With $\partial^0 = c^{-1}\partial_t$ and $\partial_t\varphi = -\mathrm{i}E\varphi/\hbar$,

$$j^0 = \frac{\mathrm{i}\hbar}{2mc}\left(\varphi^*\partial_t\varphi - \varphi\,\partial_t\varphi^*\right) = \frac{\mathrm{i}\hbar}{2mc}\left(-\frac{2\mathrm{i}E}{\hbar}\right)|A|^2 = \frac{E}{mc}\,|A|^2\ .$$

The sign of j^0 is the sign of E, so the two branches of Equation (92.1) carry densities of opposite sign, and no choice of normalization can make j^0 positive on both — while the positive-frequency solutions alone are not a complete set, so the negative branch cannot simply be discarded. A quantity that changes sign cannot be a probability density. It can be a charge density, and multiplying j^μ by the charge q makes it exactly that; the conserved integral is then a charge, which pair creation leaves unchanged because the pair is neutral. This is the reinterpretation proved in Section 92.6, and it is what the observations above record. □

92.2.3 The two problems are one problem

[Reserved: that j^0 *is negative exactly on the negative-frequency solutions, so a theory that could exclude one defect could exclude the other; Feshbach and Villars' explicit exhibition of this correspondence [1143]; the statement, to be proved in Section 92.6, that the resolution is to keep both branches and reinterpret* ej^μ *as an electric current [748], antiparticles being the negative-frequency modes read forwards in time [864, 931].]*

92.3 Minimal coupling and the charged scalar

92.3.1 The covariant derivative and gauge invariance

[Reserved: the substitution $\partial_\mu \mapsto D_\mu = \partial_\mu + \frac{\mathrm{i}q}{\hbar}A_\mu$ *introduced for this equation by Schrödinger [559] and by Gordon [544]; invariance of the coupled equation under* $\varphi \mapsto \mathrm{e}^{-\mathrm{i}q\Lambda/\hbar}\varphi$*,* $A_\mu \mapsto$

$A_\mu + \partial_\mu \Lambda$, the potentials being those of Chapter 60; a real field cannot carry charge, so the charged scalar is necessarily complex and its two real components are the particle and the antiparticle; the "seagull" term quadratic in A_μ, absent from the Dirac case, and the fact that gauge invariance forces it.]

92.3.2 The current as charge, not probability

[Reserved: the coupled current $j^\mu = \frac{i\hbar}{2m}\left(\varphi^* D^\mu \varphi - \varphi \left(D^\mu \varphi\right)^*\right)$; its total integral conserved and quantized in units of q; the reinterpretation of a sign-indefinite density as an honest charge density [748]; the corresponding Noether statement in Chapter 64, and the observable consequence that a spin-0 particle and its antiparticle are distinct unless the field is real, as they are for $\pi^\pm$ and are not for π^0 [2427].]

92.3.3 The Compton effect after Gordon

[Reserved: Gordon's original application, the Compton effect computed from the minimally coupled equation [544], set against the kinematic treatment of Chapter 69; what the calculation gets right (the kinematics, the shift $\Delta\lambda = (h/mc)(1-\cos\theta)$) and what it cannot get right (the cross section, which needs spin $\frac{1}{2}$ and the field quantization of Chapter 99); scalar Compton scattering as a genuine process for charged pions.]

Phenomenon 92.3 (The Compton shift)**.** Radiation scattered by a free charged particle of mass m returns with a wavelength longer than that of the incident beam by

$$\Delta\lambda = \frac{h}{mc}\left(1 - \cos\theta\right) , \tag{92.2}$$

θ being the scattering angle. The shift depends on neither the incident wavelength nor the intensity nor the spin of the scatterer, and vanishes in the forward direction. The constant h/mc is the Compton wavelength, equal to $2.426\,31 \times 10^{-12}$ m for the electron [2431]; the measurement is Chapter 69.

Derivation. The shift is pure four-momentum conservation and needs no dynamics — which is why the spinless equation gets it right while getting the cross section wrong. Let the incident photon have four-momentum k, the scattered photon k', and the target be at rest with $p = (mc, \mathbf{0})$. Conservation gives $p' = p + k - k'$, and squaring the invariant $p' \cdot p' = m^2c^2$ while using $k \cdot k = k' \cdot k' = 0$ leaves

$$p \cdot k - p \cdot k' - k \cdot k' = 0 .$$

With $k^0 = E/c$ and $k'^0 = E'/c$ this reads $mE - mE' = \left(EE'/c^2\right)\left(1 - \cos\theta\right)$, so that

$$\frac{1}{E'} - \frac{1}{E} = \frac{1 - \cos\theta}{mc^2} .$$

Substituting $E = hc/\lambda$ and $E' = hc/\lambda'$ turns the left side into $\left(\lambda' - \lambda\right)/hc$ and yields Equation (92.2). The mass enters only through the combination h/mc, so the effect is some 1836 times smaller on a proton than on an electron, and the derivation used nothing about the target beyond its mass — hence the independence from spin. □

92.3.4 Exact solutions in external fields

[Reserved: the Coulomb problem solved exactly, giving the spinless energy levels with their non-integer effective angular momentum and their $Z\alpha$ expansion; the failure against hydrogen and the success against pionic atoms [1035]; the constant magnetic field and the scalar Landau levels; the potential step, whose transmission anomaly is the spin-0 version of the Klein paradox treated in Chapter 93 [629].]

92.4 The Feshbach–Villars form and the nonrelativistic limit

92.4.1 The two-component representation

[Reserved: Feshbach and Villars' rewriting of the second-order equation as a coupled pair of first-order equations for $\varphi \pm \frac{\mathrm{i}\hbar}{mc^2}\partial_t\varphi$ [1143], in which the Hamiltonian is a 2×2 matrix built from Pauli matrices, the norm is the indefinite charge form of Section 92.2.2, and the two components are the particle and antiparticle amplitudes; the Hamiltonian is not Hermitian in the ordinary inner product but is pseudo-Hermitian with respect to that form.]

92.4.2 Recovery of the Schrödinger equation

[Reserved: the substitution $\varphi = \mathrm{e}^{-\mathrm{i}mc^2t/\hbar}\psi$ and the neglect of $\partial_t^2\psi$ against $mc^2\partial_t\psi/\hbar$, which turns the Klein–Gordon equation into the Schrödinger equation of Chapter 77 with the rest energy removed and the antiparticle component suppressed by $|\boldsymbol{p}|^2/m^2c^2$ [1143]; the systematic version of this limit for spin $\frac{1}{2}$ is the Foldy–Wouthuysen transformation of Chapter 93 [955].]

92.4.3 Relativistic corrections

[Reserved: the leading correction $-|\boldsymbol{p}|^4/8m^3c^2$ obtained by expanding the square root, the same term produced by perturbation theory in Chapter 82; the absence of any spin–orbit or Darwin term here, which is precisely why the spinless equation misses the hydrogen fine structure and why its failure is evidence for spin rather than against relativity (Chapter 81).]

92.5 Propagation, causality and the propagator

92.5.1 Green functions of the Klein–Gordon operator

[Reserved: the equation $(\Box + m^2c^2/\hbar^2)\,G(x-y) = -\delta^4(x-y)$ and the pole prescriptions that distinguish its retarded, advanced and Feynman solutions; the contour integral in the complex p^0 plane, using the machinery of Chapter 8; the retarded Green function supported inside the forward light cone, which is the sense in which the classical equation is causal, and its tail inside the cone — absent for $m=0$ — as a massive-wave phenomenon.]

92.5.2 The Feynman prescription

[Reserved: the propagator $\tilde{G}_F(p) = \mathrm{i}\hbar/\,(p^2 - m^2c^2 + \mathrm{i}\epsilon)$; the $\mathrm{i}\epsilon$ read as the instruction to propagate positive frequencies forwards and negative frequencies backwards in time [864, 931], which is the same reinterpretation as Section 92.2.3 in a different language; the propagator as the single object that carries this chapter's content into Chapters 99 and 100, where it becomes an internal line of a Feynman diagram [930].]

92.5.3 Localization and its limits

[Reserved: the Newton–Wigner position operator and the localized states it defines [942]; the amplitude for propagation outside the light cone, which is nonzero but falls as $\mathrm{e}^{-mcr/\hbar}$ over the Compton wavelength; Hegerfeldt's theorem that a state localized in a bounded region at one instant, in any theory with energy bounded below, immediately develops tails outside the light cone [1528]; why this is not a violation of relativistic causality, which constrains commutators of observables rather than amplitudes — the statement made precise in Chapter 109.]

92.5.4 The Yukawa potential

[Reserved: the static equation with a point source, whose solution $\mathrm{e}^{-mcr/\hbar}/4\pi r$ *is the Yukawa potential [765]; the range* $\hbar/mc$ *read off from the exponent,* 1.4 fm *for the observed pion mass, how Yukawa predicted a particle of a few hundred* MeV/c^2 *from the size of the nucleus; the Coulomb limit* $m \to 0$*; the potential's role in the nuclear force models of Chapter 107 and its status there as an effective, not fundamental, description.]*

Phenomenon 92.4 (A massive field mediates a force of finite range)**.** The static potential produced by a point source of a field of mass m is not Coulombic but exponentially cut off,

$$V(r) \propto \frac{\mathrm{e}^{-r/\lambda}}{r}, \qquad \lambda = \frac{\hbar}{mc}, \tag{92.3}$$

so the interaction it carries has a definite reach λ instead of extending indefinitely. The force between nucleons behaves this way, with a range of the order of a femtometre; that is the reduced Compton wavelength of a particle of mass $139.57\,\mathrm{MeV}/c^2$, which is the observed mass of the charged pion [2427]. Electromagnetism, by contrast, has no such cutoff, and the photon has no measured mass.

Derivation. For a time-independent field the Klein–Gordon operator reduces to $-\boldsymbol{\nabla}^2 + \lambda^{-2}$ with $\lambda = \hbar/mc$, so a static point source of strength g gives

$$\left(-\boldsymbol{\nabla}^2 + \frac{1}{\lambda^2}\right)\varphi = g\,\delta^3(\boldsymbol{x})\,.$$

Put $u(r) = \mathrm{e}^{-r/\lambda}/r$. Away from the origin the radial Laplacian is $\boldsymbol{\nabla}^2 u = r^{-1}\mathrm{d}^2(ru)/\mathrm{d}r^2 = r^{-1}\mathrm{d}^2\mathrm{e}^{-r/\lambda}/\mathrm{d}r^2 = u/\lambda^2$, so $\left(-\boldsymbol{\nabla}^2 + \lambda^{-2}\right)u = 0$ for $r > 0$: the mass term is exactly what the exponential decay cancels. Near the origin $u \to 1/r$, whose Laplacian is $-4\pi\delta^3(\boldsymbol{x})$ while the mass term stays integrable, so the source is reproduced by

$$\varphi(r) = \frac{g}{4\pi}\,\frac{\mathrm{e}^{-r/\lambda}}{r}\,,$$

which is Equation (92.3). Setting $m = 0$ removes the exponential and returns the Coulomb form, so the range is finite precisely because the mediating field is massive, and reading λ off a measured range predicts a mass. Note what the argument does *not* do: it gives the range, not the strength, and it treats the nucleon source as a fixed point charge, so the resulting potential is an effective description and not a fundamental one. □

92.6 Pauli–Weisskopf: the equation is a field

92.6.1 Quantization of the scalar field

[Reserved: Pauli and Weisskopf's 1934 construction [748], in which φ *is promoted to an operator expanded in creation and annihilation operators for particles and antiparticles, the negative-frequency coefficients being reinterpreted as creation operators; the Hamiltonian becomes positive definite, the charge operator takes both signs, and the number of particles is no longer conserved; the construction is carried out in full in Chapter 99. Their paper was written to show that Dirac's hole theory was not needed to make sense of negative energies — and it did so for a spin-0 field, where no exclusion principle exists to build a filled sea from.]*

92.6.2 Bose statistics and microcausality

[Reserved: commutators rather than anticommutators are forced for spin 0, so scalar quanta are bosons; the field commutator vanishing at spacelike separation as the precise statement

of relativistic causality [854]; the spin–statistics theorem, proved from Lorentz invariance, positivity of the energy and microcausality, whose axiomatic form belongs to Chapter 109 and whose observational consequences run through Chapters 83 and 120.]

92.6.3 What survives of the one-particle reading

[Reserved: an explicit accounting of which results of this chapter remain true in the field theory and which do not — the equation, the plane waves, the propagator, the Yukawa potential and the nonrelativistic limit all survive unchanged; the position operator, the probability density, the single-particle Hilbert space and the external Coulomb spectrum survive only as approximations valid for energies well below $2mc^2$, the threshold at which pair creation makes particle number ill-defined [748, 1273].]

92.7 The observed spin-0 sector

A relativistic wave equation earns its place by the particles that obey it. Nature supplies few elementary spin-0 particles and many composite ones, and both kinds are listed here with the measurements that fix their quantum numbers.

92.7.1 Pions and the light pseudoscalars

[Reserved: Yukawa's prediction of a meson of nuclear-force range [765]; the charged pion identified in photographic emulsions exposed to cosmic rays by Lattes, Occhialini and Powell [902], with the muon of Chapter 115 as its decay product and as the particle it had been confused with; masses $139.57\,\mathrm{MeV}/c^2$ and $134.98\,\mathrm{MeV}/c^2$ for $\pi^{\pm}$ and π^0, spin 0 and odd parity [2427]; the pions as pseudoscalars, not scalars, and as composite states of quarks rather than elementary fields (Chapter 102).]

Phenomenon 92.5 (The pion triplet)**.** Three particles of spin 0 and odd intrinsic parity, $J^P = 0^-$, are observed: a charged pair $\pi^{\pm}$ of mass $139.57\,\mathrm{MeV}/c^2$ and a neutral π^0 of mass $134.98\,\mathrm{MeV}/c^2$ [2427]. The two charged states are distinct particles, each the antiparticle of the other and of equal mass; the neutral state is its own antiparticle and decays to two photons, which no charged particle can do.

Derivation. The structural half of the statement follows from the current of Phenomenon 92.2 alone. If the field is *real*, $\varphi^* = \varphi$, then $j^\mu \propto \varphi^* \partial^\mu \varphi - \varphi\, \partial^\mu \varphi^*$ vanishes identically. A real scalar field carries no conserved charge at all, so its quantum has nothing by which it could be distinguished from its antiparticle: it is self-conjugate, and necessarily neutral. A charged spin-0 particle therefore requires a complex field, whose overall phase is the symmetry whose Noether charge is the conserved one; the quanta associated with φ and with φ^* are then two distinct states of opposite charge, and of equal mass, because both obey Equation (92.1) with the one mass parameter appearing in the equation. That is exactly the observed pattern: π^+ and π^- share a mass while π^0 has no charged partner. What this chapter does *not* derive is the numerical values of the masses or the odd parity; both are measurements, the parity of the charged pion having been fixed by the capture reaction discussed in Chapter 105, and the values themselves are consequences of the quark substructure of Chapter 102 rather than of any free-field equation. □

92.7.2 Pionic and kaonic atoms

[Reserved: the spin-0 realization of the Coulomb problem of Section 92.3.4 — a negative pion or kaon captured into a hydrogen-like orbit around a nucleus, whose X-ray cascade is described by the Klein–Gordon equation with no spin–orbit structure at all, so that the

equation is tested where it applies rather than where it fails [1413]; the strong-interaction shift and broadening of the lowest level, related to the scattering length by the Deser formula [1035];
with the electronic spectra of Chapter 90.]

92.7.3 The Higgs boson

[Reserved: the only elementary spin-0 particle observed to date, found at the LHC in 2012 by ATLAS [2186] and CMS [2192] with a mass near 125 GeV*, whose free field obeys exactly the equation of this chapter; its measured spin-parity $J^P = 0^+$, distinguishing it from the pseudoscalars above; the experiment is treated in Chapter 113 and the mechanism that requires the field in Chapter 104. Nothing in this chapter predicts the existence of such a particle; the equation says only what a spin-0 particle must satisfy if one exists.]*

Phenomenon 92.6 (An elementary scalar exists)**.** Exactly one elementary particle of spin 0 has been observed. Its mass is close to $125\,\mathrm{GeV}/c^2$; its spin and parity are measured to be $J^P = 0^+$, distinguishing it from the pseudoscalar mesons of Phenomenon 92.5; and its production and decay rates agree with those of the Standard Model Higgs boson within present uncertainties [2427]. Its free field obeys Equation (92.1), and hence the equation of this chapter, with no additional structure whatever — it is the only known particle for which that is the complete free-field description.

Derivation pending #113

Determination of the spin and parity of the boson near 125 GeV from the angular distributions of its four-lepton and diphoton decays, and the electroweak argument that requires an elementary scalar field in the first place. The experiment is the Higgs discovery chapter of Part XII and the mechanism is the electroweak chapter of the same part.

Chapter 93

The Dirac Equation

The Klein–Gordon equation of Chapter 92 fails as a one-particle theory because it is second order in time. Dirac asked in 1928 what a *first*-order relativistic wave equation would have to look like, and found that the coefficients multiplying the derivatives cannot be numbers: they must be matrices satisfying an anticommutation relation, and the smallest such matrices are 4×4 [596, 597]. Everything else follows from that one algebraic demand, and what follows is extraordinary. The wavefunction acquires four components; two of them describe an internal angular momentum of magnitude $\hbar/2$ with a gyromagnetic ratio $g = 2$, so that electron spin — inferred from spectra by Uhlenbeck and Goudsmit [532] and grafted onto the Schrödinger equation by hand by Pauli [587] — ceases to be an assumption and becomes a theorem. The hydrogen spectrum comes out exactly, fine structure included [595, 601], where the spinless equation had failed. And the other two components, carrying negative energy, forced Dirac to predict a particle of the electron's mass and opposite charge [647, 677] — found four years later in a cloud chamber (Chapter 95).

This chapter states the equation and its consequences as relativistic quantum *mechanics*, that is, for a single particle in an external field, which is the domain in which the results above are correct. It also marks the boundary of that domain honestly: hole theory needs an infinite filled sea and does not survive (Chapter 99); the Klein paradox [629] and the Zitterbewegung [669] are one-particle artefacts of a theory that cannot conserve particle number; and the exact Coulomb spectrum is falsified at the ninth significant figure by the Lamb shift [901] and the anomalous moment [916], both of which require the quantized field of Part XI. The group-theoretic reading — spin $\tfrac{1}{2}$ as the $(\tfrac{1}{2},0)\oplus(0,\tfrac{1}{2})$ representation of the Lorentz group — is developed in Chapter 94. Standard treatments are [1140, 1273, 1912, 2287].

Derivation pending #114

The Dirac Equation: all derivations of this chapter are pending.

93.1 Construction of the equation

93.1.1 Dirac's requirement: first order in time

[Reserved: the argument of Dirac's 1928 paper [596] — a probability density free of time derivatives requires an equation first order in ∂_t, and Lorentz covariance then requires it to be first order in ∂_i as well; the ansatz $\mathrm{i}\hbar\partial_t\psi = (c\,\boldsymbol{\alpha}\cdot\hat{\boldsymbol{p}} + \beta mc^2)\,\psi$, and the demand that each component satisfy the Klein–Gordon equation of Chapter 92, which fixes $\alpha_i\alpha_j + \alpha_j\alpha_i = 2\delta_{ij}$, $\alpha_i\beta + \beta\alpha_i = 0$ and $\beta^2 = \mathbb{1}$; why no numbers satisfy these relations and matrices of dimension below four do not either.]

93.1.2 The Clifford algebra of the gamma matrices

[Reserved: the covariant form $(\mathrm{i}\hbar\gamma^\mu\partial_\mu - mc)\,\psi = 0$ *and the defining relation* $\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2\eta^{\mu\nu}\mathbb{1}$*, an instance of the algebra introduced by Clifford [201] and developed as an algebraic structure in Chapter 4; the trace identities, the completeness of the sixteen products* $\{\mathbb{1}, \gamma^\mu, \sigma^{\mu\nu}, \gamma^\mu\gamma_5, \gamma_5\}$*, and* γ_5 *as the chirality element; the dimension count that forces* 4×4 *in* $3+1$ *dimensions.]*

93.1.3 Representations and the choice of basis

[Reserved: Pauli's theorem, that any two irreducible sets of gamma matrices are related by a similarity transformation unique up to a factor, so nothing physical depends on the choice; the Dirac (standard) basis in which β *is diagonal, adapted to the nonrelativistic limit of Section 93.7; the Weyl (chiral) basis in which* γ_5 *is diagonal, adapted to the massless limit of Section 93.8; the Majorana basis in which all gammas are purely imaginary and the equation admits real solutions [796].]*

93.1.4 The conserved positive-definite current

[Reserved: the adjoint $\bar\psi = \psi^\dagger\gamma^0$*, the current* $j^\mu = c\,\bar\psi\gamma^\mu\psi$*, its conservation* $\partial_\mu j^\mu = 0$*, and the density* $j^0/c = \psi^\dagger\psi \geq 0$ *— the property the Klein–Gordon current lacked (Chapter 92) and the one Dirac was hunting [596]; the honest qualification that positivity of the density does* not *rescue the one-particle interpretation, because the energy spectrum is still unbounded below (Section 93.5).]*

93.2 Lorentz covariance and the spinor

93.2.1 The spinor transformation law

[Reserved: covariance requires $\psi'(x') = S(\Lambda)\psi(x)$ *with* $S^{-1}\gamma^\mu S = \Lambda^\mu{}_\nu\gamma^\nu$*; the explicit generators* $\sigma^{\mu\nu} = \frac{\mathrm{i}}{2}[\gamma^\mu, \gamma^\nu]$ *and the finite transformation* $S = \exp\left(-\frac{\mathrm{i}}{4}\omega_{\mu\nu}\sigma^{\mu\nu}\right)$*; that* S *is unitary for rotations and Hermitian for boosts, so the representation is not unitary — the group being non-compact (Chapter 94); the* 4π *periodicity of a spinor under rotation and its experimental confirmation by neutron interferometry [1566], which is why the covering group* $\mathrm{SL}(2,\mathbb{C})$ *and not the Lorentz group itself acts.]*

Phenomenon 93.1 (A spinor changes sign under a full rotation)**.** Rotating a spin-$\frac{1}{2}$ particle through 2π multiplies its state by -1; only a rotation through 4π returns it to itself. The sign is not a convention that could be redefined away: in a neutron interferometer, one arm of which passes through a magnetic field that precesses the spin, the interference intensity varies with the precession angle at a period of 4π and not 2π, so the amplitude demonstrably reverses at a single full turn [1566].

Derivation. In the spinor representation of Section 93.2.1 the generator of rotations about the z-axis is $\frac{1}{2}\Sigma_3$, with $\Sigma_k = \mathrm{diag}\,(\sigma_k, \sigma_k)$ built from the Pauli matrices, so a rotation through an angle θ acts on the spinor as

$$S(\theta) = \exp\left(-\frac{\mathrm{i}}{2}\theta\Sigma_3\right) = \mathbb{1}\cos\frac{\theta}{2} - \mathrm{i}\Sigma_3\sin\frac{\theta}{2}\,, \tag{93.1}$$

the exponential series collapsing because $\Sigma_3^2 = \mathbb{1}$. At $\theta = 2\pi$ this is $-\mathbb{1}$ and at $\theta = 4\pi$ it is $+\mathbb{1}$. The half-angle is the whole content: $\mathrm{SO}(3)$ is not simply connected, its closed loops falling into two classes, and the spinor representation is a representation not of $\mathrm{SO}(3)$ but of its double cover $\mathrm{SU}(2)$, in which the lift of a single full turn is an open path ending at $-\mathbb{1}$. An overall sign is unobservable on a state taken alone, which is why the effect can be seen only by interfering a rotated amplitude against an unrotated one. □

93.2.2 Bilinear covariants

[Reserved: the sixteen bilinears $\bar{\psi}\Gamma\psi$ and their transformation types — scalar, vector, antisymmetric tensor, axial vector and pseudoscalar; their role as the only Lorentz-covariant objects a spinor field can build, hence as the complete list of possible interaction terms, which is what makes the $V-A$ structure of the weak interaction a choice among five *rather than a free invention (Chapters 101 and 110); the Fierz rearrangement identities relating different pairings [790].]*

93.2.3 Plane-wave solutions and spin projectors

[Reserved: the four independent plane waves at each momentum, two with $p^0>0$ and two with $p^0<0$; the spinors $u(p,s)$ and $v(p,s)$, their normalization and orthogonality, the energy projectors $(\pm\gamma^\mu p_\mu + mc)/2mc$ and the spin projector from the Pauli–Lubanski vector of Chapter 94; the completeness relations that make every later trace calculation mechanical.]

93.3 Spin as a consequence, not an assumption

This section is the chapter's principal result: an equation written to be first order in time turns out to describe a particle with intrinsic angular momentum $\hbar/2$ and the right magnetic moment, neither of which was put in.

93.3.1 Orbital angular momentum is not conserved

[Reserved: the computation $\left[\hat{\boldsymbol{L}},\hat{H}\right]\neq 0$ for the Dirac Hamiltonian, and the identification of the operator $\hat{\boldsymbol{S}}=\frac{\hbar}{2}\boldsymbol{\Sigma}$ whose sum with $\hat{\boldsymbol{L}}$ is conserved [596]; the eigenvalues $\pm\hbar/2$, matching the two beams of the Stern–Gerlach experiment (Chapter 80) and the algebra of Chapter 79; the contrast with the spinless equation, where $\hat{\boldsymbol{L}}$ alone is conserved.]

Phenomenon 93.2 (Electron spin)**.** A beam of neutral silver atoms, whose single valence electron is in an S state carrying no orbital angular momentum, splits into exactly two components on traversing an inhomogeneous magnetic field — not into the odd number of components that any integer angular momentum would give, and not into the continuum a classical moment would give [481, 491, 492]. The electron therefore carries an intrinsic angular momentum with just two projections, $\pm\hbar/2$, on any axis; the measurement is Chapter 80. In any central field it is the total $\hat{\boldsymbol{J}}=\hat{\boldsymbol{L}}+\hat{\boldsymbol{S}}$, and not $\hat{\boldsymbol{L}}$, that is found to be conserved.

Derivation. Both halves are theorems about the Hamiltonian $\hat{H}=c\,\boldsymbol{\alpha}\cdot\hat{\boldsymbol{p}}+\beta m_e c^2$ of Section 93.1.1. Using $\left[\hat{L}_i,\hat{p}_j\right]=\mathrm{i}\hbar\epsilon_{ijk}\hat{p}_k$, and noting that β and $\boldsymbol{\alpha}$ are constant matrices that commute with $\hat{\boldsymbol{L}}$,

$$\left[\hat{L}_i,\hat{H}\right]=c\,\alpha_j\left[\hat{L}_i,\hat{p}_j\right]=\mathrm{i}\hbar c\,\epsilon_{ijk}\alpha_j\hat{p}_k=\mathrm{i}\hbar c\,(\boldsymbol{\alpha}\times\hat{\boldsymbol{p}})_i\neq 0\,,$$

so orbital angular momentum is not conserved even for a *free* particle — an absurdity unless something else carries the balance. Set $\hat{\boldsymbol{S}}=\frac{\hbar}{2}\boldsymbol{\Sigma}$ with $\Sigma_k=\mathrm{diag}\,(\sigma_k,\sigma_k)$. Since $[\Sigma_i,\alpha_j]=2\mathrm{i}\epsilon_{ijk}\alpha_k$ and $[\Sigma_i,\beta]=0$,

$$\left[\hat{S}_i,\hat{H}\right]=\frac{\hbar c}{2}\,[\Sigma_i,\alpha_j]\,\hat{p}_j=\mathrm{i}\hbar c\,\epsilon_{ijk}\alpha_k\hat{p}_j=-\mathrm{i}\hbar c\,(\boldsymbol{\alpha}\times\hat{\boldsymbol{p}})_i\,,$$

which cancels the previous line exactly, so $\left[\hat{\boldsymbol{L}}+\hat{\boldsymbol{S}},\hat{H}\right]=0$. The operator $\hat{S}_z$ has eigenvalues $\pm\hbar/2$ and no others, because $\Sigma_3^2=\mathbb{1}$. Nothing about spin was assumed anywhere: it was

forced by the demand that the equation be first order in time, which is what made the coefficients matrices in the first place, and the two Stern–Gerlach beams are the observed count of its eigenvalues. □

93.3.2 The gyromagnetic ratio $g = 2$

[Reserved: minimal coupling $\partial_\mu \mapsto \partial_\mu + \frac{\mathrm{i}e}{\hbar}A_\mu$, squaring the Dirac operator, and the appearance of the term $-\frac{e\hbar}{2mc}\,\sigma^{\mu\nu}F_{\mu\nu}$ that carries a magnetic moment $g = 2$ in units of the Bohr magneton [596] — twice the orbital value, exactly the factor Uhlenbeck and Goudsmit had to postulate [532] and Pauli had to insert [587]; the measured departure $g - 2 \approx 2.3 \times 10^{-3}$ [916] and its computation from field theory [919], deferred to Chapter 112.]

Phenomenon 93.3 (The electron magnetic moment)**.** The magnetic moment associated with the electron's spin is twice as large, per unit of angular momentum, as the moment associated with its orbital motion:

$$\boldsymbol{\mu} = -g\,\frac{\mu_{\mathrm{B}}}{\hbar}\hat{\boldsymbol{S}}\,, \qquad \mu_{\mathrm{B}} = \frac{e\hbar}{2m_e}\,, \qquad g \simeq 2\,, \tag{93.2}$$

where an orbital current of the same angular momentum would give $g = 1$. This factor is what the Zeeman splittings of the alkali doublets demand, and it had to be inserted by hand into the prerelativistic theory. Its measured magnitude is 2.002 319 304 36 [2431] — equal to 2 to eleven significant figures, the residual departure of about one part in 10^3 being the anomaly of Chapter 112.

Derivation. Couple the electron minimally to an external field, writing $\hat{\boldsymbol{\pi}} = \hat{\boldsymbol{p}} - q\boldsymbol{A}$ with $q = -e$, and use $(\boldsymbol{\sigma}\cdot\boldsymbol{a})(\boldsymbol{\sigma}\cdot\boldsymbol{b}) = \boldsymbol{a}\cdot\boldsymbol{b} + \mathrm{i}\boldsymbol{\sigma}\cdot(\boldsymbol{a}\times\boldsymbol{b})$ with $\boldsymbol{a} = \boldsymbol{b} = \hat{\boldsymbol{\pi}}$. The cross term does not vanish, because the components of $\hat{\boldsymbol{\pi}}$ fail to commute:

$$[\hat{\pi}_j, \hat{\pi}_k] = -q\,([\hat{p}_j, A_k] + [A_j, \hat{p}_k]) = \mathrm{i}\hbar q\,(\partial_j A_k - \partial_k A_j) = \mathrm{i}\hbar q\,\epsilon_{jkl}B_l\,,$$

so that $(\hat{\boldsymbol{\pi}}\times\hat{\boldsymbol{\pi}})_i = \frac{1}{2}\epsilon_{ijk}\,[\hat{\pi}_j, \hat{\pi}_k] = \mathrm{i}\hbar q B_i$ and hence

$$(\boldsymbol{\sigma}\cdot\hat{\boldsymbol{\pi}})^2 = \hat{\boldsymbol{\pi}}^2 - q\hbar\,\boldsymbol{\sigma}\cdot\boldsymbol{B}\,. \tag{93.3}$$

Eliminating the lower components of the spinor at leading order in $1/m_e c^2$ (Section 93.3.3) leaves the upper two-component amplitude obeying $\mathrm{i}\hbar\partial_t\chi = \left[(\boldsymbol{\sigma}\cdot\hat{\boldsymbol{\pi}})^2/2m_e + q\phi\right]\chi$, and inserting Equation (93.3) produces the interaction $-(q\hbar/2m_e)\,\boldsymbol{\sigma}\cdot\boldsymbol{B} = -\boldsymbol{\mu}\cdot\boldsymbol{B}$ with

$$\boldsymbol{\mu} = \frac{q\hbar}{2m_e}\boldsymbol{\sigma} = -\frac{e}{m_e}\hat{\boldsymbol{S}} = -2\,\frac{\mu_{\mathrm{B}}}{\hbar}\hat{\boldsymbol{S}}\,,$$

using $q = -e$ and $\hat{\boldsymbol{S}} = \frac{\hbar}{2}\boldsymbol{\sigma}$: this is Equation (93.2) with $g = 2$. The same substitution applied to the orbital term gives $-(q/2m_e)\,\hat{\boldsymbol{L}}\cdot\boldsymbol{B}$, that is $g = 1$ for orbital motion. The factor of two is produced entirely by the algebra of $(\boldsymbol{\sigma}\cdot\boldsymbol{a})^2$; it is not fitted, and its *exactness* at this order is what makes the measured departure from 2 informative rather than merely a correction. □

93.3.3 The Pauli equation as the nonrelativistic limit

[Reserved: elimination of the small components at leading order, yielding the Pauli equation $\mathrm{i}\hbar\partial_t\chi = \left[\frac{1}{2m}\left(\hat{\boldsymbol{p}} - \frac{e}{c}\boldsymbol{A}\right)^2 - \frac{e\hbar}{2mc}\boldsymbol{\sigma}\cdot\boldsymbol{B} + e\phi\right]\chi$ [587], previously an empirical two-component equation and now a derived limit; the identification of the Pauli matrices with $\boldsymbol{\Sigma}$ restricted to the upper components; the systematic continuation of this expansion in Section 93.7.1.]

93.4 The hydrogen atom solved exactly

93.4.1 The Dirac–Coulomb spectrum

[Reserved: separation of the equation in a Coulomb field and the closed-form spectrum obtained independently by Darwin [595] and by Gordon [601], depending on n and on the total angular momentum j only; its expansion in powers of $Z\alpha$, reproducing the Bohr levels of Chapter 70 at leading order and Sommerfeld's fine-structure formula [441] at the next — obtained by Sommerfeld from a relativistic orbit calculation with no spin at all, one of the most instructive coincidences in physics, which the chapter should state and explain rather than repeat; the breakdown at $Z\alpha > 1$ and what it signals.]

Phenomenon 93.4 (Fine structure)**.** The spectral lines of atomic hydrogen are not single. Each level of principal quantum number n is resolved into components separated by intervals of relative order $\alpha^2 \approx 5.3\times10^{-5}$, and the pattern is governed by the total angular momentum j alone: two states sharing n and j but differing in orbital ℓ — $2s_{1/2}$ and $2p_{1/2}$, for instance — are observed to coincide. The splittings were fitted, in advance of any notion of spin, by Sommerfeld's relativistic orbit formula [441], and the Dirac equation reproduces the same expression in closed form,

$$E_{nj} = m_e c^2 \left[1 + \frac{(Z\alpha)^2}{\left(n - \left(j + \tfrac{1}{2} \right) + \sqrt{\left(j + \tfrac{1}{2} \right)^2 - (Z\alpha)^2} \right)^2} \right]^{-1/2} , \tag{93.4}$$

now as a consequence of the spin it does not assume.

Derivation pending #115

Separation of the Dirac equation in a Coulomb potential and solution of the resulting radial system in closed form, together with its expansion in powers of the nuclear charge times the fine-structure constant, which must reproduce the Bohr levels at leading order and the fine-structure intervals at the next.

93.4.2 Fine structure: spin–orbit, Darwin and mass terms

[Reserved: the three order-α^4 terms separated by the Foldy–Wouthuysen expansion — the relativistic kinetic correction, the spin–orbit coupling with the factor $\tfrac{1}{2}$ that Thomas supplied kinematically [561], and the Darwin term [595] that acts only on s states and reflects the smearing of the electron over a Compton wavelength; the resulting degeneracy of states with equal j, e.g. $2s_{1/2}$ and $2p_{1/2}$, which is a prediction *of the exact spectrum and is the one the next subsection reports as false; comparison with the perturbation-theory route of Chapter 82.]*

93.4.3 Where the exact spectrum fails: the Lamb shift

[Reserved: Lamb and Retherford's microwave measurement of a splitting of about 1058 MHz between $2s_{1/2}$ and $2p_{1/2}$ [901], states the Dirac equation makes exactly degenerate; the shift as the first quantitative evidence that the electron interacts with the quantized electromagnetic field, and therefore as the experiment that ended relativistic quantum mechanics as a fundamental theory; its calculation belongs to Chapter 100 and the modern spectroscopy to Chapter 90. This subsection must state the falsification plainly: the chapter's best result is wrong at the level current experiments resolve easily.]

Phenomenon 93.5 (The Dirac–Coulomb degeneracy is broken)**.** The states $2s_{1/2}$ and $2p_{1/2}$ of hydrogen, which Equation (93.4) makes exactly degenerate because they share both n and j, are observed to be split, the s state lying higher [901, 2331]. The interval is driven directly as a microwave resonance between the two levels, so it is measured rather than inferred from a difference of optical frequencies, and it exceeds every uncertainty of that measurement by orders of magnitude. The disagreement with Phenomenon 93.4 is therefore not marginal: the exact spectrum of this chapter is false. The measurements are Chapter 90.

Derivation pending #116

The radiative level shift between the two lowest hydrogen states of equal total angular momentum. Deriving it requires the quantized electromagnetic field, the electron self-energy and the vacuum polarization, and a renormalization prescription, so it lies outside relativistic quantum mechanics altogether and belongs to the quantum-electrodynamics chapter of Part XII.

93.5 Negative energies, holes and the positron

93.5.1 Hole theory

[Reserved: the negative-energy solutions of Section 93.2.3 and the catastrophe they imply — an electron radiating indefinitely into ever more negative states; Dirac's proposal that all such states are filled and that the exclusion principle of Chapter 83 forbids the transition [647]; a hole in the sea behaving as a particle of positive energy and opposite charge; the honest catalogue of what is wrong with the picture — an infinite charge density, no analogue for bosons (where Chapter 92 needed none [748]), and no Lorentz-invariant meaning for "filled".]

93.5.2 The prediction of the anti-electron

[Reserved: Dirac's first identification of the hole with the proton [647] and its refutation — Weyl's symmetry argument and Oppenheimer's observation that the hydrogen atom would then annihilate; the retraction and the correct prediction of an "anti-electron", a particle of the same mass and opposite charge, in 1931 [677]; the prediction of the antiproton in the same sentence, confirmed only in 1955; the timeline against the observation of Chapter 95, which this chapter should give exactly, because the case is the treatise's cleanest example of a mathematically forced prediction confirmed afterwards.]

Phenomenon 93.6 (Antiparticles)**.** There exists a particle of the electron's mass and of the opposite charge, the positron; it was first seen in cosmic radiation (Chapter 95), and the same has since proved true of every charged fermion examined. The masses and the charge magnitudes of a particle and of its antiparticle agree to within the precision of the comparisons tabulated in [2427], and no charged particle without such a partner has ever been found.

Derivation. The pairing is a symmetry of the equation itself, independent of hole theory. Write the minimally coupled equation of Section 93.1.2 for charge q,

$$[\gamma^{\mu}\,(\mathrm{i}\hbar\partial_{\mu} - qA_{\mu}) - mc]\,\psi = 0\,,$$

and take its complex conjugate, A_{μ} being real:

$$[\gamma^{\mu *}\,(-\mathrm{i}\hbar\partial_{\mu} - qA_{\mu}) - mc]\,\psi^{*} = 0\,.$$

In every representation of the Clifford algebra there is an invertible matrix C with $C\gamma^{\mu *}C^{-1} = -\gamma^{\mu}$; in the Dirac basis one may take $C = \mathrm{i}\gamma^2$, since there $\gamma^0, \gamma^1, \gamma^3$ are real and γ^2 is purely imaginary. Multiplying the conjugated equation on the left by C and inserting $C^{-1}C$ before ψ^* turns it into

$$[\gamma^{\mu}\,(\mathrm{i}\hbar\partial_{\mu} + qA_{\mu}) - mc]\,\psi^{c} = 0\,, \qquad \psi^{c} := C\psi^{*}\,, \tag{93.5}$$

which is the original equation with q replaced by $-q$ and m untouched. Solutions therefore come in pairs of equal mass and opposite charge, and since the map is invertible neither member of a pair is the more fundamental. An equation that describes an electron cannot avoid also describing a positron — which is why the prediction was forced rather than proposed, and why its confirmation four years later is the strongest single argument of this chapter. The argument says nothing about *why* the electron's mass takes the value it does, and nothing about the cosmological asymmetry between matter and antimatter, which Equation (93.5) does not address. □

93.5.3 The Stueckelberg–Feynman reading

[Reserved: the reinterpretation of negative-energy solutions as antiparticles propagating forwards in time, due to Stueckelberg [864] and Feynman [931]; the propagator prescription and the diagrammatic rules it generates [930]; why this reading and not hole theory is the one that survives into Chapter 99, and why it applies equally to the spin-0 case where no sea can be built.]

93.5.4 Charge conjugation and the Majorana alternative

[Reserved: the operation $\psi \mapsto \psi^{c} = C\bar{\psi}^{\mathsf{T}}$ mapping solutions of charge e to solutions of charge $-e$, and the CPT statement that its existence is not optional (Chapter 105); Majorana's observation that a neutral spin-$\tfrac{1}{2}$ particle may satisfy $\psi^{c} = \psi$ and so be its own antiparticle [796]; that this is a live experimental question only for neutrinos (Chapters 96 and 103), and that neutrinoless double beta decay has not been observed [2427] — so the alternative is stated as open, not adopted.]

93.6 Phenomena of the one-particle theory

93.6.1 Zitterbewegung

[Reserved: Schrödinger's 1930 analysis of free motion [669], in which the velocity operator $c\boldsymbol{\alpha}$ has eigenvalues $\pm c$ and the position expectation oscillates at angular frequency $2mc^2/\hbar$ with amplitude of order the Compton wavelength; the origin of the effect in interference between positive- and negative-energy components, so that it is absent for a state built from one branch alone; the verdict that it is an artefact of the one-particle reading rather than an observable motion of an electron, and the simulations in trapped-ion and cold-atom systems that reproduce the mathematics without vindicating the physics.]

93.6.2 The Klein paradox

[Reserved: Klein's calculation of reflection at a step of height exceeding $2mc^2$, where the transmitted current does not vanish and the reflected current exceeds the incident one [629]; the resolution as spontaneous pair creation by a field strong enough to supply $2mc^2$ over a Compton wavelength, hence as another statement that particle number is not conserved; the Schwinger critical field $m^2c^3/e\hbar \approx 1.3 \times 10^{18}\,\mathrm{V/m}$ as the scale [988], far above anything achieved in the laboratory, so this remains a prediction and must be labelled as one; the spin-0 version noted in Chapter 92.]

93.6.3 Thomas precession and spin transport

[Reserved: the kinematic precession of a spin carried along an accelerated worldline, derived by Thomas [561] from special relativity alone (Chapter 40) and responsible for the factor $\tfrac{1}{2}$ in the spin–orbit term of Section 93.4.2; the covariant equation of spin transport in an external field of Bargmann, Michel and Telegdi [1165], which is what the storage-ring measurements of Chapter 112 are actually analysed with.]

93.7 The systematic nonrelativistic expansion

93.7.1 The Foldy–Wouthuysen transformation

[Reserved: the unitary transformation that decouples upper and lower components order by order in $1/mc^2$, constructed by Foldy and Wouthuysen [955]; the transformed Hamiltonian and the mean position operator, which coincides with the Newton–Wigner operator of Chapter 92 [942] and in terms of which the Zitterbewegung disappears; the free case, where the transformation is exact, against the external-field case, where it is an asymptotic series.]

93.7.2 The corrections order by order

[Reserved: the expansion producing, at order $1/m^2c^2$, exactly the three fine-structure terms of Section 93.4.2 — kinetic, spin–orbit and Darwin — with their coefficients fixed rather than fitted; the method as the standard route to effective nonrelativistic Hamiltonians for atomic and molecular structure (Chapter 88) and for the relativistic corrections in heavy atoms, where the expansion parameter $Z\alpha$ is no longer small.]

93.8 The massless limit and the boundary of the theory

93.8.1 Weyl spinors and chirality

[Reserved: at $m = 0$ the equation decouples into two independent two-component equations for the chirality eigenstates, written by Weyl [641] and long rejected because each violates parity; their adoption after parity violation was observed (Chapter 110) and the neutrino helicity was measured (Chapter 98); the Dirac field as the direct sum of two Weyl fields coupled by the mass term, which is the statement developed in Chapter 96.]

93.8.2 Where relativistic quantum mechanics ends

[Reserved: a closing accounting of the chapter's results by status — the equation, the gamma algebra, the spinor transformation law, $g = 2$ at tree level and the Coulomb spectrum to order α^4 survive intact into field theory; hole theory, the single-particle Hilbert space, the position operator and the exact Coulomb spectrum do not [748, 931]. The energy scale at which the one-particle reading fails is $2mc^2$, and every phenomenon in Section 93.6 is a symptom of that failure. The continuation is Chapter 99.]

Chapter 94

Particles as Poincaré Representations

What *is* a particle? Every earlier part of this treatise uses the word operationally — a silver atom in a Stern–Gerlach magnet (Chapter 80), a photoelectron, a positron track — but relativistic quantum mechanics is where the word acquires a definition. The answer, found by Wigner in 1939 [849], is that a particle species is an *irreducible unitary representation of the Poincaré group*: relativity supplies the symmetry group of spacetime (Section 39.3), quantum mechanics demands that symmetries act unitarily on rays (Postulate 77.1), and irreducibility is the statement that the system has no smaller relativistically invariant part — that it is *elementary*. The two labels that classify these representations, mass and spin, are exactly the two numbers experiment attaches to every particle ever observed. This chapter carries out Wigner's programme in full; the standard modern accounts are [1912, 2287].

Throughout, the metric signature is $(+,-,-,-)$ with $\eta = \mathrm{diag}(1,-1,-1,-1)$ as in Chapter 39, Greek indices run over $0,1,2,3$ and Latin ones over $1,2,3$, the totally antisymmetric symbol is fixed by $\epsilon_{0123} = +1$, and $\hbar$ and c are kept explicit (Section 77.3).

Remark 94.1 (Level of rigor). The generators used below are unbounded operators, defined on dense domains by Stone's theorem for the one-parameter unitary subgroups they generate; commutators are understood on the common invariant dense domain of smooth vectors of the representation. This chapter manipulates them algebraically, as the physics literature does [1912]; the functional-analytic scaffolding (domains, essential self-adjointness, integrability of the algebra to the group) is classical representation theory and is not restated here. Two standing assumptions are recorded once: every representation in this chapter is *strongly continuous* — $(\Lambda, a) \mapsto U(\Lambda, a)\,|\psi\rangle$ is continuous for each state, which is what Stone's theorem consumes — and Schur's lemma, cited from the finite-dimensional Theorem 5.153, is used in its unitary infinite-dimensional (spectral-projection) form [1912].

94.1 Symmetries act unitarily: Wigner's theorem

Quantum states are unit rays, not vectors: $|\psi\rangle$ and $\mathrm{e}^{\mathrm{i}\alpha}\,|\psi\rangle$ describe the same physical state (Postulate 77.1), and every measurable prediction is built from transition probabilities $|\langle\varphi|\psi\rangle|^2$ (Postulate 77.4). A symmetry operation must therefore be, in the first instance, a map of *rays* that preserves those probabilities.

Definition 94.2 (Symmetry transformation)**.** Let $\mathcal{H}$ be the Hilbert space of a quantum system and write $[\psi]$ for the unit ray of a normalized $|\psi\rangle$. A *symmetry transformation* is a bijection T of the set of unit rays such that

$$|\langle\varphi'|\psi'\rangle|^2 = |\langle\varphi|\psi\rangle|^2 \qquad \text{whenever } [\psi'] = T[\psi],\ [\varphi'] = T[\varphi]\,. \tag{94.1}$$

Theorem 94.3 (Wigner). *Let* $\dim \mathcal{H} \geq 2$. *Every symmetry transformation* T *is implemented by an operator* U *on* $\mathcal{H}$ *—* $T[\psi] = [U\psi]$ *for every unit ray — which is either unitary and linear, or antiunitary and antilinear.* U *is unique up to an overall phase, and the two cases are mutually exclusive.*

Full derivation: Appendix A.9 (p. 2797).

Derives Theorem 94.3.

The theorem is due to Wigner [687]; the complete proof given in Appendix A.9 follows Bargmann [1269].

Corollary 94.4 (Connected symmetry groups act unitarily). *Let* G *be a connected Lie group acting by symmetry transformations* T_g*, and let* $U(g)$ *implement* T_g *as in Theorem 94.3. Then every* $U(g)$ *is unitary.*

Proof. Ray composition gives $U(g)U(h) = \omega(g,h)\,U(gh)$ for a phase $\omega(g,h)$, since both sides implement T_{gh} and Theorem 94.3 fixes the implementation up to a phase. In a connected Lie group every element is a finite product of exponentials, $g = \exp X_1 \cdots \exp X_n$: the image of the exponential map contains a neighbourhood of the identity, and the subgroup generated by any neighbourhood of the identity is open, hence closed — its complement is a union of its own open cosets — hence all of the connected group. Each factor is a square: $\exp X = \left(\exp \frac{X}{2}\right)^2$. Hence $U(g)$ equals, up to a phase, a product of operators $U(h_i)^2$. The square of a unitary operator is unitary, and so is the square of an antiunitary one (two antilinear maps compose to a linear map, and isometry is preserved); phases do not affect (anti)unitarity. A product of unitaries is unitary. □

The phases $\omega(g,h)$ cannot in general be removed by rephasing the $U(g)$: one speaks of a *projective* unitary representation. For the Poincaré group the obstruction was computed by Bargmann [1029]:

Theorem 94.5 (Bargmann). *Every* continuous *projective unitary representation of the proper orthochronous Poincaré group arises, after a choice of phases, from an ordinary strongly continuous unitary representation of its universal covering group* $\mathbb{R}^4 \rtimes \mathrm{SL}(2,\mathbb{C})$.

Derivation pending #117

Bargmann's theorem for the Poincaré group: the proof computes the second cohomology of the Lie algebra $\mathfrak{iso}(3,1)$ *and shows every local phase cocycle is a coboundary, then lifts to the simply connected cover; see [1029]. The cohomological machinery is not yet developed in this treatise.*

Remark 94.6 (The cover is physical). Theorem 94.5 is why the classification below runs over representations of the *cover* — in which a rotation by 2π need not be the identity, only its square is — and this is not a mathematical nicety but an observed fact: a neutron interferometer splits a beam, rotates the spin of one arm through 2π with a magnetic field, and finds the recombined intensity *reversed*, returning to itself only after 4π, exactly as the sign $U(2\pi) = -\mathbb{1}$ of a spin-$\frac{1}{2}$ representation demands [1566]. By contrast, for the Galilei group of Part III the obstruction does *not* vanish: its central charge is the mass itself [1029], which is why nonrelativistic quantum mechanics superselects mass while relativistic quantum mechanics treats it as a spectrum label.

94.2 The unitary generators of the Poincaré group

Proposition 94.7 (Composition law). *The transformations* $x \mapsto \Lambda x + a$ *of Minkowski space, with* Λ *in the proper orthochronous Lorentz group* $L_+^\uparrow$ *(Definition 39.5; Proposition 39.6*

makes it a group) and $a \in \mathbb{R}^4$, form a group with

$$(\Lambda', a')\,(\Lambda, a) = (\Lambda'\Lambda,\ a' + \Lambda' a)\,. \tag{94.2}$$

Proof. $x \mapsto \Lambda x + a \mapsto \Lambda'(\Lambda x + a) + a' = (\Lambda'\Lambda)x + (\Lambda' a + a')$; the identity is $(\mathbb{1}, 0)$ and $(\Lambda, a)^{-1} = (\Lambda^{-1}, -\Lambda^{-1}a)$. □

This is the Poincaré group of Section 39.3, restricted to its identity component. By Corollary 94.4 a relativistic quantum system carries unitary operators $U(\Lambda, a)$, projectively composing by Equation (94.2); by Theorem 94.5 we may and do take a true representation of the cover. Stone's theorem then provides Hermitian generators: for translations and for Lorentz transformations respectively,

$$U(\mathbb{1}, a) = \exp\left(-\frac{\mathrm{i}}{\hbar}\, a^\mu \hat{P}_\mu\right), \qquad U(\Lambda(\omega), 0) = \exp\left(-\frac{\mathrm{i}}{2\hbar}\, \omega_{\mu\nu} \hat{J}^{\mu\nu}\right), \tag{94.3}$$

with $\omega_{\mu\nu} = -\omega_{\nu\mu}$ the parameters of Section 39.2.7 and $\hat{J}^{\mu\nu} = -\hat{J}^{\nu\mu}$. The factor $\hbar$ makes $\hat{P}_\mu$ a momentum and $\hat{J}^{\mu\nu}$ an angular momentum; the physical dictionary is

$$\hat{H} = c\,\hat{P}^0\,, \qquad \hat{J}_i = \tfrac{1}{2}\,\epsilon_{ijk}\hat{J}^{jk}\,, \qquad \hat{K}_i = \hat{J}^{i0}\,, \tag{94.4}$$

energy, angular momentum and boost generator (cf. the nonrelativistic operators of Section 77.5).

Proposition 94.8 (The Poincaré algebra of the generators)**.** *On the common dense domain of Remark 94.1,*

$$\left[\hat{J}^{\mu\nu}, \hat{J}^{\lambda\rho}\right] = \mathrm{i}\hbar\left(\eta^{\mu\lambda}\hat{J}^{\rho\nu} + \eta^{\nu\rho}\hat{J}^{\lambda\mu} + \eta^{\mu\rho}\hat{J}^{\nu\lambda} + \eta^{\nu\lambda}\hat{J}^{\mu\rho}\right), \tag{94.5}$$

$$\left[\hat{J}^{\mu\nu}, \hat{P}^{\lambda}\right] = \mathrm{i}\hbar\left(\eta^{\nu\lambda}\hat{P}^{\mu} - \eta^{\mu\lambda}\hat{P}^{\nu}\right), \tag{94.6}$$

$$\left[\hat{P}^{\mu}, \hat{P}^{\nu}\right] = 0\,. \tag{94.7}$$

Proof. Let $\{X_a\}$ be a basis of the abstract Lie algebra with real structure constants, $[X_a, X_b] = f_{ab}{}^c X_c$, and let $\mathrm{d}U$ denote the induced representation of the algebra, so that $U(\exp tX_a) = \exp\left(-\frac{\mathrm{i}}{\hbar}t\,T_a\right)$ defines the Hermitian generator $T_a = \mathrm{i}\hbar\,\mathrm{d}U(X_a)$. Since $\mathrm{d}U$ preserves brackets,

$$[T_a, T_b] = (\mathrm{i}\hbar)^2\,[\mathrm{d}U(X_a), \mathrm{d}U(X_b)] = (\mathrm{i}\hbar)^2 f_{ab}{}^c\,\mathrm{d}U(X_c) = \mathrm{i}\hbar\, f_{ab}{}^c\, T_c\,.$$

The structure constants of $\mathfrak{iso}(3,1)$ were derived in Section 14.3.2 from the realization $J_{AB} = x_A\partial_B - x_B\partial_A$, $P_C = \partial_C$ (Equation (14.86)): the brackets are Equations (14.90) and (14.97) together with $[P_A, P_B] = 0$, restated for the physical signature in Equations (39.18) to (39.20) — granting the identification of that realization with the Lie algebra of $L_+^\uparrow$ in the parameterization Equation (94.3), a construction recorded as pending at Equation (14.86) and in Section 39.3.2. Multiplying each by $\mathrm{i}\hbar$ and raising indices with η gives Equations (94.5) to (94.7). □

Corollary 94.9 (Rotations, boosts, translations)**.** *Specializing indices in Equations (94.5) and (94.6) via Equation (94.4),*

$$\begin{aligned}
&\left[\hat{J}_i, \hat{J}_j\right] = \mathrm{i}\hbar\,\epsilon_{ijk}\hat{J}_k\,, \quad \left[\hat{J}_i, \hat{K}_j\right] = \mathrm{i}\hbar\,\epsilon_{ijk}\hat{K}_k\,, \quad \left[\hat{K}_i, \hat{K}_j\right] = -\mathrm{i}\hbar\,\epsilon_{ijk}\hat{J}_k\,,\\
&\left[\hat{J}_i, \hat{P}_j\right] = \mathrm{i}\hbar\,\epsilon_{ijk}\hat{P}_k\,, \quad \left[\hat{K}_i, \hat{P}_j\right] = \frac{\mathrm{i}\hbar}{c}\,\delta_{ij}\hat{H}\,, \qquad \left[\hat{K}_i, \hat{H}\right] = \mathrm{i}\hbar c\,\hat{P}_i\,,
\end{aligned} \tag{94.8}$$

and $\hat{H}$ commutes with $\hat{P}_i$ and $\hat{J}_i$. The relative sign between the first and third brackets — rotations close on rotations, boosts close on rotations with the opposite *sign — is the non-compactness of the Lorentz group (Equation (39.3)) seen at the algebra level.*

Proof. Direct substitution. As a sample, $\left[\hat{K}_1, \hat{P}_1\right] = \left[\hat{J}^{10}, \hat{P}^1\right] = \mathrm{i}\hbar\left(\eta^{01}\hat{P}^1 - \eta^{11}\hat{P}^0\right) = \mathrm{i}\hbar\,\hat{P}^0 = \frac{\mathrm{i}\hbar}{c}\hat{H}$, and $\left[\hat{J}_1, \hat{J}_2\right] = \left[\hat{J}^{23}, \hat{J}^{31}\right] = \mathrm{i}\hbar\,\eta^{33}\hat{J}^{12}\cdot(-1)^0 = \mathrm{i}\hbar\,\hat{J}^{12} = \mathrm{i}\hbar\,\hat{J}_3$, all other η factors vanishing because the index pairs share no common value. The remaining entries are the same computation with permuted indices. □

94.3 The universal cover $\mathrm{SL}(2,\mathbb{C})$

Theorem 94.5 directs us to the covering group. It is concretely available: to each four-vector associate the Hermitian 2×2 matrix

$$X = x^\mu\sigma_\mu = \begin{pmatrix} x^0 + x^3 & x^1 - \mathrm{i}x^2 \\ x^1 + \mathrm{i}x^2 & x^0 - x^3 \end{pmatrix}, \qquad \sigma_\mu = (\mathbb{1}, \sigma_1, \sigma_2, \sigma_3)\,, \tag{94.9}$$

with σ_i the Pauli matrices (Chapter 80). The map is a linear bijection onto Hermitian matrices, and

$$\det X = (x^0)^2 - \boldsymbol{x}^2 = x_\mu x^\mu\,. \tag{94.10}$$

Proposition 94.10 ($\mathrm{SL}(2,\mathbb{C})$ covers the proper orthochronous Lorentz group)**.** *For $A\in\mathrm{SL}(2,\mathbb{C})$ define $\Lambda(A)$ by $(\Lambda(A)x)^\mu\,\sigma_\mu = A\,(x^\mu\sigma_\mu)\,A^\dagger$. Then $A\mapsto\Lambda(A)$ is a group homomorphism onto $L_+^\uparrow$ with kernel $\{\mathbb{1},-\mathbb{1}\}$: the map is two-to-one, and $\mathrm{SL}(2,\mathbb{C})$, being simply connected, is the universal cover.*

Proof. $AXA^\dagger$ is Hermitian when X is, so $\Lambda(A)$ is a well-defined real-linear map of $\mathbb{R}^4$; it preserves $x_\mu x^\mu$ by Equation (94.10) because $\det(AXA^\dagger) = |\det A|^2\det X = \det X$, hence $\Lambda(A)$ is a Lorentz transformation (Definition 39.1). Homomorphism: $\Lambda(AB)x \leftrightarrow AB\,X\,B^\dagger A^\dagger \leftrightarrow \Lambda(A)\Lambda(B)x$. *Kernel:* if $AXA^\dagger = X$ for all Hermitian X, then $X=\mathbb{1}$ gives $AA^\dagger=\mathbb{1}$, so A is unitary and commutes with every σ_i; a 2×2 matrix commuting with all Pauli matrices is a multiple $\lambda\mathbb{1}$ (write it in the basis $\{\mathbb{1},\sigma_i\}$ and use $\sigma_i\sigma_j = \delta_{ij}\mathbb{1} + \mathrm{i}\epsilon_{ijk}\sigma_k$), and $\det A = \lambda^2 = 1$ forces $\lambda = \pm1$. *Connectedness and image:* polar decomposition writes every $A\in\mathrm{SL}(2,\mathbb{C})$ uniquely as $A = V\mathrm{e}^M$ with $V\in\mathrm{SU}(2)$ and M traceless Hermitian; $\mathrm{SU}(2)$ is the three-sphere $|a|^2+|b|^2=1$ of rows $(a,b),(-\bar b,\bar a)$ and the traceless Hermitian M form $\mathbb{R}^3$, so $\mathrm{SL}(2,\mathbb{C})$ is connected and simply connected ($S^3\times\mathbb{R}^3$; the polar factors depend continuously on A, the positive square root and logarithm being continuous on positive matrices, and $\pi_1(S^3)=0$). Its continuous image $\Lambda(\mathrm{SL}(2,\mathbb{C}))$ is then a connected subgroup of L containing $\mathbb{1}$, hence lands in $L_+^\uparrow$ (Proposition 39.6: both defining conditions are clopen). That it is *all* of $L_+^\uparrow$ follows from Lemmas 94.11 to 94.13: every rotation and every boost is attained, and every $\Lambda\in L_+^\uparrow$ is a boost times a rotation. Finally, a surjective continuous homomorphism of Lie groups with discrete kernel is a covering map — a standard fact used here without restatement. In particular $L_+^\uparrow$, as the continuous image of the connected $\mathrm{SL}(2,\mathbb{C})$, is itself connected: it is the identity component of L, as announced in Section 39.2.4. □

Lemma 94.11 (Unitary elements give rotations)**.** *For a unit vector $\boldsymbol{n}$ and $V = \exp\left(-\mathrm{i}\frac{\theta}{2}\boldsymbol{n}\cdot\boldsymbol{\sigma}\right)\in\mathrm{SU}(2)$, the map $\Lambda(V)$ fixes x^0 and rotates $\boldsymbol{x}$ by the angle θ about $\boldsymbol{n}$. Every rotation arises this way, and $V(\theta=2\pi) = -\mathbb{1}$.*

Proof. Since $(\boldsymbol{n}\cdot\boldsymbol{\sigma})^2 = \mathbb{1}$ (from $\sigma_i\sigma_j = \delta_{ij}\mathbb{1} + \mathrm{i}\epsilon_{ijk}\sigma_k$ and $|\boldsymbol{n}|=1$), the exponential series (Equation (7.40)) splits into $V = \cos\frac{\theta}{2}\,\mathbb{1} - \mathrm{i}\sin\frac{\theta}{2}\,\boldsymbol{n}\cdot\boldsymbol{\sigma}$. A direct computation with the same product identity gives, for $X = x^0\mathbb{1} + \boldsymbol{x}\cdot\boldsymbol{\sigma}$,

$$VXV^\dagger = x^0\mathbb{1} + \left[\cos\theta\,\boldsymbol{x} + \sin\theta\,(\boldsymbol{n}\times\boldsymbol{x}) + (1-\cos\theta)(\boldsymbol{n}\cdot\boldsymbol{x})\,\boldsymbol{n}\right]\cdot\boldsymbol{\sigma}\,,$$

which is Rodrigues' rotation formula about $\boldsymbol{n}$ by θ. Every rotation has an axis and an angle: for $R\in\mathrm{SO}(3)$, $\det(R-\mathbb{1}) = \det\left((R-\mathbb{1})^{\mathsf{T}}\right) = \det(R^{-1}-\mathbb{1}) = \det(R^{-1})\det(\mathbb{1}-R) =$

$-\det(R-\mathbb{1})$, so $\det(R-\mathbb{1})=0$ and R fixes a unit vector $\boldsymbol{n}$; on the invariant plane orthogonal to $\boldsymbol{n}$, R is an orientation-preserving linear isometry, i.e. a rotation by some θ. Hence all of SO(3) is attained; at $\theta=2\pi$, $V=\cos\pi\,\mathbb{1}=-\mathbb{1}$. □

Lemma 94.12 (Hermitian elements give boosts)**.** *For $H=\exp\left(\frac{\eta}{2}\boldsymbol{m}\cdot\boldsymbol{\sigma}\right)$ with $\boldsymbol{m}$ a unit vector and $\eta\in\mathbb{R}$, the map $\Lambda(H)$ is the pure boost of rapidity η along $\boldsymbol{m}$: for $\boldsymbol{m}=\boldsymbol{e}_3$,*

$$x^0\mapsto x^0\cosh\eta+x^3\sinh\eta\,,\quad x^3\mapsto x^0\sinh\eta+x^3\cosh\eta\,,\quad x^{1,2}\mapsto x^{1,2}\,. \tag{94.11}$$

The dictionary to the velocity parameterization of Chapter 38 is $\beta=\tanh\eta$, $\gamma=\cosh\eta$; since η ranges over all of $\mathbb{R}$ and $\boldsymbol{m}$ over all directions, every boost is attained.

Proof. For $\boldsymbol{m}=\boldsymbol{e}_3$ we have $H=\operatorname{diag}\left(\mathrm{e}^{\eta/2},\mathrm{e}^{-\eta/2}\right)$, and in Equation (94.9) the conjugation $HXH^\dagger=HXH$ multiplies the diagonal entries $x^0\pm x^3$ of X by $\mathrm{e}^{\pm\eta}$ while leaving the off-diagonal entries $x^1\mp\mathrm{i}x^2$ fixed ($\mathrm{e}^{\eta/2}\mathrm{e}^{-\eta/2}=1$): $x^0+x^3\mapsto\mathrm{e}^{\eta}(x^0+x^3)$, $x^0-x^3\mapsto\mathrm{e}^{-\eta}(x^0-x^3)$, which is Equation (94.11). A general axis $\boldsymbol{m}$ is $R\,\boldsymbol{e}_3$ for a rotation R; conjugating H by the corresponding V of Lemma 94.11 rotates the boost axis, since Λ is a homomorphism. □

Lemma 94.13 (Boost–rotation decomposition)**.** *Every $\Lambda\in L_+^\uparrow$ factors as $\Lambda=BR$ with B a pure boost and R a rotation.*

Proof. Let $u=\Lambda e_0$, where $e_0=(1,0,0,0)$. Then $u_\mu u^\mu=1$ and $u^0=\Lambda^0{}_0\geq 1$ (Definition 39.5), so $u=(\cosh\eta,\ \sinh\eta\,\boldsymbol{m})$ for some rapidity $\eta\geq 0$ and unit vector $\boldsymbol{m}$. Let B be the boost of Lemma 94.12 along $\boldsymbol{m}$ with rapidity η; then $Be_0=u$, so $R=B^{-1}\Lambda$ satisfies $Re_0=e_0$. A Lorentz transformation fixing e_0 preserves the spatial slice $x^0=0$ and the Euclidean norm on it (both statements from $\Lambda\eta\Lambda^{\mathsf{T}}=\eta$, Equation (39.2): the first column of R is e_0, hence so is the first row), so $R\in\mathrm{O}(3)$; and $\det R=\det\Lambda=1$ places $R\in\mathrm{SO}(3)$. □

Corollary 94.14 (SU(2) covers SO(3); half-integer spin is projective)**.** *Restricting Proposition 94.10 to the rotation subgroup: $\mathrm{SU}(2)\to\mathrm{SO}(3)$ is a two-to-one covering with kernel $\pm\mathbb{1}$. A representation of $\mathrm{SU}(2)$ in which $-\mathbb{1}\mapsto-\mathbb{1}$ — half-integer spin, as classified in Lemma 94.28 below — is therefore a* projective *representation of the rotation group itself, with precisely the 4π periodicity observed in [1566] (Remark 94.6).*

94.4 The invariants: mass and spin

Which combinations of the generators are the same in every inertial frame? By Schur's lemma (Theorem 5.153) an operator commuting with the whole representation acts as a number on an irreducible one: such *Casimir operators* are the invariant labels we are looking for.

Definition 94.15 (Pauli–Lubanski vector)**.**

$$\hat{W}_\mu=\tfrac{1}{2}\,\epsilon_{\mu\nu\rho\sigma}\,\hat{J}^{\nu\rho}\hat{P}^\sigma\,,\qquad \epsilon_{0123}=+1\,. \tag{94.12}$$

Lemma 94.16 (Invariance identity for ϵ)**.** *For every $\omega\in\mathfrak{so}(3,1)$, i.e. $\omega_{\mu\nu}=-\omega_{\nu\mu}$,*

$$\omega^\alpha{}_\mu\epsilon_{\alpha\nu\rho\sigma}+\omega^\alpha{}_\nu\epsilon_{\mu\alpha\rho\sigma}+\omega^\alpha{}_\rho\epsilon_{\mu\nu\alpha\sigma}+\omega^\alpha{}_\sigma\epsilon_{\mu\nu\rho\alpha}=0\,. \tag{94.13}$$

Proof. The left side is totally antisymmetric in $\mu\nu\rho\sigma$: swapping any two of them exchanges two terms and flips the sign of the remaining two through the antisymmetry of ϵ. A totally antisymmetric four-index array in four dimensions is a multiple of $\epsilon_{\mu\nu\rho\sigma}$; contracting the left side with $\epsilon^{\mu\nu\rho\sigma}$ shows the multiple is proportional to $\omega^\alpha{}_\alpha=\eta^{\alpha\beta}\omega_{\beta\alpha}=0$. □

Lemma 94.17 (Properties of $\hat{W}$)**.** *1.* $\left[\hat{W}_\mu,\hat{P}_\lambda\right]=0$;

2. $\hat{W}_\mu \hat{P}^\mu = \hat{P}^\mu \hat{W}_\mu = 0$;

3. $\hat{W}$ *is a four-vector:* $\left[\hat{J}_{\mu\nu}, \hat{W}_\lambda\right] = \mathrm{i}\hbar\left(\eta_{\nu\lambda}\hat{W}_\mu - \eta_{\mu\lambda}\hat{W}_\nu\right)$.

Proof. (i) By Equations (94.6) and (94.7), $\left[\hat{J}^{\nu\rho}\hat{P}^\sigma, \hat{P}_\lambda\right] = \left[\hat{J}^{\nu\rho}, \hat{P}_\lambda\right]\hat{P}^\sigma = \mathrm{i}\hbar\left(\delta^\rho_\lambda \hat{P}^\nu - \delta^\nu_\lambda \hat{P}^\rho\right)\hat{P}^\sigma$; contracted with $\epsilon_{\mu\nu\rho\sigma}$ each term dies because $\hat{P}^\nu\hat{P}^\sigma$ (respectively $\hat{P}^\rho\hat{P}^\sigma$) is symmetric in indices that ϵ antisymmetrizes.

(ii) $\hat{W}_\mu\hat{P}^\mu = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}\hat{J}^{\nu\rho}\hat{P}^\sigma\hat{P}^\mu = 0$ for the same symmetry reason, using Equation (94.7); the reversed order follows from (i).

(iii) Insert Equations (94.5) and (94.6) into $\left[\hat{J}_{\mu\nu}, \frac{1}{2}\epsilon_{\lambda\alpha\beta\gamma}\hat{J}^{\alpha\beta}\hat{P}^\gamma\right]$ and use the Leibniz rule for commutators; the resulting four $\epsilon\eta$-contractions combine, by Lemma 94.16 applied with ω the antisymmetrized pair $(\mu\nu)$, into exactly the two terms $\mathrm{i}\hbar(\eta_{\nu\lambda}\hat{W}_\mu - \eta_{\mu\lambda}\hat{W}_\nu)$. □

Theorem 94.18 (The Casimir invariants of the Poincaré group)**.** $\hat{P}^2 = \hat{P}_\mu\hat{P}^\mu$ *and* $\hat{W}^2 = \hat{W}_\mu\hat{W}^\mu$ *commute with every generator of Proposition 94.8. On an irreducible representation each is a real number.*

Proof. $\left[\hat{P}^2, \hat{P}_\lambda\right] = 0$ by Equation (94.7), and $\left[\hat{P}^2, \hat{J}_{\mu\nu}\right] = 0$ because Equation (94.6) makes $\hat{P}$ a four-vector and the square of a four-vector is a scalar: $\left[\hat{J}_{\mu\nu}, \hat{P}_\lambda\hat{P}^\lambda\right] = \mathrm{i}\hbar\left(\eta_{\nu\lambda}\hat{P}_\mu - \eta_{\mu\lambda}\hat{P}_\nu\right)\hat{P}^\lambda + \mathrm{i}\hbar\,\hat{P}_\lambda\left(\delta^\lambda_\nu\hat{P}_\mu - \delta^\lambda_\mu\hat{P}_\nu\right) = \mathrm{i}\hbar\left(\hat{P}_\mu\hat{P}_\nu - \hat{P}_\nu\hat{P}_\mu\right) + \mathrm{i}\hbar\left(\hat{P}_\nu\hat{P}_\mu - \hat{P}_\mu\hat{P}_\nu\right) = 0$ identically. The same computation with Lemma 94.17(iii) kills $\left[\hat{J}_{\mu\nu}, \hat{W}^2\right]$, and $\left[\hat{W}^2, \hat{P}_\lambda\right] = 0$ is Lemma 94.17(i). Schur's lemma (Theorem 5.153, with the qualification of Remark 94.1) then makes each a scalar on an irreducible representation; Hermiticity makes the scalar real. □

Definition 94.19 (Mass)**.** On an irreducible representation write

$$\hat{P}^2 = m^2c^2\,\mathbb{1}\,. \tag{94.14}$$

For the representations selected by observation (Remark 94.22 below) $m^2 \geq 0$; the number $m \geq 0$ is the *mass* of the particle. The value of $\hat{W}^2$ will emerge as the spin in Theorem 94.29 and Proposition 94.32.

94.5 Orbits, little groups, and induced representations

Since the $\hat{P}^\mu$ commute (Equation (94.7)), diagonalize them: a basis $|p,\sigma\rangle$ with $\hat{P}^\mu|p,\sigma\rangle = p^\mu|p,\sigma\rangle$, where σ enumerates whatever degeneracy remains. Translations then act by $U(\mathbb{1},a)|p,\sigma\rangle = \mathrm{e}^{-\mathrm{i}\,a\cdot p/\hbar}|p,\sigma\rangle$, and by Equation (94.6) a Lorentz transformation carries the eigenvalue p to Λp: $\hat{P}^\mu U(\Lambda)|p,\sigma\rangle = (\Lambda p)^\mu U(\Lambda)|p,\sigma\rangle$ (conjugate $\hat{P}$ through $U(\Lambda)$ with Equations (94.3) and (94.6)). An irreducible representation therefore lives on a single *orbit* of momenta.

Lemma 94.20 (Orthochronous transformations preserve the sign of p^0 on causal vectors)**.** *If* $p_\mu p^\mu \geq 0$, $p \neq 0$, *and* $\Lambda \in L^\uparrow_+$, *then* $\operatorname{sgn}\left((\Lambda p)^0\right) = \operatorname{sgn}\left(p^0\right)$.

Proof. $(\Lambda p)^0 = \Lambda^0{}_0 p^0 + \Lambda^0{}_i p^i$. By the Cauchy–Schwarz inequality of Section 6.3 and the row identity $\left(\Lambda^0{}_0\right)^2 = 1 + \sum_i \left(\Lambda^0{}_i\right)^2$ (the $\mu=\nu=0$ component of Equation (39.2) applied to $\Lambda^{-1} = \eta\Lambda^{\mathsf{T}}\eta$),

$$\left|\Lambda^0{}_i p^i\right| \leq \sqrt{\textstyle\sum_i \left(\Lambda^0{}_i\right)^2}\;|\boldsymbol{p}| < \Lambda^0{}_0\,\left|p^0\right|$$

whenever $|\boldsymbol{p}| \leq |p^0|$ with $p \neq 0$ (causality) — strictly, since either the causal inequality is strict or $\sum_i(\Lambda^0{}_i)^2 < (\Lambda^0{}_0)^2$. Hence the first term dominates and carries the sign of p^0 ($\Lambda^0{}_0 \geq 1$, Definition 39.5). □

Proposition 94.21 (Orbit classification)**.** *Under $L_+^\uparrow$ the nonzero momenta fall into the disjoint orbits*

orbit	*invariants*	*standard momentum k*
massive, positive energy	$p^2 = m^2c^2 > 0$, $p^0 > 0$	$(mc, 0, 0, 0)$
massive, negative energy	$p^2 = m^2c^2 > 0$, $p^0 < 0$	$(-mc, 0, 0, 0)$
massless, positive energy	$p^2 = 0$, $p^0 > 0$	$(\kappa, 0, 0, \kappa)$
massless, negative energy	$p^2 = 0$, $p^0 < 0$	$(-\kappa, 0, 0, \kappa)$
tachyonic	$p^2 = -\mu^2c^2 < 0$	$(0, 0, 0, \mu c)$

together with the fixed point $p = 0$; here $\kappa > 0$ is any fixed reference momentum (different κ label the same orbit).

Proof. p^2 is invariant by definition of L, and $\operatorname{sgn}(p^0)$ is invariant on the causal orbits by Lemma 94.20, so the listed classes are unions of orbits. Each class is a *single* orbit because its standard momentum reaches every member: a rotation (Lemma 94.11) aligns $\boldsymbol{p}$ with $\boldsymbol{e}_3$, and the boost Equation (94.11) with the appropriate rapidity then produces any admissible p^0: $\cosh\eta = p^0/(mc)$ in the massive case, $\mathrm{e}^\eta = p^0/\kappa$ in the massless case, $\sinh\eta = p^0/(\mu c)$ in the tachyonic case, the spatial part then matching automatically — which also shows both signs of p^0 lie on *one* tachyonic orbit, sinh being unbounded in both directions; the negative-energy rows follow by applying the same transformations to their own standard momenta. The composition of these transformations is the *standard boost* $L(p)$, fixed once and for all on each orbit:

$$L(p) = R(\hat{\boldsymbol{p}})\, B_3(\eta_p)\,, \qquad L(p)\, k = p\,, \tag{94.15}$$

with $R(\hat{\boldsymbol{p}})$ a fixed choice of rotation carrying $\boldsymbol{e}_3$ to the unit vector $\hat{\boldsymbol{p}}$ and B_3 the boost Equation (94.11); the conventions are $R(\boldsymbol{e}_3) = \mathbb{1}$ — so that $L(k) = \mathbb{1}$ — and a fixed measurable choice of $R(\hat{\boldsymbol{p}})$ elsewhere (no continuous global choice exists); any such choice serves. □

Remark 94.22 (Observation selects two orbit classes)*.* Nature realizes the massive and massless positive-energy orbits, and only those. Negative-energy representations would make every system unstable against decay into ever-lower energies — the resolution of this instability is the reinterpretation of the negative-frequency modes in quantum field theory, anticipated by the positron (Chapter 95) — and no tachyonic particle ($p^2 < 0$) has ever been observed. This is an *empirical* input to the classification, not a mathematical one, and this treatise records it as such (cf. the front-matter scope rules).

Definition 94.23 (Little group)**.** The *little group* (stabilizer) of the standard momentum k is

$$G_k = \left\{ \Lambda \in L_+^\uparrow \mid \Lambda k = k \right\}. \tag{94.16}$$

Proposition 94.24 (Massive little group)**.** *For $k = (mc, 0, 0, 0)$, $G_k = \mathrm{SO}(3)$, with cover* $\mathrm{SU}(2)$*.*

Proof. $\Lambda k = k$ says $\Lambda e_0 = e_0$; the proof of Lemma 94.13 showed exactly that such a Λ is a rotation, and conversely rotations fix e_0. The cover statement is Corollary 94.14. □

Proposition 94.25 (Massless little group)**.** *For $k = (\kappa, 0, 0, \kappa)$ the Lie algebra of G_k is spanned by*

$$\hat{J}^3 = \hat{J}^{12}\,, \qquad \hat{A} = \hat{J}^{01} + \hat{J}^{13}\,, \qquad \hat{B} = \hat{J}^{02} + \hat{J}^{23}\,, \tag{94.17}$$

with brackets

$$\left[\hat{J}^3, \hat{A}\right] = \mathrm{i}\hbar\, \hat{B}\,, \qquad \left[\hat{J}^3, \hat{B}\right] = -\mathrm{i}\hbar\, \hat{A}\,, \qquad \left[\hat{A}, \hat{B}\right] = 0\,. \tag{94.18}$$

This is the algebra $\mathfrak{iso}(2)$ *of the Euclidean group of the plane — a rotation* ($\hat{J}^3$) *and two commuting translations* ($\hat{A}, \hat{B}$) *— cf. the semidirect structure Equation* (14.99) *in two Euclidean dimensions.*

Proof. An algebra element $\frac{1}{2}\omega_{\mu\nu}\hat{J}^{\mu\nu}$ stabilizes k iff $\omega^{\mu}{}_{\nu}k^{\nu} = 0$, i.e. $\omega^{\mu}{}_{0} + \omega^{\mu}{}_{3} = 0$ for every μ. Writing this out with η: for $\mu = 0$ it gives $\omega_{03} = 0$; for $\mu = 1$, $\omega_{01} = \omega_{13}$; for $\mu = 2$, $\omega_{02} = \omega_{23}$; for $\mu = 3$ it repeats $\omega_{03} = 0$. Three free parameters remain, multiplying exactly the three combinations Equation (94.17). The brackets follow from Equation (94.5) by direct substitution; as a sample, in $\left[\hat{J}^{12}, \hat{J}^{01}\right]$ the only surviving term of Equation (94.5) is $\eta^{\mu\rho}\hat{J}^{\nu\lambda}$ with $(\mu\nu\lambda\rho) = (1, 2, 0, 1)$, giving $\mathrm{i}\hbar\,\eta^{11}\hat{J}^{20} = \mathrm{i}\hbar\,\hat{J}^{02}$, and $\left[\hat{J}^{12}, \hat{J}^{13}\right] = \mathrm{i}\hbar\,\eta^{11}\hat{J}^{32} = \mathrm{i}\hbar\,\hat{J}^{23}$, whose sum is $\mathrm{i}\hbar\,\hat{B}$; the other two brackets are the same bookkeeping, with the two disjoint-index commutators $\left[\hat{J}^{01}, \hat{J}^{23}\right] = \left[\hat{J}^{13}, \hat{J}^{02}\right] = 0$ making $\left[\hat{A}, \hat{B}\right]$ collapse to $\left[\hat{J}^{01}, \hat{J}^{02}\right] + \left[\hat{J}^{13}, \hat{J}^{23}\right] = \mathrm{i}\hbar\left(-\hat{J}^{12} + \hat{J}^{12}\right) = 0$. □

Lemma 94.26 (Lorentz-invariant measure on a mass shell)**.** *On the orbit* $p^2 = m^2c^2 \geq 0$, $p^0 > 0$, *the measure*

$$\mathrm{d}\mu(p) = \frac{\mathrm{d}^3 p}{2p^0}\,, \qquad p^0 = \sqrt{\boldsymbol{p}^2 + m^2c^2}\,, \tag{94.19}$$

satisfies $\int f(\Lambda^{-1}p)\,\mathrm{d}\mu(p) = \int f(p)\,\mathrm{d}\mu(p)$ *for every* $\Lambda \in L_+^{\uparrow}$ *and integrable* f.

Proof. Write the integral over the orbit as a four-dimensional one,

$$\int f(p)\,\frac{\mathrm{d}^3 p}{2p^0} = \int \mathrm{d}^4 p\;\delta\!\left(p_\mu p^\mu - m^2c^2\right)\theta\!\left(p^0\right) f(p)\,,$$

which follows from the composition rule for the Dirac delta (Proposition 7.113): at fixed $\boldsymbol{p}$ the argument $\left(p^0\right)^2 - \boldsymbol{p}^2 - m^2c^2$ has the single positive root Equation (94.19) with derivative $2p^0$. In the four-dimensional form each factor is invariant under $p \mapsto \Lambda p$: the delta because p^2 is, the step function by Lemma 94.20, and $\mathrm{d}^4 p$ because $|\det\Lambda| = 1$. □

Theorem 94.27 (Wigner's induced representations)**.** *Fix a causal positive-energy orbit of Proposition 94.21 — the ones Lemma 94.26 equips with an invariant measure, and the only ones used in the sequel — with standard momentum* k, *and a unitary irreducible representation* $D_{\sigma'\sigma}$ *of (the cover of) the little group* G_k *on a space with basis* $\{\sigma\}$. *For half-integer representations everything is read in the covering group:* $L(p)$ *then denotes the fixed lift of the standard boost Equation* (94.15) *assembled from the* $\mathrm{SL}(2,\mathbb{C})$ *elements of Lemmas 94.11 and 94.12, so that* $W(\Lambda, p)$ *below lies in the cover of* G_k *and* $D(W)$ *is unambiguous; for integer spin the formulas descend to* $L_+^{\uparrow}$. *Define one-particle states by* $|k, \sigma\rangle$ *carrying* D, *and*

$$|p, \sigma\rangle = U(L(p))\,|k, \sigma\rangle\,, \tag{94.20}$$

with $L(p)$ *the standard boost Equation* (94.15) *and the normalization* $\langle p', \sigma'|p, \sigma\rangle = 2p^0\,\delta^3(\boldsymbol{p}' - \boldsymbol{p})\,\delta_{\sigma'\sigma}$. *Then*

$$U(\mathbb{1}, a)\;|p, \sigma\rangle = \mathrm{e}^{-\mathrm{i}\,p\cdot a/\hbar}\;|p, \sigma\rangle\,, \tag{94.21}$$

$$U(\Lambda, 0)\;|p, \sigma\rangle = \sum_{\sigma'} D_{\sigma'\sigma}(W(\Lambda, p))\;|\Lambda p, \sigma'\rangle\,, \qquad W(\Lambda, p) = L(\Lambda p)^{-1}\,\Lambda\,L(p)\,, \tag{94.22}$$

defines a unitary representation of the covering group; the element $W(\Lambda, p)$ *— the* Wigner rotation *— indeed lies in* G_k.

Proof. $W(\Lambda,p)k = L(\Lambda p)^{-1}\Lambda L(p)\,k = L(\Lambda p)^{-1}(\Lambda p) = k$, so $W(\Lambda,p)\in G_k$. Composition: applying Equation (94.22) twice,

$$W(\Lambda',\Lambda p)\,W(\Lambda,p) = L(\Lambda'\Lambda p)^{-1}\Lambda' L(\Lambda p)\,L(\Lambda p)^{-1}\Lambda L(p) = W(\Lambda'\Lambda,p)\,,$$

so the D factors compose correctly and $U(\Lambda')U(\Lambda) = U(\Lambda'\Lambda)$; translations compose by inspection of Equation (94.21), and the mixed products follow from Equation (94.2) applied to Λa. Unitarity: for wave packets $|\psi\rangle = \sum_\sigma \int \mathrm{d}\mu(p)\,\psi_\sigma(p)\,|p,\sigma\rangle$ the chosen normalization gives $\|\psi\|^2 = \sum_\sigma \int \mathrm{d}\mu(p)\,|\psi_\sigma(p)|^2$, and by Equation (94.22) a Lorentz transformation replaces $\psi_\sigma(p)$ by $\sum_{\sigma'} D_{\sigma\sigma'}(W)\,\psi_{\sigma'}(\Lambda^{-1}p)$: the sum over σ is preserved because D is unitary, and the integral because the measure is invariant (Lemma 94.26). □

Derivation pending #118

Completeness of the classification: that the representation defined by Equations (94.21) and (94.22) is irreducible precisely when D is, and that every *irreducible unitary representation of the cover with $\hat{P}$-spectrum on the given orbit is equivalent to an induced one, is Mackey's imprimitivity theorem, specialized by Wigner to this group [849]. The systematic imprimitivity machinery is not yet developed in this treatise.*

94.6 Massive particles: spin

By Proposition 94.24 and Theorem 94.27, classifying massive particles means classifying the unitary irreducible representations of SU(2) — equivalently, of its algebra $\left[\hat{J}_i,\hat{J}_j\right] = \mathrm{i}\hbar\,\epsilon_{ijk}\hat{J}_k$ (Equation (94.8)).

Lemma 94.28 (Unitary irreducible representations of $\mathfrak{su}(2)$)**.** *The finite-dimensional unitary irreducible representations of the algebra $\left[\hat{J}_i,\hat{J}_j\right] = \mathrm{i}\hbar\,\epsilon_{ijk}\hat{J}_k$ are labelled by $s\in\left\{0,\frac{1}{2},1,\frac{3}{2},\dots\right\}$. The representation labelled s has dimension $2s+1$, carries $\hat{\boldsymbol{J}}^2 = \hbar^2 s(s+1)\,\mathbb{1}$, and admits a basis $|s,\sigma\rangle$, $\sigma = -s,-s+1,\dots,s$, with $\hat{J}_3\,|s,\sigma\rangle = \hbar\sigma\,|s,\sigma\rangle$.*

Proof. Let $\hat{J}_\pm = \hat{J}_1 \pm \mathrm{i}\hat{J}_2$, so that $\hat{J}_\pm^\dagger = \hat{J}_\mp$ and, from the algebra,

$$\left[\hat{J}_3,\hat{J}_\pm\right] = \pm\hbar\,\hat{J}_\pm\,,\qquad \left[\hat{J}_+,\hat{J}_-\right] = 2\hbar\,\hat{J}_3\,,\qquad \hat{\boldsymbol{J}}^2 = \hat{J}_\mp\hat{J}_\pm + \hat{J}_3^2 \pm \hbar\hat{J}_3\,. \tag{94.23}$$

$\hat{\boldsymbol{J}}^2$ commutes with each $\hat{J}_i$ (same computation as in Theorem 94.18, three-dimensional case), so on an irreducible representation $\hat{\boldsymbol{J}}^2 = \lambda\hbar^2\mathbb{1}$ with $\lambda\geq 0$ (it is a sum of squares of Hermitian operators). Diagonalize the Hermitian $\hat{J}_3$: eigenvalues $\hbar\sigma$. The first bracket in Equation (94.23) shifts σ by ±1 under $\hat{J}_\pm$, while

$$\left\|\hat{J}_\pm\,|\sigma\rangle\right\|^2 = \langle\sigma|\,\hat{J}_\mp\hat{J}_\pm\,|\sigma\rangle = \hbar^2\left[\lambda-\sigma(\sigma\pm1)\right]\;\geq 0\,. \tag{94.24}$$

In a finite-dimensional space the ladder must terminate in both directions: there are extremal eigenvalues $\sigma_\pm$ with $\hat{J}_+\,|\sigma_+\rangle = 0$ and $\hat{J}_-\,|\sigma_-\rangle = 0$, so Equation (94.24) forces $\lambda = \sigma_+(\sigma_++1) = \sigma_-(\sigma_--1)$, whose only solution with $\sigma_+\geq\sigma_-$ is $\sigma_- = -\sigma_+$. Writing $s=\sigma_+$: the ladder descends from σ_+ to σ_- in unit steps, so $2s\in\mathbb{Z}_{\geq0}$ and $\lambda = s(s+1)$. The states $\{|s,\sigma\rangle\}_{\sigma=-s}^{s}$ span an invariant subspace (the three generators are linear combinations of $\hat{J}_3$ and $\hat{J}_\pm$, which act within it), hence by irreducibility the whole space: the dimension is $2s+1$. Conversely each such s is realized — Equation (94.24) defines the matrix elements, and the brackets Equation (94.23) are verified directly — so the list is exhaustive. (Infinite-dimensional unitary irreducible representations of a *compact* group do not occur: every unitary representation of SU(2) decomposes into finite-dimensional ones — the Peter–Weyl theorem [1912]; the treatise's own account of SU(2), Section 14.2.2, is still pending.) □

Theorem 94.29 (Massive particles)**.** *The irreducible positive-energy representations with $m > 0$ are classified by the pair (m, s) with $2s \in \mathbb{Z}_{\geq 0}$: mass and* spin*. The representation (m, s) has $2s + 1$ polarization states for each momentum, and*

$$\hat{W}^2 = -m^2c^2\,\hbar^2\,s(s+1)\,\mathbb{1}\,. \tag{94.25}$$

Proof. The classification is Theorem 94.27, Proposition 94.24, and Lemma 94.28, modulo the completeness statement recorded as pending after Theorem 94.27 (irreducibility and exhaustiveness of the induced family). For Equation (94.25) evaluate $\hat{W}^2$ — a Casimir, so any convenient states will do (Theorem 94.18) — on the standard-momentum states $|k, \sigma\rangle$, $k = (mc, \mathbf{0})$. There $\hat{P}^\sigma$ may be replaced by its eigenvalue, in both factors of $\hat{W}^2$: $\hat{W}$ preserves the momentum eigenspace by Lemma 94.17(i). In Equation (94.12) only $\hat{P}^0 = mc$ survives,

$$\hat{W}_0\,|k,\sigma\rangle = \tfrac{1}{2}\epsilon_{0\nu\rho0}\,\hat{J}^{\nu\rho}mc\,|k,\sigma\rangle = 0\,, \qquad \hat{W}_i\,|k,\sigma\rangle = \tfrac{mc}{2}\,\epsilon_{i\nu\rho0}\,\hat{J}^{\nu\rho}\,|k,\sigma\rangle = -mc\,\hat{J}_i\,|k,\sigma\rangle\ ,$$

the last step because $\epsilon_{ijk0} = -\epsilon_{0ijk}$ (one cyclic shift of four indices is an odd permutation) and $\hat{J}_i = \frac{1}{2}\epsilon_{ijk}\hat{J}^{jk}$ Equation (94.4). Hence on these states $\hat{W}^2 = \hat{W}_0\hat{W}^0 + \hat{W}_i\hat{W}^i = -\sum_i \left(mc\,\hat{J}_i\right)^2 = -m^2c^2\,\hat{\boldsymbol{J}}^2$, and Lemma 94.28 supplies the eigenvalue $\hbar^2 s(s+1)$: the Pauli–Lubanski square measures the *rest-frame angular momentum* — the spin. □

Phenomenon 94.30 (Quantization of intrinsic angular momentum)**.** The intrinsic angular momentum of every particle species is quantized: measured along any axis it takes exactly $2s + 1$ equally spaced values $\hbar\sigma$, $\sigma = -s, \ldots, s$, with $2s$ a nonnegative integer characteristic of the species. For the electron and for silver atoms, $s = \frac{1}{2}$: a magnetic-gradient analyzer splits an unpolarized beam into exactly *two* components (Section 80.2), never a classical continuum; light transfers angular momentum to matter in units set by $\hbar$ per photon [767].

Derivation. Theorem 94.29: a massive particle species is an irreducible representation (m, s), its polarization space is the $(2s + 1)$-dimensional representation of Lemma 94.28, and any axis may be taken as the 3-axis by Proposition 94.24, so a measurement of the spin projection resolves the $2s+1$ eigenvalues $\hbar\sigma$ of $\hat{J}_3$ (Postulate 77.3). The massless counterpart — helicity $\pm\hbar$ for the photon — is Proposition 94.32 below. The experimental record is analyzed in Chapter 80 and [767]. □

94.7 Massless particles: helicity

Proposition 94.31 (Massless representations)**.** *On the massless positive-energy orbit, the representations realized by observed particles have $\hat{A}$ and $\hat{B}$ (Equation (94.17)) acting as zero. The little group then effectively reduces to the rotations $\mathrm{e}^{-\mathrm{i}\theta\hat{J}^3/\hbar}$ about the momentum axis, whose irreducible unitary representations are one-dimensional,*

$$D_\theta = \mathrm{e}^{-\mathrm{i}h\theta}\,, \qquad \hat{J}^3 = \hbar h\,\mathbb{1}\,, \qquad h \in \tfrac{1}{2}\mathbb{Z}\,, \tag{94.26}$$

and the number h — the helicity *— replaces spin: a massless species carries a single polarization state per momentum.*

Proof. Suppose instead $\hat{A}$ (say) had a nonzero eigenvalue a on some state. Since $\left[\hat{A}, \hat{B}\right] = 0$ Equation (94.18), diagonalize both; conjugating by the rotation $\mathrm{e}^{-\mathrm{i}\theta\hat{J}^3/\hbar}$ rotates the eigenvalue pair (a, b) by the angle θ in the plane (this is Equation (94.18) exponentiated), so the spectrum would contain the *whole circle* of pairs — a continuous infinity of internal states at fixed momentum, Wigner's "continuous spin" representations [849]. No observed massless particle has more than two polarization states, so observation forces $a = b = 0$: $\hat{A} = \hat{B} = 0$

on the physical representation (the same empirical selection as Remark 94.22). What remains of the little group is the one-parameter rotation subgroup; its irreducible unitary representations are one-dimensional because the group is abelian: each D_θ commutes with the whole representation, so by Schur's lemma (Theorem 5.153, with the qualification of Remark 94.1) it is a scalar, every line is then invariant, and irreducibility forces dimension one (cf. the SO(2) analysis of Section 14.2.1). Thus $D_\theta = \mathrm{e}^{-\mathrm{i}h\theta}$ with $\hat{J}^3$ acting as the number $\hbar h$. *Quantization of h:* in the covering group the rotation subgroup about $\boldsymbol{e}_3$ is $V(\theta) = \exp\left(-\mathrm{i}\frac{\theta}{2}\sigma_3\right)$ (Lemma 94.11), which closes only at $\theta = 4\pi$; single-valuedness of D on the cover demands $\mathrm{e}^{-4\pi\mathrm{i}h} = 1$, i.e. $2h \in \mathbb{Z}$. (A rotation by 2π multiplies the state by $\mathrm{e}^{-2\pi\mathrm{i}h} = (-1)^{2h}$, exactly as for massive spin, Corollary 94.14.) □

Proposition 94.32 (Helicity is the projection of angular momentum on the momentum)**.** *On a massless representation with helicity h,*

$$\hat{W}_\mu = \hbar h\, \hat{P}_\mu\,, \qquad \textit{equivalently} \qquad \frac{\hat{\boldsymbol{J}}\cdot\hat{\boldsymbol{P}}}{\left|\hat{\boldsymbol{P}}\right|} = \hbar h\, \mathbb{1}\,, \tag{94.27}$$

and $\hat{W}^2 = 0$.

Proof. Evaluate the components of Equation (94.12) on the standard-momentum states, $p = k = (\kappa, 0, 0, \kappa)$, replacing $\hat{P}$ by its eigenvalue ($k^0 = k^3 = \kappa$):

$$\hat{W}_0 = \tfrac{1}{2}\epsilon_{0\nu\rho3}\hat{J}^{\nu\rho}\kappa = \kappa\,\hat{J}^{12} = \kappa\,\hat{J}^3\,, \qquad \hat{W}_3 = \tfrac{1}{2}\epsilon_{3\nu\rho0}\hat{J}^{\nu\rho}\kappa = -\kappa\,\hat{J}^{12} = -\kappa\,\hat{J}^3\,,$$
$$\hat{W}_1 = -\kappa\left(\hat{J}^{23} + \hat{J}^{02}\right) = -\kappa\,\hat{B}\,, \qquad \hat{W}_2 = \kappa\left(\hat{J}^{13} + \hat{J}^{01}\right) = \kappa\,\hat{A}\,,$$

each line by direct expansion of the ϵ sums with $\epsilon_{0123} = +1$. On the physical representation $\hat{A} = \hat{B} = 0$ and $\hat{J}^3 = \hbar h$ (Proposition 94.31), so $\hat{W}_\mu = \hbar h\,(\kappa, 0, 0, -\kappa)_\mu = \hbar h\, k_\mu$ on these states. Both sides of $\hat{W}_\mu = \hbar h \hat{P}_\mu$ are four-vectors built on the representation (Lemma 94.17), so equality at the standard momentum propagates to the whole orbit by conjugation with $U(L(p))$. Contracting with itself, $\hat{W}^2 = \hbar^2 h^2 \hat{P}^2 = 0$; taking the spatial part at momentum $\boldsymbol{p}$ gives the stated projection formula ($\hat{W}^i$ reduces to $p^0\hat{J}_i$-terms along $\hat{\boldsymbol{p}}$). □

Remark 94.33 (The photon). The photon is massless to spectacular experimental accuracy ($m_\gamma c^2 < 1 \times 10^{-18}$ eV [2427]) and carries helicity $h = \pm 1$: circularly polarized light exerts a measurable torque, $\pm\hbar$ of angular momentum per photon, first detected by Beth with a torsion pendulum of birefringent plates [767]. The two signs are exchanged by spatial reflection, so the parity-symmetric electrodynamics of Part VII bundles $h = +1$ and $h = -1$ into one species, "the photon", with two polarization states — and *only* two: the missing longitudinal state of a massive spin-1 particle is not a small correction but a different orbit of the Poincaré group altogether. That a state $h = 0$ is absent is the group-theoretic seed of gauge invariance, taken up in Part XI. The same counting will reappear for the graviton candidates of Part XIII: helicity ± 2, two polarizations — the two polarizations derived for gravitational waves in Appendix A.1.

94.8 The particle dictionary

Definition 94.34 (Particle)**.** A *particle species* is an irreducible unitary representation of the universal cover $\mathbb{R}^4 \rtimes \mathrm{SL}(2,\mathbb{C})$ of the proper orthochronous Poincaré group, realized on the positive-energy massive or massless orbits, labelled by (m, s) with $m > 0$ and $2s \in \mathbb{Z}_{\geq 0}$, or by $(0, h)$ with $2h \in \mathbb{Z}$.

Every column of the experimental particle tables [2427] is an instance:

species	mc^2	spin/helicity	polarization states
electron	0.510 998 95 MeV [2392]	$s = \frac{1}{2}$	2 (Section 80.2)
proton	938.27 MeV [2427]	$s = \frac{1}{2}$	2 (composite, but still a $(m, \frac{1}{2})$ representation)
photon	0 ($< 1 \times 10^{-18}$ eV [2427])	$h = \pm 1$	2 [767]
Higgs boson	125.2 GeV [2427]	$s = 0$	1

The wave equations of the two preceding chapters are the *field-theoretic realizations* of these representations: the Klein–Gordon equation (Chapter 92) is nothing but the Casimir statement $\hat{P}^2 = m^2c^2$ Equation (94.14) written on wavefunctions, and the Dirac equation (Chapter 93) realizes the $(m, \frac{1}{2})$ representation on a field carrying the parity-paired $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$ representation of the Lorentz group. Wigner's 1939 paper [849] thus stands at the head of everything Part XI builds: quantum field theory is the machinery that makes interactions compatible with this classification, and the Standard Model is a specific, experimentally determined list of which representations Nature uses.

Chapter 95

Experiment: The Positron

On 2 August 1932 a cosmic-ray track crossed Carl Anderson's cloud chamber at Caltech, curved the wrong way for an electron, and passed through a 6 mm lead plate emerging with less momentum than it entered — which fixed its direction of travel, and so its sign. Anderson announced the particle in *Science* within weeks [691] and published the full analysis the following March under the title "The Positive Electron" [713]. It was the first antiparticle ever seen, and it had been predicted: Dirac's equation (Chapter 93) required a particle of the electron's mass and opposite charge [647, 677], and no other theory then in existence asked for one. This chapter records the measurement in full phenomenological detail — apparatus, procedure, numbers with their uncertainties in SI units, and the inferences the numbers do and do not support — using the structured `experiment` environment of this treatise when the content is written.

Two things make the case worth the space. First, the inference chain is short and checkable: a track's curvature in a known field gives $B\rho$ and hence momentum, its ionization density gives a bound on the charge and mass, and the lead plate gives the direction; nothing else is needed to establish that the particle is positive, light, and not a proton. Second, the confirmation was immediate and independent — Blackett and Occhialini, using a counter-triggered chamber, published photographs of electron–positron showers within months [714], identifying pair production as the mechanism [726, 732] — and the sequel has run for ninety years, through annihilation radiation [741], positronium [980], the antiproton [1057] and trapped antihydrogen [2280], to a hospital imaging technique that works by annihilating antimatter [1563].

Experiment: The Positron: all derivations of this chapter are pending.

95.1 Historical context and the prediction under test

95.1.1 Dirac's hole theory as a falsifiable prediction

[Reserved: the negative-energy solutions of the Dirac equation, Dirac's filled sea and his first, wrong identification of a hole with the proton [647]; the retraction and the 1931 prediction of an "anti-electron" of equal mass and opposite charge [677]; what exactly was predicted — mass equal to m_e, charge $+e$, and production in pairs — and therefore what the experiment had to measure to confirm or refute it; the state of the theory as of Chapter 93, and the honest note that Anderson was not looking for Dirac's particle and did not cite him.]

95.1.2 Cosmic rays as the available source

[Reserved: the penetrating radiation established by Hess's balloon ascents [387], the only source of particles above 100 MeV *available in 1932; the Caltech programme of measuring cosmic-ray energies in a magnetic cloud chamber; why the question "are the primaries positive or negative?" motivated the apparatus, and how that question made the positron an unintended discovery; the cosmic-ray physics itself is Chapter 115.]*

95.1.3 What else the track could have been

[Reserved: the exhaustive list of alternatives Anderson had to exclude [713] — a negative electron travelling upwards, excluded by the lead plate; a proton of the observed curvature, excluded by ionization density and by range, since a proton of 0.21 T m *would have stopped within about* 5 mm *while the track ran over* 5 cm*; a light nucleus; a chance coincidence of two unrelated tracks. The subsection should state each alternative with the observable that kills it, because this is the anatomy of an experimental claim.]*

95.2 Apparatus

95.2.1 The cloud chamber

[Reserved: Wilson's expansion chamber, in which a sudden adiabatic expansion supersaturates a vapour and ions left along a charged particle's path seed visible droplets [394]; Anderson's vertical chamber of about 17 cm *diameter and* 3 cm *depth, its gas filling and expansion ratio, and the stereoscopic camera pair [713]; the physical mechanism — ionization energy loss — linking droplet density to charge and velocity, and its treatment in Chapter 86.]*

95.2.2 The magnet

[Reserved: the water-cooled electromagnet producing a field of about 1.5 T *across the chamber, then among the strongest available; its calibration and uniformity, which set the systematic floor on every momentum quoted; the relation $p = qB\rho$ from Chapter 59 and its relativistic validity (Chapter 40), so that a measured sagitta gives a momentum without any assumption about the particle's mass.]*

95.2.3 The lead plate

[Reserved: the 6 mm *lead plate mounted across the middle of the chamber [713] — the single component that turns an ambiguous photograph into a measurement, since a particle loses energy in crossing it and therefore curves more tightly on the far side, which fixes the direction of travel and hence the sign of the charge; the design as the model for every later use of a degrader to break the sign–direction degeneracy.]*

95.3 Procedure

95.3.1 Expansion, triggering and photography

[Reserved: random expansion at fixed intervals in Anderson's setup, with roughly one usable cosmic-ray track in fifty photographs [713]; the counter-controlled trigger introduced by Blackett and Occhialini, in which coincident Geiger counters above and below fire the expansion so that most photographs contain a track [714] — an efficiency gain of well over an order of magnitude and the reason their shower photographs came so quickly; scanning and selection criteria, and the selection bias each introduces.]

95.3.2 Track reconstruction and momentum from curvature

[Reserved: reprojection of the stereoscopic pair, fitting a circle to the droplet trail, and the propagation of the sagitta uncertainty into $B\rho$ and thence into momentum, following the error-analysis conventions of Chapter 2; the dominant systematics — multiple scattering in the chamber gas, turbulence and droplet diffusion, distortion of the optics — and why they matter more for high momenta, where the track is nearly straight.]

95.4 Observations

The quantities below are what the chapter will tabulate, each with its uncertainty, in SI units.

95.4.1 The photograph of 2 August 1932

[Reserved: the single track that carries the claim [713]: $B\rho = 0.21\,\mathrm{T\,m}$ above the plate and $0.075\,\mathrm{T\,m}$ below, corresponding to momenta of $63\,\mathrm{MeV}/c$ and $23\,\mathrm{MeV}/c$; curvature sense opposite to that of an electron in the same field; visible track length over $5\,\mathrm{cm}$ beyond the plate; droplet density indistinguishable from that of a fast electron. The figure itself is to be re-authored as a labelled TikZ diagram of the track geometry, not reproduced as an image.]

Phenomenon 95.1 (The positive electron)**.** Cosmic radiation contains singly charged particles whose tracks curve in a magnetic field in the sense opposite to an electron's, whose droplet density along the path is that of a fast electron rather than that of a proton of the same curvature, and whose range exceeds by an order of magnitude the few millimetres such a proton could traverse. Their charge is therefore $+e$ and their mass is the electron's, not the proton's. The particle is stable in vacuum, and its mass and the magnitude of its charge equal the electron's to within the precision of present comparisons [2427].

Derivation. One relation turns the photograph into a measurement, and it is exact relativistically. A particle of charge q in a uniform field $\boldsymbol{B}$ obeys $\mathrm{d}\boldsymbol{p}/\mathrm{d}t = q\,\boldsymbol{v} \times \boldsymbol{B}$. The force is perpendicular to $\boldsymbol{v}$, so it does no work; the speed is constant, hence so is γ, hence so is the magnitude of $\boldsymbol{p} = \gamma m \boldsymbol{v}$. Motion in the plane normal to $\boldsymbol{B}$ is then uniform circular motion of some radius ρ, for which $|\mathrm{d}\boldsymbol{p}/\mathrm{d}t| = |\boldsymbol{p}|\,v/\rho$, while the right-hand side has magnitude $|q|\,vB$. Equating and cancelling v,

$$|\boldsymbol{p}| = |q|\;B\rho\,. \tag{95.1}$$

Equation (95.1) contains no reference to the mass, so a measured sagitta in a calibrated field yields a momentum whatever the particle turns out to be. Three further inferences follow, and between them they exhaust the alternatives.

First, the *sense* of the curvature gives the sign of q once the direction of travel is known, and the lead plate supplies that: a particle can only lose energy in crossing it, so by Equation (95.1) it must emerge with the smaller $B\rho$, and the side of the plate carrying the tighter curve is the far side. Second, the mass enters the *other* observables: at fixed momentum the velocity is $v/c = |\boldsymbol{p}|\,c/\sqrt{|\boldsymbol{p}|^2 c^2 + m^2 c^4}$, and ionization per unit path rises steeply as v falls. A proton carrying the measured momentum would be slow, would ionize far more densely than the track shows, and would come to rest within a few millimetres of chamber gas; a particle of electronic mass at the same momentum is ultrarelativistic, near minimum ionizing, and crosses the chamber. Third, an ordinary electron travelling upward would reproduce the curvature but not the energy loss across the plate, and is excluded by the same argument that fixed the direction. Charge $+e$ and mass m_e are what remains. □

95.4.2 The tabulated quantities

[Reserved: a booktabs table, set with `captionof` *inside the experiment box, listing for each of the fifteen positive tracks reported in [713]: momentum above and below the plate in* MeV/c*, inferred energy loss in the lead, specific ionization relative to a minimum-ionizing electron, and the resulting upper bound on the mass, quoted by Anderson as under twenty electron masses and tightened by later work to consistency with* m_e *[2427]; the modern reference values of* m_e *and* e *from CODATA [2431].]*

95.4.3 Uncertainties and systematics

[Reserved: the uncertainty budget — field calibration, sagitta measurement, energy loss in lead computed from the stopping-power formula, and the statistical weight of a single event; the reason the claim survived on one photograph, namely that the alternatives of Section 95.1.3 are excluded by qualitative observables that do not depend on the momentum precision; the contrast with modern discovery thresholds (Chapter 113), which this chapter should draw explicitly rather than leave implicit.]

95.5 Interpretation

95.5.1 Identification with Dirac's anti-electron

[Reserved: the inference from charge sign, mass bound and ionization to a positive particle of electronic mass [691, 713]; the identification with the hole of Chapter 93 [677], made by Blackett and Occhialini rather than by Anderson [714]; the methodological point that a confirmed prediction and an unmotivated discovery here coincide, and that the treatise records who claimed what.]

95.5.2 Independent confirmation and pair production

[Reserved: the counter-triggered showers of Blackett and Occhialini, showing positive and negative tracks in equal numbers and emerging from a common origin [714]; the interpretation as materialization of a photon into an electron–positron pair above the threshold $2m_ec^2 = 1.022\,\mathrm{MeV}$ *[726], with the cross section computed by Bethe and Heitler [732]; positrons from artificial radioactivity observed independently by Curie and Joliot [737], which made the particle available in the laboratory without cosmic rays and connects to the* β^+ *decays of Chapter 107.]*

Phenomenon 95.2 (Pair production)**.** A photon of sufficient energy passing through matter disappears, and an electron and a positron appear together at the same point; in showers the positive and negative tracks emerge from a common vertex in equal numbers. The process has a threshold — no pair appears below a photon energy of $2m_ec^2 = 1.022\,\mathrm{MeV}$ [2431] — and it requires the presence of a nucleus: a photon travelling in empty space never converts, however energetic.

Derivation. Both statements are kinematic and need no cross section. A single photon has $p_\gamma \cdot p_\gamma = 0$, whereas any electron–positron pair has $(p_+ + p_-)\cdot(p_+ + p_-) \geq (2m_ec)^2$, the minimum being reached when the two are at relative rest. The total four-momentum is conserved and its square is invariant, so $\gamma \to e^+e^-$ in vacuum would demand $0 \geq (2m_ec)^2$, which is false: a third body must be present to absorb momentum. Take that body to be a nucleus of mass M initially at rest. The invariant squared energy is

$$s = M^2c^4 + 2E_\gamma Mc^2\,,$$

and the lightest final state allowed by charge and lepton-number conservation is the nucleus together with the pair, all at relative rest, so that at threshold $\sqrt{s} = (M + 2m_e)\,c^2$. Expanding and cancelling M^2c^4,

$$2E_\gamma Mc^2 = 4Mm_ec^4 + 4m_e^2c^4 \qquad \Longrightarrow \qquad E_\gamma^{\mathrm{thr}} = 2m_ec^2\left(1 + \frac{m_e}{M}\right). \tag{95.2}$$

For any nucleus m_e/M is below 10^{-4}, so the threshold is $2m_ec^2$ to far better than a cloud chamber can measure; the correction is the recoil the nucleus must take, and it is the same term that vanishes only in the unphysical limit $M \to \infty$. Finally, the equality of the numbers of positive and negative tracks is charge conservation applied to a neutral initial state. □

95.5.3 Annihilation radiation

[Reserved: Klemperer's measurement of the radiation emitted when positrons stop in matter [741] — two photons of 511 keV *emitted back to back, as energy and momentum conservation require for a pair annihilating at rest; the process as the exact inverse of pair production and as the first direct evidence that matter and antimatter destroy each other; the astrophysical counterpart, the* 511 keV *line from the Galactic centre mapped by INTEGRAL [2079]; the cross section belongs to Chapter 100.]*

Phenomenon 95.3 (Annihilation radiation)**.** Positrons brought to rest in matter vanish, and in their place two photons appear, each of energy $m_ec^2 = 511.0\,\mathrm{keV}$ [2431] and travelling in opposite directions. Matter and antimatter are not merely oppositely charged: brought together they are destroyed entirely, their whole rest energy converted into radiation. No single photon is ever observed from such an event.

Derivation. Take the pair at rest, so that the initial four-momentum is $(2m_ec, \mathbf{0})$. If two photons are produced, conservation of momentum makes their three-momenta sum to zero, so $\boldsymbol{k}_2 = -\boldsymbol{k}_1$; both being massless their energies are then equal, and conservation of energy gives $E_1 = E_2 = m_ec^2$, the two emerging back to back. Exactly one photon is impossible in any frame: a single photon has $p\cdot p = 0$ while the initial state has $p\cdot p = (2m_ec)^2 \neq 0$, and no change of frame alters an invariant — the same obstruction, read backwards, that forbids a free photon from converting in Phenomenon 95.2. Three or more photons are kinematically allowed and do occur, at a rate suppressed by a further power of the fine-structure constant; which channel is permitted at all is decided not by kinematics but by the charge-conjugation quantum number of the annihilating state, a selection rule belonging to Chapter 105. □

95.5.4 The muon: the same apparatus, a different particle

[Reserved: the honest sequel, in which Anderson's own chamber produced tracks too penetrating for electrons and too light for protons, announced as a particle of intermediate mass [797] and long mistaken for Yukawa's nuclear-force meson; the muon's actual identity as a heavy lepton (Chapter 115); included here because it shows the same apparatus and the same style of argument yielding one correct identification and one wrong one, and because it disciplines the reading of Section 95.5.1.]

Phenomenon 95.4 (A second charged lepton)**.** The chambers that showed the positron also showed singly charged particles that penetrate far more matter than an electron of the same momentum and ionize far less than a proton of the same momentum: particles of intermediate mass. They are the muons — charge $\pm e$, spin $\frac{1}{2}$, mass $105.658\,\mathrm{MeV}/c^2$, some 207 times the electron's, and mean life about $2.2\,\mu\mathrm{s}$ [2427]. They are not the quantum of the nuclear force, which had been predicted with roughly that mass; they behave in every respect as a heavy copy of the electron, and nothing in this part of the treatise explains why a second copy should exist.

Derivation pending #120

The identification of the penetrating cosmic-ray component as a heavy lepton rather than as the quantum of the nuclear force: its anomalously weak absorption in nuclei against the strong coupling a nuclear-force carrier must have, and the three-body shape of its decay electron spectrum. The muon's own phenomenology is taken up in the cosmic-ray chapter of Part XII.

95.6 Modern repetitions and precision

95.6.1 Positronium

[Reserved: Deutsch's observation of the bound electron–positron system in gases [980]; the two ground states — the singlet decaying to two photons in about 125 ps *and the triplet to three photons in about* 142 ns *[2427] — as a direct test of the annihilation selection rules and of charge-conjugation symmetry (Chapter 105); positronium as a purely leptonic "atom" whose spectrum tests the bound-state theory of Chapter 81 with no nuclear structure at all.]*

95.6.2 The antiproton and antihydrogen

[Reserved: the antiproton produced at the Bevatron and identified by simultaneous momentum and velocity measurement [1057], closing the argument that antimatter is general rather than a peculiarity of the electron; antihydrogen trapped at CERN and its $1S$–$2S$ *transition measured and found consistent with hydrogen [2280], the sharpest laboratory test of CPT available (Chapter 105); the direct observation that antihydrogen falls downwards [2417], a test of the equivalence principle of Chapter 42 on antimatter.]*

95.6.3 Precision comparisons of positron and electron

[Reserved: the Penning-trap comparison of the g factors of the electron and the positron, agreeing to about two parts in 10^{12} *[1798], which is simultaneously the tightest test of CPT for leptons and a measurement of the anomaly discussed in Chapter 112; the charge-to-mass ratio comparisons; how each such null result is quoted as a bound rather than as a confirmation, per the conventions of Chapter 2.]*

Phenomenon 95.5 (Particle and antiparticle properties are equal and opposite)**.** Every comparison so far made between a particle and its antiparticle has found their masses equal, their lifetimes equal, their magnetic moments equal in magnitude and opposite in sign, and their charges equal in magnitude and opposite in sign. For the electron and the positron the agreement of the g factors and of the charge-to-mass ratios is among the sharpest such tests available, and no significant difference has been reported in any of them [2427].

Derivation pending #121

The CPT theorem — that any local, Lorentz-invariant quantum field theory with a Hermitian Hamiltonian and the normal spin–statistics connection is invariant under the combined operation of charge conjugation, parity and time reversal — together with the equalities of mass, lifetime and magnetic moment that follow from it, and the reasons a null result here bounds rather than confirms.

95.6.4 Applied annihilation: positron emission tomography

[Reserved: the imaging technique built directly on Section 95.5.3 — a β^+ emitter administered to a patient, the two $511\,\mathrm{keV}$ photons detected in coincidence, and the line of response reconstructed tomographically, as realized in the first transaxial positron tomographs [1557, 1563]; the back-to-back emission geometry, whose small departure from π from residual momentum sets a floor on spatial resolution; included because it is the plainest available demonstration that a 1932 cosmic-ray track is now routine engineering.]

Chapter 96

The Weyl Equation and Neutrinos

The Dirac equation of Chapter 93 is reducible: for a massless particle its four components split into two independent two-component equations, one for each chirality. That split is Weyl's equation [641], and its history is the cleanest case in the book of a mathematically impeccable theory being rejected on a physical prejudice and then reinstated by experiment. Weyl's equation violates parity manifestly, so for a quarter of a century it was dismissed as unphysical; when parity turned out not to be a symmetry of the weak interaction [1091, 1133] the same equation became, within months, the accepted description of the neutrino [1118, 1121, 1130], and its central prediction — that the neutrino has one definite helicity — was measured directly a year later [1148]. This chapter therefore sits after Chapters 93 and 94, which supply the spinor representations it decomposes, and immediately before the experiment that tests it, Chapter 98; the parity measurements themselves are Chapter 110.

The chapter closes on the one place where the Weyl picture is now known to be incomplete. Neutrino flavour oscillations [1954, 2021] require at least two nonzero neutrino masses, and a massive fermion cannot be described by a single Weyl field: the mass must be either of Dirac type, pairing two Weyl fields, or of Majorana type [796], pairing a Weyl field with itself and violating lepton number. Which of the two Nature chose is still an open experimental question, and the searches that would settle it have so far returned null results [2350, 2414]. The phenomenology of the massive case belongs to Chapter 103 and its evidence to Chapter 114; what is settled here is the massless two-component theory, its chirality structure, and the exact point at which it fails. Standing references are [1912, 2427].

Derivation pending #122

The Weyl Equation and Neutrinos: all derivations of this chapter are pending.

96.1 The two-component equation

96.1.1 Weyl's equation

[Reserved: the massless two-component equation $\mathrm{i}\sigma^{\mu}\partial_{\mu}\psi_{L}=0$ *with* $\sigma^{\mu}=(\mathbb{1},-\boldsymbol{\sigma})$*, written down by Weyl in the first of his papers on the electron and gravitation [641]; its plane-wave solutions and the dispersion* $E=|\boldsymbol{p}|\,c$*; the conserved current* $j^{\mu}=\psi_{L}^{\dagger}\sigma^{\mu}\psi_{L}$ *and its positive-definite density; why the equation is first order yet has only two components, and why no Lorentz-invariant mass term can be built from* ψ_{L} *alone.]*

96.1.2 Two-component spinors and $\mathrm{SL}(2,\mathbb{C})$

[Reserved: the undotted and dotted spinor calculus of van der Waerden [640]; $\mathrm{SL}(2,\mathbb{C})$ *as the double cover of the proper orthochronous Lorentz group and its two inequivalent*

fundamental representations $(\frac{1}{2},0)$ *and* $(0,\frac{1}{2})$*, per the classification of Chapter 94; the invariant antisymmetric* ϵ *tensor raising and lowering spinor indices; how a four-vector is a bispinor,* $p_\mu\sigma^\mu$*, with* $\det(p_\mu\sigma^\mu) = p^2$*.]*

96.1.3 Chirality and helicity

[Reserved: chirality as the eigenvalue of γ^5*, a Lorentz-invariant label attached to the representation; helicity as the projection* $\boldsymbol{\sigma}\cdot\hat{\boldsymbol{p}}$ *of spin on momentum, a Poincaré label in Wigner's classification [849] that is invariant only for a massless particle; the two coincide exactly at* $m = 0$ *and differ at order* m/E *otherwise — the single fact that governs everything else in this chapter and every helicity suppression in Chapter 101; the Weyl equation as the statement that helicity is fixed and the same for all observers.]*

96.1.4 Relation to the Dirac equation

[Reserved: the chiral (Weyl) basis of the Dirac matrices, in which the Dirac equation of [596] becomes two coupled two-component equations with the mass as the only coupling; the decomposition $\psi = \psi_L + \psi_R$ *with* $P_{L,R} = \frac{1}{2}(\mathbb{1} \mp \gamma^5)$*; the massless limit as a decoupling, so that a Dirac field is exactly two Weyl fields when* $m = 0$*; parity as the operation exchanging the two, developed in Chapter 105.]*

96.1.5 Discrete symmetries of a Weyl field

[Reserved: a single Weyl field is not invariant under parity or under charge conjugation separately, but is invariant under their product CP *and, by the theorem of Chapter 109, under* CPT*; the historical objection that this made the equation unphysical, voiced by Pauli and repeated for twenty-five years without ever being put to a test; how the objection was disposed of, not answered, by Chapter 110; the residual* CP *question deferred to Chapter 111.]*

96.2 The neutrino hypothesis

96.2.1 The continuous beta spectrum

[Reserved: Chadwick's magnetic-spectrometer measurement showing that beta rays emerge with a continuous distribution of energies rather than the line spectrum a two-body decay demands [414]; the calorimetric confirmation by Ellis and Wooster, whose measured heat per disintegration of radium E matched the mean and not the endpoint energy [574], closing the escape route that the missing energy was radiated later; the resulting choice between abandoning energy conservation and inventing a new particle.]

Phenomenon 96.1 (The beta spectrum is continuous)**.** The electrons emitted in a given nuclear beta decay do not all carry the same energy. They emerge with a continuous distribution of kinetic energies, running from zero up to a sharp endpoint fixed by the mass difference of the two nuclei [414], and the heat released per disintegration, measured calorimetrically, equals the *mean* of that distribution rather than its endpoint [574, 662] — so the balance is not carried off by radiation emitted later. A decay into two bodies cannot produce such a spectrum.

Derivation. Let a nucleus of mass M decay at rest into exactly two bodies, of masses M' and m. Four-momentum conservation gives $p_M = p_{M'} + p_m$, so $(p_M - p_m)^2 = p_{M'}^2$, that is

$$M^2c^2 - 2\,p_M\cdot p_m + m^2c^2 = M'^2c^2\,.$$

In the parent's rest frame $p_M = (Mc, \mathbf{0})$ and $p_M \cdot p_m = ME$, where E is the light particle's total energy, so

$$E = \frac{\left(M^2 + m^2 - M'^2\right) c^2}{2M} \,. \tag{96.1}$$

This is a single number, fixed entirely by three masses: a two-body decay emits a *line*, and repeating identical decays cannot broaden it beyond the natural width of the levels. If instead a third body leaves with the electron, the recoiling system is no longer a single particle of fixed mass; its invariant mass W may take any value between the sum of the two remaining rest masses and $Mc^2 - mc^2$, and Equation (96.1) with M' replaced by W/c^2 then sweeps out a continuum. The observed spectrum is therefore evidence that a third particle is emitted, and the endpoint — reached when that particle takes away nothing but its rest energy — bounds its mass. What the spectrum alone does not fix is the new particle's spin or its charge; those come from the angular-momentum balance of the decay and from the absence of any observed ionization, and are the content of the hypothesis of Section 96.2.2. □

96.2.2 Pauli's 1930 letter

[Reserved: Pauli's "desperate remedy" — the letter of 4 December 1930 to the Tübingen conference proposing a neutral, spin-$\frac{1}{2}$, weakly interacting constituent of the nucleus with a mass not exceeding that of the electron [665], so that beta decay is a three-body process and the spectrum is continuous; the spin-statistics argument for nitrogen-14 that motivated it as much as the energy balance did; Brown's historical reconstruction of the letter and its reception [1617]; Fermi's renaming of the particle after the discovery of the neutron.]

96.2.3 Fermi's theory of beta decay

[Reserved: Fermi's four-fermion contact interaction [738], built by analogy with the electromagnetic current coupling and giving the first quantitative beta spectrum shape, the Kurie plot and the ft systematics of Chapter 107; the coupling constant G_F, its dimension, and its modern value as tabulated in [2427]; the cross-section estimate that made the neutrino look undetectable, and the extension to the general Lorentz-invariant four-fermion couplings that Section 96.4.3 then reduces to one.]

96.2.4 Detection: Reines and Cowan

[Reserved: the inverse beta reaction $\bar{\nu}_e + p \to n + e^+$ as the detection channel; the 1953 Hanford attempt [1026] and the 1956 Savannah River confirmation with a delayed-coincidence signature of positron annihilation followed by cadmium neutron capture [1085, 1097]; the measured cross-section of order $1 \times 10^{-47}\,\mathrm{m}^2$ per fission antineutrino; Davis's null result for $\bar{\nu}_e + {}^{37}\mathrm{Cl}$ [1062] showing that neutrino and antineutrino are distinct, and lepton number as the bookkeeping [1022].]

96.2.5 How many neutrinos

[Reserved: the two-neutrino experiment at the AGS establishing that $\nu_\mu \neq \nu_e$ [1223]; direct observation of ν_τ interactions by DONUT [2016]; the invisible width of the Z measured at LEP and SLC, giving $N_\nu = 2.9840 \pm 0.0082$ light active species [2104] — the strongest statement that the count is three; flavour mixing itself left to Chapter 103.]

Phenomenon 96.2 (There are three light neutrino species)**.** The neutrinos produced together with the electron, with the muon and with the tau are three distinct particles, and there is no fourth of the same kind. The sharpest statement comes from the Z boson: the

part of its decay width that leaves no trace in any detector, divided by the width the theory assigns to a single neutrino species, gives three to better than one per cent [2427]. The count is a count of species light enough for the Z to decay into and coupling to it in the standard way; it excludes neither heavier neutral leptons nor species that do not couple to the Z at all.

Derivation pending #123

Extraction of the invisible width of the Z from the measured total and visible widths at the resonance peak, and the Standard Model expression for the partial width into one neutrino species, whose ratio is the species count. The measurement requires the electroweak theory of Part XII to convert a width into a number.

96.3 Parity and the reinstatement of the equation

96.3.1 Parity as an assumed symmetry

[Reserved: parity invariance as an inference from atomic and nuclear spectroscopy, where it holds, illegitimately extended to the weak interaction where it had never been tested; Lee and Yang's survey showing that no existing experiment constrained parity in weak processes, together with the concrete experiments that would [1091]; the θ–τ puzzle — two particles alike in mass and lifetime decaying to final states of opposite parity — as the anomaly that forced the question.]

96.3.2 The measurements

[Reserved: the beta asymmetry from polarized ^{60}Co [1133]; the pion–muon–electron chain, in which the muon is produced polarized and decays asymmetrically [1109, 1110]; the longitudinal polarization of beta electrons, measured as v/c with the sign fixed by Mott scattering [1108]; the circular polarization of the gamma rays following beta decay [1131]; full apparatus and uncertainties in Chapter 110.]

96.3.3 Maximal violation

[Reserved: why the observed asymmetries are not merely nonzero but as large as kinematics allows, i.e. the weak current couples to one chirality only; the immediate consequence that the two-component massless equation discarded in Section 96.1.5 is the correct one; the distinction between parity violation as an experimental fact and maximality as a further, separately measured fact, quantified by the Michel parameters of muon decay [965] and their modern values [2170].]

96.4 The two-component theory of the neutrino

96.4.1 Landau, Lee–Yang and Salam

[Reserved: the three independent 1957 papers proposing the massless two-component neutrino — Landau's, framed as the conservation of combined inversion [1118]; Lee and Yang's, which derives the observable consequences for beta decay and pion decay [1121]; and Salam's, which ties the two-component form to the vanishing of the neutrino mass and to γ^5 invariance [1130]; the shared prediction that the neutrino has a single definite helicity, and the sign left open by all three.]

96.4.2 The measured helicity

[Reserved: the Goldhaber–Grodzins–Sunyar measurement of the helicity of the neutrino emitted in K-capture by ^{152m}Eu, which found it negative — the neutrino is left-handed [1148]; the recoil-Doppler resonant-scattering trick and the analysing magnet, given in full in Chapter 98; the mirror statement for the antineutrino inferred from the $\bar{\nu}$ helicity in beta decay, and why no equally direct measurement of it exists.]

96.4.3 The V–A current

[Reserved: the reduction of Fermi's five possible couplings to the single combination $\gamma^{\mu}(\mathbb{1}-\gamma^{5})$ by Feynman and Gell-Mann [1144] and, independently, by Sudarshan and Marshak [1162]; the conserved vector current hypothesis and the universality of G_F; helicity suppression of $\pi^- \to e^-\bar{\nu}_e$ relative to $\pi^- \to \mu^-\bar{\nu}_\mu$ as the sharpest V–A test; the embedding of V–A in the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ theory of Chapter 104.]

Phenomenon 96.3 (Helicity suppression of the electronic pion decay)**.** The charged pion decays overwhelmingly to a muon and only very rarely to an electron, although the electronic channel has by far the larger phase space available to it. The measured ratio is

$$\frac{\Gamma\left(\pi^- \to e^-\bar{\nu}_e\right)}{\Gamma\left(\pi^- \to \mu^-\bar{\nu}_\mu\right)} \approx 1.23 \times 10^{-4} \tag{96.2}$$

[2427]: the kinematically favoured channel is suppressed by four orders of magnitude, which is the opposite of what phase space alone predicts and is the sharpest available test of the chirality of the charged weak current.

Derivation. The pion has spin 0, so in its rest frame the charged lepton and the antineutrino leave back to back with total angular momentum zero and their spin projections on the decay axis must cancel. Because the two travel in opposite directions, cancelling projections means *equal* helicities. The charged weak current couples only to the left-chiral fields; for a massless antineutrino left chirality is helicity $+1$ exactly, so the charged lepton is forced into helicity $+1$ as well. But the current couples to the left-chiral part of the charged lepton too, and for a lepton of mass m_ℓ, energy E and momentum p the amplitude for the left-chiral field to be found with positive helicity, relative to its amplitude for the negative helicity, is

$$\sqrt{\frac{E - pc}{E + pc}} \simeq \frac{m_\ell c^2}{2E}\,,$$

using $E^2 - p^2c^2 = m_\ell^2 c^4$ and $E \gg m_\ell c^2$. The amplitude therefore vanishes linearly in m_ℓ and the rate quadratically, so the electronic channel is suppressed relative to the muonic one by roughly $(m_e/m_\mu)^2 \approx 2.3 \times 10^{-5}$, which the larger electronic phase space then partly offsets. Carrying the phase-space factors through gives the tree-level prediction

$$\frac{\Gamma\left(\pi \to e\nu\right)}{\Gamma\left(\pi \to \mu\nu\right)} = \frac{m_e^2}{m_\mu^2}\left(\frac{m_\pi^2 - m_e^2}{m_\pi^2 - m_\mu^2}\right)^2 \approx 1.28 \times 10^{-4}\,,$$

which differs from Equation (96.2) by a few per cent, the difference being radiative corrections. A parity-conserving interaction, coupling equally to both chiralities, would impose no such constraint and would leave the electronic mode the commoner of the two; the observed ratio therefore measures the chirality structure directly and does not merely permit it. □

96.5 Chirality in the Standard Model

96.5.1 Left-handed doublets, right-handed singlets

[Reserved: the Standard Model as a chiral gauge theory — the left-handed fields form $\mathrm{SU}(2)_L$ *doublets and the right-handed fields are singlets, so that the fermion content is naturally a list of Weyl fields rather than Dirac fields [1912]; the absence of any right-handed neutrino field in the minimal content, which is exactly why the minimal Standard Model predicts massless neutrinos; hypercharge assignments and the resulting electric charges, cross-referenced to Chapter 104.]*

96.5.2 The chiral anomaly

[Reserved: the axial current, conserved classically for massless fermions, is not conserved on quantization — the triangle anomaly of Adler [1388] and of Bell and Jackiw [1391]; the $\pi^0 \to \gamma\gamma$ *rate as its measured consequence [2427]; anomaly cancellation as a nontrivial constraint on the chiral fermion content of each Standard Model generation, and its failure mode if any charge assignment is altered; renormalization context in Chapters 100 and 108.]*

96.5.3 Chiral fermions on a lattice

[Reserved: the Nielsen–Ninomiya theorem, that a local, Hermitian, translation-invariant lattice action with the correct continuum limit necessarily doubles chiral fermions into pairs of opposite chirality [1673]; the homotopy argument behind it; why this is a genuine obstruction to simulating the weak interaction rather than a technical nuisance, in contrast with the vector-like case of Chapter 102; the same doubling reappearing as a theorem about band structures in Section 96.8.]

96.6 Mass, and where the massless picture fails

96.6.1 Dirac and Majorana mass terms

[Reserved: the two Lorentz-invariant bilinears that can give a Weyl field a mass — the Dirac term $m\bar{\psi}_L\psi_R$*, which requires a second, independent Weyl field and conserves lepton number, and the Majorana term* $\frac{1}{2}m\,\overline{\psi_L^c}\,\psi_L$*, which does not [796]; the general mass matrix mixing both; the statement that a massive neutrino cannot be a single Weyl particle, and that helicity therefore ceases to be Lorentz-invariant.]*

96.6.2 Oscillations as the evidence for mass

[Reserved: flavour oscillation, proposed by Pontecorvo [1127] and given its mixing-matrix form by Maki, Nakagawa and Sakata [1237]; the atmospheric ν_μ *deficit of Super-Kamiokande [1954] and the neutral-current measurement by SNO showing the solar* ν_e *flux is transformed and not lost [2021]; the measured splittings* $\Delta m^2_{21} \approx 7.5\times10^{-5}\,\mathrm{eV}^2$ *and* $|\Delta m^2_{31}| \approx 2.5\times10^{-3}\,\mathrm{eV}^2$ *[2427]; full treatment in Chapters 103 and 114.]*

Phenomenon 96.4 (Neutrinos change flavour, and therefore have mass)**.** A source of neutrinos of one flavour, allowed to propagate, delivers the other flavours as well. The atmospheric muon-neutrino flux is depleted by an amount depending on the path length through the Earth, and the solar electron-neutrino flux is not lost but converted, the total over all three flavours agreeing with what the Sun is calculated to produce. Fitting the dependence on distance and energy yields two independent mass-squared differences,

$$\Delta m^2_{21} \approx 7.5\times10^{-5}\,\mathrm{eV}^2/c^4\,, \qquad \left|\Delta m^2_{31}\right| \approx 2.5\times10^{-3}\,\mathrm{eV}^2/c^4\,, \tag{96.3}$$

both nonzero [2427]. At least two of the three neutrinos are therefore massive, and the massless two-component description of this chapter cannot be the whole of the story.

Derivation. Suppose the states of definite flavour are superpositions of states of definite mass; take two for simplicity, $|\nu_\alpha\rangle = \cos\theta\,|\nu_1\rangle + \sin\theta\,|\nu_2\rangle$ and $|\nu_\beta\rangle = -\sin\theta\,|\nu_1\rangle + \cos\theta\,|\nu_2\rangle$. A state of definite mass and momentum p propagates with the phase $\mathrm{e}^{-\mathrm{i}E_i t/\hbar}$, and the mass-shell relation expanded for $m_i c^2 \ll E$ gives $E_i \simeq pc + m_i^2 c^3/2p$. The common term pc contributes an overall phase and drops out; over a flight of length $L \simeq ct$ the relative phase is

$$\Delta\phi = \frac{(E_2 - E_1)\,t}{\hbar} \simeq \frac{\Delta m^2 c^4 L}{2\hbar c E}\,, \qquad \Delta m^2 := m_2^2 - m_1^2\,.$$

Projecting the propagated state back onto $|\nu_\beta\rangle$,

$$P\left(\nu_\alpha \to \nu_\beta\right) = \sin^2 2\theta\,\sin^2\left(\frac{\Delta m^2 c^4 L}{4\hbar c E}\right). \tag{96.4}$$

The probability oscillates in L/E with an amplitude set by the mixing angle and a period set by Δm^2, and it is identically zero when $\Delta m^2 = 0$, whatever the mixing. An observed oscillation is therefore a proof that the mass eigenvalues differ, and hence that at least one of them is nonzero. Two things follow that the chapter must not overstate. Equation (96.4) is insensitive to the common scale of the masses, which is why Equation (96.3) reports differences only; and it is insensitive to the sign of Δm^2 in vacuum, which is why the ordering of the states is fixed only by measurements involving matter. □

96.6.3 Absolute mass bounds

[Reserved: oscillations fix differences of squared masses and not the scale, so the scale needs independent measurements; the KATRIN tritium endpoint bound $m_\nu < 0.8\,\mathrm{eV}/c^2$ at 90 per cent confidence [2399]; the cosmological bound on $\sum m_\nu$ of order $0.12\,\mathrm{eV}/c^2$ from the CMB and large-scale structure [2348], with its model dependence stated honestly; the resulting hierarchy question, still open.]

Phenomenon 96.5 (The neutrino mass scale is very small)**.** Oscillations fix mass *differences*; the scale itself has never been measured, only bounded. The endpoint region of the tritium beta spectrum constrains the effective electron-neutrino mass to below about $1\,\mathrm{eV}/c^2$ [2427], and the imprint of free-streaming neutrinos on the cosmic microwave background and on the growth of large-scale structure constrains the sum of the three masses to of order $0.1\,\mathrm{eV}/c^2$ [2348] — the latter only within an assumed cosmological model, and so not a laboratory measurement. Either bound places the neutrino masses at least five orders of magnitude below the electron's, a gap that nothing in this part explains.

Derivation pending #124

The shape of the beta spectrum near its endpoint as a function of the neutrino mass, and the reason the observable is the incoherent sum of squared mixing amplitudes times squared masses rather than any single mass; and, separately, the free-streaming suppression of the matter power spectrum by massive neutrinos, whose derivation belongs to the cosmology part and whose model dependence must be stated with the bound.

96.6.4 Where the mass could come from

[Reserved: the dimension-five lepton-number-violating operator that generates a Majorana mass in the effective theory below any new scale [1646], and the fact that it is a parametrization of ignorance rather than a mechanism; the seesaw realization with heavy right-handed singlets [1605], named here with the honest statement that no direct evidence for it exists; the alternative that neutrinos are Dirac particles with very small Yukawa couplings, equally unconstrained; open-problem status in Chapter 133.]

96.7 The Majorana question

96.7.1 Majorana's symmetric theory

[Reserved: Majorana's real representation of the Dirac matrices and the self-conjugate field $\psi = \psi^c$ [796]; the degrees-of-freedom count — two, not four — and the equivalence of a Majorana field to one Weyl field with a mass; Racah's observation that the neutrino–antineutrino identity is testable in nuclear processes [799]; why no charged fermion can be Majorana, and why the neutrino is the only Standard Model candidate.]

96.7.2 Neutrinoless double beta decay

[Reserved: Furry's calculation of the lepton-number-violating transition $(A, Z) \to (A, Z + 2) + 2e^-$ [836]; the sharp two-electron sum-energy peak at the Q value distinguishing it from the allowed two-neutrino mode; the effective mass $m_{\beta\beta} = \left|\sum U_{ei}^2 m_i\right|$ and the nuclear matrix element as the dominant systematic; the Schechter–Valle argument that observing the decay implies a Majorana mass whatever the mechanism [1701].]

96.7.3 Null results and present status

[Reserved: the background-free ^{76}Ge result of GERDA and its half-life limit [2350]; the ^{136}Xe limit from KamLAND-Zen, $T^{0\nu}_{1/2} > 2 \times 10^{26}$ yr, entering the inverted-ordering band [2414]; the honest verdict — the Dirac versus Majorana question is open, the searches so far are null, and no result in this book depends on the answer; what a positive result would change, and what a continued null result can and cannot exclude.]

Phenomenon 96.6 (Neutrinoless double beta decay has not been seen)**.** Several nuclei that cannot decay by single beta emission do decay by emitting two electrons and two antineutrinos at once; this second-order weak process is observed, and the summed energy of its two electrons is continuous, as Phenomenon 96.1 requires of a decay with unobserved particles in the final state. The lepton-number-violating variant, in which only the two electrons are emitted and their summed energy is a sharp line at the full decay energy, has not been observed in any isotope; the best half-life limits exceed 10^{26} years [2427]. Whether the neutrino is its own antiparticle is therefore an open experimental question, and this treatise records it as one.

Derivation pending #125

The two-neutrino and neutrinoless double beta decay rates: the phase-space and nuclear-matrix-element factorization, the effective Majorana mass that the neutrinoless rate measures, and the argument that observing the decay implies a Majorana mass term whatever mechanism drives it. The nuclear matrix elements are the dominant systematic and must be presented as such.

96.8 Weyl fermions as an observed phenomenon

[Reserved: no elementary Weyl fermion is known, since every observed neutrino has mass; but the equation itself is realized as the low-energy excitation spectrum around isolated band-touching points in crystals without inversion symmetry — the Weyl semimetals, observed in TaAs by angle-resolved photoemission through their Fermi arcs [2257, 2262]; the arcs as the surface signature required by the doubling theorem [1673]; the chiral anomaly measured as negative longitudinal magnetoresistance; band-structure background in Chapter 126.]

Chapter 97

Higher-Spin Wave Equations

Wigner's classification [849] assigns a mass and a spin to every unitary irreducible representation of the Poincaré group, and Chapter 94 shows that the list is unbounded in spin. A relativistic wave equation is the covariant field-theoretic carrier of one entry in that list, and the covariant carrier is always larger than the entry: a symmetric tensor or tensor–spinor has far more components than the representation has states, so every higher-spin equation is a field equation plus a set of constraints that remove the surplus. This chapter follows that pattern up the spin ladder — Proca's spin-1 equation [785], the Rarita–Schwinger spin-$\frac{3}{2}$ equation [862], the Fierz–Pauli spin-2 equation [834], and the general constructions of Singh and Hagen [1534] and Fronsdal [1620, 1622] — and it follows the pathologies with equal care, because the constraints are what break first when the field is coupled to anything [1211, 1408, 1409]. It therefore sits after Chapters 92 and 93, which are the spin-0 and spin-$\frac{1}{2}$ members of the same family, and after Chapter 96, which decomposed the spin-$\frac{1}{2}$ case.

The honest experimental summary is short and is the reason the chapter ends where it does. Elementary massive spin-1 particles exist and are measured to high precision — the W and Z bosons discovered at the CERN $\mathrm{p\bar{p}}$ collider [1710, 1711, 1713, 1714], with the Proca mass supplied by the mechanism of Chapter 104. A massless spin-2 field is required by the observed gravitational radiation of Part V, treated in Chapter 46 and measured in Chapter 47, and its interacting completion is general relativity itself. Spin $\frac{3}{2}$ is realized only as a composite hadronic resonance, the $\Delta(1232)$ [994, 2427]. No elementary particle of spin greater than 2 has ever been observed, and Section 97.6 collects the theorems — Weinberg's soft theorems [1299], Weinberg–Witten [1661] and Coleman–Mandula [1343] — which say why that absence is expected rather than accidental. Speculative higher-spin programmes are named in Section 97.7.2 only to record that they have no evidential support, per the scope rule stated in the front matter.

Derivation pending #126

Higher-Spin Wave Equations: all derivations of this chapter are pending.

97.1 The classification problem

97.1.1 From representations to field equations

[Reserved: Wigner's little-group construction and the mass–spin labelling of unitary irreducible representations [849]; the Bargmann–Wigner equations, which build the spin-s representation as a totally symmetric product of $2s$ Dirac indices, each satisfying the Dirac equation [908]; why a massless representation has two helicity states rather than $2s+1$; the counting that every later section must reproduce, with the group theory in Chapter 14.]

97.1.2 What a wave equation must deliver

[Reserved: the four requirements — the correct on-shell degree of freedom count, a mass-shell condition $(\Box + m^2)\phi = 0$ on every component, positive-definite energy, and hyperbolic propagation inside the light cone; auxiliary conditions $\partial^\mu \phi_{\mu\nu\ldots} = 0$ and tracelessness as the mechanism that removes lower-spin content; the pattern, common to [785, 834, 862], that the constraints follow from the field equations only in the free theory — the observation Section 97.3.2 then turns into a no-go.]

97.2 Spin 1: the Proca field

97.2.1 The Proca equation

[Reserved: the Lagrangian $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}m^2 A_\mu A^\mu$ and the field equation $\partial_\mu F^{\mu\nu} + m^2 A^\nu = 0$ written down by Proca [785]; the divergence of the field equation giving the Lorenz condition $\partial_\mu A^\mu = 0$ as a consequence rather than a gauge choice, so that a Proca field carries three states; the propagator and its $k^\mu k^\nu / m^2$ term; the $m \to 0$ discontinuity in the state count against Maxwell theory (Chapter 60), the spin-1 ancestor of Section 97.4.2.]

97.2.2 The Duffin–Kemmer form

[Reserved: the first-order matrix formulation with β-matrices satisfying $\beta^\mu\beta^\nu\beta^\lambda + \beta^\lambda\beta^\nu\beta^\mu = \eta^{\mu\nu}\beta^\lambda + \eta^{\lambda\nu}\beta^\mu$, due to Duffin [814] and Kemmer [841]; its five-dimensional and ten-dimensional representations describing spin 0 and spin 1 in a single Dirac-like formalism; what is gained (Dirac-style manipulations, a clean current) and what is not (the algebra has no inverse element, so the analogy is incomplete).]

97.2.3 Stueckelberg's restoration of gauge invariance

[Reserved: the introduction of a compensating scalar $A_\mu \to A_\mu + m^{-1}\partial_\mu \varphi$ that makes the massive vector theory gauge invariant [821]; the consequences — a smooth massless limit, power counting improved to renormalizable, and the longitudinal mode exhibited as the would-be Goldstone boson; the relation to the Higgs mechanism [1275, 1283] taken up in Chapter 104; why this trick works for spin 1 and has no unproblematic analogue at spin 2.]

97.2.4 Massive vectors in Nature

[Reserved: the $W^\pm$ and Z^0 bosons as the observed elementary Proca fields — discovery in $\mathrm{p\bar{p}}$ collisions by UA1 [1710, 1711] and UA2 [1713, 1714], with the missing-energy and dilepton-mass signatures; the present masses $m_W = 80.37\,\mathrm{GeV}/c^2$ and $m_Z = 91.19\,\mathrm{GeV}/c^2$ [2427]; the photon as the massless limit, with the experimental bound on its mass; the ρ meson as a composite spin-1 state, not a fundamental Proca field.]

97.3 Spin 3/2: the Rarita–Schwinger field

97.3.1 The equation and its constraints

[Reserved: the vector–spinor ψ_μ and the field equation $(\mathrm{i}\gamma^\nu\partial_\nu - m)\psi_\mu = 0$ supplemented by $\gamma^\mu\psi_\mu = 0$ and $\partial^\mu\psi_\mu = 0$, formulated by Rarita and Schwinger [862]; the covariant Lagrangian with its $\gamma^{\mu\nu\rho}$ kinetic operator; the counting from sixteen components to four physical states; the massless limit and its gauge invariance $\psi_\mu \to \psi_\mu + \partial_\mu \epsilon$, stated here as a property of the free wave equation only.]

97.3.2 The Velo–Zwanziger causality problem

[Reserved: coupling ψ_μ minimally to an external electromagnetic field spoils the constraint algebra — the characteristic surfaces of the resulting system lie outside the light cone, so wave fronts propagate superluminally [1408, 1409]; the earlier indefinite-anticommutator inconsistency found by Johnson and Sudarshan [1211]; the general lesson that the constraints of a higher-spin equation are fragile under interaction, and the survey of which couplings evade the problem and at what cost.]

97.3.3 The $\Delta(1232)$ resonance

[Reserved: the first pion–nucleon resonance, found as a peak in the $\pi^+\mathrm{p}$ total cross-section by Anderson, Fermi, Long and Nagle [994]; its quantum numbers $J^P = \frac{3}{2}^+$, $I = \frac{3}{2}$, mass near $1232\,\mathrm{MeV}/c^2$ and width near $117\,\mathrm{MeV}$ [2427]; the point of principle that this is a composite three-quark state described by Chapter 102, so it is evidence for spin $\frac{3}{2}$ existing in Nature but not for an elementary Rarita–Schwinger field; higher-spin baryon and meson recurrences organized on Regge trajectories [1174, 1200].]

97.4 Spin 2: the Fierz–Pauli field

97.4.1 The Fierz–Pauli Lagrangian

[Reserved: the symmetric tensor $h_{\mu\nu}$ and the unique quadratic Lagrangian free of ghosts, with the relative coefficient of h^2 and $h_{\mu\nu}h^{\mu\nu}$ in the mass term fixed to -1 [834]; the constraints $\partial^\mu h_{\mu\nu} = 0$ and $h^\mu{}_\mu = 0$ reducing ten components to five; the massless case with its linearized diffeomorphism invariance $h_{\mu\nu} \to h_{\mu\nu} + \partial_{(\mu}\xi_{\nu)}$ and two helicity states, which is the linearized Einstein equation of Chapter 44.]

97.4.2 The vDVZ discontinuity

[Reserved: the massless limit of Fierz–Pauli theory does not reproduce linearized general relativity — the extra helicity-0 mode survives and couples to the trace of the source, changing the light-bending prediction relative to the Newtonian potential by a factor $\frac{3}{4}$, discovered independently by van Dam and Veltman [1419] and by Zakharov [1439]; why this is a discontinuity in the propagator and not in the spectrum alone; the measured light deflection of Chapter 42 as the datum it contradicts.]

97.4.3 The Boulware–Deser ghost and the Vainshtein radius

[Reserved: Vainshtein's observation that the linear analysis breaks down inside a radius r_V around a source, so the discontinuity may be an artefact of perturbation theory [1487]; Boulware and Deser's counter-result that generic nonlinear completions propagate a sixth, ghost-like mode [1468]; the ghost-free tuning of de Rham, Gabadadze and Tolley [2181] and the review of the subject [2194], named with the honest statement that no observation requires a graviton mass.]

97.4.4 The massless graviton and its evidence

[Reserved: the theorem that a self-coupled massless spin-2 field is general relativity — Gupta's iterative construction [1042] and Deser's one-step derivation from the first-order form [1420]; the evidence, which is the quadrupole energy loss of the binary pulsar [1550, 1703, 2275] and the two transverse-traceless polarizations of the detected waves [2264, 2278]; the graviton mass bound of order $1 \times 10^{-23}\,\mathrm{eV}/c^2$ from the arrival-time comparison of GW170817 with

its electromagnetic counterpart [2278]; full treatment in Part V, quantization status in Chapter 135.]

97.5 General spin

97.5.1 Massive fields of arbitrary spin

[Reserved: the Singh–Hagen Lagrangians, which achieve a consistent massive spin-s description only at the price of a tower of auxiliary traceless fields of ranks $s-2, s-3, \dots, 0$ [1534]; the pattern that the number of auxiliary fields grows with spin; the Fierz–Pauli conditions $\partial^{\mu}\phi_{\mu\dots} = 0$, $\phi^{\mu}{}_{\mu\dots} = 0$ as the general statement; why no such Lagrangian has ever been needed to describe an observed elementary particle.]

97.5.2 Massless fields of arbitrary spin

[Reserved: Fronsdal's gauge-invariant equations for massless integer spin, with doubly-traceless fields and traceless gauge parameters [1622], and the half-integer case of Fang and Fronsdal [1620]; the two helicity states $\pm s$ that survive; the massless limit of the massive theory as a decomposition into helicities, in contrast with the discontinuity of Section 97.4.2; the free theory as the last point at which higher spin is uncontroversial.]

97.5.3 Coupling obstructions

[Reserved: the systematic obstructions to interacting higher-spin fields — loss of the constraint algebra [1408, 1409], non-positive commutators [1211], and the failure of gauge invariance to survive minimal coupling to gravity; the contrast with spins $0, \tfrac{1}{2}, 1, \tfrac{3}{2}, 2$, each of which has a consistent interacting realization; the statement of the problem in the form the no-go theorems of Section 97.6 then answer.]

97.6 No-go theorems

97.6.1 Soft theorems and Weinberg's low-energy argument

[Reserved: Weinberg's covariant Feynman rules for any spin [1298]; the soft-emission analysis showing that Lorentz invariance of the S matrix forces a massless spin-1 particle to couple to a conserved charge and a massless spin-2 particle to couple universally with a single constant — the equivalence principle derived rather than assumed [1299]; the extension to infrared photons and gravitons [1322]; the conclusion that a massless particle of spin ≥ 3 cannot couple to any conserved quantity that survives at low energy.]

97.6.2 Weinberg–Witten

[Reserved: the theorem that a theory with a Lorentz-covariant, conserved current forbids massless particles of helicity $|h| > \tfrac{1}{2}$ carrying that charge, and that a Lorentz-covariant, conserved stress tensor forbids massless particles of helicity $|h| > 1$ [1661]; the precise reading of the hypotheses, without which the theorem appears to exclude the graviton and the gluon — neither has a gauge-invariant covariant current or stress tensor of the required kind; what the theorem does and does not exclude, stated carefully.]

97.6.3 Coleman–Mandula

[Reserved: the theorem that under an S-matrix with a mass gap, analyticity and a finite number of particle types below any mass, the largest symmetry Lie algebra is the direct

product of the Poincaré algebra with internal symmetries [1343]; the corollary that conserved charges carrying more than one spacetime index would force the scattering amplitude to be trivial; the standard graded-algebra escape route, named here only to record that it lies outside the scope of this book.]

97.7 Experimental status

97.7.1 The observed spectrum

[Reserved: the complete list of elementary particles and their spins as measured — spin 0 (the Higgs boson, see Chapter 113), spin $\frac{1}{2}$ (quarks and leptons), spin 1 (photon, gluons, W, Z), and spin 2 inferred for the graviton from the polarization content of gravitational waves [2264, 2278]; the tabulated composite states of higher spin [2427], all hadronic, all with Regge-organized recurrences [1174, 1200]; how a spin assignment is actually measured, from angular distributions and decay correlations.]

97.7.2 Programmes without evidence

[Reserved: an honest closing statement — no elementary particle of spin $\frac{3}{2}$ or of spin greater than 2 has been observed, and searches place limits but no signal [2427]; the theoretical programmes that postulate them, including graded extensions of the Poincaré algebra and infinite higher-spin towers, are named here solely to record that they have no observational support and are therefore outside the scope of this treatise; the open questions that remain within scope are collected in Chapters 133 and 135.]

Chapter 98

Experiment: Neutrino Helicity

The two-component theory of Chapter 96 predicts that the neutrino is produced in a single helicity state, and the three papers that proposed it [1118, 1121, 1130] left the sign open. Goldhaber, Grodzins and Sunyar measured that sign in 1958 [1148], in what remains one of the most economical experiments in physics: the neutrino is never detected at all. Its helicity is read off the circular polarization of a gamma ray emitted by the recoiling nucleus, using a kinematic accident of the ^{152m}Eu decay scheme that makes only those photons emitted antiparallel to the neutrino Doppler-shifted enough to scatter resonantly. Angular-momentum conservation in the K-capture then transfers the neutrino's helicity to the photon, and a magnetized-iron analyser measures the photon's circular polarization by transmission. The answer — negative helicity, a left-handed neutrino — fixed the sign in the V–A current within weeks [1144, 1162].

The chapter is an experiment chapter and, when written, will use the structured `experiment` environment with its `ExpApparatus`, `ExpProcedure`, `ExpObservations`, `ExpInterpretation` and `ExpReferences` fields, all quantities in SI with uncertainties. It sits immediately after the theory chapter it tests and is the companion of Chapter 110, which reports the parity-violation measurements that made the two-component theory admissible in the first place; the nuclear-structure background it relies on is Chapter 107.

Derivation pending #127

Experiment: Neutrino Helicity: all derivations of this chapter are pending.

98.1 Historical context and the prediction under test

98.1.1 From parity violation to the two-component neutrino

[Reserved: the sequence Lee–Yang [1091], the ^{60}Co asymmetry [1133] and the muon-decay asymmetry [1109, 1110], which together made parity violation a fact; the immediate revival of Weyl's equation [1118, 1121, 1130]; the prediction to be tested — that the neutrino has definite helicity ± 1, with the sign undetermined by theory — and the corresponding statement for the antineutrino; cross-reference to Chapters 96 and 110.]

98.1.2 Why direct neutrino polarimetry is impossible

[Reserved: the neutrino interaction cross-section, of order $1 \times 10^{-47}\,\mathrm{m}^2$ at MeV energies [1085], forbidding any analyser placed in the neutrino's path; the consequent strategy of inferring the helicity from a particle that is *detectable, by angular-momentum bookkeeping in a decay where the kinematics selects a single emission direction; the earlier neutrino-recoil*

experiments that proved the technique — Rodeback and Allen's measurement of the ^{37}Ar *recoil following K-capture [1009].]*

98.1.3 The chosen decay scheme

[Reserved: why ^{152m}Eu *is the unique practical choice — a* $J = 0$ *parent of half-life about* 9.3 h *capturing a K electron to a* $J = 1$ *excited state of* ^{152}Sm *that decays by a* 961 keV *gamma to a* $J = 0$ *ground state, so the whole chain is* $0 \to 1 \to 0$ *and the photon must carry the full unit of angular momentum; the two-body kinematics fixing the nuclear recoil momentum from a monoenergetic neutrino; the resulting Doppler shift, of a few electronvolts, comparable to the recoil energy loss on emission.]*

Phenomenon 98.1 (Nuclear resonance fluorescence is recoil-forbidden, and here recoil–compensated)**.** A gamma ray emitted by a free nucleus is not in general resonantly absorbed by a second nucleus of the same species: emission and absorption each cost a recoil energy, and the resulting mismatch is far larger than the width of the nuclear level, so the resonance is lost. In the decay chain used here it is restored — but only for photons emitted into the hemisphere towards which the emitting nucleus is already moving, having recoiled against the neutrino, that is, only for photons emitted antiparallel to the neutrino. Resonant scattering therefore selects a direction of emission, and the selection is what is observed: photons that have not been Doppler-compensated do not scatter resonantly at all [1148].

Derivation. Let the excited nucleus have mass M and level energy E_0. If it is at rest when it emits, energy and momentum conservation give the photon $E_\gamma = E_0 - E_\mathrm{R}$ with recoil energy $E_\mathrm{R} = E_0^2/2Mc^2$; to excite a second nucleus, itself initially at rest, a photon must instead supply $E_0 + E_\mathrm{R}$. The emitted photon is thus short of the absorption energy by

$$2E_\mathrm{R} = \frac{E_0^2}{Mc^2}\,, \tag{98.1}$$

and resonance fails whenever this exceeds the width of the level. For a transition of about 1 MeV in a nucleus of mass number 152, Equation (98.1) is a few electronvolts, orders of magnitude larger than a nuclear level width, so free-nucleus resonance fluorescence simply does not occur.

Now let the emitting nucleus be moving, with speed $v \ll c$, because it recoiled against a neutrino of energy E_ν, so that $v = E_\nu/Mc$. A photon emitted into the direction of that motion is Doppler-shifted upward by

$$\Delta E = \frac{v}{c}E_\gamma = \frac{E_\nu E_\gamma}{Mc^2}\,,$$

and comparison with Equation (98.1) shows the shortfall is made good when $E_\nu \gtrsim E_\gamma$. That is the kinematic accident on which the whole experiment rests: in this decay the neutrino and the photon carry nearly the same energy, and M cancels between the two expressions, so the compensation is a comparison of E_ν with E_γ and of nothing else. A photon emitted at any other angle receives a smaller shift, and one emitted backwards is shifted the wrong way, so only those emitted antiparallel to the neutrino can scatter resonantly. Selecting the resonantly scattered photons therefore selects that direction, with no angular measurement made anywhere in the apparatus. The selection is not perfect: the excited state has a finite lifetime, during which the recoiling nucleus may be deflected in the source, and this dilutes the correlation — it cannot reverse it, since the resonance condition still admits only the forward hemisphere. □

98.2 Apparatus

98.2.1 The source

[Reserved: the ^{152m}Eu source, produced by neutron activation of europium and used within a few half-lives; source strength, geometry and self-absorption; the source mounted at the top of the analysing magnet so that the photons of interest traverse the magnetized iron; the practical constraint that the short half-life imposes on counting time, and hence on the achievable statistical uncertainty.]

98.2.2 The analysing magnet

[Reserved: the magnetized iron block as a circular-polarization analyser — Compton scattering of circularly polarized photons on the aligned electron spins of the iron has a transmission that depends on the relative sign of photon helicity and electron polarization; the magnitude of the effect, a few per cent, and why the measurement is therefore a difference of two large counting rates; the solenoid and its field reversal; the same polarimetric method used for beta-decay gamma rays by Schopper [1131].]

98.2.3 Resonant scatterer and detector

[Reserved: the ring of ^{152}Sm (as $\mathrm{Sm_2O_3}$) placed to scatter transmitted photons into the detector; nuclear resonance fluorescence as the selector, possible only for photons whose Doppler shift compensates the recoil loss, i.e. only for photons emitted opposite to the neutrino; the sodium-iodide scintillation counter and its shielding; the remark that this is recoil-compensated resonance and not the recoil-free absorption that Mössbauer reported the same year [1154].]

98.3 Procedure

98.3.1 Selecting the recoil-aligned photons

[Reserved: the argument, to be given step by step, that resonant scattering selects photons emitted antiparallel to the neutrino; the angular-momentum balance $J_\gamma = -J_\nu$ along that axis for a $0 \to 1 \to 0$ chain, so that the photon helicity equals the neutrino helicity; the finite lifetime of the intermediate state and the resulting partial loss of the recoil direction, which dilutes but does not reverse the correlation; quantitative estimate of that dilution.]

98.3.2 Field reversal and counting

[Reserved: alternating the magnet polarity at fixed geometry so that all geometric efficiencies cancel in the ratio; the counting asymmetry $\delta = (N_+ - N_-)/(N_+ + N_-)$ as the measured quantity; run lengths set by the source half-life; background subtraction using a non-resonant scatterer of the same electron density; the calibration of the analysing power with gamma rays of known circular polarization.]

98.4 Observations

98.4.1 The counting asymmetry

[Reserved: the measured asymmetry, of order one per cent, with its statistical uncertainty; conversion to the circular polarization of the resonantly scattered photons, found to be negative and of magnitude about two thirds of the kinematic maximum, quoted with an

absolute uncertainty of roughly ten per cent [1148]; the resulting neutrino helicity, consistent with -1 and excluding $+1$ by a wide margin; all quantities to be tabulated with SI uncertainties in a booktabs table carried by `captionof` *inside the experiment box, since a float cannot live there.]*

98.4.2 Systematic checks

[Reserved: the checks performed — resonance verified by comparing scatterers, the polarization sign calibrated against a source of known handedness, magnet-reversal cycling against drift, and the insensitivity of the result to detector threshold; the dominant systematic, which is the analysing power of the magnetized iron; the honest statement of what the total uncertainty was and why the result was nonetheless decisive — the two hypotheses differ in sign, not in magnitude.]

98.5 Interpretation

98.5.1 The neutrino is left-handed

[Reserved: the conclusion that the neutrino emitted in K-capture has negative helicity [1148], fixing the sign left open by [1118, 1121, 1130]; the mirror statement for the antineutrino, inferred from beta-decay electron polarization [1108] together with CPT; the caveat, made explicit, that a helicity eigenstate is Lorentz-invariant only for a massless particle, so the result is a statement about the chirality of the current at the energies used.]

Phenomenon 98.2 (The neutrino is left-handed)**.** The neutrino emitted in the K-capture of ^{152m}Eu has negative helicity: its spin points opposite to its momentum. The measurement is wholly indirect — no neutrino is detected — and reads the helicity off the circular polarization of the 961 keV gamma ray emitted by the recoiling ^{152}Sm nucleus, which is found to be left circularly polarized [1148]. The magnitude is consistent with the maximal value -1 and the opposite sign is excluded by a wide margin, so the neutrino is produced in a single helicity state, as a two-component theory requires and as no parity-conserving theory permits.

Derivation. The inference is angular-momentum bookkeeping along a single axis, and it assumes no dynamics at all. Take the axis along the neutrino's momentum, call that direction $+z$, and use the decay scheme of Section 98.1.3: a $J = 0$ parent captures a K electron of spin projection $m_e = \pm\frac{1}{2}$ and emits a neutrino of helicity $h_\nu = \pm 1$, leaving a $J = 1$ nucleus of projection m_N recoiling along $-z$. Conservation of J_z gives

$$m_e = \tfrac{1}{2} h_\nu + m_N \,. \tag{98.2}$$

That nucleus then decays to a $J = 0$ ground state, so the photon must carry away the whole of m_N; and Phenomenon 98.1 says that the photons reaching the detector are those emitted along $-z$. A photon travelling along $-z$ with angular-momentum projection m_γ on $+z$ has helicity $h_\gamma = -m_\gamma$, and a real photon has no projection zero along its own direction of motion, so $m_\gamma = m_N = \pm 1$. With $m_e = \pm\frac{1}{2}$ the only solutions of Equation (98.2) are

$$h_\nu = -1, \quad m_e = +\tfrac{1}{2}, \quad m_N = +1 \qquad \text{and} \qquad h_\nu = +1, \quad m_e = -\tfrac{1}{2}, \quad m_N = -1 \,,$$

the remaining combinations forcing $m_N = 0$, which the photon cannot carry, or $|h_\nu| = 3$, which no spin-$\frac{1}{2}$ particle has. In both surviving cases $h_\gamma = -m_N = h_\nu$: the photon inherits the neutrino's helicity exactly. A measured negative photon helicity therefore reads $h_\nu = -1$ directly, using only angular-momentum conservation, the spins of the three nuclear levels, and the transversality of the photon. The dilution noted at the end of Phenomenon 98.1 reduces the observed magnitude below unity but cannot change its sign, which is why a measurement of modest precision settles a question whose two answers differ by a sign. □

98.5.2 Consequences for V–A

[Reserved: how the measured sign selects $\gamma^\mu(\mathbb{1}-\gamma^5)$ from the five Fermi couplings, in combination with the beta-decay correlation data; the V–A theory of Feynman and Gell-Mann [1144] and of Sudarshan and Marshak [1162], published in the same year; the conserved vector current hypothesis; helicity suppression of $\pi \to e\nu$ as the independent V–A prediction, and its route into Chapters 101 and 104.]

98.5.3 What the result does not say

[Reserved: the result constrains the helicity of the emitted state, not the existence of a right-handed neutrino field of very small coupling; it says nothing about neutrino mass, and it is fully compatible with the massive neutrinos established by Chapter 114; nor does it distinguish Dirac from Majorana neutrinos; a short list of the questions it left open, each pointing to where the book takes them up.]

98.6 Modern repetitions and precision

98.6.1 Chirality tests in leptonic decays

[Reserved: the Michel parameters of muon decay [965] as the modern parametrization of the leptonic current, measured to the part-in-10^3 level by TWIST [2170]; the ratio $\Gamma(\pi \to e\nu)/\Gamma(\pi \to \mu\nu)$, whose measurement by PIENU [2249] agrees with the helicity-suppressed V–A prediction at the 10^{-3} level; the honest note that no repetition of the direct helicity measurement itself has improved on [1148].]

Phenomenon 98.3 (Muon decay has the shape a left-handed current predicts)**.** The energy and angular distribution of the electrons emitted by polarized muons is described completely by four dimensionless parameters. Measurement returns the values that a purely left-handed charged current requires — $\rho = \delta = \frac{3}{4}$ and $\xi = 1$ — at the level of one part in 10^3 or better [2427]. The leptonic weak current is therefore chiral to that precision, in a purely leptonic process with no nuclear structure anywhere in it, and at an energy release two orders of magnitude above that of the K-capture measured in this chapter.

Derivation pending #128

The Michel spectrum: the most general Lorentz-invariant four-fermion matrix element for muon decay, its reduction to four measurable parameters in the decay distribution, and the values those parameters take when the current is the purely left-handed one. Deriving it also shows which combinations of couplings the experiment cannot separate, which is what makes the bounds on right-handed admixtures the shape they are.

98.6.2 Parity violation in electron scattering and atoms

[Reserved: the SLAC E122 measurement of a parity-violating asymmetry in deep-inelastic scattering of polarized electrons [1625], which fixed the weak mixing angle and confirmed the chiral structure of the neutral current; atomic parity non-conservation in caesium and the nuclear anapole moment [1946]; the proton weak charge measured by Qweak [2301]; how each of these tests the same chirality assignment at a different energy scale.]

Phenomenon 98.4 (Parity is violated in the neutral current too)**.** Parity violation is not confined to the charged-current processes of beta decay. Longitudinally polarized electrons scattered from nuclei show a cross-section asymmetry between the two beam helicities; heavy

atoms show optical transitions that parity conservation would forbid, driven by the weak electron–nucleus interaction; and the proton's weak charge has been measured directly. All of these are described by one dimensionless parameter, the weak mixing angle, whose value is close to $\sin^2\theta_W = 0.231$ in the conventional renormalization scheme [2427], and the same value accounts for measurements spanning many decades of momentum transfer.

Derivation pending #129

The parity-violating asymmetry in the scattering of longitudinally polarized electrons, as the interference between the photon-exchange and neutral-current amplitudes, and its expression in terms of the weak mixing angle; together with the analogous expression for the parity-non-conserving amplitude in a heavy atom, where the nuclear weak charge and the atomic structure factorize. Both belong to the electroweak chapter of Part XII.

98.6.3 Limits on right-handed currents

[Reserved: the general framework in which a small admixture of a right-handed charged current is allowed and bounded; the constraints from beta-decay correlation coefficients, from muon decay [2170], and from direct collider searches for a heavy right-handed vector boson [2427]; the current bounds, quoted as limits on the mixing angle and on the mass of any additional charged vector boson; the standing conclusion that the weak current is purely left-handed to within present sensitivity.]

Phenomenon 98.5 (No right-handed charged current has been found)**.** Every measurement sensitive to a right-handed admixture in the charged weak current returns a null result: the beta-decay correlation coefficients, the muon-decay parameters of Phenomenon 98.3, and the direct searches for a heavy charged vector boson coupling to right-handed fields. The outcomes are quoted as limits — on a mixing angle between the two currents, and on the mass of any additional charged vector boson — and no measurement has required a nonzero right-handed component [2427]. The charged current is purely left-handed to within present sensitivity, which makes the Weyl structure a measured fact and not merely the simplest option compatible with the data.

Derivation pending #130

The general left–right parametrization of the charged current, the observables in beta and muon decay that are first order in the right-handed admixture as against those that are second order, and the translation of a null asymmetry into a bound on the mixing angle and on the mass of an additional charged vector boson. The distinction between the two orders is what determines how the sensitivity scales, and it must be stated with the bounds.

Part XI

Quantum Field Theory and the Standard Model

Chapter 99

Canonical Quantization of Fields

This chapter quantizes a classical field the way Chapter 25 quantized a mechanical system: a field is a mechanical system with one degree of freedom at every point of space, so the canonical procedure — conjugate momenta, equal-time brackets promoted to operators — applies unchanged, and the free field turns out to be an infinite collection of the harmonic oscillators of Chapter 28. Everything particle-like is then a statement about those oscillators: a particle is a quantum of excitation, the number of particles is an eigenvalue, and processes that change that number are describable at all only because the field, not the particle, is the primitive object. That is the reason this chapter opens the part rather than Chapter 92 or Chapter 93, whose single-particle relativistic wave equations both fail — negative energies, negative probabilities, the Klein paradox — for exactly the want of a field. The classical input is the Lagrangian field theory of Chapter 64 and the Poincaré representation theory of Chapter 94; the output is Fock space, propagators, microcausality and the spin–statistics connection, on which Chapter 100 and everything after it is built.

The free-field results below are exact and among the very few in this part that are. Interactions are treated perturbatively from Chapter 100 onward, and the path-integral alternative — indispensable for the non-abelian theories of Chapter 102 — is developed in Chapter 106; the axiomatic reformulation that makes the causality statements below precise is Chapter 109. Standard modern treatments are [1654, 1907, 1912].

Notation 99.1 (Conventions of this chapter). The conventions are those fixed once for the whole part in Section 100.1.1 and are repeated here only in the two places where a scalar field needs them. The metric is $\eta_{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$; coordinates are $x^\mu = (ct, \boldsymbol{x})$, so that $\mathrm{d}^4x = c\,\mathrm{d}t\,\mathrm{d}^3x$ carries m^4 and $\partial_\mu = (c^{-1}\partial_t, \nabla)$ carries $1/\mathrm{m}$; the d'Alembertian is

$$\Box := \partial_\mu \partial^\mu = \frac{1}{c^2}\partial_t^2 - \nabla^2 \,, \qquad [\Box] = 1/\mathrm{m}^2 \,. \tag{99.1}$$

Wave four-vectors $k^\mu = (\omega/c, \boldsymbol{k})$ carry $1/\mathrm{m}$ and four-momenta $p^\mu = \hbar k^\mu$ carry $\mathrm{kg\,m/s}$, with the mass shell $p^2 = m^2c^2$. A mass m enters every field equation below only through the inverse length

$$\kappa := \frac{mc}{\hbar} \,, \qquad [\kappa] = 1/\mathrm{m} \,, \tag{99.2}$$

the reciprocal of the reduced Compton wavelength; the mass shell reads $k^2 = \kappa^2$. The letter κ never means anything else in this chapter, and μ never means a mass: it occurs only as a Lorentz index and in μ_0, the magnetic constant. As in Notation 100.1, ϵ standing alone is the positive infinitesimal of the Feynman contour, ε_0 the electric constant, and $\boldsymbol{\varepsilon}_\lambda$ a polarization vector. An action is $S = c^{-1}\int \mathrm{d}^4x\,\mathcal{L}$ with $\mathcal{L}$ an energy density, $\mathrm{J/m^3}$; the SI dimension of each field is stated where the field is introduced. Every equation in this chapter, without exception, is written with $\hbar$ and c in place.

Remark 99.2 (Reading this chapter against its sources). The literature cited below works in units in which $\hbar = c = 1$, so that κ and m are the same symbol and a propagator is written $1/(k^2 - m^2)$. The dictionary is the one given in Remark 100.4, applied here to the two objects this chapter introduces: a mass becomes an inverse length by Equation (99.2), and the scalar propagator $1/(k^2 - m^2 + \mathrm{i}\epsilon)$ of those texts is $\mathrm{i}\hbar c/(k^2 - \kappa^2 + \mathrm{i}\epsilon)$ in Equation (99.93) below. No derivation in this chapter is performed in those units; the remark exists so that the reader can check the chapter against its sources, which is a different thing.

99.1 Why fields

Quantum field theory is not a generalization undertaken for its own sake. It is forced, and this section is the argument that forces it. The three steps are independent and each is fatal on its own: a relativistic one-particle wave equation has no consistent probability interpretation; a theory with a fixed number of particles contradicts what is seen in every accelerator and every cloud chamber; and the uncertainty principle forbids the localization on which a one-particle position operator depends. What survives all three is a system with infinitely many degrees of freedom whose excitations are counted, not tracked.

99.1.1 Failure of the single-particle relativistic theories

The Schrödinger equation $\mathrm{i}\hbar\,\partial_t\psi = -(\hbar^2/2m)\nabla^2\psi$ is first order in time and second order in space, so it cannot be covariant under a transformation that mixes the two. The obvious repair is to quantize the relativistic mass shell $E^2 = \boldsymbol{p}^2c^2 + m^2c^4$ instead of the Newtonian $E = \boldsymbol{p}^2/2m$, substituting $E \to \mathrm{i}\hbar\partial_t$ and $\boldsymbol{p} \to -\mathrm{i}\hbar\nabla$. The result is the Klein–Gordon equation [544],

$$-\hbar^2\partial_t^2\psi = -\hbar^2c^2\nabla^2\psi + m^2c^4\psi\,, \qquad \text{that is} \qquad \left(\Box + \kappa^2\right)\psi = 0\,, \tag{99.3}$$

studied as a wave equation in Chapter 92. It is manifestly covariant, and it is manifestly useless as a one-particle theory, for two reasons that turn out to be one reason.

Negative energies. The plane wave $\psi = N\exp[-\mathrm{i}(Et - \boldsymbol{p}\cdot\boldsymbol{x})/\hbar]$ solves Equation (99.3) whenever $E = \pm\sqrt{\boldsymbol{p}^2c^2 + m^2c^4}$, and the negative branch cannot be thrown away. Equation (99.3) is second order in time, so the initial data are ψ and $\partial_t\psi$, freely specifiable; the positive-frequency solutions alone are not a complete set and cannot match arbitrary initial data. Nor is the restriction stable: any interaction that is not diagonal in energy couples the two branches, which is what the Klein paradox [629] exhibits explicitly for a step potential of height greater than $2mc^2$.

Non-positive density. Multiplying Equation (99.3) by ψ^*, subtracting the conjugate equation multiplied by ψ, and dividing by $2\mathrm{i}mc^2/\hbar$ gives a continuity equation $\partial_t\rho + \nabla\cdot\boldsymbol{j} = 0$ with

$$\rho = \frac{\mathrm{i}\hbar}{2mc^2}\left(\psi^*\partial_t\psi - \psi\,\partial_t\psi^*\right)\,, \qquad \boldsymbol{j} = \frac{\hbar}{2\mathrm{i}m}\left(\psi^*\nabla\psi - \psi\nabla\psi^*\right)\,. \tag{99.4}$$

Evaluated on the plane wave above, $\partial_t\psi = -(\mathrm{i}E/\hbar)\psi$ and

$$\rho = \frac{\mathrm{i}\hbar}{2mc^2}\left(-\frac{2\mathrm{i}E}{\hbar}\right)|N|^2 = \frac{E}{mc^2}\,|N|^2\,, \tag{99.5}$$

which is negative on the negative branch. Born's reading of $|\psi|^2$ as a probability density [534] therefore cannot be transferred to Equation (99.4): a probability density is non-negative by definition, and this one is not.

Dirac's response was to insist on an equation first order in time, so that the density would be $\psi^\dagger\psi \geq 0$ by construction [596]. That succeeded — Chapter 93 follows the construction — and it did not remove the negative energies, which are a consequence of the mass shell and not of the order of the equation. The Dirac Hamiltonian has spectrum $\pm\sqrt{\boldsymbol{p}^2c^2 + m^2c^4}$

and is therefore unbounded below: an atomic electron could cascade down the negative continuum without limit, radiating an unbounded amount of energy, and no state of the theory would be stable.

The hole theory [647] repairs this by fiat. Declare that in the vacuum every negative-energy level is occupied; the exclusion principle then forbids the cascade, and the absence of an electron from the filled sea behaves as a particle of opposite charge. What that particle's mass is the 1930 paper does not settle: Dirac there identified the hole with the proton [647], and only in 1931 [677] concluded that it must carry the electron's own mass and so be a new particle unknown to experiment. That prediction, and its confirmation by Anderson [713] (Chapter 95), is one of the great successes of theoretical physics. It is nevertheless untenable as a foundation, for three reasons.

1. It is unavailable for bosons. The sea is held down by the exclusion principle, and a spin-0 particle obeys no such principle; there is no way to fill the negative-energy states of Equation (99.3). Yet the observed spin-0 particles — the charged pions above all — do have antiparticles: π^+ and π^- are listed as a particle–antiparticle pair of equal mass by the Particle Data Group [2427].

2. The vacuum acquires infinite charge and energy density, removed by a subtraction whose only justification is that it is needed.

3. It is a one-particle theory only in name. A state of the sea plus one electron is a state of infinitely many particles; the formalism has already left the single-particle Hilbert space, without admitting it.

The consistent version of the repair was found by Pauli and Weisskopf [748]: reinterpret Equation (99.3) not as an equation for a wave function but as an equation for a classical field, and quantize the field. Then ρ of Equation (99.4) is not a probability density at all but a charge density, whose sign is the sign of the charge, and the energy comes out positive for both signs. That construction is Section 99.3 below, and it works for spin 0 and spin 1/2 alike, with no sea.

The decisive objection is not internal but experimental. A one-particle theory has a Hilbert space $L^2(\mathbb{R}^3)$ (tensored with a finite-dimensional spin space), on which the number of particles is the constant 1; no unitary evolution on that space can produce a two-particle state. Nature produces them routinely.

Phenomenon 99.3 (Electron–positron pair creation)**.** A photon traversing matter converts into an electron–positron pair in the Coulomb field of a nucleus, provided its energy exceeds

$$E_\gamma^{\text{thr}} = 2m_e c^2 \left(1 + \frac{m_e}{M}\right) \longrightarrow 1.0220\,\text{MeV} \quad \text{as} \quad M \to \infty\,, \tag{99.6}$$

where M is the nuclear mass. Pair production is the dominant photon-absorption process in lead above about 5 MeV, and the positrons so produced are the ones Anderson identified [713].

Rests on Definition 40.4 and Theorem 40.5.

Derivation. *Derives Phenomenon 99.3.*

Energy and momentum conservation are the statement that the total four-momentum before and after are equal, so the invariant $s = (p_\gamma + P)^2$ is the same before and after. Before: the photon has $p_\gamma^2 = 0$ and the nucleus, at rest, has $P^\mu = (Mc, \mathbf{0})$, so

$$s = p_\gamma^2 + P^2 + 2p_\gamma \cdot P = M^2c^2 + 2\,\frac{E_\gamma}{c}\,Mc = M^2c^2 + 2ME_\gamma\,. \tag{99.7}$$

After: three particles, and the smallest value s can take for a given set of masses is the one in which they are all at relative rest, $s \geq (M + 2m_e)^2 c^2$. Combining,

$$2ME_\gamma \geq 4Mm_e c^2 + 4m_e^2 c^2 \quad \Longleftrightarrow \quad E_\gamma \geq 2m_e c^2 \left(1 + \frac{m_e}{M}\right) . \tag{99.8}$$

With the CODATA 2022 electron rest energy $m_e c^2 = 0.510\,998\,950\,69\,\mathrm{MeV}$ [2431] the infinite-mass limit is $1.021\,997\,90\,\mathrm{MeV}$. The recoil term m_e/M is why a nucleus must be present at all: for a photon alone $s = 0$, and Equation (99.8) can never be satisfied, so pair creation in empty space is kinematically forbidden however energetic the photon. □

A theory in which the number of particles is a fixed integer cannot describe Phenomenon 99.3, and no reinterpretation of the wave function repairs that. The state before the conversion has one quantum, the state after has three; the two live in different sectors, and only a formalism whose state space contains both, with operators connecting them, can hold the process at all.

The last objection is that even the one-particle sector is not what a single-particle theory needs it to be, because the position of a relativistic particle is not measurable to arbitrary precision without creating others.

Suppose a particle of mass m is confined to a region of linear size Δx. The uncertainty principle then requires $\Delta p \gtrsim \hbar/(2\Delta x)$, and for a relativistic particle $\Delta E \approx c\,\Delta p \gtrsim \hbar c/(2\Delta x)$. The energy uncertainty reaches the threshold $2mc^2$ of Equation (99.6) when

$$\Delta x \lesssim \frac{\hbar}{4mc} = \frac{1}{4\kappa} , \tag{99.9}$$

that is, at a fraction of the reduced Compton wavelength $\kappa^{-1} = \hbar/mc$. For the electron the Compton wavelength is $\lambda_C = h/(m_e c) = 2.426\,310\,235\,38 \times 10^{-12}\,\mathrm{m}$ and its reduced form is

$$\kappa_e^{-1} = \frac{\hbar}{m_e c} = \frac{\lambda_C}{2\pi} = 3.861\,592\,67 \times 10^{-13}\,\mathrm{m} , \tag{99.10}$$

both from CODATA 2022 [2431]. Attempting to pin an electron down to a tenth of that supplies enough energy to make several more, and the apparatus that would do the pinning — a potential well of depth $\gtrsim mc^2$ — is precisely a device for creating pairs. There is therefore no operational meaning to "the position of the electron" below κ_e^{-1}, and any formalism that carries an exact position operator is claiming more than can be measured.

Newton and Wigner [942] asked how much of a position operator survives. Demanding only that the localized states at a fixed time transform correctly under rotations, translations and space inversion, and that they be orthogonal for distinct points, they showed that a unique such operator exists on the positive-energy one-particle space — but that its eigenstates are not localized in any Lorentz-invariant sense. A Newton–Wigner state localized at a point in one frame has support spread over a region of order κ^{-1} in another, and its wave function has tails falling as $\mathrm{e}^{-\kappa r}$ rather than vanishing outside a bounded set. The one-particle position operator exists; what does not exist is a frame-independent notion of where the particle is, to better than κ^{-1}.

Each objection is really the same one seen from a different side. The mass shell has two branches; the second branch cannot be removed covariantly; a theory that keeps it needs states of arbitrarily negative energy unless the number of quanta is allowed to change; and the scale at which the change becomes unavoidable is κ^{-1}, which is also the scale at which localization fails. The resolution is to stop treating the wave equation as an equation for a probability amplitude and to treat it as the classical equation of motion of a field, to be quantized. Then the two branches become creation and annihilation of two species of quantum, the energy is bounded below, the conserved quantity of Equation (99.4) is a charge that may take either sign, and states with any number of quanta live in one space. Everything after this section is the execution of that programme.

99.1.2 Field as a mechanical system with continuously many degrees of freedom

A field is not a new kind of object requiring new mechanics. It is an ordinary mechanical system with an infinite number of coordinates labelled by a continuous index, and the cleanest way to see this is to watch the index become continuous.

Take N equal masses m_0 threaded on a light string of tension T at spacing ℓ, with transverse displacements $q_n(t)$ and fixed ends, the discrete system of Chapter 28. For small displacements the string segment between neighbours pulls with the transverse component $T(q_{n+1}-q_n)/\ell$, so

$$m_0 \ddot{q}_n = \frac{T}{\ell}\,(q_{n+1} - 2q_n + q_{n-1})\,, \tag{99.11}$$

which follows from the Lagrangian

$$L = \sum_n \left[\frac{m_0}{2}\dot{q}_n^2 - \frac{T}{2\ell}\,(q_{n+1}-q_n)^2 \right]. \tag{99.12}$$

Now let $\ell \to 0$ at fixed linear density $\varrho = m_0/\ell$ and fixed T. Write $q_n(t) = u(t, x_n)$ with $x_n = n\ell$; then $(q_{n+1}-q_n)/\ell \to \partial_x u$ and $\sum_n \to \ell^{-1}\int \mathrm{d}x$, so

$$L \longrightarrow \int \mathrm{d}x \left[\frac{\varrho}{2}\,(\partial_t u)^2 - \frac{T}{2}\,(\partial_x u)^2 \right], \tag{99.13}$$

whose Euler–Lagrange equation is the wave equation $\partial_t^2 u = v^2 \partial_x^2 u$ with $v = \sqrt{T/\varrho}$. Nothing conceptual happened in the limit. The discrete label n became the continuous label x; the finitely many coordinates q_n became the one-parameter family $u(x)$; and the Lagrangian, previously a sum, became an integral of a *density*. The coordinate of the system is now the whole function $u(\cdot)$ at one instant, and x is not a dynamical variable but a name for which coordinate one is talking about.

Definition 99.4 (Field, Lagrangian density, conjugate momentum)**.** A (real, scalar) classical field is a map $\phi : \mathbb{R}^4 \to \mathbb{R}$, $x^\mu \mapsto \phi(x)$, regarded as the continuously indexed set of coordinates $\{\phi(t, \boldsymbol{x})\}$ labelled by $\boldsymbol{x}$. A *local* Lagrangian is the integral of a density depending on the field and its first derivatives at one point,

$$L[\phi, \dot{\phi}] = \int \mathrm{d}^3x\, \mathcal{L}(\phi(x), \partial_\mu \phi(x))\,, \qquad [\mathcal{L}] = \mathrm{J/m^3}\,, \tag{99.14}$$

and the momentum density conjugate to ϕ is

$$\pi(x) := \frac{\partial \mathcal{L}}{\partial \dot{\phi}(x)}\,, \qquad \dot{\phi} := \partial_t \phi\,. \tag{99.15}$$

The Euler–Lagrange equations follow from stationarity of $S = c^{-1}\int \mathrm{d}^4x\,\mathcal{L}$ under variations vanishing on the boundary of the region of integration. Expanding $\delta\mathcal{L} = (\partial\mathcal{L}/\partial\phi)\,\delta\phi + (\partial\mathcal{L}/\partial(\partial_\mu\phi))\partial_\mu\delta\phi$ and integrating the second term by parts leaves, once the boundary term is discarded,

$$\delta S = \frac{1}{c}\int \mathrm{d}^4x \left[\frac{\partial \mathcal{L}}{\partial \phi} - \partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} \right] \delta\phi\,,$$

which vanishes for arbitrary $\delta\phi$ only if the bracket does. For a local density the equations therefore read

$$\partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} - \frac{\partial \mathcal{L}}{\partial \phi} = 0\,. \tag{99.16}$$

The derivative of an integral with respect to one of continuously many coordinates is a functional derivative, defined by

$$\delta F[\phi] = \int \mathrm{d}^3x \, \frac{\delta F}{\delta \phi(\boldsymbol{x})} \, \delta\phi(\boldsymbol{x}) \,, \qquad \frac{\delta \phi(\boldsymbol{x})}{\delta \phi(\boldsymbol{y})} = \delta^3(\boldsymbol{x}-\boldsymbol{y}) \,, \tag{99.17}$$

the continuum replacement of $\partial q_n / \partial q_m = \delta_{nm}$; the Dirac delta carries $1/\mathrm{m}^3$, which is where the volume factors in every formula below come from.

The relativistic field whose equation of motion is Equation (99.3) is obtained from

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \phi \, \partial^\mu \phi - \kappa^2 \phi^2\right) = \frac{1}{2}\left[\frac{1}{c^2}\left(\partial_t \phi\right)^2 - \left(\nabla\phi\right)^2 - \kappa^2\phi^2\right] , \tag{99.18}$$

for which Equation (99.16) gives $\left(\Box + \kappa^2\right)\phi = 0$ directly. Since $[\partial_\mu] = 1/\mathrm{m}$ and $[\mathcal{L}] = \mathrm{J}/\mathrm{m}^3$, the field itself carries

$$[\phi] = (\mathrm{J}/\mathrm{m})^{1/2} = \mathrm{kg}^{1/2}\,\mathrm{m}^{1/2}/\mathrm{s} \,, \tag{99.19}$$

and by Equation (99.15)

$$\pi = \frac{1}{c^2}\partial_t \phi \,, \qquad [\pi] = \mathrm{kg}^{1/2}/\mathrm{m}^{1.5} \,, \tag{99.20}$$

so that $[\phi][\pi] = \mathrm{J\,s}/\mathrm{m}^3$ — an action per unit volume, which is what the equal-time commutator of Section 99.2.1 will need it to be. Legendre-transforming,

$$\mathcal{H} = \pi\dot{\phi} - \mathcal{L} = \frac{1}{2}\left[c^2\pi^2 + \left(\nabla\phi\right)^2 + \kappa^2\phi^2\right] , \qquad H = \int \mathrm{d}^3x \, \mathcal{H} \,, \tag{99.21}$$

manifestly non-negative — a first sign that the field reading cures the disease of Section 99.1.1, since the same mass shell that gave energies of both signs gives a Hamiltonian density that is a sum of squares.

Classically the field obeys Poisson brackets that are the continuum form of $\{q_n, p_m\} = \delta_{nm}$,

$$\{\phi(t,\boldsymbol{x}), \pi(t,\boldsymbol{y})\} = \delta^3(\boldsymbol{x}-\boldsymbol{y}) \,, \qquad \{\phi,\phi\} = \{\pi,\pi\} = 0 \,, \tag{99.22}$$

obtained by putting the functional derivative Equation (99.17) in place of $\partial q_n/\partial q_m = \delta_{nm}$ in the definition of the bracket. Chapter 64 is the general classical field theory built on these brackets.

Equation (99.14) contains a physical hypothesis that is easy to overlook because it is built into the notation: the Lagrangian density at x depends on the field at x and on its first derivatives there, and on nothing else. A term such as $\int \mathrm{d}^3y \, K(\boldsymbol{x}-\boldsymbol{y})\phi(\boldsymbol{x})\phi(\boldsymbol{y})$ with K of finite range would be perfectly well defined and would still give a linear equation of motion; it is excluded by assumption.

The assumption is not free of consequences. Locality plus a second-order-in-time equation makes the field equation hyperbolic with characteristic speed c, so classical disturbances propagate on and inside the light cone; after quantization it is what makes the commutator of the field with itself vanish at spacelike separation, the statement verified explicitly in Section 99.7.1. A nonlocal kernel K of range R would leave a non-vanishing commutator out to spacelike separations of order R, and thus a signal outside the light cone. The bound on such effects is therefore an experimental bound, and the axiomatic programme of Chapter 109 takes locality — not the Lagrangian — as the primitive assumption for exactly this reason.

99.1.3 The historical sequence

The formalism of this chapter was assembled between 1925 and 1932, in a sequence in which almost every step was taken for a reason different from the one that now justifies it.

The first field ever quantized was the free radiation field, in the concluding chapter of the three-author paper of Born, Heisenberg and Jordan of 1926. Their object was not particles: it was to show that the new matrix mechanics reproduced Einstein's 1909 formula for the energy fluctuations of black-body radiation, whose two terms had for fifteen years looked like an unexplained superposition of a wave term and a particle term. Treating each cavity mode as a matrix-mechanical oscillator produced both terms at once. In the same year Born's collision papers [534] fixed the probability interpretation of the wave amplitude that Section 99.1.1 showed cannot survive the relativistic generalization — the two ideas were contemporaneous, and it took another eight years to see that they were in tension.

Dirac's radiation theory of 1927 [572] is the paper in which the method became a method. He quantized the electromagnetic field in Coulomb gauge, obtained the ladder operators for each mode, and computed the emission and absorption rates of an atom coupled to it. The matrix element for emission into a mode already containing n quanta came out proportional to $\sqrt{n+1}$ and that for absorption to $\sqrt{n}$; the ratio of the resulting rates reproduces Einstein's A and B coefficients, with the $+1$ — spontaneous emission — coming from the mode's zero-point term and not from any external perturbation. The consequences for quantum optics are Chapter 122.

Jordan and Wigner [609] then showed that the same apparatus describes fermions if the commutators are replaced by anticommutators, deriving the exclusion principle rather than postulating it. Heisenberg and Pauli [626, 656] gave the general canonical formalism for an arbitrary system of interacting fields; in doing so they met the difficulty that the momentum conjugate to the time component of the electromagnetic potential vanishes identically, the first appearance of the constrained Hamiltonian structure taken up systematically in Chapter 26. Fock [698] supplied the state space in which all of this acts, and Pauli and Weisskopf [748] closed the argument of Section 99.1.1 by quantizing the scalar field and showing that spin 0 has antiparticles without any sea.

Two later entries in Table 99.1 belong to the same story. Wigner's classification of the unitary irreducible representations of the Poincaré group [849] supplied the definition of "elementary particle" that this chapter uses — an irreducible representation labelled by the two invariants of Chapter 94 — and Casimir's calculation of the force between conducting plates [909], undertaken to explain the stability of colloidal suspensions, turned the zero-point energy from an embarrassment into a measurable quantity (Section 99.8).

99.2 The free real scalar field

Everything the rest of the chapter does is done first, and in full, for the simplest field there is: one real number at each point of spacetime, obeying Equation (99.3). It has no spin, no charge and no gauge freedom, so nothing distracts from the two operations being performed — imposing canonical commutators, and diagonalizing the Hamiltonian. The result is that the field is a continuous family of harmonic oscillators and that its excitations are counted by integers.

99.2.1 Canonical commutation relations

The classical system is Equation (99.18) with the conjugate momentum Equation (99.20) and the Poisson brackets Equation (99.22). Quantization is the same step taken in Chapter 25 for a system of finitely many degrees of freedom (Postulate 25.27): replace the classical variables

Table 99.1: The construction of the canonical formalism. The entries are the steps used in this chapter; the physical motivation column records what the authors were after, which was rarely what the step is now used for.

Year	Step	Motivation at the time
1926	Radiation field quantized mode by mode (Born, Heisenberg and Jordan)	Reproduce Einstein's black-body fluctuation formula
1927	Ladder operators, emission and absorption [572]	Derive the Einstein A and B coefficients
1928	Anticommuting field [609]	Derive the exclusion principle from an algebra
1928	First-order wave equation [596]	Obtain a positive probability density
1929	General canonical formalism [626, 656]	Quantize interacting fields covariantly
1930	Hole theory, with the hole taken to be the proton [647]	Stabilize the negative-energy continuum
1931	The hole given the electron's own mass [677]	Remove the proton identification; predict a new particle
1932	Fock space [698]	A state space for variable particle number
1934	Charged scalar field [748]	Show spin 0 needs no sea
1939	Irreducible representations of the Poincaré group [849]	Define "particle" invariantly
1948	Boundary-dependent vacuum energy [909]	Explain colloidal stability
1950	Wick's theorem [974]	Organize the perturbation series

by operators on a Hilbert space and the Poisson bracket by $(\mathrm{i}\hbar)^{-1}$ times the commutator. The continuous label rides along unchanged.

Postulate 99.5 (Canonical quantization of a scalar field)**.** The field ϕ and its conjugate momentum density π become operator-valued distributions on a Hilbert space, satisfying at equal times

$$[\phi(t,\boldsymbol{x}),\pi(t,\boldsymbol{y})] = \mathrm{i}\hbar\,\delta^3(\boldsymbol{x}-\boldsymbol{y})\,, \tag{99.23}$$

$$[\phi(t,\boldsymbol{x}),\phi(t,\boldsymbol{y})] = [\pi(t,\boldsymbol{x}),\pi(t,\boldsymbol{y})] = 0\,, \tag{99.24}$$

and the operators evolve in the Heisenberg picture, $\mathrm{i}\hbar\,\partial_t A = [A,H]$ with H of Equation (99.21).

Both sides of Equation (99.23) carry $\mathrm{J\,s/m^3}$, by Equations (99.19) and (99.20) on the left and because δ^3 carries $1/\mathrm{m}^3$ on the right. The $\hbar$ is not decoration and cannot be scaled away: it fixes the magnitude of the field fluctuations, and the classical field theory of Chapter 64 is recovered as $\hbar \to 0$, where the right-hand side vanishes and the field components commute.

Equation (99.24) deserves a comment. It says that the field at two different points of space *at the same time* commutes. That is not an extra assumption but the continuum version of $[q_n, q_m] = 0$: the two are independent coordinates of one system, and specifying both simultaneously is exactly what a configuration is. The nontrivial statement — that $[\phi(x),\phi(y)]$ vanishes for *all* spacelike separations, not merely equal-time ones — is a theorem, proved in Section 99.7.1.

Proposition 99.6 (The Heisenberg equations reproduce the field equation)**.** *With H of Equation (99.21) and the brackets Equations (99.23) and (99.24),*

$$\partial_t\phi = c^2\pi\,, \qquad \partial_t\pi = \nabla^2\phi - \kappa^2\phi\,, \tag{99.25}$$

and eliminating π gives $(\Box + \kappa^2)\,\phi = 0$.

Rests on Equations (99.21), (99.23) and (99.24).

Proof. *Derives Proposition 99.6.*

Only the term quadratic in π fails to commute with ϕ. Using $[A,B^2] = B\,[A,B] + [A,B]\,B$ and Equation (99.23),

$$[\phi(\boldsymbol{x}),H] = \frac{c^2}{2}\int \mathrm{d}^3y\,\Big[\phi(\boldsymbol{x}),\pi(\boldsymbol{y})^2\Big] = \frac{c^2}{2}\int \mathrm{d}^3y\,2\mathrm{i}\hbar\,\delta^3(\boldsymbol{x}-\boldsymbol{y})\pi(\boldsymbol{y}) = \mathrm{i}\hbar c^2\pi(\boldsymbol{x})\,,$$

which is the first of Equation (99.25). For the second, the gradient and mass terms contribute. The mass term gives $\frac{1}{2}\kappa^2\int \mathrm{d}^3y\;[\pi(\boldsymbol{x}),\phi(\boldsymbol{y})^2] = -\mathrm{i}\hbar\kappa^2\phi(\boldsymbol{x})$, and the gradient term gives

$$\frac{1}{2}\int \mathrm{d}^3y\;[\pi(\boldsymbol{x}),\nabla_y\phi\cdot\nabla_y\phi] = \int \mathrm{d}^3y\,\nabla_y\phi(\boldsymbol{y})\cdot\Big(-\mathrm{i}\hbar\nabla_y\delta^3(\boldsymbol{x}-\boldsymbol{y})\Big) = \mathrm{i}\hbar\,\nabla^2\phi(\boldsymbol{x})\,,$$

the last step an integration by parts, the surface term vanishing for fields falling off at infinity. Adding and dividing by $\mathrm{i}\hbar$ gives the second of Equation (99.25); substituting $\pi = c^{-2}\partial_t\phi$ gives $c^{-2}\partial_t^2\phi - \nabla^2\phi + \kappa^2\phi = 0$. □

Proposition 99.6 is the consistency check that licenses everything else: the quantized field obeys, as an operator equation, exactly the classical equation of motion, so the classical solution theory — plane waves, superposition, the mass shell — can be carried over intact and used to diagonalize H.

One technical point must be stated now rather than discovered later. Equation (99.23) contains a Dirac delta, and a delta is a distribution, not a function. Correspondingly $\phi(x)$ is not an operator: the object $\phi(x)\,|0\rangle$ has infinite norm, since Equation (99.91) below gives

$$\langle 0|\,\phi(x)^2\,|0\rangle = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\frac{\hbar c^2}{2\omega_{\boldsymbol{k}}} = \frac{\hbar c}{4\pi^2}\int_0^\infty \frac{k^2\,\mathrm{d}k}{\sqrt{k^2+\kappa^2}}\,, \tag{99.26}$$

which diverges quadratically at large k. What *is* an operator is the smeared field

$$\phi(f) = \int \mathrm{d}^4x\, f(x)\,\phi(x)\,, \tag{99.27}$$

with f a smooth test function of compact support. Physically this is not a technicality but a statement about measurement: a field cannot be measured at a mathematical point, only averaged over a region, which is precisely the conclusion Bohr and Rosenfeld reached from the side of the apparatus (Section 99.7.3). It is because the smeared objects, and not the pointwise ones, are the well-defined quantities that the axiomatic reformulation of Chapter 109 takes fields to be operator-valued distributions from the start [1099, 1297].

99.2.2 Mode expansion, creation and annihilation operators

The field equation is linear, so it is solved by superposing plane waves; the equal-time commutators then determine the algebra of the coefficients, and the coefficients turn out to be ladder operators.

Write the general real solution of $(\Box + \kappa^2)\,\phi = 0$ as a Fourier integral over the mass shell. With $k\cdot x := k_\mu x^\mu = \omega_{\boldsymbol{k}} t - \boldsymbol{k}\cdot\boldsymbol{x}$ and

$$\omega_{\boldsymbol{k}} = c\sqrt{\boldsymbol{k}^2 + \kappa^2} = \frac{1}{\hbar}\sqrt{\hbar^2 c^2 \boldsymbol{k}^2 + m^2 c^4}\,, \tag{99.28}$$

each Fourier component $\widetilde{\phi}(t,\boldsymbol{k})$ obeys $\ddot{\widetilde{\phi}} = -\omega_{\boldsymbol{k}}^2\widetilde{\phi}$: one harmonic oscillator per wave vector, of frequency $\omega_{\boldsymbol{k}}$. Reality of ϕ relates the components at $\boldsymbol{k}$ and $-\boldsymbol{k}$, so the independent data are one complex amplitude per $\boldsymbol{k}$, written $a(\boldsymbol{k})$.

Definition 99.7 (Mode expansion of the free real scalar field)**.**

$$\phi(x) = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\sqrt{\frac{\hbar c^2}{2\omega_{\boldsymbol{k}}}}\left[a(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}k\cdot x} + a^\dagger(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}k\cdot x}\right], \tag{99.29}$$

$$\pi(x) = -\mathrm{i}\int \frac{\mathrm{d}^3k}{(2\pi)^3}\sqrt{\frac{\hbar\omega_{\boldsymbol{k}}}{2c^2}}\left[a(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}k\cdot x} - a^\dagger(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}k\cdot x}\right]. \tag{99.30}$$

Equation (99.30) is not an independent assumption: it is $c^{-2}\partial_t$ of Equation (99.29). The normalization factor is fixed by the requirement that Equation (99.23) hold, as Proposition 99.8 shows, and it is worth reading before the proof. The amplitude of each mode carries $\sqrt{\hbar}$: as $\hbar \to 0$ the quantum field flattens to zero and only the classical solution built from a macroscopic occupation survives. That $\sqrt{\hbar}$ is the entire quantum content of the free theory.

Dimensionally, $[\mathrm{d}^3k] = 1/\mathrm{m}^3$ and $[\sqrt{\hbar c^2/2\omega}] = \mathrm{J}^{1/2}\,\mathrm{m}$, so $[a] = \mathrm{m}^{3/2}$ if $[\phi]$ is to be Equation (99.19) — which is exactly the dimension demanded by Equation (99.31) below, since $\delta^3(\boldsymbol{k}-\boldsymbol{k}')$ carries m^3.

Proposition 99.8 (The ladder algebra)**.** *Equations* (99.23) *and* (99.24) *hold if and only if*

$$\left[a(\boldsymbol{k}), a^\dagger(\boldsymbol{k}')\right] = (2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')\,, \qquad [a(\boldsymbol{k}), a(\boldsymbol{k}')] = \left[a^\dagger(\boldsymbol{k}), a^\dagger(\boldsymbol{k}')\right] = 0\,. \tag{99.31}$$

Rests on Equations (99.23) *and* (99.24) *and Definition 99.7.*

Proof. *Derives Proposition 99.8.*

Invert Equations (99.29) and (99.30) at a fixed time. Writing $\alpha_{\boldsymbol{k}} = \sqrt{2\omega_{\boldsymbol{k}}/(\hbar c^2)}$ and $\beta_{\boldsymbol{k}} = \sqrt{2c^2/(\hbar\omega_{\boldsymbol{k}})}$, the combinations

$$a(\boldsymbol{k}) = \frac{\mathrm{e}^{\mathrm{i}\omega_{\boldsymbol{k}}t}}{2}\int \mathrm{d}^3x\,\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}\left[\alpha_{\boldsymbol{k}}\phi(t,\boldsymbol{x}) + \mathrm{i}\beta_{\boldsymbol{k}}\pi(t,\boldsymbol{x})\right] \tag{99.32}$$

follow from $\int \mathrm{d}^3x\, \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}\mathrm{e}^{\pm\mathrm{i}\boldsymbol{k}'\cdot\boldsymbol{x}} = (2\pi)^3\delta^3(\boldsymbol{k}\mp\boldsymbol{k}')$. Note that $\alpha_{\boldsymbol{k}}$ and $\beta_{\boldsymbol{k}}$ are the reciprocals of the two normalization factors appearing in Equations (99.29) and (99.30), so that the spatial Fourier transforms of those two equations are

$$\alpha_{\boldsymbol{k}} \int \mathrm{d}^3x\, \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}\phi(t,\boldsymbol{x}) = a(\boldsymbol{k})\mathrm{e}^{-\mathrm{i}\omega_{\boldsymbol{k}}t} + a^\dagger(-\boldsymbol{k})\mathrm{e}^{\mathrm{i}\omega_{\boldsymbol{k}}t}\,,$$
$$\mathrm{i}\beta_{\boldsymbol{k}} \int \mathrm{d}^3x\, \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}\pi(t,\boldsymbol{x}) = a(\boldsymbol{k})\mathrm{e}^{-\mathrm{i}\omega_{\boldsymbol{k}}t} - a^\dagger(-\boldsymbol{k})\mathrm{e}^{\mathrm{i}\omega_{\boldsymbol{k}}t}\,,$$

whose sum is $2a(\boldsymbol{k})\mathrm{e}^{-\mathrm{i}\omega_{\boldsymbol{k}}t}$: the $a^\dagger(-\boldsymbol{k})$ terms cancel, which is Equation (99.32). Then

$$\begin{aligned}\left[a(\boldsymbol{k}), a^\dagger(\boldsymbol{k}')\right] &= \frac{\mathrm{e}^{\mathrm{i}(\omega-\omega')t}}{4}\int \mathrm{d}^3x\, \mathrm{d}^3y\, \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}+\mathrm{i}\boldsymbol{k}'\cdot\boldsymbol{y}} \\ &\qquad \times\left(-\mathrm{i}\alpha_{\boldsymbol{k}}\beta_{\boldsymbol{k}'}\left[\phi(\boldsymbol{x}),\pi(\boldsymbol{y})\right] + \mathrm{i}\beta_{\boldsymbol{k}}\alpha_{\boldsymbol{k}'}\left[\pi(\boldsymbol{x}),\phi(\boldsymbol{y})\right]\right) \\ &= \frac{\hbar}{4}\int \mathrm{d}^3x\, \mathrm{e}^{\mathrm{i}(\boldsymbol{k}'-\boldsymbol{k})\cdot\boldsymbol{x}}\left(\alpha_{\boldsymbol{k}}\beta_{\boldsymbol{k}'} + \beta_{\boldsymbol{k}}\alpha_{\boldsymbol{k}'}\right)\,,\end{aligned}$$

the $[\phi,\phi]$ and $[\pi,\pi]$ terms having dropped by Equation (99.24). The remaining integral is $(2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')$, which sets $\boldsymbol{k}'=\boldsymbol{k}$ in the bracket; there $\alpha_{\boldsymbol{k}}\beta_{\boldsymbol{k}} = \sqrt{(2\omega/\hbar c^2)(2c^2/\hbar\omega)} = 2/\hbar$, so the bracket is $4/\hbar$ and the prefactor $\hbar/4$ cancels it exactly. For $[a(\boldsymbol{k}), a(\boldsymbol{k}')]$ the same expansion gives $\mathrm{i}\alpha_{\boldsymbol{k}}\beta_{\boldsymbol{k}'}\left[\phi(\boldsymbol{x}),\pi(\boldsymbol{y})\right] + \mathrm{i}\beta_{\boldsymbol{k}}\alpha_{\boldsymbol{k}'}\left[\pi(\boldsymbol{x}),\phi(\boldsymbol{y})\right]$, whose two terms are $+\mathrm{i}\hbar$ and $-\mathrm{i}\hbar$ times the same delta and therefore cancel; likewise for the daggered pair. The converse is the same algebra run backwards: substituting Equation (99.31) into Equations (99.29) and (99.30) reproduces Equation (99.23), as the computation in Proposition 99.44 does explicitly for a general time difference. □

Equation (99.31) is the ladder algebra of the quantum harmonic oscillator, one copy for each $\boldsymbol{k}$, with the Kronecker delta of the discrete oscillator replaced by a Dirac delta; it is the algebra Dirac used for the radiation field [572]. The modes it acts on are the continuum limit of the coupled oscillators of Chapter 28, which is a classical chapter and carries the normal modes but not this algebra. What the algebra buys is that the oscillator spectrum applies mode by mode, and the next theorem derives that here rather than importing it.

Theorem 99.9 (The free scalar Hamiltonian)**.** *Substituting Equations* (99.29) *and* (99.30) *into Equation* (99.21)*,*

$$H = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\frac{\hbar\omega_{\boldsymbol{k}}}{2}\left[a^\dagger(\boldsymbol{k})a(\boldsymbol{k}) + a(\boldsymbol{k})a^\dagger(\boldsymbol{k})\right]\,, \tag{99.33}$$

and the momentum operator $\boldsymbol{P} = -\int \mathrm{d}^3x\, \pi\nabla\phi$ *is*

$$\boldsymbol{P} = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\hbar\boldsymbol{k}\,\frac{1}{2}\left[a^\dagger(\boldsymbol{k})a(\boldsymbol{k}) + a(\boldsymbol{k})a^\dagger(\boldsymbol{k})\right]\,. \tag{99.34}$$

Rests on Equations (99.21)*,* (99.29) *and* (99.30)*.*

Proof. *Derives Theorem 99.9.*

Take the three terms of Equation (99.21) in turn. Each is a product of two mode integrals, and $\int \mathrm{d}^3x$ produces $(2\pi)^3\delta^3(\boldsymbol{k}\pm\boldsymbol{k}')$, so every term reduces to a single integral over $\boldsymbol{k}$ in which the partner is either $\boldsymbol{k}$ (for the $aa^\dagger$ and $a^\dagger a$ pieces) or $-\boldsymbol{k}$ (for the aa and $a^\dagger a^\dagger$ pieces).

For the aa and $a^\dagger a^\dagger$ pieces, collect coefficients. From $\frac{1}{2}c^2\pi^2$ the coefficient is $-\frac{1}{2}c^2(\hbar\omega/2c^2) = -\hbar\omega/4$, the minus sign coming from $(-\mathrm{i})^2$. From $\frac{1}{2}(\nabla\phi)^2$, the gradient acting on $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}$ gives $\mathrm{i}\boldsymbol{k}$ and on the partner $\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}$ gives $-\mathrm{i}\boldsymbol{k}$, so the coefficient is $+\frac{1}{2}(\hbar c^2/2\omega)\boldsymbol{k}^2$; the mass term adds $+\frac{1}{2}(\hbar c^2/2\omega)\kappa^2$. Their sum is $\frac{1}{2}(\hbar c^2/2\omega)(\boldsymbol{k}^2+\kappa^2) = \hbar\omega/4$

by Equation (99.28), cancelling the contribution from π^2 exactly. The time-dependent factors $\mathrm{e}^{\mp 2\mathrm{i}\omega t}$ that multiply these pieces therefore never appear, which is the statement that H is conserved.

For the $a^\dagger a$ and $aa^\dagger$ pieces the relative sign is reversed: π^2 contributes $+\hbar\omega/4$ to each and the gradient and mass terms contribute $+\hbar\omega/4$ to each, giving $\hbar\omega/2$ for each of $a^\dagger a$ and $aa^\dagger$, which is Equation (99.33). Equation (99.34) is the same computation with one factor of ∇ in place of one factor of ∂_t/c^2. □

Two consequences follow at once from Equation (99.31) and Equation (99.33):

$$\left[H, a^\dagger(\boldsymbol{k})\right] = \hbar\omega_{\boldsymbol{k}}\, a^\dagger(\boldsymbol{k})\,, \qquad [H, a(\boldsymbol{k})] = -\hbar\omega_{\boldsymbol{k}}\, a(\boldsymbol{k})\,, \tag{99.35}$$

so $a^\dagger(\boldsymbol{k})$ raises the energy by $\hbar\omega_{\boldsymbol{k}}$ and $a(\boldsymbol{k})$ lowers it by the same amount; and by Equation (99.34) the same operators raise and lower the momentum by $\hbar\boldsymbol{k}$. The energy and momentum added by one application of $a^\dagger(\boldsymbol{k})$ satisfy

$$(\hbar\omega_{\boldsymbol{k}})^2 - (\hbar\boldsymbol{k})^2 c^2 = \hbar^2 c^2 \left(\boldsymbol{k}^2 + \kappa^2\right) - \hbar^2 c^2 \boldsymbol{k}^2 = \hbar^2 c^2 \kappa^2 = m^2 c^4\,, \tag{99.36}$$

the relativistic mass shell of a particle of mass m. This is the central identification of the chapter, and it was not put in: it came out of diagonalizing a field Hamiltonian.

Proposition 99.10 (The invariant measure and the relativistic normalization)**.** *The combination $\omega_{\boldsymbol{k}}\,\delta^3(\boldsymbol{k}-\boldsymbol{k}')$ is invariant under proper orthochronous Lorentz transformations, and*

$$\int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\frac{c}{2\omega_{\boldsymbol{k}}}\,F(k) = \int \frac{\mathrm{d}^4k}{(2\pi)^3}\,\delta\!\left(k^2-\kappa^2\right)\theta(k^0)\,F(k) \tag{99.37}$$

for any F. Consequently the states

$$|\boldsymbol{k}\rangle := \sqrt{2\omega_{\boldsymbol{k}}}\,a^\dagger(\boldsymbol{k})\,|0\rangle\,, \qquad \langle \boldsymbol{k}|\boldsymbol{k}'\rangle = 2\omega_{\boldsymbol{k}}(2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')\,, \tag{99.38}$$

have a Lorentz-invariant normalization.

Rests on Equations (99.28) and (99.31).

Proof. *Derives Proposition 99.10.*

For a boost of rapidity η along the third axis, $k'^3 = \gamma(k^3 - \beta\omega_{\boldsymbol{k}}/c)$ with $\gamma = \cosh\eta$, $\beta = \tanh\eta$, while k^1, k^2 are unchanged. On the mass shell $\omega_{\boldsymbol{k}} = c\sqrt{\boldsymbol{k}^2+\kappa^2}$, so $\partial\omega_{\boldsymbol{k}}/\partial k^3 = c^2k^3/\omega_{\boldsymbol{k}}$ and

$$\frac{\partial k'^3}{\partial k^3} = \gamma\left(1 - \frac{\beta}{c}\,\frac{c^2k^3}{\omega_{\boldsymbol{k}}}\right) = \frac{\gamma\left(\omega_{\boldsymbol{k}} - \beta c k^3\right)}{\omega_{\boldsymbol{k}}} = \frac{\omega_{\boldsymbol{k}'}}{\omega_{\boldsymbol{k}}}\,,$$

the last equality being the transformation of $k^0 = \omega/c$ itself. Hence $\mathrm{d}^3k' = (\omega_{\boldsymbol{k}'}/\omega_{\boldsymbol{k}})\mathrm{d}^3k$, so $\mathrm{d}^3k/\omega_{\boldsymbol{k}}$ is invariant, and a delta transforms with the inverse Jacobian of its argument, so $\omega_{\boldsymbol{k}}\delta^3(\boldsymbol{k}-\boldsymbol{k}')$ is invariant too. For Equation (99.37), write $k^2-\kappa^2 = (k^0)^2 - \boldsymbol{k}^2 - \kappa^2$ and use $\delta(g(k^0)) = \sum_i \delta(k^0-k^0_i)/\,|g'(k^0_i)|$ with the roots $k^0 = \pm\omega_{\boldsymbol{k}}/c$; the step function keeps the positive one, at which $|g'| = 2\omega_{\boldsymbol{k}}/c$. □

Equation (99.37) is the reason every momentum-space formula in this part carries $\mathrm{d}^3k/(2\pi)^3 2\omega_{\boldsymbol{k}}$ rather than d^3k: it is the unique (up to normalization) Lorentz-invariant measure on the mass shell, and using anything else makes covariance invisible. The convention Equation (99.38) is the one Chapter 100 uses, where the external-line spinors of Proposition 100.14 carry the matching normalization $\bar{u}u = 2m_e c$ and $u^\dagger u = 2E/c$; Chapter 86 is deliberately nonrelativistic and does not use it.

99.2.3 Fock space

The spectrum of Equation (99.33) is built exactly as for one oscillator: find the state annihilated by every lowering operator, then climb.

Definition 99.11 (Vacuum, Fock space, number operator)**.** The *vacuum* $|0\rangle$ is the normalized state with

$$a(\boldsymbol{k})\,|0\rangle = 0 \quad \text{for every } \boldsymbol{k}\,, \qquad \langle 0|0\rangle = 1\,. \tag{99.39}$$

The n-quantum states are $a^\dagger(\boldsymbol{k}_1)\cdots a^\dagger(\boldsymbol{k}_n)\,|0\rangle$, their closed span is the n-particle sector $\mathcal{F}_n$, and *Fock space* is the completed direct sum

$$\mathcal{F} = \bigoplus_{n=0}^{\infty} \mathcal{F}_n = \bigoplus_{n=0}^{\infty} \mathrm{Sym}^n(\mathcal{H}_1)\ , \tag{99.40}$$

with $\mathcal{H}_1$ the one-quantum space. The number operator is

$$N = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\, a^\dagger(\boldsymbol{k})a(\boldsymbol{k})\,, \tag{99.41}$$

whose eigenvalue on $\mathcal{F}_n$ is n.

This is Fock's construction [698]. Three properties make it the right state space, and each is a direct consequence of Equation (99.31).

The one-quantum states are particles. By Equation (99.35) and its momentum analogue, $a^\dagger(\boldsymbol{k})\,|0\rangle$ is a simultaneous eigenstate of H and $\boldsymbol{P}$ with eigenvalues $\hbar\omega_{\boldsymbol{k}}$ and $\hbar\boldsymbol{k}$ (measured from the vacuum values, which Section 99.2.4 disposes of), related by Equation (99.36). The space $\mathcal{H}_1$ they span carries a unitary representation of the Poincaré group, and by Proposition 99.25 below that representation is irreducible with $\hat{P}^2 = m^2c^2$ and $\hat{W}^2 = 0$ — mass m, spin 0, in the classification Wigner obtained for the group itself [849] and which Chapter 94 carries out in full. That is what entitles one to call the excitation a particle rather than a wave amplitude.

Multi-quantum states are automatically symmetric. Since $\left[a^\dagger(\boldsymbol{k}), a^\dagger(\boldsymbol{k}')\right] = 0$,

$$a^\dagger(\boldsymbol{k}_1)a^\dagger(\boldsymbol{k}_2)\,|0\rangle = a^\dagger(\boldsymbol{k}_2)a^\dagger(\boldsymbol{k}_1)\,|0\rangle\ , \tag{99.42}$$

so the two-quantum state is unchanged under exchange of its labels. The symmetrization postulate of Chapter 83 is therefore not a postulate here but a consequence of the choice of commutators, and with it the Bose–Einstein counting that Chapter 120 builds the statistical mechanics of photons and phonons on. The point deserves emphasis: identical particles are identical in this formalism because they are not particles at all but quanta of one field, and there is nothing to label. What the label $\boldsymbol{k}$ names is a mode, not an individual.

The construction is exhaustive and stable. Every state of the free theory is reached from $|0\rangle$ by creation operators, because Equation (99.33) is a sum of commuting oscillator Hamiltonians each of which has the familiar nondegenerate ladder spectrum; and $[N, H] = 0$ by Equations (99.31) and (99.33), so the number of quanta of a free field is conserved. It is exactly the addition of an interaction term to H — something cubic or quartic in ϕ, hence not commuting with N — that lets the number change, which is what Section 99.1.1 demanded and what Chapter 100 exploits.

Proposition 99.12 (Normalization of the n-quantum states)**.** *With* $|\boldsymbol{k}_1\ldots\boldsymbol{k}_n\rangle = \prod_i \sqrt{2\omega_{\boldsymbol{k}_i}}\, a^\dagger(\boldsymbol{k}_i)\,|0\rangle$,

$$\langle \boldsymbol{k}_1\ldots\boldsymbol{k}_n|\boldsymbol{k}'_1\ldots\boldsymbol{k}'_n\rangle = \sum_{\sigma\in S_n}\prod_{i=1}^{n} 2\omega_{\boldsymbol{k}_i}(2\pi)^3\delta^3\!\left(\boldsymbol{k}_i - \boldsymbol{k}'_{\sigma(i)}\right)\ , \tag{99.43}$$

and the resolution of the identity on $\mathcal{F}$ is

$$\mathbb{1} = |0\rangle\langle 0| + \sum_{n\geq 1} \frac{1}{n!} \int \prod_{i=1}^{n} \frac{\mathrm{d}^3 k_i}{(2\pi)^3 2\omega_{\boldsymbol{k}_i}} \; |\boldsymbol{k}_1 \dots \boldsymbol{k}_n\rangle\langle \boldsymbol{k}_1 \dots \boldsymbol{k}_n| \; . \tag{99.44}$$

Rests on Equations (99.31) *and* (99.38).

Proof. *Derives Proposition 99.12.*

Move every annihilation operator of the bra to the right through the creation operators of the ket using Equation (99.31). Each annihilator must be contracted with exactly one creator, since any uncontracted annihilator meets $|0\rangle$ and gives zero; the sum over which creator it meets is the sum over permutations, and each contraction supplies one factor $(2\pi)^3\delta^3$, while the normalization factors supply 2ω. Equation (99.44) follows because the $1/n!$ compensates the $n!$ permutations in Equation (99.43) when the identity is applied to a symmetric state. □

Remark 99.13 (Fock space is a choice, not a deduction). Definition 99.11 presupposes that a state annihilated by every $a(\boldsymbol{k})$ exists and is unique. For the free field it does. For an interacting field it is exactly what Haag's theorem (Section 99.9.1) denies: the interacting theory's vacuum is not in the free theory's Fock space, and the two representations of Equation (99.23) are unitarily inequivalent. Nothing in this section is wrong, but its scope is the free field, and the reader should not carry the picture of "the" Fock space into the interacting theory without the warning of Section 99.9.1.

99.2.4 Normal ordering and the vacuum energy

Equation (99.33) was left in symmetric form on purpose. Using Equation (99.31) to move the annihilator to the right,

$$H = \int \frac{\mathrm{d}^3 k}{(2\pi)^3}\, \hbar\omega_{\boldsymbol{k}} \left[a^\dagger(\boldsymbol{k}) a(\boldsymbol{k}) + \frac{1}{2}(2\pi)^3\delta^3(\boldsymbol{0}) \right] , \tag{99.45}$$

and $(2\pi)^3\delta^3(\boldsymbol{0}) = \int \mathrm{d}^3 x = V$ is the volume of space. The vacuum energy is therefore $E_0 = V\varrho_0$ with energy density

$$\varrho_0 = \int \frac{\mathrm{d}^3 k}{(2\pi)^3} \frac{\hbar\omega_{\boldsymbol{k}}}{2} = \frac{\hbar c}{4\pi^2} \int_0^\infty \mathrm{d}k \; k^2 \sqrt{k^2 + \kappa^2} \, , \tag{99.46}$$

which diverges as the fourth power of the upper limit: cutting the integral off at wave number $\Lambda \gg \kappa$ gives

$$\varrho_0 \approx \frac{\hbar c}{4\pi^2} \int_0^\Lambda k^3 \, \mathrm{d}k = \frac{\hbar c \Lambda^4}{16\pi^2} \, . \tag{99.47}$$

It is one half-quantum $\frac{1}{2}\hbar\omega_{\boldsymbol{k}}$ per mode — the zero-point energy of a single quantum oscillator, which Phenomenon 78.6 derives from the uncertainty relation and which is measured in the isotope shift of a band spectrum — summed over infinitely many modes.

Definition 99.14 (Normal ordering)**.** The normal-ordered product $:X:$ of a product of free-field operators is the same product with every creation operator moved to the left of every annihilation operator, the moves performed as if all the operators commuted — that is, discarding the commutators generated.

The prescription is Wick's [974], and by construction $\langle 0| :X: |0\rangle = 0$. Replacing H by

$$:H: = \int \frac{\mathrm{d}^3 k}{(2\pi)^3}\, \hbar\omega_{\boldsymbol{k}}\, a^\dagger(\boldsymbol{k}) a(\boldsymbol{k}) \tag{99.48}$$

removes Equation (99.46) and assigns the vacuum zero energy. It is essential to be honest about what this step is and is not.

What it *is*: a choice of the additive constant in the Hamiltonian. The equations of motion involve only commutators with H, and a c-number added to H commutes with everything, so no Heisenberg equation, no scattering amplitude, no energy difference and no transition rate in flat space depends on the choice. Ordering ambiguities of exactly this kind arise whenever a classical product is promoted to an operator product, and the free field is the case in which the ambiguity is a pure constant.

What it is *not*: a proof that zero-point energy is unphysical. There are two situations in which the constant is not free, and both are experimental questions rather than formal ones.

Boundary-dependent differences. If boundaries restrict which modes exist, ϱ_0 depends on the geometry, and the *difference* between two geometries is finite even though each is infinite. It is measured. That is the Casimir effect, computed and compared with experiment in Section 99.8.

Gravitational coupling. General relativity couples to the total energy–momentum tensor, not to energy differences, so the constant that Equation (99.48) discards is, in principle, gravitationally visible as a cosmological constant. Taking Equation (99.47) at face value with the cutoff at an energy $E_c = \hbar c \Lambda$ gives

$$\varrho_0 \approx \frac{E_c^4}{16\pi^2(\hbar c)^3} = \begin{cases} 1.3 \times 10^{47}\,\mathrm{J/m^3}\,, & E_c = 1\,\mathrm{TeV}\,, \\ 2.9 \times 10^{111}\,\mathrm{J/m^3}\,, & E_c = E_\mathrm{P} = 1.956 \times 10^{9}\,\mathrm{J}\,, \end{cases} \tag{99.49}$$

against an observed dark-energy density of order $1 \times 10^{-9}\,\mathrm{J/m^3}$: a discrepancy of some 56 orders of magnitude if one stops at the highest energy at which the Standard Model has been tested, and of some 120 if one runs to the Planck energy. This is the cosmological constant problem [1828]. No symmetry of the Standard Model forbids the term, no cancellation among the known fields achieves it, and the problem is stated as open in Chapter 48 and Chapter 133; nothing in this chapter solves it, and the reader should treat any text that quietly normal-orders the problem away as having changed the subject.

Remark 99.15 (What the estimate does and does not assume). Equation (99.49) is a cutoff estimate, and a sharp cutoff in $|\boldsymbol{k}|$ is not Lorentz invariant — it treats the modes as if there were a preferred frame, and a Lorentz-invariant regulator gives an energy density with the equation of state $p = -\varrho$ appropriate to a cosmological constant rather than the $p = \varrho/3$ that Equation (99.47) naively suggests. What survives the change of regulator is the *magnitude*, which is set by the fourth power of the largest energy at which the field description is assumed valid. It is the magnitude, not the tensor structure, that is 10^{56} times too large.

99.3 The complex scalar field and antiparticles

A real field describes one species of quantum, which is its own antiquantum and carries no charge. Allowing the field to be complex doubles the classical degrees of freedom, and the doubling shows up in the quantum theory as two species of quantum of equal mass and opposite charge. Antimatter is a prediction of field theory, obtained here without any reference to a filled sea.

99.3.1 Global phase symmetry and conserved charge

Let ϕ be a complex field with Lagrangian density

$$\mathcal{L} = \partial_\mu \phi^\dagger \partial^\mu \phi - \kappa^2 \phi^\dagger \phi = \frac{1}{c^2}\partial_t \phi^\dagger \partial_t \phi - \nabla\phi^\dagger \cdot \nabla\phi - \kappa^2 \phi^\dagger \phi\,, \tag{99.50}$$

with $[\phi]$ again given by Equation (99.19); the factor $\frac{1}{2}$ of Equation (99.18) is absent because ϕ and $\phi^\dagger$ are independent. Both ϕ and $\phi^\dagger$ obey $(\Box + \kappa^2)\,\phi = 0$. The conjugate momenta are

$$\pi = \frac{\partial \mathcal{L}}{\partial \dot{\phi}} = \frac{1}{c^2}\dot{\phi}^\dagger\,, \qquad \pi^\dagger = \frac{1}{c^2}\dot{\phi}\,, \tag{99.51}$$

and the canonical brackets are

$$[\phi(t,\boldsymbol{x}), \pi(t,\boldsymbol{y})] = \left[\phi^\dagger(t,\boldsymbol{x}), \pi^\dagger(t,\boldsymbol{y})\right] = \mathrm{i}\hbar\,\delta^3(\boldsymbol{x}-\boldsymbol{y})\,, \tag{99.52}$$

all others vanishing.

Equation (99.50) is invariant under the global phase rotation

$$\phi \longmapsto \mathrm{e}^{-\mathrm{i}\theta}\phi\,, \qquad \phi^\dagger \longmapsto \mathrm{e}^{\mathrm{i}\theta}\phi^\dagger\,, \qquad \theta \in \mathbb{R} \text{ constant}\,, \tag{99.53}$$

a representation of the group $\mathrm{U}(1)$ of unit-modulus complex numbers. That group is isomorphic to the rotation group $\mathrm{SO}(2,\mathbb{R})$ of Section 14.2.1 by $\mathrm{e}^{\mathrm{i}\theta} \mapsto R(\theta)$ — the section is written for $\mathrm{SO}(2,\mathbb{R})$ and does not mention $\mathrm{U}(1)$, but its representation theory transfers along the isomorphism unchanged. By Noether's theorem [456], in the field form derived in Section 99.4.1 below, the symmetry carries a conserved current.

Proposition 99.16 (The U(1) current and charge)**.** *The current*

$$j^\mu = \mathrm{i}\left(\phi^\dagger \partial^\mu \phi - \phi\,\partial^\mu \phi^\dagger\right)\,, \qquad [j^\mu] = \mathrm{J/m^2}\,, \tag{99.54}$$

satisfies $\partial_\mu j^\mu = 0$ on solutions, and the dimensionless quantity

$$Q = \frac{1}{\hbar c}\int \mathrm{d}^3x\, j^0 = \frac{\mathrm{i}}{\hbar}\int \mathrm{d}^3x\left(\phi^\dagger\pi^\dagger - \pi\phi\right) \tag{99.55}$$

is conserved. The electric charge of a field of charge quantum q is qQ.

Rests on Equations (99.50)*,* (99.51) *and* (99.53)*.*

Proof. *Derives Proposition 99.16.*

Conservation is direct: $\partial_\mu j^\mu = \mathrm{i}(\phi^\dagger\Box\phi - \phi\Box\phi^\dagger) = \mathrm{i}(-\kappa^2\phi^\dagger\phi + \kappa^2\phi\phi^\dagger) = 0$, the cross terms $\partial_\mu\phi^\dagger\partial^\mu\phi$ cancelling identically and the field equation supplying the rest. That Equation (99.54) is the Noether current of Equation (99.53) is Theorem 99.22 applied with $\delta\phi = -\mathrm{i}\phi$, $\delta\phi^\dagger = +\mathrm{i}\phi^\dagger$:

$$j^\mu = \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)}(-\mathrm{i}\phi) + \frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi^\dagger)}(\mathrm{i}\phi^\dagger) = -\mathrm{i}\phi\,\partial^\mu\phi^\dagger + \mathrm{i}\phi^\dagger\partial^\mu\phi\,.$$

For Equation (99.55), note $j^0 = \mathrm{i}(\phi^\dagger c^{-1}\partial_t\phi - (c^{-1}\partial_t\phi^\dagger)\phi) = \mathrm{i}c(\phi^\dagger\pi^\dagger - \pi\phi)$ by Equation (99.51) — the second factor written to the right of its derivative, as the Noether construction delivers it, since ϕ and π do not commute and the two orderings differ by the c-number $[\pi,\phi]$ that Equation (99.60) normal-orders away. Dividing by $\hbar c$ makes the integrand an inverse volume: $[j^0] = \mathrm{J/m^2}$ and $[\hbar c] = \mathrm{J\,m}$. Conservation of Q follows from $\partial_\mu j^\mu = 0$ by integrating over a spatial slice and discarding the surface term at infinity. □

This settles the interpretive question left open in Section 99.1.1. The density Equation (99.4) that could not be a probability density *is* Equation (99.54) up to normalization, and the reason it may take either sign is that it is a charge density. Charge densities of either sign are unremarkable; probability densities of either sign are nonsense. Nothing had to be repaired — the quantity had been misidentified. The same reading is what makes minimal coupling $\partial_\mu \to \partial_\mu + \mathrm{i}qA_\mu/\hbar$ legitimate, since $-j^\mu A_\mu$ is then the interaction energy of a charge distribution with the potential, exactly as in Theorem 100.5; a probability current has no business coupling to the electromagnetic field.

Notice also what has *not* been explained. Nothing above forces the eigenvalues of Q to be integers times one universal quantum, and nothing forces the electron and proton charges to be equal and opposite to the precision at which that is measured. The U(1) of Equation (99.53) acts on one field, and nothing fixes the phase a second field of a different charge would pick up: the symmetry actually forced is a group of real phases, whose representations are labelled by a real number. That the observed charges are integer multiples of one quantum is an experimental fact — its current status, including the fractional quark charges never seen free, is Section 63.11.3 — which the free field theory does not derive and which nothing in this chapter explains.

99.3.2 Two species of quantum: particle and antiparticle

The field is complex, so its Fourier coefficients at $\boldsymbol{k}$ and the conjugates at $-\boldsymbol{k}$ are no longer related. Two independent families of ladder operators appear.

Definition 99.17 (Mode expansion of the complex scalar)**.**

$$\phi(x) = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\sqrt{\frac{\hbar c^2}{2\omega_{\boldsymbol{k}}}}\left[a(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}k\cdot x} + b^\dagger(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}k\cdot x}\right], \tag{99.56}$$

$$\phi^\dagger(x) = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\sqrt{\frac{\hbar c^2}{2\omega_{\boldsymbol{k}}}}\left[b(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}k\cdot x} + a^\dagger(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}k\cdot x}\right], \tag{99.57}$$

with

$$\left[a(\boldsymbol{k}), a^\dagger(\boldsymbol{k}')\right] = \left[b(\boldsymbol{k}), b^\dagger(\boldsymbol{k}')\right] = (2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}'), \tag{99.58}$$

and every other commutator among $a, a^\dagger, b, b^\dagger$ vanishing.

That Equation (99.58) is equivalent to Equation (99.52) is the computation of Proposition 99.8 repeated: the $[\phi,\pi]$ bracket receives the a contribution with one sign and the b contribution with the other, and the two add rather than cancel because $\left[b^\dagger, b\right] = -\left[b, b^\dagger\right]$; the normalization $\sqrt{\hbar c^2/2\omega}$ is unchanged.

Theorem 99.18 (Energy and charge of the complex scalar)**.** *With normal ordering,*

$$:H: = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\hbar\omega_{\boldsymbol{k}}\left[a^\dagger(\boldsymbol{k})a(\boldsymbol{k}) + b^\dagger(\boldsymbol{k})b(\boldsymbol{k})\right], \tag{99.59}$$

$$:Q: = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\left[a^\dagger(\boldsymbol{k})a(\boldsymbol{k}) - b^\dagger(\boldsymbol{k})b(\boldsymbol{k})\right]. \tag{99.60}$$

The two species have identical dispersion Equation (99.28), hence identical mass, and charges $+1$ *and* -1.

Rests on Definition 99.17, Equation (99.55), and Theorem 99.9.

Proof. *Derives Theorem 99.18.*

The Hamiltonian density is $\mathcal{H} = c^2\pi^\dagger\pi + \nabla\phi^\dagger\cdot\nabla\phi + \kappa^2\phi^\dagger\phi$; substituting Equations (99.56) and (99.57) and integrating over $\boldsymbol{x}$ proceeds exactly as in Theorem 99.9, the aa and $a^\dagger a^\dagger$ pieces cancelling between the π term and the gradient-plus-mass terms, and yields $\int_{\boldsymbol{k}}\hbar\omega_{\boldsymbol{k}}(a^\dagger a + b\,b^\dagger)$, which normal-ordering turns into Equation (99.59). For the charge, insert Equation (99.51) into Equation (99.55):

$$Q = \frac{\mathrm{i}}{\hbar c^2}\int \mathrm{d}^3x\left(\phi^\dagger\dot\phi - \dot\phi^\dagger\phi\right),$$

and substitute the expansions. The spatial integral pairs each mode either with itself or with its reflection, and the terms pairing two annihilation or two creation operators — $b\,a$ carrying $\mathrm{e}^{-2\mathrm{i}\omega t}$ and $a^\dagger b^\dagger$ carrying $\mathrm{e}^{2\mathrm{i}\omega t}$ — occur in $\phi^\dagger\dot\phi$ and in $\dot\phi^\dagger\phi$ with the same coefficient

and cancel in the difference. The surviving terms occur with opposite coefficients in the two products and therefore add: $a^\dagger a$ with $-2\mathrm{i}\omega_{\boldsymbol{k}} f_{\boldsymbol{k}}^2$ and $b\,b^\dagger$ with $+2\mathrm{i}\omega_{\boldsymbol{k}} f_{\boldsymbol{k}}^2$, where $f_{\boldsymbol{k}}^2 = \hbar c^2/2\omega_{\boldsymbol{k}}$. Multiplying by the prefactor $\mathrm{i}/\hbar c^2$ turns these into $+1$ and -1, giving $Q = \int_{\boldsymbol{k}} (a^\dagger a - b\,b^\dagger)$ and Equation (99.60) after normal ordering. □

Both terms of Equation (99.59) are non-negative: the b quanta cost positive energy, not negative. The negative-energy solutions of Section 99.1.1 have not been suppressed, filled or forbidden — they have been reinterpreted. The coefficient of the "negative-frequency" exponential $\mathrm{e}^{+\mathrm{i}k\cdot x}$ in Equation (99.56) is not the amplitude to find a particle of negative energy but the operator that *creates* an antiparticle of positive energy. This is the Stueckelberg–Feynman reading [864, 931], and Section 99.6.1 shows that the same exponential is what makes a single propagator serve for both species.

Remark 99.19 (No sea, and what that costs). Compare with Section 99.1.1. Hole theory required an infinitely occupied vacuum, which is unavailable for bosons, and it predicted antiparticles only for fermions. Here the antiparticle appears for a spin-0 field, with a vacuum containing no quanta at all, and it appears for exactly the reason the hole picture could not accommodate: the field, not the particle, is fundamental, and a complex field has two kinds of excitation because it has two independent real components. That is Pauli and Weisskopf's argument [748], and it is the reason the hole theory [647] is now of historical interest only, correct predictions notwithstanding.

Two experimental anchors are worth naming precisely, since the claim being tested is not the existence of antimatter but the exact degeneracy that Theorem 99.18 asserts. The first is the positron itself: predicted, then found in cloud-chamber tracks whose curvature in a magnetic field gave a positive particle of about the electron mass [713], the subject of Chapter 95. The second is the modern programme of antiproton and antihydrogen measurements pursued in Chapter 90, which tests the equality of particle and antiparticle masses and charges directly rather than inferring it. Both belong to the wider CPT programme of Chapter 105: the degeneracy asserted here follows from CPT, so a measured violation of it would be a violation of one of the assumptions — Lorentz invariance, locality, or the positivity of the energy — on which this whole chapter rests.

99.3.3 Charge conjugation

The doubling of species comes with a discrete symmetry that exchanges them.

Definition 99.20 (Charge conjugation on the free complex scalar)**.** C is the unitary operator with

$$C\,a(\boldsymbol{k})\,C^{-1} = \eta_C\,b(\boldsymbol{k})\,, \qquad C\,b(\boldsymbol{k})\,C^{-1} = \eta_C^*\,a(\boldsymbol{k})\,, \qquad C\,|0\rangle = |0\rangle\,, \tag{99.61}$$

with $|\eta_C| = 1$ a convention-dependent phase, conventionally $\eta_C = 1$.

Proposition 99.21 (Action of C on field and current)**.** *With $\eta_C = 1$,*

$$C\,\phi(x)\,C^{-1} = \phi^\dagger(x)\,, \qquad C\,j^\mu(x)\,C^{-1} = -j^\mu(x)\,, \qquad C\,{:}Q{:}\,C^{-1} = -\,{:}Q{:}\,, \tag{99.62}$$

and $[C, H] = 0$ for the free field.

Rests on Equations (99.60) and (99.61) and Definition 99.17.

Proof. *Derives Proposition 99.21.*

Apply Equation (99.61) term by term to Equation (99.56): the coefficient of $\mathrm{e}^{-\mathrm{i}k\cdot x}$ becomes $b(\boldsymbol{k})$ and that of $\mathrm{e}^{\mathrm{i}k\cdot x}$ becomes $a^\dagger(\boldsymbol{k})$, which is Equation (99.57). Then $j^\mu = \mathrm{i}(\phi^\dagger\partial^\mu\phi - \phi\partial^\mu\phi^\dagger)$ maps to $\mathrm{i}(\phi\partial^\mu\phi^\dagger - \phi^\dagger\partial^\mu\phi) = -j^\mu$, and integrating gives the statement for Q; equivalently, Equation (99.60) is manifestly odd under $a \leftrightarrow b$. That Equation (99.59) is even under the same exchange is $[C, H] = 0$. □

For a *real* scalar field $\phi^\dagger = \phi$, so Equation (99.62) forces $C\phi C^{-1} = \pm\phi$: a real field is its own antifield, has $Q \equiv 0$, and carries an intrinsic C parity. The electromagnetic field has $C = -1$, since C reverses all charges and hence all currents and the potentials they source; a state of n photons therefore has $C = (-1)^n$, which is why the C-even neutral pion decays to two photons and not to three.

Beyond this the account must be deferred. C alone is one of three discrete operations, and the free complex scalar is too simple a system to show what is interesting about them: the weak interaction violates C and P separately and maximally (Chapter 101), the combination CP is violated too but only slightly, and the combination CPT is a theorem of any Lorentz-invariant local field theory with a bounded-below Hamiltonian [1115, 1123] — the same three hypotheses that appear in the spin–statistics theorem of Section 99.7.2. That is not an accident, and it is the subject of Chapter 105.

99.4 Noether charges and the Poincaré algebra

Two results used repeatedly above were stated as they were needed: that a continuous symmetry of the Lagrangian density gives a conserved current, and that the one-quantum states of a free field carry an irreducible representation of the Poincaré group labelled by a mass and a spin. This section proves both. They are what make the phrase "a particle of mass m and spin s" a definition rather than a description.

99.4.1 Noether's theorem in field form

Theorem 99.22 (Noether, for fields)**.** *Let $\mathcal{L}(\phi_a, \partial_\mu \phi_a)$ be a local Lagrangian density for a collection of fields ϕ_a, and let the infinitesimal transformation $\phi_a \mapsto \phi_a + \varepsilon F_a[\phi]$ change $\mathcal{L}$ by at most a total divergence, $\delta\mathcal{L} = \varepsilon\, \partial_\mu K^\mu$. Then*

$$j^\mu = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} F_a - K^\mu \tag{99.63}$$

satisfies $\partial_\mu j^\mu = 0$ on solutions of the field equations, and $Q = c^{-1}\int \mathrm{d}^3x\, j^0$ is constant in time whenever the fields fall off fast enough at spatial infinity.

Rests on Definition 99.4 and Equation (99.16).

Proof. *Derives Theorem 99.22.*

Compute $\delta\mathcal{L}$ two ways. Directly from the chain rule, with summation over a,

$$\delta\mathcal{L} = \varepsilon\left[\frac{\partial \mathcal{L}}{\partial \phi_a} F_a + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \partial_\mu F_a\right] = \varepsilon\left[\left(\frac{\partial \mathcal{L}}{\partial \phi_a} - \partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)}\right) F_a + \partial_\mu\left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} F_a\right)\right].$$

On a solution the first bracket vanishes by Equation (99.16). By hypothesis the same $\delta\mathcal{L}$ equals $\varepsilon \partial_\mu K^\mu$, so $\partial_\mu\big(\partial\mathcal{L}/\partial(\partial_\mu\phi_a)\, F_a - K^\mu\big) = 0$. Integrating $\partial_\mu j^\mu = 0$ over a spatial slice, $\partial_t \int \mathrm{d}^3x\, j^0/c = -\int \mathrm{d}^3x\, \nabla\cdot\boldsymbol{j}$, which is a surface term at infinity. □

In the quantum theory the conserved charge does more than sit there: it generates the symmetry it came from.

Proposition 99.23 (Charges generate their symmetries)**.** *For the* U(1) *charge of Equation (99.55),*

$$[Q, \phi(x)] = -\phi(x)\,, \qquad \mathrm{e}^{\mathrm{i}\theta Q}\phi(x)\,\mathrm{e}^{-\mathrm{i}\theta Q} = \mathrm{e}^{-\mathrm{i}\theta}\phi(x)\,, \tag{99.64}$$

which is Equation (99.53).

Rests on Equations (99.53), (99.58) and (99.60).

Proof. *Derives Proposition 99.23.*

From Equation (99.60) and Equation (99.58), $[:Q:, a(\boldsymbol{k})] = -a(\boldsymbol{k})$ and $\left[:Q:, b^\dagger(\boldsymbol{k})\right] = -b^\dagger(\boldsymbol{k})$; both coefficients in Equation (99.56) are therefore lowered by one unit, giving the first equation. The second follows from the identity $\mathrm{e}^{X} Y \mathrm{e}^{-X} = Y + [X,Y] + \frac{1}{2!}[X,[X,Y]] + \cdots$ with $X = \mathrm{i}\theta Q$, which here terminates into an exponential series because $[Q,\cdot]$ acts as multiplication by -1 on ϕ. □

Applying Theorem 99.22 to spacetime translations $\phi_a(x) \mapsto \phi_a(x + \varepsilon e)$, for which $\delta\mathcal{L} = \varepsilon\, e^\nu \partial_\nu \mathcal{L}$ is a total divergence with $K^\mu = e^\mu \mathcal{L}$, gives four conserved currents assembled into the canonical energy–momentum tensor

$$T^{\mu\nu} = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi_a)} \partial^\nu \phi_a - \eta^{\mu\nu}\mathcal{L}\,, \qquad \partial_\mu T^{\mu\nu} = 0\,, \qquad \hat{P}^\nu = \frac{1}{c}\int \mathrm{d}^3x\, T^{0\nu}\,, \tag{99.65}$$

of which $\hat{P}^0 = H/c$ and $\hat{P}^i = \boldsymbol{P}$ recover Equations (99.33) and (99.34): for the real scalar, $T^{00} = \mathcal{H}$ of Equation (99.21) and $T^{0i} = c^{-1}\partial_t\phi\,\partial^i\phi = -c\pi\partial_i\phi$. Lorentz transformations $\delta\phi = \frac{1}{2}\omega_{\rho\sigma}(x^\rho\partial^\sigma - x^\sigma\partial^\rho)\phi$ give six more currents,

$$\mathcal{M}^{\mu\rho\sigma} = x^\rho T^{\mu\sigma} - x^\sigma T^{\mu\rho} \quad \text{(spin 0)}\,, \qquad \hat{J}^{\rho\sigma} = \frac{1}{c}\int \mathrm{d}^3x\, \mathcal{M}^{0\rho\sigma}\,, \tag{99.66}$$

which for fields carrying spin acquire an extra term from the rotation of the field components themselves — the term whose separation from the orbital piece is the Belinfante–Rosenfeld problem [850] treated in Chapter 64.

99.4.2 The Poincaré algebra and the labels of a particle

The ten charges $\hat{P}^\mu, \hat{J}^{\rho\sigma}$ of Equations (99.65) and (99.66) are Hermitian operators on Fock space, and they close on the Poincaré algebra Equations (94.5) to (94.7) of Proposition 94.8, with an $\mathrm{i}\hbar$ in every bracket because the generators are the physical momentum and angular momentum and not the dimensionless differential operators of Section 14.3.2. That the same algebra appears here as an algebra of field integrals, and in Chapter 94 as an algebra of abstract generators, is the whole content of the phrase "the field theory is Poincaré invariant".

Proposition 99.24 (Translations act correctly on the field)**.** $\left[\hat{P}^\mu, \phi(x)\right] = -\mathrm{i}\hbar\,\partial^\mu\phi(x)$*, so that* $\mathrm{e}^{\mathrm{i}a\cdot\hat{P}/\hbar}\phi(x)\mathrm{e}^{-\mathrm{i}a\cdot\hat{P}/\hbar} = \phi(x+a)$*, and* $\left[\hat{P}^\mu, \hat{P}^\nu\right] = 0$*.*

Rests on Proposition 99.6 and Equations (99.31) and (99.34).

Proof. *Derives Proposition 99.24.*

For $\mu = 0$, where $\hat{P}^0 = H/c$, this is the Heisenberg equation $\mathrm{i}\hbar\,\partial_t\phi = [\phi, H]$ of Proposition 99.6. For the spatial components use Equation (99.34) and Equation (99.31): $[\boldsymbol{P}, a(\boldsymbol{k})] = -\hbar\boldsymbol{k}\,a(\boldsymbol{k})$ and $\left[\boldsymbol{P}, a^\dagger(\boldsymbol{k})\right] = +\hbar\boldsymbol{k}\,a^\dagger(\boldsymbol{k})$, so in Equation (99.29) each term acquires the factor that $-\mathrm{i}\hbar\nabla$ would produce on its exponential. The two components commute because both are diagonal in $\boldsymbol{k}$. □

Proposition 99.25 (The one-quantum sector is an irreducible representation)**.** *On* $\mathcal{H}_1 = \mathrm{Sym}^1(\mathcal{H}_1)$ *of the free real scalar field,*

$$\hat{P}^2 = \hat{P}_\mu\hat{P}^\mu = m^2c^2\,\mathbb{1}\,, \qquad \hat{W}^2 = \hat{W}_\mu\hat{W}^\mu = 0\,, \tag{99.67}$$

with $\hat{W}_\mu = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}\hat{J}^{\nu\rho}\hat{P}^\sigma$ *the Pauli–Lubanski vector of Definition 94.15, and the representation is irreducible: the free real scalar field describes one species of particle of mass* m *and spin* 0*.*

Rests on Proposition 99.24, Theorem 94.18, and Definition 94.15.

Proof. *Derives Proposition 99.25.*

By Proposition 99.24 the state $a^\dagger(\boldsymbol{k})\,|0\rangle$ is a simultaneous eigenstate of $\hat{P}^\mu$ with eigenvalue $\hbar k^\mu = (\hbar\omega_{\boldsymbol{k}}/c, \hbar\boldsymbol{k})$, so $\hat{P}^2$ has eigenvalue $\hbar^2k^2 = \hbar^2\kappa^2 = m^2c^2$ by Equations (99.2) and (99.28) — which is Equation (94.14), the definition of mass. For $\hat{W}^2$, evaluate in the rest frame, legitimate because $\hat{W}^2$ is a Casimir (Theorem 94.18) and therefore frame independent: there $\hat{P}^\mu = (mc, \mathbf{0})$ and $\hat{W}_i = -mc\,\hat{J}_i$, $\hat{W}_0 = 0$, so $\hat{W}^2 = -m^2c^2\hat{\boldsymbol{J}}^2$. For a scalar field $\hat{J}^{\rho\sigma}$ is purely orbital by Equation (99.66), so $\hat{\boldsymbol{J}}$ annihilates a zero-momentum one-quantum state and $\hat{W}^2 = 0$: comparing with $\hat{W}^2 = -m^2c^2\hbar^2 s(s+1)$ of Equation (94.25) gives $s = 0$. Irreducibility: the states $a^\dagger(\boldsymbol{k})\,|0\rangle$ for $\boldsymbol{k}$ on the mass shell form a single orbit of the proper orthochronous Lorentz group (Proposition 94.21), and the little group of a massive momentum is SU(2) (Proposition 94.24), acting here on a one-dimensional space, so there is no invariant subspace. □

Remark 99.26 (Why the classification matters, and where it stops). Wigner's theorem [849] makes "particle" a group-theoretic notion: a species is a unitary irreducible representation of the Poincaré group, labelled by the two invariants of Theorem 94.18, and the free fields of this chapter are devices for realizing those representations on a Fock space where quanta can be created and destroyed. The classification is complete for free particles and is silent about interacting ones: an interacting theory's asymptotic states are again irreducible representations (that is what makes scattering theory possible, Chapter 86), but a confined quark, which never appears asymptotically, is not classified by it at all (Chapter 102). The massless case is different in kind and not merely in the value of m: there $\hat{P}^2 = \hat{W}^2 = 0$ forces $\hat{W}^\mu \propto \hat{P}^\mu$, the proportionality constant is the helicity, and a massless particle of nonzero spin has two states rather than $2s+1$ (Proposition 94.32) — which is why the photon of Section 99.5.2 has two polarizations and the massive vector of Section 99.5.3 has three.

99.5 Fermions and gauge fields

The scalar field is the whole method in miniature, but it is not any field that occurs in Nature. The matter fields of the Standard Model carry spin 1/2, and the force fields carry spin 1 and a gauge redundancy. Each brings a genuinely new feature, and in both cases the new feature is forced rather than chosen.

99.5.1 The Dirac field and anticommutation

The classical Dirac field is a four-component object $\psi_a(x)$ with Lagrangian density

$$\mathcal{L} = \bar{\psi}\left(\mathrm{i}\hbar c\,\gamma^\mu\partial_\mu - mc^2\right)\psi\,, \qquad \bar{\psi} = \psi^\dagger\gamma^0\,, \tag{99.68}$$

with $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbb{1}$, $(\gamma^0)^\dagger = \gamma^0$ and $(\gamma^i)^\dagger = -\gamma^i$, exactly as constructed in Chapter 93 and used in Equation (100.5). The field carries $[\psi] = 1/\mathrm{m}^{3/2}$ (Definition 100.2), so that $\psi^\dagger\psi$ is a number density and both terms of Equation (99.68) are energy densities. The Euler–Lagrange equation is $(\mathrm{i}\hbar\gamma^\mu\partial_\mu - mc)\psi = 0$, and every component separately satisfies $(\Box + \kappa^2)\psi_a = 0$, obtained by applying $(\mathrm{i}\hbar\gamma^\nu\partial_\nu + mc)$ and using the Clifford algebra.

The conjugate momentum is peculiar. Since $\mathcal{L} \supset \mathrm{i}\hbar c\,\bar{\psi}\gamma^0 c^{-1}\partial_t\psi = \mathrm{i}\hbar\,\psi^\dagger\partial_t\psi$,

$$\pi_a = \frac{\partial\mathcal{L}}{\partial\dot{\psi}_a} = \mathrm{i}\hbar\,\psi_a^\dagger\,, \tag{99.69}$$

that is, the momentum is the field's own conjugate rather than something new: Equation (99.68) is first order in time, so ψ and $\psi^\dagger$ are not independent initial data but together

constitute the phase space. This is a constrained system in the sense of Chapter 26, and the canonical bracket that survives the constraint analysis is the one between ψ and $\psi^\dagger$ alone.

The question this subsection answers is whether that bracket should be a commutator or an anticommutator. The classical theory says nothing: the canonical procedure of Chapter 22 produces a Poisson bracket, and both promotions reduce to it as $\hbar \to 0$. Nature decides, through the requirement that the energy be bounded below.

Definition 99.27 (Mode expansion of the Dirac field)**.** Write $p^\mu = \hbar k^\mu$ and let $u_s(p), v_s(p)$, $s = 1, 2$, be the positive- and negative-frequency spinor solutions of Chapter 93, normalized as in Proposition 100.14 by

$$\bar u_s(p) u_{s'}(p) = 2mc\,\delta_{ss'}\,, \qquad u_s^\dagger(p) u_{s'}(p) = \frac{2E_p}{c}\,\delta_{ss'}\,, \qquad \sum_s u_s(p)\bar u_s(p) = \gamma^\mu p_\mu + mc\,, \tag{99.70}$$

with $E_p = \hbar\omega_{\boldsymbol{k}}$. The negative-frequency spinors are *not* normalized by copying these: the Lorentz scalar changes sign while the norm, being a density, does not, so

$$\bar v_s(p) v_{s'}(p) = -2mc\,\delta_{ss'}\,, \qquad v_s^\dagger(p) v_{s'}(p) = \frac{2E_p}{c}\,\delta_{ss'}\,, \qquad \sum_s v_s(p)\bar v_s(p) = \gamma^\mu p_\mu - mc\,. \tag{99.71}$$

The two are consistent: tracing the completeness relations gives $\sum_s \bar u_s u_s = +4mc$ and $\sum_s \bar v_s v_s = -4mc$. Then

$$\psi(x) = \sum_{s=1,2} \int \frac{\mathrm{d}^3k}{(2\pi)^3} \sqrt{\frac{c}{2\hbar\omega_{\boldsymbol{k}}}} \left[b_s(\boldsymbol{k}) u_s(p)\, \mathrm{e}^{-\mathrm{i}k\cdot x} + d_s^\dagger(\boldsymbol{k}) v_s(p)\, \mathrm{e}^{\mathrm{i}k\cdot x} \right]. \tag{99.72}$$

The normalization is fixed by dimensions: $[\sqrt{c/2\hbar\omega}] = \mathrm{s}^{1/2}/\mathrm{kg}^{1/2}\,\mathrm{m}^{1/2}$ and the spinors carry the inverse of that by Equation (99.70), leaving $[\psi] = 1/\mathrm{m}^{3/2}$ once $[\mathrm{d}^3k]$ and $[b] = \mathrm{m}^{3/2}$ are counted.

Theorem 99.28 (Anticommutation is forced by positivity of the energy)**.** *Let the mode operators of Equation* (99.72) *obey either commutation or anticommutation relations of the canonical form. Then the Hamiltonian is*

$$H = \sum_s \int \frac{\mathrm{d}^3k}{(2\pi)^3}\, \hbar\omega_{\boldsymbol{k}} \left[b_s^\dagger(\boldsymbol{k}) b_s(\boldsymbol{k}) - d_s(\boldsymbol{k}) d_s^\dagger(\boldsymbol{k}) \right], \tag{99.73}$$

which is unbounded below if $\left[d_s(\boldsymbol{k}), d_{s'}^\dagger(\boldsymbol{k}') \right] = \delta_{ss'}(2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')$*, and equal to a non-negative operator plus a constant if*

$$\left\{ b_s(\boldsymbol{k}), b_{s'}^\dagger(\boldsymbol{k}') \right\} = \left\{ d_s(\boldsymbol{k}), d_{s'}^\dagger(\boldsymbol{k}') \right\} = \delta_{ss'}(2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')\,, \tag{99.74}$$

all other brackets vanishing. The corresponding equal-time relation for the field is

$$\left\{ \psi_a(t,\boldsymbol{x}), \psi_b^\dagger(t,\boldsymbol{y}) \right\} = \delta_{ab}\,\delta^3(\boldsymbol{x}-\boldsymbol{y})\,, \qquad \{\psi_a, \psi_b\} = \left\{ \psi_a^\dagger, \psi_b^\dagger \right\} = 0\,. \tag{99.75}$$

Rests on Equations (99.68)*,* (99.69) *and* (99.72)*.*

Proof. *Derives Theorem 99.28.*

From Equations (99.68) and (99.69) the Hamiltonian density is $\mathcal{H} = \pi\dot\psi - \mathcal{L} = \psi^\dagger\left(-\mathrm{i}\hbar c\,\gamma^0\gamma^i\partial_i + mc^2\gamma^0\right)\psi$, and the operator in brackets acting on a solution $\mathrm{e}^{\mp\mathrm{i}k\cdot x}$ returns $\pm\hbar\omega_{\boldsymbol{k}}$ — this is just the Dirac equation solved for $\mathrm{i}\hbar\partial_t\psi$. Substituting Equation (99.72) and integrating over $\boldsymbol{x}$, the $\mathrm{e}^{\pm 2\mathrm{i}\omega t}$ cross terms vanish by $u_s^\dagger(p)v_{s'}(\tilde p) = 0$ with $\tilde p = (p^0, -\boldsymbol{p})$, and the diagonal terms are weighted by $u^\dagger u = v^\dagger v = 2E_p/c$, which cancels the $c/2\hbar\omega$ of the

normalization and leaves Equation (99.73), the minus sign on the d term coming from the sign of the eigenvalue on the negative-frequency solutions.

Now compare the two options. With commutators, $-d\,d^\dagger = -d^\dagger d - (2\pi)^3\delta^3(\mathbf{0})$, so

$$H = \sum_s \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\hbar\omega_{\boldsymbol{k}}\left[b^\dagger b - d^\dagger d\right] + \text{const}\,,$$

and $d^\dagger$ applied repeatedly lowers the energy without limit: the spectrum is unbounded below, the vacuum is not the ground state, and no state is stable. With anticommutators, $-d\,d^\dagger = +d^\dagger d - (2\pi)^3\delta^3(\mathbf{0})$ by Equation (99.74), so

$$:H: = \sum_s \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\hbar\omega_{\boldsymbol{k}}\left[b_s^\dagger(\boldsymbol{k})b_s(\boldsymbol{k}) + d_s^\dagger(\boldsymbol{k})d_s(\boldsymbol{k})\right]\,, \tag{99.76}$$

a sum of non-negative operators, since $\left\{d, d^\dagger\right\} \geq 0$ makes $d^\dagger d$ positive semi-definite. Equation (99.75) follows by substituting Equation (99.72) and using the completeness relation

$$\sum_s u_s(p)u_s^\dagger(p) + \sum_s v_s(\tilde{p})v_s^\dagger(\tilde{p}) = (\gamma^\mu p_\mu + mc)\,\gamma^0 + (\gamma^\mu \tilde{p}_\mu - mc)\,\gamma^0 = 2p^0\,\mathbb{1} = \frac{2\hbar\omega_{\boldsymbol{k}}}{c}\,\mathbb{1}\,,$$

which cancels the normalization factor and leaves $\int \mathrm{d}^3k\,(2\pi)^{-3}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{y})}\delta_{ab}$. That Equation (99.75) is the correct canonical relation is confirmed by Equation (99.69): the naive prescription $\{\psi, \pi\} = \mathrm{i}\hbar\delta^3$ with $\pi = \mathrm{i}\hbar\psi^\dagger$ gives exactly $\left\{\psi, \psi^\dagger\right\} = \delta^3$, without any $\hbar$ surviving — the field is dimensionless in the appropriate sense, and the $\hbar$ has been absorbed into the constraint. □

The choice is therefore not a convention. Given Equation (99.68), commutators produce a theory with no ground state, which is not a theory of anything; anticommutators produce a positive Hamiltonian. This is one half of the spin–statistics connection; the other half — that a scalar quantized with anticommutators is equally impossible, for a different reason — is Section 99.7.2.

Phenomenon 99.29 (The Pauli exclusion principle)**.** No two quanta of a Dirac field occupy the same mode: a state containing two electrons of identical momentum and spin does not exist. The consequences are the periodic table (Chapter 88) and the degeneracy pressure that supports white dwarfs and neutron stars (Chapter 49).

Rests on Theorem 99.28 and Equation (99.74)*.*

Derivation. Derives Phenomenon 99.29.

Setting $s = s'$ and $\boldsymbol{k}' = \boldsymbol{k}$ in the second family of Equation (99.74) gives $\left\{b_s^\dagger(\boldsymbol{k}), b_s^\dagger(\boldsymbol{k})\right\} = 2\left(b_s^\dagger(\boldsymbol{k})\right)^2 = 0$, so

$$\left(b_s^\dagger(\boldsymbol{k})\right)^2 = 0 \tag{99.77}$$

identically as an operator. Any state containing two quanta in the same mode would be $b_s^\dagger(\boldsymbol{k})b_s^\dagger(\boldsymbol{k})\,|\cdots\rangle$, which is the zero vector, not a state. Equivalently, the number operator for one mode, $n = b^\dagger b$, satisfies $n^2 = b^\dagger b b^\dagger b = b^\dagger(1 - b^\dagger b)b = n$ by Equations (99.74) and (99.77), so its eigenvalues satisfy $n^2 = n$ and are 0 or 1. The antisymmetry of the multi-quantum wave function follows from the same relation with distinct labels: $b_s^\dagger(\boldsymbol{k})b_{s'}^\dagger(\boldsymbol{k}')\,|0\rangle = -b_{s'}^\dagger(\boldsymbol{k}')b_s^\dagger(\boldsymbol{k})\,|0\rangle$. □

Phenomenon 99.29 is worth pausing on. In Chapter 83 the antisymmetry of the fermionic wave function is a postulate, added to quantum mechanics because it is observed. Here it is a theorem, following from Equation (99.74), which in turn follows from requiring the energy to be bounded below. Nothing was assumed about identical particles at all — there are no particles in Equation (99.68), only a field, and the quanta are identical because they are excitations of one field.

Remark 99.30 (The Dirac sea is not needed and is not used). Equation (99.76) contains two non-negative terms and a vacuum defined by $b_s(\boldsymbol{k})\,|0\rangle = d_s(\boldsymbol{k})\,|0\rangle = 0$: no level is occupied, and the positron is a d quantum, not a hole. The hole picture of Section 99.1.1 survives only as a mnemonic. It is not merely superfluous: the constant discarded in passing from Equation (99.73) to Equation (99.76) is $-\sum_s \int_{\boldsymbol{k}} \hbar\omega_{\boldsymbol{k}}(2\pi)^3\delta^3(\boldsymbol{0})$, negative where the bosonic zero-point energy Equation (99.46) was positive, so a fermion field's vacuum energy has the opposite sign to a boson's. That sign is a genuine structural fact — it is what makes the cancellation of Equation (99.49) conceivable in principle — and it is invisible in the sea picture, where the negative energy is attributed to occupied states.

99.5.2 The electromagnetic field and gauge redundancy

The electromagnetic field is the first case in which the canonical procedure does not simply run. The Lagrangian density is

$$\mathcal{L} = -\frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu} = \frac{\varepsilon_0}{2}\boldsymbol{E}^2 - \frac{1}{2\mu_0}\boldsymbol{B}^2\,, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu\,, \tag{99.78}$$

with $[A^\mu] = \mathrm{V\,s/m}$ and $[F_{\mu\nu}] = \mathrm{T}$ as in Definition 100.2, and $\boldsymbol{E} = -\nabla A^0 c - \partial_t \boldsymbol{A}$, $\boldsymbol{B} = \nabla\times\boldsymbol{A}$ in terms of $A^\mu = (A^0, \boldsymbol{A})$. The conjugate momenta are

$$\pi^i = \frac{\partial\mathcal{L}}{\partial\dot{A}_i} = +\varepsilon_0 E^i\,, \qquad \pi^0 = \frac{\partial\mathcal{L}}{\partial\dot{A}_0} = 0\,. \tag{99.79}$$

The sign is the index placement and nothing else: differentiating Equation (99.78) with respect to $\dot{A}^i$, the contravariant component appearing in $\boldsymbol{E}$, gives $-\varepsilon_0 E^i$, and $A_i = -A^i$ then flips it. Both indices are read the same way in every commutator below, so that $\boldsymbol{E}$ appears there through its covariant components $E_i = -E^i$.

The vanishing of π^0 is not an accident of a bad variable choice and cannot be repaired by one. $F_{\mu\nu}$ is antisymmetric, so $\dot{A}_0$ appears nowhere in Equation (99.78), and $\pi^0 = 0$ holds identically rather than dynamically: it is a *primary constraint*, the prototype of the structures analysed by Dirac's algorithm in Chapter 26 and the difficulty Heisenberg and Pauli met first [626, 656]. Consistency, $\partial_t\pi^0 = 0$, then generates the secondary constraint $\nabla\cdot\boldsymbol{\pi} = 0$, that is Gauss's law $\nabla\cdot\boldsymbol{E} = 0$ in vacuum. The canonical commutator $[A_0, \pi^0] = \mathrm{i}\hbar\delta^3$ is inconsistent with $\pi^0 = 0$, so Postulate 99.5 cannot be imposed on all four components. The underlying reason is gauge invariance: A_μ and $A_\mu + \partial_\mu\Lambda$ describe the same $F_{\mu\nu}$ and the same physics, so A_μ carries more components than there are degrees of freedom, and the extra ones have no dynamics to quantize.

Two treatments are standard, and they differ in which of covariance and positivity is given up first.

Coulomb gauge. Impose $\nabla\cdot\boldsymbol{A} = 0$. Gauss's law then makes A^0 obey $\nabla^2 A^0 = 0$ in vacuum, so $A^0 = 0$ with sensible boundary conditions: no dynamics, and two independent components of $\boldsymbol{A}$ remain. This is what Born, Heisenberg and Jordan did in 1926 and what Dirac [572] systematized. The expansion is

$$\boldsymbol{A}(x) = \sum_{\lambda=1,2}\int \frac{\mathrm{d}^3k}{(2\pi)^3}\sqrt{\frac{\hbar\mu_0 c^2}{2\omega_{\boldsymbol{k}}}}\left[\boldsymbol{\varepsilon}_\lambda(\boldsymbol{k})a_\lambda(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}k\cdot x} + \mathrm{h.c.}\right], \qquad \omega_{\boldsymbol{k}} = c\,|\boldsymbol{k}|\,, \tag{99.80}$$

with $\boldsymbol{\varepsilon}_\lambda\cdot\boldsymbol{k} = 0$ enforcing the gauge condition, $\left[a_\lambda(\boldsymbol{k}), a^\dagger_{\lambda'}(\boldsymbol{k}')\right] = \delta_{\lambda\lambda'}(2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')$, and the factor μ_0 making the dimensions come out: $[\sqrt{\hbar\mu_0 c^2/2\omega}] = \mathrm{V\,s\,m^{1/2}}$, which with $[\mathrm{d}^3k]$ and $[a]$ gives $\mathrm{V\,s/m}$. The price is that the gauge condition is not Lorentz invariant, and that the equal-time commutator is modified: since $\nabla\cdot\boldsymbol{A} = 0$ holds as an operator equation, $[A_i, \pi_j]$

cannot be proportional to $\delta_{ij}\delta^3$, whose divergence does not vanish. The correct relation is

$$[A_i(t,\boldsymbol{x}),E_j(t,\boldsymbol{y})] = -\frac{\mathrm{i}\hbar}{\varepsilon_0}\,\delta^{\mathrm{T}}_{ij}(\boldsymbol{x}-\boldsymbol{y})\,, \qquad \delta^{\mathrm{T}}_{ij}(\boldsymbol{r}) = \delta_{ij}\delta^3(\boldsymbol{r}) + \partial_i\partial_j\frac{1}{4\pi\,|\boldsymbol{r}|}\,, \tag{99.81}$$

the transverse delta, which is the projector onto divergence-free vector fields and satisfies $\partial_i\delta^{\mathrm{T}}_{ij}=0$. Its long-range second term is the Coulomb interaction in disguise: in this gauge the instantaneous Coulomb field is not a dynamical variable but part of the constraint, which is why the gauge is convenient for bound states and awkward for scattering.

Derivation. *Derives Equation (99.81).*

Only the transverse part of $\boldsymbol{A}$ is a dynamical variable, so the canonical bracket can only be the transverse part of $\mathrm{i}\hbar\,\delta_{ij}\delta^3$; the whole content of Equation (99.81) is which distribution that is. Work in momentum space, writing $\delta^{\mathrm{T}}_{ij}(\boldsymbol{r}) = \int \mathrm{d}^3k\,(2\pi)^{-3}\,\widetilde{\delta}^{\mathrm{T}}_{ij}(\boldsymbol{k})\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}$. The gauge condition $\nabla\cdot\boldsymbol{A}=0$ is $\boldsymbol{k}\cdot\widetilde{\boldsymbol{A}}=0$, so $\widetilde{\delta}^{\mathrm{T}}_{ij}$ must annihilate every longitudinal vector and act as the identity on every transverse one. A symmetric tensor built from δ_{ij} and $\boldsymbol{k}$ with those two properties is unique:

$$\widetilde{\delta}^{\mathrm{T}}_{ij}(\boldsymbol{k}) = \delta_{ij} - \frac{k_ik_j}{\boldsymbol{k}^2}\,, \tag{99.82}$$

which indeed obeys $k_i\widetilde{\delta}^{\mathrm{T}}_{ij}=0$ and $\widetilde{\delta}^{\mathrm{T}}_{ik}\widetilde{\delta}^{\mathrm{T}}_{kj}=\widetilde{\delta}^{\mathrm{T}}_{ij}$, and whose trace is 2: the two transverse polarizations of Equation (99.80).

Now transform back term by term. The δ_{ij} gives $\delta_{ij}\delta^3(\boldsymbol{r})$. For the second term use $\int \mathrm{d}^3k\,(2\pi)^{-3}\boldsymbol{k}^{-2}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} = 1/(4\pi\,|\boldsymbol{r}|)$, which is the Coulomb Green function, together with the fact that $\partial_i\partial_j$ acting on $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}$ brings down $(\mathrm{i}k_i)(\mathrm{i}k_j)=-k_ik_j$. Hence $-k_ik_j/\boldsymbol{k}^2$ transforms to $+\partial_i\partial_j(4\pi\,|\boldsymbol{r}|)^{-1}$, and the sign in Equation (99.81) is a plus.

The position-space statement confirms it independently: $\partial_i\delta^{\mathrm{T}}_{ij} = \partial_j\delta^3(\boldsymbol{r}) + \partial_j\nabla^2(4\pi\,|\boldsymbol{r}|)^{-1} = \partial_j\delta^3(\boldsymbol{r}) - \partial_j\delta^3(\boldsymbol{r}) = 0$, whereas a minus sign would leave $2\partial_j\delta^3(\boldsymbol{r})$. Carrying out the derivatives gives the explicit form $\delta^{\mathrm{T}}_{ij}(\boldsymbol{r}) = \frac{2}{3}\delta_{ij}\delta^3(\boldsymbol{r}) + (3\hat r_i\hat r_j-\delta_{ij})/(4\pi r^3)$, whose second piece has the angular structure of a point dipole's field. Finally, the prefactor: the canonical relation is $\left[A_i,\pi^j\right] = \mathrm{i}\hbar\,\delta^{\mathrm{T}}_{ij}$ with $\pi^j=\varepsilon_0E^j$ by Equation (99.79), and $E_j=-E^j$ supplies the minus sign shown. □

Covariant (Gupta–Bleuler) quantization. Add to Equation (99.78) the gauge-fixing term $-(2\mu_0\xi)^{-1}(\partial_\mu A^\mu)^2$, which makes $\dot A_0$ appear and removes the constraint by hand (Equation (100.16)). All four polarizations are then quantized covariantly, at the cost that the timelike one has the wrong sign:

$$\left[a_\lambda(\boldsymbol{k}),a^\dagger_{\lambda'}(\boldsymbol{k}')\right] = -\eta_{\lambda\lambda'}(2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')\,, \tag{99.83}$$

so that $\langle 0|\,a_0a_0^\dagger\,|0\rangle<0$ and the state space has an indefinite metric — there are states of negative norm, which cannot be probabilities.

Derivation pending #131

The indefinite-metric mode algebra of covariant quantization, displayed just above: that the gauge-fixing term makes all four components of the potential dynamical, that the covariant equal-time bracket $[A_\mu,\pi^\nu]$ then delivers $-\eta_{\lambda\lambda'}$ where the Coulomb-gauge algebra has $\delta_{\lambda\lambda'}$, and hence that the timelike mode has negative norm. It needs a basis of four polarization vectors orthonormal in the Minkowski metric, which this chapter does not set up, so it belongs in the long-proof appendix.

Gupta and Bleuler [953, 958] showed that the theory is nevertheless consistent if the physical states are restricted by the subsidiary condition

$$(\partial_\mu A^\mu)^{(+)}\,|\mathrm{phys}\rangle = 0\,, \tag{99.84}$$

the superscript denoting the positive-frequency (annihilation) part. On the subspace so defined the norm is non-negative, the timelike and longitudinal quanta enter only in combinations of zero norm, and their contributions to every observable cancel, leaving the two transverse polarizations of Equation (99.80).

Derivation pending #132

Consistency of the Gupta–Bleuler subsidiary condition displayed just above: that the subspace it selects carries a non-negative norm, that timelike and longitudinal quanta occur in it only in zero-norm combinations, and that those combinations contribute nothing to any observable, so that the counting reduces to the two transverse polarizations. It runs through the mode decomposition of the gauge-fixed field and belongs in the long-proof appendix, next to the indefinite-metric algebra above.

The gauge parameter ξ survives in the propagator (Equation (100.17)) and must cancel from every observable, a requirement that is one of the strongest internal checks on a QED calculation (Chapter 100).

That the photon has two states and not three is not a choice of gauge: it is Remark 99.26. A massless particle is classified by helicity, and the two helicities ± 1 are the whole content of the representation; the third polarization of a massive spin-1 particle has nowhere to go as $m \to 0$. Gauge redundancy is the field-theoretic expression of that representation-theoretic fact, and this is the sense in which the difficulty of the constraints is not a technical nuisance but a consequence of masslessness.

What has been suppressed here, and belongs to Chapter 122, is the phenomenology of the photon number operator: the coherent states that are eigenstates of a_λ and approximate a classical wave, the photon-counting statistics that distinguish them from thermal and number states, and the experiments that measure those statistics directly.

99.5.3 Massive vector fields and the general spin case

Adding a mass term to Equation (99.78) gives Proca's theory [785],

$$\mathcal{L} = -\frac{1}{4\mu_0} F_{\mu\nu}F^{\mu\nu} + \frac{\kappa^2}{2\mu_0} A_\mu A^\mu , \qquad \kappa = \frac{m_V c}{\hbar} , \tag{99.85}$$

whose field equation is $\partial_\mu F^{\mu\nu} + \kappa^2 A^\nu = 0$. The mass term breaks gauge invariance, and the constraint structure changes character.

Proposition 99.31 (Three polarizations, and no gauge freedom)**.** *For $\kappa \neq 0$ the Proca field satisfies $\partial_\mu A^\mu = 0$ as a consequence of its equation of motion, not as a gauge choice; each component then obeys $(\Box + \kappa^2)A^\nu = 0$, and the physical polarizations number three.*

Rests on Equation (99.85) and Proposition 94.24.

Proof. *Derives Proposition 99.31.*

Take ∂_ν of the field equation. The first term vanishes identically, $\partial_\nu\partial_\mu F^{\mu\nu} = 0$, being a symmetric derivative contracted with an antisymmetric tensor, so $\kappa^2 \partial_\nu A^\nu = 0$, and for $\kappa \neq 0$ this forces $\partial_\nu A^\nu = 0$. Substituting back, $\partial_\mu(\partial^\mu A^\nu - \partial^\nu A^\mu) = \Box A^\nu$, so $(\Box + \kappa^2)A^\nu = 0$. Four components subject to one covariant condition leave three; equivalently, the little group of a massive momentum is SU(2) (Proposition 94.24) and the spin-1 representation is three-dimensional. □

Since there is no gauge freedom, $\pi^0 = 0$ is still a constraint but it now *determines* A^0 in terms of the other variables rather than generating a redundancy, and the canonical quantization of the three remaining polarizations proceeds as for three scalars. The consequence

that matters downstream is the propagator. Inverting the quadratic form of Equation (99.85) in the same way as Proposition 100.8 does for the photon gives

$$\widetilde{D}^{\mu\nu}(k) \propto \frac{-\eta^{\mu\nu} + k^{\mu}k^{\nu}/\kappa^{2}}{k^{2} - \kappa^{2} + \mathrm{i}\epsilon}\,, \tag{99.86}$$

and the numerator's second term does not fall off at large k: the propagator tends to a constant $\propto k^{\mu}k^{\nu}/(\kappa^{2}k^{2})$ rather than to zero. In a theory in which massive vector bosons are exchanged between currents that are not conserved, amplitudes then grow with energy without limit, violating the unitarity bound at a calculable scale. That growth is the argument — not an aesthetic preference for symmetry — that forces the weak interaction to be a spontaneously broken gauge theory rather than a Proca theory with arbitrary couplings, and it is carried out quantitatively in Chapter 101.

For spin greater than 1 the pattern continues and worsens. A free field of spin s can be constructed as a symmetric traceless tensor subject to auxiliary conditions, and Fierz and Pauli [834] showed that the conditions can be imposed consistently for the free field; but coupling such a field to an external electromagnetic field generically destroys the constraint algebra, producing either fewer propagating modes than the spin requires or propagation faster than light. The observed spectrum contains no elementary particle of spin greater than 1 — the hadronic resonances of higher spin are composite — and the obstructions are summarized in Chapter 97.

99.6 Propagators

A propagator is the vacuum expectation value of a time-ordered product of two fields. It is the object that perturbation theory is built from, it is a Green function of the classical field equation, and the particular Green function it is — which of the possible contours — is fixed by the requirement that positive frequencies propagate forward in time and negative frequencies backward. This section derives it, and derives it by contour integration, using the residue calculus of Section 8.7 rather than rebuilding it.

99.6.1 Time ordering and the Feynman propagator

Definition 99.32 (Time ordering and the two-point functions)**.** For bosonic fields,

$$T\{\phi(x)\phi(y)\} = \theta(x^{0}-y^{0})\,\phi(x)\phi(y) + \theta(y^{0}-x^{0})\,\phi(y)\phi(x)\,, \tag{99.87}$$

and the Feynman propagator, Wightman function and Pauli–Jordan function of the free real scalar are

$$D_{F}(x-y) = \langle 0|\,T\{\phi(x)\phi(y)\}\,|0\rangle\,, \tag{99.88}$$

$$D^{+}(x-y) = \langle 0|\,\phi(x)\phi(y)\,|0\rangle\,, \tag{99.89}$$

$$\Delta(x-y) = \frac{1}{\mathrm{i}\hbar}\,\langle 0|\,[\phi(x),\phi(y)]\,|0\rangle\,. \tag{99.90}$$

Lemma 99.33 (The Wightman function)**.**

$$D^{+}(x-y) = \int \frac{\mathrm{d}^{3}k}{(2\pi)^{3}}\,\frac{\hbar c^{2}}{2\omega_{\boldsymbol{k}}}\,\mathrm{e}^{-\mathrm{i}k\cdot(x-y)} = \hbar c\int \frac{\mathrm{d}^{4}k}{(2\pi)^{3}}\,\delta\!\left(k^{2}-\kappa^{2}\right)\theta(k^{0})\,\mathrm{e}^{-\mathrm{i}k\cdot(x-y)}\,, \tag{99.91}$$

of SI dimension $\mathrm{J/m}$*; it solves* $(\Box+\kappa^{2})\,D^{+}=0$ *and is manifestly Lorentz invariant.*
Rests on Equations (99.29)*,* (99.31) *and* (99.37)*.*

Proof. *Derives Lemma 99.33.*

Substitute Equation (99.29) twice. Of the four terms only $a(\boldsymbol{k})a^\dagger(\boldsymbol{k}')$ survives between vacua, because $a\,|0\rangle = 0 = \langle 0|\,a^\dagger$; using $\langle 0|\,a(\boldsymbol{k})a^\dagger(\boldsymbol{k}')\,|0\rangle = (2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')$ from Equation (99.31) collapses the double integral to the first form. The second form is Equation (99.37). Both exponents lie on the mass shell, so $(\Box+\kappa^2)$ annihilates the integrand: $\Box \mathrm{e}^{-\mathrm{i}k\cdot x} = -k^2\mathrm{e}^{-\mathrm{i}k\cdot x}$ and $k^2=\kappa^2$ on the support of the delta. The dimension is $[\hbar c^2/\omega]1/\mathrm{m}^3 = \mathrm{J\,m^2}\cdot 1/\mathrm{m}^3$. □

Theorem 99.34 (The Feynman propagator is a Green function)**.**

$$\left(\Box+\kappa^2\right) D_F(x-y) = -\mathrm{i}\hbar c\,\delta^4(x-y)\,, \tag{99.92}$$

where $\delta^4(x)=\delta(x^0)\delta^3(\boldsymbol{x})$ carries $1/\mathrm{m}^4$; both sides carry $\mathrm{J/m^3}$.
Rests on Equations (99.23), (99.24) and (99.87).

Proof. *Derives Theorem 99.34.*

Differentiate Equation (99.87) with respect to $t=x^0/c$, using $\partial_t\theta(x^0-y^0)=\delta(t_x-t_y)$:

$$\partial_t D_F = \delta(t_x-t_y)\,\langle 0|\,[\phi(x),\phi(y)]\,|0\rangle + \theta\,\langle 0|\,\partial_t\phi(x)\phi(y)\,|0\rangle + \theta\,\langle 0|\,\phi(y)\partial_t\phi(x)\,|0\rangle\,,$$

and the first term vanishes by Equation (99.24). Differentiating again, the delta now multiplies the equal-time commutator of $\partial_t\phi = c^2\pi$ with ϕ:

$$\partial_t^2 D_F = \delta(t_x-t_y)\,c^2\,\langle 0|\,[\pi(x),\phi(y)]\,|0\rangle + (\theta\text{-terms}) = -\mathrm{i}\hbar c^2\,\delta(t_x-t_y)\delta^3(\boldsymbol{x}-\boldsymbol{y}) + (\theta\text{-terms})\,,$$

using Equation (99.23). The θ-terms are the time-ordered product of $\partial_t^2\phi$ with ϕ, and the spatial and mass parts of $(\Box+\kappa^2)$ pass through the θ functions untouched, so

$$\left(\Box+\kappa^2\right) D_F = -\mathrm{i}\hbar\,\delta(t_x-t_y)\delta^3(\boldsymbol{x}-\boldsymbol{y}) + \langle 0|\,T\left\{\left(\Box+\kappa^2\right)\phi(x)\,\phi(y)\right\}|0\rangle\,,$$

whose second term vanishes by the field equation. Finally $\delta(t_x-t_y)=c\,\delta(x^0-y^0)$, giving Equation (99.92). □

Theorem 99.35 (Momentum-space form and the Feynman contour)**.**

$$D_F(x-y) = \int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\frac{\mathrm{i}\hbar c}{k^2-\kappa^2+\mathrm{i}\epsilon}\,\mathrm{e}^{-\mathrm{i}k\cdot(x-y)}\,, \tag{99.93}$$

with $\epsilon\to 0^+$, and this — and no other choice of contour — reproduces Equation (99.88). In terms of four-momenta $p=\hbar k$ with the measure $\mathrm{d}^4p/(2\pi\hbar)^4$ the same statement reads

$$\widetilde{D}_F(p) = \frac{\mathrm{i}\hbar^3 c}{p^2-m^2c^2+\mathrm{i}\epsilon}\,, \qquad [\widetilde{D}_F] = \mathrm{J\,m^3}\,. \tag{99.94}$$

Rests on Equations (99.88), (99.91) and (99.92).

Proof. *Derives Theorem 99.35.*

That Equation (99.93) solves Equation (99.92) is immediate: $\Box\to -k^2$ turns the integrand into $\mathrm{i}\hbar c(\kappa^2-k^2)/(k^2-\kappa^2) = -\mathrm{i}\hbar c$, whose Fourier transform is $-\mathrm{i}\hbar c\,\delta^4(x-y)$. The content of the theorem is that the $\mathrm{i}\epsilon$ is the right prescription, and that is decided by doing the k^0 integral.

Write $k^2-\kappa^2 = (k^0)^2 - \boldsymbol{k}^2 - \kappa^2 = (k^0)^2 - (\omega_{\boldsymbol{k}}/c)^2$ by Equation (99.28). The $\mathrm{i}\epsilon$ displaces the two poles of the integrand off the real k^0 axis:

$$(k^0)^2 - \frac{\omega_{\boldsymbol{k}}^2}{c^2} + \mathrm{i}\epsilon = \left(k^0 - \frac{\omega_{\boldsymbol{k}}}{c} + \mathrm{i}\epsilon'\right)\left(k^0 + \frac{\omega_{\boldsymbol{k}}}{c} - \mathrm{i}\epsilon'\right)\,, \tag{99.95}$$

with $\epsilon' = c\epsilon/2\omega_{\boldsymbol{k}} > 0$: the positive-frequency pole sits *below* the real axis and the negative-frequency pole *above* it. Since $x^0 = ct$, the exponential is $\mathrm{e}^{-\mathrm{i}k^0(x^0-y^0)}$, which decays exponentially as $\Im k^0 \to -\infty$ when $x^0 > y^0$ and as $\Im k^0 \to +\infty$ when $x^0 < y^0$. The integrand also falls as $|k^0|^{-2}$, so a large semicircle in the half plane where the exponential decays contributes nothing as its radius grows and the contour may be closed there; the residue theorem of Section 8.7 then evaluates the integral.

For $x^0 > y^0$, closing below encircles the pole at $k^0 = \omega_{\boldsymbol{k}}/c$ clockwise, contributing $-2\pi\mathrm{i}$ times the residue:

$$\int \frac{\mathrm{d}k^0}{2\pi} \frac{\mathrm{i}\hbar c\, \mathrm{e}^{-\mathrm{i}k^0(x^0-y^0)}}{(k^0 - \omega_{\boldsymbol{k}}/c)(k^0 + \omega_{\boldsymbol{k}}/c)} = \frac{-2\pi\mathrm{i}}{2\pi} \cdot \frac{\mathrm{i}\hbar c\, \mathrm{e}^{-\mathrm{i}\omega_{\boldsymbol{k}}(t_x-t_y)}}{2\omega_{\boldsymbol{k}}/c} = \frac{\hbar c^2}{2\omega_{\boldsymbol{k}}}\, \mathrm{e}^{-\mathrm{i}\omega_{\boldsymbol{k}}(t_x-t_y)}\,,$$

which, reinserted into the remaining d^3k integral, is exactly $D^+(x-y)$ of Equation (99.91). For $x^0 < y^0$, closing above encircles $k^0 = -\omega_{\boldsymbol{k}}/c$ counterclockwise and gives $(\hbar c^2/2\omega_{\boldsymbol{k}})\mathrm{e}^{+\mathrm{i}\omega_{\boldsymbol{k}}(t_x-t_y)}$, which after $\boldsymbol{k} \to -\boldsymbol{k}$ in the spatial integral is $D^+(y-x)$. Together these are Equation (99.88).

Any other placement of the poles gives a different function. Displacing both poles downward gives zero for $x^0 < y^0$ — the retarded function of Section 99.6.2 — and both upward gives the advanced one. The Feynman choice is the unique one that propagates the positive-frequency part forward and the negative-frequency part backward in time, which is the analytic statement of the Stueckelberg–Feynman reading of Section 99.3.2 [864, 930, 931]. Finally, $k = p/\hbar$ turns $k^2 - \kappa^2$ into $(p^2 - m^2c^2)/\hbar^2$ and $\mathrm{d}^4k/(2\pi)^4$ into $\mathrm{d}^4p/(2\pi\hbar)^4$, giving Equation (99.94); its dimension follows from $[\hbar^3 c] = \mathrm{J}^3\,\mathrm{s}^3\,\mathrm{m/s}$ divided by $[p^2]$. □

Equation (99.94) is the scalar member of the family whose fermionic and photonic partners are Equations (100.17) and (100.23); the $\mathrm{i}\epsilon$ there is the one fixed here, which is why Proposition 100.8 refers the prescription back to this chapter. Note that the pole is at $p^2 = m^2c^2$, the mass shell Equation (100.1): a propagator carries information about a particle precisely through the position of its pole, which is what makes the pole a definition of mass in the interacting theory (Chapter 100) and what the Källén–Lehmann representation [1003, 1048] generalizes.

Proposition 99.36 (The propagator outside the light cone)**.** *At spacelike separation, evaluated in the frame where the two points are simultaneous and a distance r apart,*

$$D_F(0,\boldsymbol{r}) = D^+(0,\boldsymbol{r}) = \frac{\hbar c\,\kappa}{4\pi^2 r}\, K_1(\kappa r) \underset{\kappa r \gg 1}{\longrightarrow} \frac{\hbar c\,\kappa}{4\pi^2 r}\sqrt{\frac{\pi}{2\kappa r}}\, \mathrm{e}^{-\kappa r}\,, \tag{99.96}$$

with K_1 the modified Bessel function of the second kind: a solution of the modified *Bessel equation $x^2y'' + xy' - (x^2+\nu^2)y = 0$, which is the Bessel equation of Section 9.8 continued to imaginary argument, and which that section does not itself treat. It is small but not zero.*

Rests on Equations (99.88) *and* (99.91)*.*

Proof. *Derives Proposition 99.36.*

At equal times Equation (99.91) reduces to $D^+ = \frac{1}{2}\hbar c \int \mathrm{d}^3k\,(2\pi)^{-3}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}(\boldsymbol{k}^2+\kappa^2)^{-1/2}$. Doing the angular integral, $\int \mathrm{d}^3k\,(2\pi)^{-3} f(|\boldsymbol{k}|)\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} = (2\pi^2 r)^{-1}\int_0^\infty \mathrm{d}k\, k \sin(kr) f(k)$, so

$$D^+(0,\boldsymbol{r}) = \frac{\hbar c}{4\pi^2 r}\int_0^\infty \mathrm{d}k\, \frac{k\sin(kr)}{\sqrt{k^2+\kappa^2}} = \frac{\hbar c\,\kappa}{4\pi^2 r}\, K_1(\kappa r)\,,$$

the last step a standard integral representation of K_1; the check $\kappa \to 0$ returns $\int_0^\infty \sin(kr)\mathrm{d}k = 1/r$ and $D^+ \to \hbar c/(4\pi^2 r^2)$, the massless Coulomb-like falloff. The asymptotic form is $K_1(z) \sim \sqrt{\pi/2z}\,\mathrm{e}^{-z}$. That $D_F = D^+$ here is because at spacelike separation the two orderings give the same answer, which is Proposition 99.44. □

The exponential in Equation (99.96) has range $\kappa^{-1} = \hbar/mc$: the reduced Compton wavelength of Equation (99.10) appears once more, now as the distance over which a virtual quantum of mass m can carry an influence. The same function, sourced by a static charge, is the Yukawa potential of Chapter 92. That D_F does not vanish outside the light cone is often reported as a violation of causality. It is not, and Section 99.7.1 explains exactly why.

99.6.2 The family of Green functions

Theorem 99.35 obtained one Green function of the Klein–Gordon operator by one choice of contour. The other choices are equally legitimate solutions of Equation (99.92) — they differ by solutions of the homogeneous equation — and each answers a different physical question. All are built from the same integrand, so the family is best displayed as one formula with four contours.

Definition 99.37 (Retarded and advanced Green functions)**.**

$$D_R(x) = \int \frac{\mathrm{d}^4k}{(2\pi)^4} \frac{\mathrm{i}\hbar c\, \mathrm{e}^{-\mathrm{i}k\cdot x}}{(k^0 + \mathrm{i}\epsilon)^2 - \boldsymbol{k}^2 - \kappa^2}\,, \tag{99.97}$$

with both poles pushed into the lower half plane, and D_A with $\mathrm{i}\epsilon \to -\mathrm{i}\epsilon$, pushing both into the upper half plane.

Closing the contour as in Theorem 99.35 shows at once that $D_R(x) = 0$ for $x^0 < 0$ (the contour closes in the upper half plane, which is now empty of poles) and $D_A(x) = 0$ for $x^0 > 0$. D_R is therefore the classical response function: it gives the field produced *after* a source acts, and it is the object behind the retarded potentials of Chapter 65, whose mathematics — the retarded and advanced Green functions of the wave operator, and the causality condition that selects the retarded one — is Chapter 10. It is *not* the object that appears in perturbation theory, because a scattering amplitude is not a response to a classical source but a matrix element of a time-ordered product, and Equation (99.87) is what the expansion of $\exp(\mathrm{i}S/\hbar)$ generates.

Proposition 99.38 (Relations among the two-point functions)**.** *With Δ of Equation (99.90),*

$$\mathrm{i}\hbar\,\Delta(x) = D^+(x) - D^+(-x)\,, \tag{99.98}$$

$$D_F(x) = \theta(x^0)D^+(x) + \theta(-x^0)D^+(-x)\,, \tag{99.99}$$

$$D_R(x) - D_A(x) = \mathrm{i}\hbar\,\Delta(x)\,, \tag{99.100}$$

and Δ is a c-number, not an operator.

Rests on Equations (99.90) and (99.91) and Definition 99.37.

Proof. *Derives Proposition 99.38.*

Equation (99.98) is the definition of the commutator written out, and Equation (99.99) is Equation (99.87) between vacua. For Equation (99.100), subtract the two contours of Definition 99.37: the difference is a closed contour encircling both poles clockwise, so it is $-2\pi\mathrm{i}$ times the sum of the residues, which is $\int \mathrm{d}^3k(2\pi)^{-3}(\hbar c^2/2\omega_{\boldsymbol{k}})(\mathrm{e}^{-\mathrm{i}k\cdot x} - \mathrm{e}^{\mathrm{i}k\cdot x}) = D^+(x) - D^+(-x)$ by Equation (99.91), and that is $\mathrm{i}\hbar\,\Delta$ by Equation (99.98). The $\hbar$ and no c is what the dimensions require: D_R, D_A and D^+ all carry J/m while $[\Delta] = 1/(\mathrm{m\,s})$, so only $\hbar\Delta$ matches. That Δ is a c-number is Proposition 99.44: the commutator of two free fields is proportional to the identity, so its vacuum expectation value determines it completely. □

The same construction applies to the other fields, with two differences.

Table 99.2: The two-point functions of the free scalar field. All are built from the same mass-shell integrand; the contour — equivalently the boundary condition — decides which. Only the first two are Green functions of $\Box+\kappa^2$; the Wightman and Pauli–Jordan functions solve the homogeneous equation.

Function	Contour in k^0	Question it answers
D_F	poles at $+\omega/c$ and $-\omega/c$ displaced into the lower and upper half plane respectively	What does a time-ordered product between vacua give? The building block of the perturbation series
D_R	both poles below the axis; vanishes for $x^0<0$	What field does a source produce afterwards? Classical radiation
D_A	both poles above the axis; vanishes for $x^0>0$	What source would have produced a given field?
D^+	positive-frequency mass shell only	What is the vacuum correlation of two field measurements, in a definite order?
Δ	both signs of frequency, no θ	Do measurements at x and y interfere? Zero outside the light cone

Proposition 99.39 (The Dirac propagator)**.** *With the fermionic time ordering* $T\{\psi(x)\bar\psi(y)\} = \theta(x^0-y^0)\psi(x)\bar\psi(y) - \theta(y^0-x^0)\bar\psi(y)\psi(x)$*, the propagator* $S_F(x-y)=\langle 0|\,T\{\psi(x)\bar\psi(y)\}\,|0\rangle$ *satisfies*

$$(\mathrm{i}\hbar\gamma^\mu\partial_\mu - mc)\,S_F(x-y) = \mathrm{i}\hbar\,\delta^4(x-y)\,, \tag{99.101}$$

whose momentum-space solution is Equation (100.23)*,*

$$\widetilde{S}_F(p) = \frac{\mathrm{i}\hbar}{\gamma^\mu p_\mu - mc + \mathrm{i}\epsilon} = \frac{\mathrm{i}\hbar\,(\gamma^\mu p_\mu + mc)}{p^2 - m^2c^2 + \mathrm{i}\epsilon}\,. \tag{99.102}$$

Rests on Equations (99.68) *and* (99.75)*.*

Proof. *Derives Proposition 99.39.*

The minus sign in the fermionic T product is not a convention but what makes the derivative of the θ functions produce an *anti*commutator: differentiating with respect to x^0,

$$\mathrm{i}\hbar\gamma^0\partial_0\left(\theta\psi\bar\psi - \theta'\bar\psi\psi\right) \supset \mathrm{i}\hbar\gamma^0\,\delta(x^0-y^0)\left\{\psi(x),\bar\psi(y)\right\} = \mathrm{i}\hbar\gamma^0\gamma^0\delta^4(x-y) = \mathrm{i}\hbar\,\delta^4(x-y)\,,$$

using $\left\{\psi_a,\bar\psi_b\right\} = \left\{\psi_a,\psi_c^\dagger\right\}\gamma^0_{cb} = \gamma^0_{ab}\delta^3(\boldsymbol{x}-\boldsymbol{y})$ from Equation (99.75) and $(\gamma^0)^2 = \mathbb{1}$. The remaining terms are the T product of the Dirac equation with $\bar\psi$ and vanish. In momentum space $\mathrm{i}\hbar\gamma^\mu\partial_\mu \to \gamma^\mu p_\mu$, and the second equality in Equation (99.102) follows from $(\gamma^\mu p_\mu + mc)(\gamma^\nu p_\nu - mc) = p^2 - m^2c^2$, itself a consequence of $\{\gamma^\mu,\gamma^\nu\} = 2\eta^{\mu\nu}$. Had the T product been defined with a plus sign, the derivative would have produced a commutator, which by Equation (99.75) is not a c-number, and no Green function would have resulted. □

The photon propagator is different again, because there is no unique answer: the field A_μ is not gauge invariant, so its two-point function depends on the gauge condition. In

Coulomb gauge it is non-covariant and contains the instantaneous Coulomb term visible in Equation (99.81); in the covariant gauges of Section 99.5.2 it is Equation (100.17), carrying the free parameter ξ. The resolution is that the gauge dependence cancels between diagrams whenever the external currents are conserved, so that every measurable quantity is gauge independent — a statement proved, along with the Ward–Takahashi identities that organize it, in Chapter 100. That such a cancellation must happen is guaranteed in advance by the fact that the physical states of Equation (99.84) are gauge invariant; that it does happen diagram by diagram is a nontrivial calculation.

99.6.3 Wick's theorem

Perturbation theory expands $\exp(\mathrm{i}S_{\mathrm{int}}/\hbar)$ and produces vacuum expectation values of time-ordered products of many fields. Wick's theorem [974] reduces every such object to propagators, and in doing so turns an operator calculation into combinatorics.

Definition 99.40 (Contraction)**.** Split the free field into its annihilation and creation parts, $\phi = \phi^+ + \phi^-$, where ϕ^+ collects the $a(\boldsymbol{k})$ terms of Equation (99.29) and ϕ^- the $a^\dagger(\boldsymbol{k})$ terms. The *contraction* of two fields is the c-number

$$\overline{\phi(x)\phi(y)} := T\{\phi(x)\phi(y)\} - :\phi(x)\phi(y): = D_F(x-y)\,. \tag{99.103}$$

That the contraction is the Feynman propagator is the two-field case of the theorem and is worth doing explicitly. For $x^0 > y^0$,

$$T\{\phi(x)\phi(y)\} = \phi(x)\phi(y) =: \phi(x)\phi(y): + \left[\phi^+(x), \phi^-(y)\right] ,$$

since normal ordering differs from the plain product only by the one commutator generated in moving $\phi^+(x)$ past $\phi^-(y)$; and $\left[\phi^+(x), \phi^-(y)\right] = \langle 0|\, \phi(x)\phi(y)\, |0\rangle = D^+(x-y)$, because the normal-ordered term has zero vacuum expectation value. For $y^0 > x^0$ the same with $x \leftrightarrow y$. Comparing with Equation (99.99) gives Equation (99.103).

Theorem 99.41 (Wick)**.** *For free fields,*

$$T\{\phi_1\phi_2\cdots\phi_n\} = :\phi_1\cdots\phi_n: + \sum_{\text{single contractions}} :\cdots: + \sum_{\text{double contractions}} :\cdots: + \cdots , \tag{99.104}$$

the sum running over all ways of contracting zero, one, two, … pairs, the uncontracted fields left inside the normal ordering. Consequently

$$\langle 0|\, T\{\phi_1\cdots\phi_n\}\, |0\rangle = \begin{cases} \displaystyle\sum_{\text{pairings}} \prod_{(i,j)} D_F(x_i - x_j)\,, & n \text{ even}, \\ 0\,, & n \text{ odd}, \end{cases} \tag{99.105}$$

with $(2r-1)!!$ *terms for* $n = 2r$.

Rests on Definition 99.14 and Equation (99.103).

Proof. *Derives Theorem 99.41.*

By induction on n. The case $n = 2$ is Equation (99.103). Suppose Equation (99.104) holds for $n-1$ fields and let the fields be labelled so that $x_1^0 > x_2^0 > \cdots > x_n^0$, which is no loss since both sides are symmetric under relabelling. Then $T\{\phi_1\cdots\phi_n\} = \phi_1\, T\{\phi_2\cdots\phi_n\}$, and by hypothesis the second factor is a sum of normal-ordered products of subsets of $\phi_2, \ldots, \phi_n$ times contractions. It therefore suffices to show that

$$\phi_1\, :\phi_2\cdots\phi_m: = :\phi_1\phi_2\cdots\phi_m: + \sum_{j=2}^{m} \overline{\phi_1\phi_j}\ :\phi_2\cdots\widehat{\phi_j}\cdots\phi_m: ,$$

where the hat omits a factor. Write $\phi_1 = \phi_1^+ + \phi_1^-$. The creation part ϕ_1^- is already to the left of everything and contributes the first term. The annihilation part must be moved through the creation operators inside the normal product; each such move generates one commutator $\left[\phi_1^+, \phi_j^-\right]$, and since x_1^0 is the latest time, $\left[\phi_1^+, \phi_j^-\right] = D^+(x_1 - x_j) = D_F(x_1 - x_j) = \overline{\phi_1 \phi_j}$. The commutators are c-numbers, so they factor out of the normal ordering, leaving the sum shown. Equation (99.105) follows because $\langle 0| :X: |0\rangle = 0$ unless X is empty, so only the terms in which every field is contracted survive; the number of ways of pairing $2r$ objects is $(2r-1)!!$. □

Once an interaction is switched on, Equation (99.105) *is* the Feynman rules: each contraction is an internal line carrying Equation (99.94), each interaction vertex is one factor from the expansion of $\exp(\mathrm{i}S_{\mathrm{int}}/\hbar)$, and the sum over pairings is the sum over diagrams, with the symmetry factors counting the pairings that give the same diagram. That translation is carried out in Proposition 100.14.

Proposition 99.42 (Wick's theorem for fermions and the closed-loop sign)**.** *For anticommuting fields the same expansion holds with two changes: the contraction is* $\overline{\psi(x)\bar\psi(y)} = S_F(x-y)$ *of Equation* (99.102)*, and each term carries the sign of the permutation needed to bring the contracted pairs adjacent. A closed loop of* n *fermion propagators therefore contributes an extra factor* -1*.*

Rests on Theorem 99.41 and Equation (99.102)*.*

Proof. *Derives Proposition 99.42.*

The induction of Theorem 99.41 goes through verbatim with commutators replaced by anticommutators, provided every interchange of two fermion operators is accompanied by a minus sign; that is the origin of the permutation signature. For the loop, consider n vertices joined in a cycle, so that the contractions are $\overline{\psi(x_1)\bar\psi(x_2)}, \overline{\psi(x_2)\bar\psi(x_3)}, \dots, \overline{\psi(x_n)\bar\psi(x_1)}$. Bringing each $\bar\psi(x_{i+1})$ next to its partner $\psi(x_i)$ can be done with an even number of transpositions for the first $n-1$ contractions, but the last one must move $\bar\psi(x_1)$ past all the remaining $2n-2$ operators *and* past the closing of the cycle, which is one odd permutation — a cyclic permutation of an even number of anticommuting objects. The net factor is -1, independent of n, and the resulting expression is the Dirac trace around the loop. □

The extra minus sign of Proposition 99.42 is not a bookkeeping detail. It is what makes the vacuum polarization of Chapter 100 screen rather than antiscreen the charge, and hence what makes the fine-structure constant increase with energy while the strong coupling of Chapter 102 decreases: the sign of the leading term in the beta function of Chapter 108 is decided by the competition between fermion loops carrying this -1 and gauge-boson loops which do not.

99.7 Causality and spin–statistics

Special relativity forbids influence outside the light cone. Quantum mechanics makes influence a statement about operators, not about trajectories, so the relativistic requirement has to be restated as an algebraic condition on the fields. The condition is microcausality, it is satisfied by the free fields constructed above, and — this is the remarkable part — it is satisfied only if bosons are quantized with commutators and fermions with anticommutators.

99.7.1 Microcausality

Definition 99.43 (Microcausality)**.** A field theory satisfies microcausality if every pair of local observables commutes at spacelike separation:

$$[\mathcal{O}_1(x), \mathcal{O}_2(y)] = 0 \qquad \text{whenever} \qquad (x-y)^2 < 0\,. \tag{99.106}$$

Proposition 99.44 (The free scalar commutator)**.** *For the free real scalar field,*

$$[\phi(x),\phi(y)] = \hbar c \int \frac{\mathrm{d}^4k}{(2\pi)^3}\,\delta\!\left(k^2-\kappa^2\right)\operatorname{sgn}(k^0)\,\mathrm{e}^{-\mathrm{i}k\cdot(x-y)}\;\mathbb{1}\,, \tag{99.107}$$

a c-number times the identity, Lorentz invariant, and equal to zero for every spacelike separation $(x-y)^2<0$.

Rests on Equations (99.29)*,* (99.31) *and* (99.91)*.*

Proof. *Derives Proposition 99.44.*

Substituting Equation (99.29) twice and using Equation (99.31),

$$[\phi(x),\phi(y)] = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\frac{\hbar c^2}{2\omega_{\boldsymbol{k}}}\left(\mathrm{e}^{-\mathrm{i}k\cdot(x-y)}-\mathrm{e}^{\mathrm{i}k\cdot(x-y)}\right) = D^+(x-y)-D^+(y-x)\,,$$

which is a c-number because Equation (99.31) is: the operators have cancelled. Writing each Wightman function in the covariant form of Equation (99.91) and sending $k\to -k$ in the second gives Equation (99.107), since $\theta(k^0)-\theta(-k^0)=\operatorname{sgn}(k^0)$.

Invariance: d^4k and $\delta(k^2-\kappa^2)$ are invariant under the full Lorentz group, and $\operatorname{sgn}(k^0)$ is invariant under the *orthochronous* subgroup, because a transformation that preserves the direction of time cannot move a four-vector from the forward mass hyperboloid to the backward one — the two sheets $k^0>0$ and $k^0<0$ of $k^2=\kappa^2$ are disconnected and each is preserved (Proposition 94.21).

Vanishing: take first the case of equal times, $x^0=y^0$, and write $\boldsymbol{r}=\boldsymbol{x}-\boldsymbol{y}$. Then

$$[\phi(x),\phi(y)] = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\frac{\hbar c^2}{2\omega_{\boldsymbol{k}}}\left(\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}-\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}\right) = 0\,,$$

because $\omega_{\boldsymbol{k}}$ depends only on $|\boldsymbol{k}|$, so substituting $\boldsymbol{k}\to-\boldsymbol{k}$ in the second term turns it into the first and the two cancel. Now let $(x-y)$ be any spacelike vector. There exists a proper orthochronous Lorentz transformation taking it to a purely spatial vector — that is the definition of spacelike — and the left side is invariant under such a transformation by the paragraph above. Hence it vanishes there too.

Note that the same argument fails for timelike separation, where no such transformation exists, and indeed it must fail: two timelike separated measurements can influence one another, and a formalism in which they could not would be describing nothing. □

Corollary 99.45 (No signalling)**.** *Let* $\mathcal{O}_1$ *be an observable localized in a region* R_1 *and let a projective measurement of it be performed. Then the expectation value of any observable* $\mathcal{O}_2$ *localized in a region* R_2 *spacelike to* R_1 *is unchanged.*

Rests on Equation (99.106) *and Proposition 99.44.*

Proof. *Derives Corollary 99.45.*

Let $\{P_i\}$ be the spectral projectors of $\mathcal{O}_1$; they are functions of $\mathcal{O}_1$ and hence localized in R_1, so $[P_i,\mathcal{O}_2]=0$ by Equation (99.106). A measurement whose outcome is not recorded takes the state ρ to $\sum_i P_i\rho P_i$, so

$$\operatorname{tr}\left(\sum_i P_i\rho P_i\,\mathcal{O}_2\right) = \operatorname{tr}\left(\rho\sum_i P_i\mathcal{O}_2P_i\right) = \operatorname{tr}\left(\rho\,\mathcal{O}_2\sum_i P_i\right) = \operatorname{tr}\left(\rho\,\mathcal{O}_2\right)\,,$$

using cyclicity, then $[P_i,\mathcal{O}_2]=0$, then $\sum_i P_i=\mathbb{1}$. □

Corollary 99.45 is what microcausality buys, and it is exactly the right amount. It does *not* say that spacelike separated measurements are uncorrelated — they are correlated, as Bell-type experiments show and as the Reeh–Schlieder theorem [1218] makes vivid by showing that the vacuum itself is entangled across any spacelike cut. It says that no local

operation can change what a spacelike observer will see, which is the only thing relativity requires.

This resolves the apparent paradox of Proposition 99.36. The propagator $D_F(x-y) = \langle 0|\, T\phi(x)\phi(y)\,|0\rangle$ is not zero outside the light cone; it falls only as $\mathrm{e}^{-\kappa r}$. But D_F is not an observable, and it is not a probability: it is one term in a perturbative expansion, and a matrix element of an ordered product. The observable statement is the commutator, and there the two orderings enter with opposite signs and cancel exactly outside the cone. The particle and antiparticle contributions — the two exponentials in Equation (99.107) — destructively interfere. That cancellation is another way of saying that antiparticles are not optional: a theory with a particle and no antiparticle of equal mass would have a nonvanishing spacelike commutator and would signal faster than light.

The axiomatic programme of Chapter 109 takes Equation (99.106) as one of the Wightman axioms [1099, 1297] rather than deriving it from a Lagrangian, which is the right order of business: it is the physical requirement, and the Lagrangian is only one way of meeting it.

99.7.2 The spin–statistics theorem

Two facts have now been established separately. A spin-1/2 field quantized with commutators has an energy unbounded below (Theorem 99.28). A scalar field quantized with commutators satisfies microcausality (Proposition 99.44). Pauli [854] showed that these are two instances of one theorem.

Theorem 99.46 (Spin and statistics)**.** *Let a relativistic field theory satisfy*

1. *invariance under the proper orthochronous Poincaré group;*
2. *a Hamiltonian bounded below, with a Poincaré-invariant state of lowest energy;*
3. *microcausality, Equation* (99.106)*.*

Then fields of integer spin must be quantized with commutators and fields of half-integer spin with anticommutators. Dropping either choice forces the abandonment of one of the three hypotheses.

Rests on Equation (99.106)*.*

The theorem in this generality requires the analytic continuation of the Wightman functions to complex Lorentz transformations, and belongs in the axiomatic setting where the hypotheses can be stated without reference to any Lagrangian. The axiomatic proofs are Burgoyne's [1139] and, independently, Lüders and Zumino's [1151]; both rest on the analyticity domain Jost established in his work on the CPT theorem [1115], which is a different theorem. The standard textbook account is [1297], and Chapter 109 returns to it.

Derivation pending #133

The spin–statistics theorem for arbitrary spin, by analytic continuation of the Wightman functions to the Jost points: this is a long argument and belongs in the long-proof appendix. The two cases relevant to the Standard Model — spin 0 and spin 1/2 — are proved in full in the text below.

What can be done here in full is the two cases that matter, and they already display the mechanism: each wrong choice destroys one hypothesis, and a different one in each case.

Proposition 99.47 (Half-integer spin cannot be quantized with commutators)**.** *Commutators for the Dirac field of Equation* (99.68) *contradict hypothesis (ii).*

Rests on Equation (99.68) *and Theorem 99.28.*

Proof. *Derives Proposition 99.47.*

This is Theorem 99.28: with commutators, Equation (99.73) becomes $\sum_s \int_{\boldsymbol{k}} \hbar\omega_{\boldsymbol{k}}(b^\dagger b - d^\dagger d)$ up to a constant, whose spectrum extends to $-\infty$ because $d^\dagger d$ has arbitrarily large eigenvalues. There is then no state of lowest energy, so no vacuum in the sense of hypothesis (ii). □

Proposition 99.48 (Integer spin cannot be quantized with anticommutators)**.** *Anticommutators for the real scalar field of Equation* (99.18) *contradict hypothesis (iii), and indeed destroy the theory entirely.*

Rests on Equations (99.18) *and* (99.96) *and Proposition 99.44.*

Proof. *Derives Proposition 99.48.*

Suppose $\left\{a(\boldsymbol{k}), a^\dagger(\boldsymbol{k}')\right\} = (2\pi)^3\delta^3(\boldsymbol{k}-\boldsymbol{k}')$ with all other anticommutators vanishing, and expand ϕ as in Equation (99.29). Repeating the computation of Proposition 99.44 with anticommutators in place of commutators changes one sign, giving

$$\{\phi(x), \phi(y)\} = D^+(x-y) + D^+(y-x)\,, \tag{99.108}$$

in which the two terms now *add* instead of cancelling. At spacelike separation both equal Equation (99.96), which is strictly positive, so Equation (99.108) does not vanish outside the light cone.

Worse, put $y = x$. Then $\{\phi(x), \phi(x)\} = 2\phi(x)^2$ equals the c-number $2D^+(0)$, so $\phi(x)^2$ is a multiple of the identity and

$$:\!\phi(x)^2\!: \;=\; \phi(x)^2 - \langle 0|\,\phi(x)^2\,|0\rangle = 0$$

identically. Every even local polynomial in ϕ is therefore a c-number and every odd one is linear in ϕ: the mass term in Equation (99.21) is a constant, an interaction $\lambda\phi^4$ is a constant, and the theory has no nontrivial local observable at all. The would-be anticommuting scalar is not a theory with the wrong causal structure; it is not a theory. □

Remark 99.49 (The theorem is about which hypothesis breaks). It is worth being exact about the logic, because Theorem 99.46 is often quoted as though it derived statistics from spin alone. It does not. It says that the three hypotheses are jointly incompatible with the wrong pairing. One *can* build a theory of anticommuting scalars — Faddeev–Popov ghosts are exactly that, and they appear in Chapters 102 and 106 — but such fields are not observables, do not appear as asymptotic states, and exist only to cancel unphysical polarizations inside loops. They violate the spin–statistics theorem precisely by not being subject to its hypotheses.

The theorem has consequences at every scale, and they are among the most thoroughly verified facts in physics.

Atomic structure. Exclusion applied to atomic electrons is what produces shells, the periodic table and chemistry (Chapter 88); without it every electron would occupy the $1s$ orbital and all elements would be chemically alike.

Stellar remnants. The pressure of a degenerate electron gas supports white dwarfs and that of a degenerate neutron gas supports neutron stars, with the Chandrasekhar limit following from the competition between degeneracy pressure and gravity (Chapter 49). Degeneracy pressure is Equation (99.77) expressed thermodynamically.

Direct tests. The exclusion principle is not merely assumed but bounded. Ramberg and Snow [1837] passed a large current through a thin copper strip and searched for the X-rays that would be emitted if a fresh conduction electron made a transition into an already full $1s$ shell — a transition whose energy differs from the ordinary K_α line by a calculable amount, so that the search is background-free in a narrow window. None were seen, bounding the probability of a Pauli-violating transition at $\beta^2/2 < 1.7 \times 10^{-26}$. The VIP-2 experiment

[2405] repeats the measurement in the low-background environment of an underground laboratory with a silicon drift detector of much better energy resolution, improving on that limit. A violation at any level would falsify one of the three hypotheses of Theorem 99.46, which is why the searches are worth the effort even though nobody expects a signal.

The same three hypotheses appear again in the CPT theorem [1115, 1123], and that is not a coincidence: both theorems are proved from the analyticity that Lorentz invariance plus positivity of the energy forces on the Wightman functions. The connection is drawn in Chapter 105.

99.7.3 Measurability of the field operators

Equation (99.27) said that the field at a point is not an operator and must be smeared. That is a mathematical statement. Bohr and Rosenfeld [715] asked the corresponding physical question — what can a real apparatus actually measure of a quantized electromagnetic field? — and found that the two answers agree.

Their apparatus is a charged test body of finite extent and finite mass, whose displacement under the field is read off. Such a body cannot measure $\boldsymbol{E}$ at a point: it necessarily averages over its own volume and over the time it is exposed. Nor can it be made arbitrarily small, because the momentum transfer needed to read a smaller displacement grows and the body's own radiation reacts back on the field being measured. What it measures is

$$\overline{E}_i(V,T) = \frac{1}{VT}\int_V \mathrm{d}^3x \int_T \mathrm{d}t\; E_i(t,\boldsymbol{x})\,, \tag{99.109}$$

an average over a spacetime region, which is Equation (99.27) with the test function equal to the indicator of that region.

Bohr and Rosenfeld's conclusion was that the uncertainties unavoidably introduced by such an apparatus are exactly those demanded by the commutators of the averaged field strengths, no more and no less: the formalism claims neither more measurability than an apparatus can deliver, nor less. The structural part of that conclusion is a corollary of what has already been proved here.

Corollary 99.50 (Compatible field averages)**.** *Let R_1 and R_2 be spacetime regions every point of which is spacelike separated from every point of the other. Then the field strengths averaged over them, in the sense of Equation (99.109), are compatible observables: the averages commute, $\big[\overline{E}_i(R_1),\overline{B}_j(R_2)\big]=0$, and the two averages may be measured simultaneously with no mutual disturbance.*

Rests on Equations (99.107) and (99.109) and Proposition 99.44.

Proof. *Derives Corollary 99.50.*

$\boldsymbol{E}$ and $\boldsymbol{B}$ are built from $F_{\mu\nu}$ and hence from derivatives of the free field, whose commutator is the c-number Equation (99.107) (with $\kappa=0$) differentiated. That c-number vanishes at spacelike separation by Proposition 99.44, and so do its derivatives, since a function vanishing on the whole spacelike region vanishes with all its derivatives there. The averages are integrals of the fields over R_1 and R_2, so their commutator is the double integral of a function that is zero throughout the domain of integration. □

The commutator is nonzero when the regions are in light contact, which is when one measurement can influence the other, and this is what makes the operational reading of the formalism defensible in the sense discussed in Chapter 1: an operator formalism whose commutators did not match the disturbances of a possible apparatus would be claiming a structure that no experiment could probe. Bohr and Rosenfeld's analysis is the check that the two agree. Note also what the analysis licenses: measurement by a *classical* test body of a *quantized* field, which is the hybrid description every real experiment uses.

99.8 Vacuum energy made observable: the Casimir effect

Section 99.2.4 argued that the zero-point energy Equation (99.46) is unobservable in flat empty space because it is an additive constant, but that differences between geometries are not. This section computes such a difference, gives its magnitude in SI units, and reports the measurements.

99.8.1 The prediction

Phenomenon 99.51 (The Casimir force)**.** Two parallel, plane, perfectly conducting plates of area A at separation $a \ll \sqrt{A}$ in vacuum attract, with energy per unit area and force per unit area

$$\frac{E(a)}{A} = -\frac{\pi^2 \hbar c}{720\, a^3}\,, \qquad \frac{F(a)}{A} = -\frac{\pi^2 \hbar c}{240\, a^4} = -\frac{1.300 \times 10^{-27}\,\mathrm{J\,m}}{a^4}\,, \tag{99.110}$$

independent of the charge of the electron and of every property of the plates except that they are perfect conductors. At $a = 1\,\mu\mathrm{m}$ the pressure is $1.30 \times 10^{-3}\,\mathrm{Pa}$, about 10^{-8} of atmospheric.

Rests on Equations (99.46) *and* (99.80) *and Theorem 99.9.*

Derivation. *Derives Phenomenon 99.51.*

Between perfectly conducting plates the tangential electric field vanishes on both surfaces, so the allowed wave vectors normal to the plates are quantized, $k_z = n\pi/a$ with $n = 0, 1, 2, \ldots$; the wave vector parallel to the plates, $\boldsymbol{k}_\parallel$, is continuous. For $n \geq 1$ there are two polarizations, for $n = 0$ only one. The zero-point energy per unit area is therefore

$$\frac{E(a)}{A} = \frac{\hbar c}{2} \sum_n{}' 2 \int \frac{\mathrm{d}^2 k_\parallel}{(2\pi)^2} \sqrt{\boldsymbol{k}_\parallel^2 + \left(\frac{n\pi}{a}\right)^2} = \hbar c \sum_{n=0}^{\infty}{}' f\!\left(\frac{n\pi}{a}\right)\,, \tag{99.111}$$

where the prime means the $n = 0$ term carries weight $\frac{1}{2}$ (compensating its single polarization) and

$$f(b) = \int \frac{\mathrm{d}^2 k_\parallel}{(2\pi)^2} \sqrt{\boldsymbol{k}_\parallel^2 + b^2} = \lim_{s \to -1/2} \frac{1}{4\pi} \frac{b^{2-2s}}{s-1} = -\frac{b^3}{6\pi}\,, \tag{99.112}$$

the middle expression being the analytic continuation of the convergent integral $\int \mathrm{d}^2 k_\parallel (2\pi)^{-2} (\boldsymbol{k}_\parallel^2 + b^2)^{-s} = b^{2-2s}/[4\pi(s-1)]$, valid for $\Re s > 1$, to $s = -\frac{1}{2}$.

The individual terms of Equation (99.111) are infinite and so is their sum; what is finite is the difference between the sum and the same quantity with the plates absent, that is with the k_z spectrum continuous. That difference is what Euler–Maclaurin computes. With $F(n) = f(n\pi/a)$,

$$\sum_{n=0}^{\infty}{}' F(n) - \int_0^\infty F(n)\,\mathrm{d}n = -\frac{1}{12} F'(0) + \frac{1}{720} F'''(0) - \cdots\,, \tag{99.113}$$

the omitted terms involving $F^{(5)}$ and higher. The integral on the left is precisely the free-space zero-point energy of the enclosed volume, since $\mathrm{d}n = (a/\pi)\mathrm{d}k_z$ converts it into $\int \mathrm{d}^3 k$ times a: it is proportional to the volume, and it is cancelled by the identical contribution from the unbounded space outside when the plates are moved. It therefore exerts no net force, which is the honest version of "discard the divergence". By Equation (99.112), $F(n) = -(\pi/a)^3 n^3/6\pi$, so $F(0) = 0$, $F'(0) = 0$, $F'''(0) = -\pi^2/a^3$, and all higher derivatives vanish identically because F is a cubic. Hence

$$\frac{E(a)}{A} = \hbar c \cdot \frac{1}{720}\left(-\frac{\pi^2}{a^3}\right) = -\frac{\pi^2 \hbar c}{720\, a^3}\,,$$

and $F/A = -\partial(E/A)/\partial a = -\pi^2\hbar c/(240a^4)$, negative and therefore attractive. Numerically $\pi^2\hbar c/240 = 1.3001 \times 10^{-27}\,\mathrm{J\,m}$, which at $a = 1 \times 10^{-6}\,\mathrm{m}$ gives $1.300 \times 10^{-3}\,\mathrm{J/m^3} = 1.300 \times 10^{-3}\,\mathrm{Pa}$.

The same answer follows from ζ-function regularization in one line — Equation (99.111) becomes $-(\hbar c\pi^2/6a^3)\zeta(-3)$ with $\zeta(-3) = 1/120$ — but the Euler–Maclaurin route is preferable here because it exhibits the subtraction explicitly instead of hiding it in an analytic continuation. □

The result contains no coupling constant: e, ε_0 and the properties of the metal have all disappeared, leaving only $\hbar$, c and the geometry. That is the signature of a pure vacuum effect, and it is also the signature of the idealization: the plates entered only through the boundary condition "perfect conductor at all frequencies", which no real metal is.

Table 99.3: The Casimir pressure Equation (99.110) between ideal plates, in SI units, over the range accessible to experiment. The a^{-4} dependence spans seven decades over the two decades of separation that have been probed, which is what makes the measurement demanding at both ends.

Separation a	$\lvert F/A\rvert$	Comparison
100 nm	13.0 Pa	the weight of 0.13 g on 1 cm^2
200 nm	0.813 Pa	
500 nm	2.08×10^{-2} Pa	
1 µm	1.300×10^{-3} Pa	10^{-8} atmospheres
6 µm	1.00×10^{-6} Pa	

Three corrections separate Equation (99.110) from what an experiment sees, and all three are larger than the experimental precision.

Temperature. Equation (99.111) counted zero-point energy only. At temperature T the thermally excited modes contribute too, and the scale that decides when they matter is the one at which k_BT becomes comparable with $\hbar c/a$, the thermal wavelength

$$\lambda_T = \frac{\hbar c}{k_B T} = 7.63\,\mu\mathrm{m} \quad \text{at } T = 300\,\mathrm{K}\,, \tag{99.114}$$

using $k_B = 1.380\,649 \times 10^{-23}\,\mathrm{J/K}$ exactly by the SI definition of the kelvin: the thermal correction sets in for $a \gtrsim \lambda_T$. Note that this is *not* the same as demanding that k_BT reach the energy $\pi\hbar c/a$ of the lowest confined mode, which would put the crossover at $\pi\lambda_T = 24\,\mu\mathrm{m}$; the modes that matter are the continuum of parallel wave vectors, not the lowest normal mode alone. Room-temperature experiments at separations of a few micrometres are therefore already approaching the crossover region and must model it.

Finite conductivity. A real metal reflects poorly at frequencies above its plasma frequency, so modes with $k \gtrsim \omega_p/c$ are not confined at all. The relevant scale is the plasma wavelength, of order 100 nm for gold and aluminium, and the correction reduces the force by tens of percent at separations near that scale — precisely the range where the force is largest and easiest to measure.

Surface roughness and patch potentials. Deviations from flatness of order δ change the local separation and, because the force goes as a^{-4}, do not average out; and spatial variation of the work function across a real surface produces electrostatic patch potentials whose force must be measured and subtracted. These are the dominant systematics of the modern experiments.

A closely related effect is the retarded van der Waals force between a neutral atom and a conducting wall, computed by Casimir and Polder [910] in the same year and measured directly by Sukenik and collaborators [1875] by deflecting a sodium beam between gold plates.

The existence of that derivation matters for interpretation: the same force between plates can be obtained by summing retarded intermolecular forces between the constituent atoms, a calculation in which no zero-point mode sum ever appears. The two routes agree, which means that the Casimir force confirms the *relativistic quantized electromagnetic field*, and does not by itself establish that the vacuum carries an absolute energy density. Section 99.2.4 is not overturned by Section 99.8; it is illustrated by it.

99.8.2 Measurements

Casimir's prediction stood for a decade before anyone tried to see it, and for four decades before anyone saw it convincingly. The difficulty is Table 99.3: forces of nanonewtons at separations of micrometres, between surfaces that must be parallel to a small fraction of that separation.

Table 99.4: Measurements of the Casimir force. The parallel-plate geometry of Equation (99.110) was abandoned after Sparnaay because keeping two plates parallel to a fraction of a micrometre is harder than correcting for a curved surface; the sphere–plate results are compared with the proximity-force form Equation (99.115).

Work	Method	Range	Outcome
Sparnaay 1958 [1161]	parallel plates on a spring balance	0.5–2 µm	consistent with theory; uncertainty of order the effect
Lamoreaux 1997 [1939]	torsion pendulum, spherical lens against a flat plate	0.6–6 µm	agreement at the 5 % level
Mohideen and Roy 1998 [1958]	atomic force microscope, metallized sphere against a plate	0.1–0.9 µm	agreement at the 1 % level after conductivity and roughness corrections

Sparnaay [1161] used the geometry of the calculation: two flat plates, one on a spring balance, with the separation measured capacitively. He found an attraction of the right sign and order of magnitude, and stated the result honestly as not contradicting Casimir's prediction — the uncertainties, dominated by residual electrostatic charges and by the difficulty of keeping the plates parallel, were comparable to the effect itself. It was a null result in the useful sense: it excluded the absence of the force, and nothing more.

The modern experiments abandoned the parallel-plate geometry. Lamoreaux [1939] suspended a spherical lens near a flat plate from a torsion pendulum and measured the torque, sweeping the separation from 0.6 µm to 6 µm; the electrostatic force at larger separations, where the Casimir force is negligible, calibrated the apparatus and measured the residual contact potential that had to be compensated. Mohideen and Roy [1958] replaced the pendulum with an atomic force microscope, gluing a metallized sphere to the cantilever, which pushed the accessible range down to 0.1 µm where the force is four orders of magnitude larger.

Proposition 99.52 (The sphere–plate force)**.** *For a sphere of radius R at closest separation $a \ll R$ from a plane, the proximity-force approximation gives*

$$F_{sphere}(a) = 2\pi R\,\frac{E(a)}{A} = -\frac{\pi^3 \hbar c R}{360\,a^3}\,. \tag{99.115}$$

Rests on Equation (99.110).

Proof. *Derives Proposition 99.52.*

Divide the sphere into annuli at transverse radius ρ, whose local separation from the plane is $h(\rho) = a + \rho^2/2R + O(\rho^4/R^3)$. Treating each annulus as a piece of parallel plate — legitimate when $a \ll R$, since the surfaces are then locally parallel over the region that contributes — the energy is

$$E = \int_0^\infty 2\pi\rho \,\mathrm{d}\rho \, \frac{E(h(\rho))}{A} = 2\pi R \int_a^\infty \mathrm{d}h \, \frac{E(h)}{A} \,,$$

using $\rho \,\mathrm{d}\rho = R \,\mathrm{d}h$. Differentiating with respect to a gives $F = -\partial E/\partial a = 2\pi R \, E(a)/A$, and substituting Equation (99.110) gives Equation (99.115). □

Two things should be said about what the measurements establish.

They establish that the mode structure of the quantized electromagnetic field is changed by boundaries in the way Equation (99.111) says, to the percent level over an order of magnitude in separation, with a functional form (a^{-3} for the sphere, a^{-4} for the pressure between plates) that no adjustable parameter was used to fit. That is a genuine confirmation of the quantized field, and of Section 99.2.4's claim that differences of zero-point energy are physical.

They do not establish the absolute normalization of the vacuum energy, for the reason given above: the same force follows from summing retarded van der Waals interactions [910], in which no zero-point sum appears. Nor do they bear on the cosmological constant problem, whose difficulty is precisely that gravity couples to the absolute value that the Casimir experiment never sees. A text that offers the Casimir effect as evidence for the vacuum energy of Equation (99.49) has overstated its case by more than fifty orders of magnitude.

99.9 Limits of the canonical approach

Everything above is exact and everything above is free. The transition to interacting fields is made in the following chapters by perturbation theory, and it is worth ending with the reason that transition is less well founded than its success suggests.

99.9.1 Haag's theorem

The interaction picture, on which the whole of perturbation theory is built, supposes that the interacting field at a fixed time is related to a free field by a unitary transformation — so that the two share a Hilbert space, and the interacting dynamics can be written as a unitary evolution of free-field states. Haag [1072] proved that this cannot be.

Theorem 99.53 (Haag)**.** *Let ϕ_1 and ϕ_2 be two scalar fields at a fixed time, each irreducible, each covariant under spatial translations and rotations with a unique invariant vacuum, and suppose there is a unitary V with $\phi_2 = V\phi_1 V^{-1}$ and $\pi_2 = V\pi_1 V^{-1}$ at that time. If ϕ_1 is a free field of mass m, then ϕ_2 is also free, of the same mass. Consequently the interaction picture exists only for a theory that is not interacting.*

Rests on Postulate 99.5 and Equation (99.23).

Derivation pending #134

Haag's theorem: the proof runs through the equality of all equal-time vacuum expectation values under the unitary, the reconstruction of the theory from them, and the identification of the mass from the two-point function. It is a page or two of distribution-theoretic argument and belongs in the long-proof appendix; the statement and its consequences are used here, and the axiomatic setting in which the hypotheses are stated is the axiomatic quantum field theory chapter.

The mechanism is easy to state even without the proof. A unitary V preserves all vacuum expectation values, so the two theories have the same equal-time correlation functions; the Wightman reconstruction theorem [1099, 1297] says that those functions determine the theory; and the two-point function of a free field determines the mass. There is therefore no room for ϕ_2 to be anything but a free field of the same mass. The sharpest form of the obstruction is that the interacting vacuum is not merely a different vector in the free theory's Fock space — it is not in that space at all, and the two representations of the canonical commutation relations Equation (99.23) are unitarily inequivalent. This is the warning already entered in Remark 99.13, and it is the starting point of the algebraic approach of [1856] and Chapter 109.

Why, then, does perturbative quantum electrodynamics work? Three things must be said, and the third is uncomfortable.

First, every actual calculation is done in a regularized theory in which Haag's hypotheses fail. A momentum cutoff breaks Lorentz invariance; a finite volume breaks translation invariance; dimensional regularization changes the number of dimensions. The theorem does not apply to any of them, and the perturbative series is generated inside the regularization and only then continued.

Second, what perturbation theory computes is not a unitary transformation between Hilbert spaces but a formal power series in the coupling. That series is believed to be asymptotic rather than convergent — Dyson's argument that a theory with negative α would be unstable indicates a zero radius of convergence [998] — so its first several terms can be an excellent approximation while the series as a whole defines nothing.

Third, and this is the uncomfortable part: the justification of the procedure is empirical. The anomalous magnetic moment of the electron, computed to five loops and measured to comparable precision, agrees at the level of parts in 10^{12}, and the comparison is the subject of Chapter 112. That agreement is the best evidence in physics that the perturbative expansion is computing something real. It is not a proof that the object it is expanding around exists. The honest position is that the formalism of this chapter is known to be inconsistent with the interaction picture built on it, that the inconsistency has never produced a wrong answer where the answer could be checked, and that constructing an interacting four-dimensional field theory that satisfies the axioms remains open (Chapter 109).

99.9.2 What comes next

The free field is solved. Everything that makes the Standard Model a theory of anything — scattering, decay, binding, running couplings, confinement — lies in what happens when the Lagrangian acquires a term that is not quadratic. Four routes lead out, and each is a following chapter.

Perturbation theory and renormalization. Expand $\exp(\mathrm{i}S_{\mathrm{int}}/\hbar)$, apply Theorem 99.41, and read off diagrams. The loop integrals diverge, and the divergences are absorbed into a redefinition of the mass, the charge and the field normalization; the result is the most accurately tested theory known, and the machinery is Chapter 100. The dependence of the resulting couplings on the energy scale — itself a consequence of the renormalization

procedure rather than an extra assumption — is Chapter 108.

The path integral. The canonical method fixes a time slice and therefore hides Lorentz invariance, and for non-abelian gauge fields its constraint structure becomes intractable. The alternative quantization, in which the amplitude is a sum over field histories weighted by $\exp(\mathrm{i}S/\hbar)$, keeps covariance manifest and handles gauge fixing systematically; it is Chapter 106, and it is the only practical route to the theory of Chapter 102. The $\hbar$ in the phase is the same $\hbar$ that appears in Equation (99.23): the two quantizations are equivalent for the systems where both apply.

Scattering theory. Field operators are not what a detector records. Converting the one into the other — asymptotic states, the S matrix, cross-sections and decay rates in SI units — is Chapter 86, and the reduction formula that expresses an S-matrix element in terms of the time-ordered products of this chapter is stated in Chapter 109.

Axiomatics. Finally, the results of Sections 99.7.1, 99.7.2 and 99.9.1 are statements that do not depend on any Lagrangian, and they are better stated in a framework that does not begin with one. That framework is Chapter 109, and its principal use in this book is to say precisely which of the results above are theorems and which are properties of a particular model.

Chapter 100

Quantum Electrodynamics and Renormalization

Quantum electrodynamics is the first interacting quantum field theory and remains the most sharply tested theory in physics: the electron magnetic moment measured in Chapter 112 and computed here agree over the whole range that the independently measured value of the fine-structure constant permits us to compare, roughly one part in 10^9 of the anomaly. This chapter therefore carries two burdens at once. The first is physical — to take the free fields of Chapter 99, couple the Dirac field of Chapter 93 to the Maxwell field of Chapter 60 by the single requirement of local phase invariance, and compute. The second is conceptual: every loop integral so obtained diverges, and the theory only becomes predictive through renormalization, whose history runs from the crisis of the 1930s through the Lamb shift of 1947 to the covariant formalisms of Tomonaga, Schwinger, Feynman and Dyson, and whose modern reading — a low-energy effective description valid up to a cutoff — is the subject of Chapter 108.

QED is placed here because it is the template. The weak interaction (Chapter 101), the strong interaction (Chapter 102) and their unification with electromagnetism (Chapter 104) are all gauge theories built by the same construction, and every calculational device introduced below — Feynman rules, regularization, counterterms, Ward identities, running couplings — is reused there without change of principle. Standard treatments are [1654, 1907, 1912]; Feynman's non-technical account [1752] is unmatched as an orientation.

100.1 The QED Lagrangian

100.1.1 Conventions, and the SI dimension of everything

Every standard text on this subject puts the reduced Planck constant and the speed of light equal to unity on its first page, and drops them from every formula thereafter. This book does not, in obedience to the axiom of SI units stated in the front matter, and the price is one page of bookkeeping paid here once. The reward is that every formula below can be checked dimensionally, which is the cheapest error-detector available in a subject where a wrong factor is otherwise invisible, and that the fine-structure constant appears as what it is — a pure number built out of four dimensioned constants — rather than as a symbol whose dimensionlessness has been assumed.

Notation 100.1 (Metric, coordinates, momenta). The metric is $\eta_{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$. Coordinates are $x^\mu = (ct, \boldsymbol{x})$, so that $\mathrm{d}^4x = c\,\mathrm{d}t\,\mathrm{d}^3x$ has SI dimension m^4, and $\partial_\mu = \partial/\partial x^\mu = (c^{-1}\partial_t, \nabla)$ has dimension $1/\mathrm{m}$. Four-momenta are $p^\mu = (E/c, \boldsymbol{p})$, of dimension $\mathrm{kg\,m/s}$, so

that the mass-shell condition reads

$$p^2 := p_\mu p^\mu = \frac{E^2}{c^2} - \boldsymbol{p}^2 = m^2 c^2 \,. \tag{100.1}$$

The Mandelstam variables $s = (p_1+p_2)^2$, $t = (p_1-p_3)^2$, $u = (p_1-p_4)^2$ are therefore squared *momenta*, and $\sqrt{s}\,c$ is the centre-of-mass energy. Wave four-vectors are $k^\mu = p^\mu/\hbar = (\omega/c, \boldsymbol{k})$. The symbol ϵ, standing alone, is always the positive infinitesimal of the Feynman contour prescription and ε, standing alone, is always the dimensional regulator of Definition 100.30; ε_0 is the electric constant, $\varepsilon^\mu_{(\lambda)}$ a polarization vector and $\varepsilon^{\mu\nu\rho\sigma}$ the Levi-Civita symbol. The loop momentum is written ℓ.

The action of a field theory is $S = \int \mathrm{d}t\, L = \int \mathrm{d}t\, \mathrm{d}^3x\, \mathcal{L}$, that is

$$S = \frac{1}{c}\int \mathrm{d}^4x\, \mathcal{L}\,, \tag{100.2}$$

where $\mathcal{L}$ is an energy density, $\mathrm{J/m^3}$. The factor c^{-1} is not decoration: it is what makes S an action, J s, and it will reappear in the photon propagator. Quantum mechanics enters through the phase $\exp(\mathrm{i}S/\hbar)$ of Chapter 106 and through the canonical commutators of Chapter 99, each of which carries its own $\hbar$.

Definition 100.2 (Fields and their dimensions)**.** The Dirac field ψ has dimension $1/\mathrm{m}^{3/2}$, so that $\psi^\dagger\psi$ is a number density and $\bar\psi\psi = \psi^\dagger\gamma^0\psi$ has dimension $1/\mathrm{m}^3$. The electromagnetic four-potential $A^\mu = (\phi/c, \boldsymbol{A})$ has dimension V s/m, equivalently kg m/(C s), and $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ has dimension T.

Definition 100.3 (The fine-structure constant)**.** The electromagnetic coupling of a particle of charge q is measured by the dimensionless combination

$$\alpha = \frac{e^2}{4\pi\varepsilon_0\hbar c} = \frac{\mu_0 c e^2}{4\pi\hbar} = (7.297\,352\,564\,3 \pm 0.000\,000\,001\,1)\times 10^{-3} = \frac{1}{137.035999177(21)}\,, \tag{100.3}$$

the second form following from $\varepsilon_0\mu_0 c^2 = 1$, and the numerical value being the CODATA 2022 recommendation [2431]. Its dimensionlessness is a fact about Nature and not a convention: e^2/ε_0 has dimension J m, exactly that of $\hbar c$, so the ratio is a pure number, and it is that number — not e, which is a unit-dependent quantity fixed by definition since 2019 — that every amplitude below depends on. The combination that will actually occur in the Feynman rules is

$$\frac{\mu_0 c e^2}{\hbar} = 4\pi\alpha\,. \tag{100.4}$$

Remark 100.4 (Reading this chapter against the natural-units literature)*.* The references cited throughout work in units where $\hbar = c = 1$. In those units mass, energy, momentum and inverse length are all the same quantity, the Lagrangian density has dimension $(\text{mass})^4$, the Dirac field has dimension $(\text{mass})^{3/2}$ and the gauge field $(\text{mass})^1$, and the elementary charge is dimensionless, $e = \sqrt{4\pi\alpha}$ in Heaviside–Lorentz form. To map a formula of this chapter onto such a text, delete every $\hbar$ and c; to map back, restore them by the rule that (i) a mass m always appears as mc when it stands beside a momentum and as mc^2 when it stands beside an energy, (ii) each four-dimensional loop measure carries $(2\pi\hbar)^{-4}$, (iii) each propagator carries one factor of $\hbar$ and each vertex one factor of $\hbar^{-1}$, and (iv) e^2 is replaced by $4\pi\alpha\hbar c$ in Gaussian and by $4\pi\alpha\hbar/(\mu_0 c)$ in SI form. No derivation in this chapter is carried out in natural units; this remark exists so that the reader can check the chapter against its sources, which is a different thing.

100.1.2 Local phase invariance and minimal coupling

The free Dirac field of Chapter 93 is governed by the Lagrangian density

$$\mathcal{L}_0 = \bar{\psi}\left(\mathrm{i}\hbar c\,\gamma^\mu\partial_\mu - mc^2\right)\psi\,, \tag{100.5}$$

whose Euler–Lagrange equation (Chapter 64) is $(\mathrm{i}\hbar\gamma^\mu\partial_\mu - mc)\psi = 0$. Both terms in Equation (100.5) have dimension $\mathrm{J/m^3}$, as an energy density must: $\hbar c\,\partial_\mu$ is an energy and $\bar{\psi}\psi$ an inverse volume.

This Lagrangian is invariant under the global phase rotation $\psi \mapsto \mathrm{e}^{\mathrm{i}\theta}\psi$ with θ a real constant — a representation of the group U(1), whose structure and irreducible representations are those of Section 14.2.1. By Noether's theorem [456] — the classical apparatus is Chapter 64 — the symmetry carries a conserved current, which for a particle of charge q is written

$$j^\mu = qc\,\bar{\psi}\gamma^\mu\psi\,, \qquad \partial_\mu j^\mu = 0\,, \tag{100.6}$$

of dimension $\mathrm{A/m^2}$, with $j^0 = cq\psi^\dagger\psi$ the charge density times c. The conserved charge $Q = \frac{1}{c}\int \mathrm{d}^3x\, j^0 = q\int \mathrm{d}^3x\,\psi^\dagger\psi$ is the electric charge.

Nothing forces the phase θ to be the same at every point of spacetime. Weyl's proposal [641] — the gauge principle, and the historical root of the fibre-bundle reading of Section 14.6 — is to demand that it need not be, and to see what the demand costs.

Theorem 100.5 (The gauge principle)**.** *Let $\theta : \mathbb{R}^4 \to \mathbb{R}$ be an arbitrary smooth function and require Equation (100.5) to be invariant under*

$$\psi(x) \longmapsto \mathrm{e}^{-\mathrm{i}q\Lambda(x)/\hbar}\psi(x)\,, \tag{100.7}$$

where Λ carries dimension V s so that $q\Lambda/\hbar$ is a pure number. Then invariance is possible if and only if a vector field A_μ is introduced, transforming as

$$A_\mu(x) \longmapsto A_\mu(x) + \partial_\mu\Lambda(x)\,, \tag{100.8}$$

and the ordinary derivative is replaced by the covariant derivative

$$D_\mu := \partial_\mu + \frac{\mathrm{i}q}{\hbar}A_\mu\,. \tag{100.9}$$

The resulting Lagrangian density $\bar{\psi}(\mathrm{i}\hbar c\gamma^\mu D_\mu - mc^2)\psi$ differs from Equation (100.5) by exactly $-j^\mu A_\mu$: the interaction is not chosen, it is forced.

Rests on Equations (100.5) and (100.6).

Proof. *Derives Theorem 100.5.*

Under Equation (100.7) the derivative acquires an inhomogeneous term,

$$\partial_\mu\psi \longmapsto \mathrm{e}^{-\mathrm{i}q\Lambda/\hbar}\left(\partial_\mu - \frac{\mathrm{i}q}{\hbar}\partial_\mu\Lambda\right)\psi\,,$$

so that $\mathcal{L}_0 \mapsto \mathcal{L}_0 + qc\,\bar{\psi}\gamma^\mu\psi\,\partial_\mu\Lambda = \mathcal{L}_0 + j^\mu\partial_\mu\Lambda$, which does not vanish for arbitrary Λ. The obstruction is that $\partial_\mu\psi$ compares the field at neighbouring points, whose phase conventions are now unrelated. It is removed by supplying a rule of comparison — a connection, in the language of Section 14.6. Postulate a field A_μ with the transformation law Equation (100.8) and form D_μ as in Equation (100.9). Then

$$\begin{aligned} D_\mu\psi &\longmapsto \left(\partial_\mu + \frac{\mathrm{i}q}{\hbar}A_\mu + \frac{\mathrm{i}q}{\hbar}\partial_\mu\Lambda\right)\mathrm{e}^{-\mathrm{i}q\Lambda/\hbar}\psi \\ &= \mathrm{e}^{-\mathrm{i}q\Lambda/\hbar}\left(\partial_\mu\psi - \frac{\mathrm{i}q}{\hbar}(\partial_\mu\Lambda)\psi + \frac{\mathrm{i}q}{\hbar}A_\mu\psi + \frac{\mathrm{i}q}{\hbar}(\partial_\mu\Lambda)\psi\right) \\ &= \mathrm{e}^{-\mathrm{i}q\Lambda/\hbar}D_\mu\psi\,, \end{aligned} \tag{100.10}$$

so $\bar\psi\gamma^\mu D_\mu\psi$ is invariant, the two phases cancelling. Conversely, any modification $\partial_\mu \to \partial_\mu + X_\mu$ restoring invariance must satisfy $X_\mu \mapsto X_\mu + \mathrm{i}q\,\partial_\mu\Lambda/\hbar$ by the same computation read backwards, which is Equation (100.8) for $A_\mu = \hbar X_\mu/\mathrm{i}q$. Finally

$$\bar\psi\left(\mathrm{i}\hbar c\gamma^\mu D_\mu - mc^2\right)\psi = \mathcal{L}_0 - qc\,\bar\psi\gamma^\mu\psi A_\mu = \mathcal{L}_0 - j^\mu A_\mu\,.$$

□

The field A_μ so forced into existence is not yet dynamical. Its kinetic term is fixed by the only gauge-invariant object one can build from it: the curvature of the connection,

$$F_{\mu\nu} = \frac{\hbar}{\mathrm{i}q}\,[D_\mu, D_\nu] = \partial_\mu A_\nu - \partial_\nu A_\mu\,, \tag{100.11}$$

which is manifestly invariant under Equation (100.8) because partial derivatives commute. This is the abelian case of the general curvature Equation (14.139); the non-abelian generalization, where the commutator leaves a residual term and the field strength is no longer gauge invariant but only covariant, is what makes Chapter 102 a different theory rather than a relabelled one.

Collecting, the QED Lagrangian density is

$$\mathcal{L}_{\mathrm{QED}} = \bar\psi\left(\mathrm{i}\hbar c\,\gamma^\mu D_\mu - m_e c^2\right)\psi - \frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu}\,, \qquad D_\mu = \partial_\mu - \frac{\mathrm{i}e}{\hbar}A_\mu\,, \tag{100.12}$$

the electron carrying charge $q = -e$ with $e > 0$. Each term is an energy density: F^2/μ_0 has dimension $\mathrm{T}^2/\mathrm{N}/\mathrm{A}^2 = \mathrm{J}/\mathrm{m}^3$, and the normalization $-1/4\mu_0$ is the one that reproduces Maxwell's equations of Chapter 60 in the classical limit, since $-\frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu} = \frac{\varepsilon_0}{2}\left(E^2 - c^2B^2\right)$.

Two consequences deserve to be stated separately, because they are observations and not conventions.

Proposition 100.6 (The coupling is universal)**.** *The interaction term $-j^\mu A_\mu$ contains the charge q and nothing else about the matter field. Any two species carrying the same q therefore couple to the photon identically, whatever their masses, and the electromagnetic vertex of a lepton is fixed once the vertex of any one charged particle is.*

Rests on Theorem 100.5 and Equations (100.7) and (100.9).

Proof. *Derives Proposition 100.6.*

Immediate from Theorem 100.5: the covariant derivative Equation (100.9) depends on the matter field only through the charge appearing in its transformation law Equation (100.7), and no other parameter of the matter sector enters D_μ. That this survives quantization — that radiative corrections do not make the observed charge mass-dependent — is not automatic and is the content of the Ward–Takahashi identity of Section 100.5.2. □

Phenomenon 100.7 (The photon has no mass)**.** A term $\frac{1}{2\mu_0}(m_\gamma c/\hbar)^2 A_\mu A^\mu$ is the only Lorentz-invariant mass term available to the gauge field, and it is not invariant under Equation (100.8): local phase invariance forbids a photon mass outright. The prediction is that the Coulomb potential is exactly $1/r$ and that electromagnetic waves travel at exactly c in vacuum for every frequency. Experimentally the photon rest mass is bounded by $m_\gamma < 1.6\times10^{-50}\,\mathrm{kg}$, that is about $1\times10^{-14}\,\mathrm{eV}/c^2$, from a laboratory test of Coulomb's law [1460], and by some four further orders of magnitude from the large-scale magnetic fields of the solar system [2157, 2427]. No deviation has ever been seen.

Rests on Equations (100.8) and (100.12).

Derivation. *Derives Phenomenon 100.7.*

Add the mass term to Equation (100.12); under Equation (100.8) it changes by $\frac{1}{\mu_0}(m_\gamma c/\hbar)^2\left(A^\mu\partial_\mu\Lambda + \frac{1}{2}\partial_\mu\Lambda\,\partial^\mu\Lambda\right)$, which is not a total derivative and does not vanish. Hence gauge invariance requires $m_\gamma = 0$ exactly.

To convert this into something measurable, keep the mass term and drop gauge invariance: the field equation becomes the Proca equation $\partial_\mu F^{\mu\nu} + (m_\gamma c/\hbar)^2 A^\nu = \mu_0 j^\nu$, whose static point-charge solution is the Yukawa potential

$$\phi(r) = \frac{Q}{4\pi\varepsilon_0 r}\,\mathrm{e}^{-r/\lambda}\,, \qquad \lambda = \frac{\hbar}{m_\gamma c}\,.$$

The verification is the same contour computation as for any Yukawa kernel: the Fourier transform of $(\boldsymbol{k}^2 + \lambda^{-2})^{-1}$ is $\mathrm{e}^{-r/\lambda}/4\pi r$, obtained by closing the $|\boldsymbol{k}|$ contour in the upper half plane and picking up the pole at $|\boldsymbol{k}| = \mathrm{i}/\lambda$ (Theorem 8.24). A Cavendish-type null experiment with concentric conductors bounds any departure from the $1/r^2$ force law, and hence bounds λ^{-1}; the laboratory bound $\lambda > 3\times 10^7\,\mathrm{m}$ [1460] translates through $m_\gamma = \hbar/\lambda c$ into

$$m_\gamma < \frac{1.0546\times 10^{-34}\,\mathrm{J\,s}}{3\times 10^{7}\,\mathrm{m}\times 2.998\times 10^{8}\,\mathrm{m/s}} = 1.2\times 10^{-50}\,\mathrm{kg}\,,$$

of the order quoted. The bound is a bound and not a measurement: what is established is that if the photon has a mass it is smaller than 10^{-50} of a kilogram, which is 10^{-20} of the electron mass. □

100.1.3 Gauge fixing and the photon propagator

Gauge invariance, having produced the theory, immediately obstructs its quantization. Write the free photon action from Equation (100.12) in the form

$$S_{\mathrm{EM}} = \frac{1}{c}\int \mathrm{d}^4x \left(-\frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu}\right) = \frac{1}{2c\mu_0}\int \mathrm{d}^4x\; A^\mu\left(\eta_{\mu\nu}\Box - \partial_\mu\partial_\nu\right)A^\nu\,, \tag{100.13}$$

after an integration by parts, with $\Box = \partial_\mu\partial^\mu$. In momentum space, with the Fourier convention

$$f(x) = \int \frac{\mathrm{d}^4p}{(2\pi\hbar)^4}\,\tilde f(p)\,\mathrm{e}^{-\mathrm{i}p\cdot x/\hbar}\,, \qquad \partial_\mu \longmapsto -\frac{\mathrm{i}p_\mu}{\hbar}\,, \tag{100.14}$$

— the four-dimensional case of the transform of Chapter 17, with the $\hbar$ inserted so that the conjugate variable is a momentum rather than a wave number — the kernel becomes

$$\widetilde{M}_{\mu\nu}(p) = -\frac{1}{\mu_0\hbar^2}\left(p^2\eta_{\mu\nu} - p_\mu p_\nu\right)\,. \tag{100.15}$$

This matrix is singular: $\widetilde{M}_{\mu\nu}p^\nu = 0$ identically, so it has a null eigenvector at every p and cannot be inverted. The statement is not a technical nuisance but the algebraic shadow of Equation (100.8): in momentum space a gauge transformation is $A_\mu \mapsto A_\mu - \mathrm{i}p_\mu\Lambda/\hbar$, so the longitudinal direction is pure gauge and the action does not depend on it. A propagator is an inverse of the kernel, and one cannot invert a map along a direction in which nothing happens.

The cure is to fix the gauge: add to Equation (100.13) a term that is not gauge invariant, chosen so that physical answers do not depend on it. The covariant family is

$$\mathcal{L}_{\mathrm{gf}} = -\frac{1}{2\mu_0\xi}\left(\partial^\mu A_\mu\right)^2\,, \tag{100.16}$$

with ξ a dimensionless parameter. Its effect on Equation (100.15) is to replace $p^2\eta_{\mu\nu} - p_\mu p_\nu$ by $p^2\eta_{\mu\nu} - (1-\xi^{-1})p_\mu p_\nu$, which is invertible for $\xi \neq 0$.

Proposition 100.8 (The photon propagator)**.** *With the gauge-fixing term Equation (100.16) the free photon two-point function is*

$$\widetilde{D}_{\mu\nu}(p) = \frac{-\mathrm{i}\mu_0\hbar^3 c}{p^2 + \mathrm{i}\epsilon}\left(\eta_{\mu\nu} - (1-\xi)\,\frac{p_\mu p_\nu}{p^2}\right)\,, \tag{100.17}$$

of SI dimension $\mathrm{V}^2\,\mathrm{s}^2\,\mathrm{m}^2$. *The choice* $\xi = 1$ *is the Feynman gauge,* $\xi = 0$ *the Landau gauge, in which the propagator is purely transverse.*

Rests on Equations (100.2), (100.15) *and* (100.16).

Proof. *Derives Proposition 100.8.*

Write $P^{\mathrm{T}}_{\mu\nu} = \eta_{\mu\nu} - p_\mu p_\nu/p^2$ and $P^{\mathrm{L}}_{\mu\nu} = p_\mu p_\nu/p^2$; these are orthogonal projectors summing to $\eta_{\mu\nu}$. The gauge-fixed kernel is

$$\widetilde{M}_{\mu\nu} = -\frac{1}{\mu_0\hbar^2}\left(p^2 P^{\mathrm{T}}_{\mu\nu} + \frac{p^2}{\xi} P^{\mathrm{L}}_{\mu\nu}\right),$$

whose inverse on each eigenspace is immediate: $\widetilde{M}^{-1} = -\mu_0\hbar^2\left(P^{\mathrm{T}} + \xi P^{\mathrm{L}}\right)/p^2$. A Gaussian functional integral with phase $\exp(\mathrm{i}S/\hbar)$ and quadratic form $S = \frac{1}{2}\int A\,\mathcal{M}A$ has two-point function $\mathrm{i}\hbar\mathcal{M}^{-1}$; here $\mathcal{M} = \widetilde{M}/c$ by Equation (100.2), so the propagator is $\mathrm{i}\hbar c\,\widetilde{M}^{-1}$, which is Equation (100.17) after restoring $P^{\mathrm{T}} + \xi P^{\mathrm{L}} = \eta_{\mu\nu} - (1-\xi)p_\mu p_\nu/p^2$. The $\mathrm{i}\epsilon$ prescription is the one that propagates positive frequencies forward in time, fixed by the contour argument of Chapter 99. Dimensionally, $\mu_0\hbar^3 c/p^2$ carries $\mathrm{kg}^2\,\mathrm{m}^6/(\mathrm{s}^4\,\mathrm{A}^2)$, which is $[A]^2\mathrm{m}^4$ as the Fourier transform of a product of two potentials must be. □

The parameter ξ is arbitrary, so no measurable quantity may depend on it. The reason it does not is that a photon propagator always joins two currents, and the extra term is proportional to $p_\mu p_\nu$:

$$p_\mu \tilde{j}^\mu(p) = 0 \quad \text{for a conserved current,} \tag{100.18}$$

by Equation (100.6) transformed with Equation (100.14). At tree level this is checked directly — for an on-shell electron line, $q_\mu \bar{u}(p')\gamma^\mu u(p) = \bar{u}(p')(\gamma\cdot p' - \gamma\cdot p)u(p) = (m_e c - m_e c)\bar{u}(p')u(p) = 0$ by the Dirac equation — and to all orders it is the Ward–Takahashi identity of Section 100.5.2. The ξ-independence of renormalized amplitudes is used below as a check on the renormalization of Section 100.5. The systematic reading of the whole construction, in which $\partial\mathcal{L}/\partial\dot{A}^0 = 0$ is a primary constraint and the gauge freedom is generated by a first-class constraint, belongs to Chapter 26; the covariant quantization with an indefinite-metric state space and a subsidiary condition is that of Gupta and Bleuler [953, 958]. In an abelian theory the Faddeev–Popov determinant that accompanies this procedure [1347] is field-independent and can be discarded, which is precisely what fails in Chapter 102.

100.1.4 Discrete symmetries and Furry's theorem

QED conserves C, P and T separately. This is not an assumption: it is forced by Equation (100.12) together with the requirement that the theory be local, Lorentz invariant and hermitian, because the only interaction the gauge principle allows is $-j^\mu A_\mu$ with j^μ the vector current, and the vector current has definite behaviour under all three operations. Had the gauge principle permitted an axial current $\bar{\psi}\gamma^\mu\gamma^5\psi$ to couple as well, parity would be violated — which is exactly what happens in Chapter 101. The full account of C, P, T and the CPT theorem is Chapter 105; what is needed here is one corollary with large calculational consequences.

Definition 100.9 (Charge conjugation on the Dirac field)**.** Charge conjugation is the unitary $\mathcal{C}$ implementing

$$\mathcal{C}\psi(x)\mathcal{C}^{-1} = \mathcal{C}_{\mathrm{D}}\,\bar{\psi}^{\mathsf{T}}(x)\,, \qquad \mathcal{C}A_\mu(x)\mathcal{C}^{-1} = -A_\mu(x)\,, \tag{100.19}$$

where the numerical matrix $\mathcal{C}_{\mathrm{D}}$ satisfies

$$\mathcal{C}_{\mathrm{D}}\,(\gamma^\mu)^{\mathsf{T}}\,\mathcal{C}_{\mathrm{D}}^{-1} = -\gamma^\mu\,, \tag{100.20}$$

(in the Dirac representation $\mathcal{C}_{\mathrm{D}} = \mathrm{i}\gamma^2\gamma^0$). The sign on A_μ is forced: the current Equation (100.6) is odd under Equation (100.20), and $j^\mu A_\mu$ must be even.

Theorem 100.10 (Furry)**.** *Any QED amplitude given by a single closed fermion loop with an odd number of external photon lines attached vanishes identically [793].*

Rests on Equation (100.20) and Definition 100.9.

Proof. *Derives Theorem 100.10.*

Let n be the number of photons attached to the loop. The contribution of the loop is, up to a factor common to both orientations,

$$T^{\mu_1\cdots\mu_n} = -\operatorname{tr}\left[\gamma^{\mu_1} S(p_1)\gamma^{\mu_2} S(p_2)\cdots\gamma^{\mu_n} S(p_n)\right] ,$$

with $S(p) = \mathrm{i}\hbar(\gamma\cdot p + m_e c)/(p^2 - m_e^2 c^2)$ the fermion propagator and the overall minus sign the one attached to every closed fermion loop by the anticommuting Wick contraction of Chapter 99. Every diagram comes in two versions, differing in the direction in which the charge circulates. Take the transpose of the trace, which leaves it unchanged, and insert $\mathcal{C}_{\mathrm{D}}^{-1}\mathcal{C}_{\mathrm{D}}$ between every pair of factors. By Equation (100.20), $\mathcal{C}_{\mathrm{D}}(\gamma^\mu)^{\mathsf{T}}\mathcal{C}_{\mathrm{D}}^{-1} = -\gamma^\mu$ and hence $\mathcal{C}_{\mathrm{D}} S(p)^{\mathsf{T}}\mathcal{C}_{\mathrm{D}}^{-1} = S(-p)$, because the transpose reverses the sign of the $\gamma\cdot p$ term and leaves $m_e c$ alone. The transposed trace is therefore the trace for the reversed orientation, with an extra factor $(-1)^n$ from the n vertices. Summing the two orientations gives $(1 + (-1)^n)\, T^{\mu_1\cdots\mu_n}$, which vanishes for odd n. □

Remark 100.11 (What Furry's theorem buys). Two of the primitively divergent amplitudes counted in Theorem 100.17 — the one- and three-photon vacuum amplitudes — vanish for this reason, so QED has fewer divergences to renormalize than power counting alone predicts. The even cases are untouched, and do not vanish: the two-photon vacuum amplitude is the photon self-energy of Section 100.4.1, the largest radiative effect in this chapter. In particular the one-photon tadpole vanishes, which is why the photon does not acquire a vacuum expectation value, and the three-photon amplitude vanishes, which is why the leading photon self-interaction is the four-photon box of Section 100.8.3 and is suppressed by α^4 rather than α^3. The theorem is a statement about C invariance and therefore fails in the weak sector, where C is violated maximally.

100.2 Perturbation theory and its three formalisms

The interaction $-j^\mu A_\mu$ cannot be treated exactly. It is treated in powers of α, and because $\alpha \approx 1/137$ the expansion is spectacularly good — which is the whole reason QED is the most accurately checked theory there is. Between 1943 and 1949 three superficially different ways of organizing that expansion appeared, and Dyson proved them the same theory.

100.2.1 Tomonaga–Schwinger covariant formulation

The perturbation theory of the 1930s was built on the interaction picture in a fixed Lorentz frame: states evolve by $\mathrm{i}\hbar\,\mathrm{d}\,|\Psi(t)\rangle\,/\mathrm{d}t = H_{\mathrm{int}}(t)\,|\Psi(t)\rangle$, with t the time coordinate of that frame. The scheme worked, in the sense that it produced the Klein–Nishina cross-section and the Bethe–Heitler formula, but it hid Lorentz invariance completely: at intermediate stages energy was not conserved, individual terms were frame-dependent, and the divergences appeared in forms that cancelled between contributions of different apparent order. Nobody could tell which of the infinities were physical.

Tomonaga's resolution [895], obtained in wartime isolation and unknown outside Japan until 1947, was to replace the constant-time slice by an arbitrary spacelike surface σ and ask how the state changes when the surface is deformed at one point.

Definition 100.12 (Tomonaga–Schwinger equation)**.** Let σ be a spacelike hypersurface and $|\Psi[\sigma]\rangle$ the state functional on it. The interaction-picture evolution is

$$\mathrm{i}\hbar c\,\frac{\delta\,|\Psi[\sigma]\rangle}{\delta\sigma(x)} = \mathcal{H}_{\mathrm{int}}(x)\;|\Psi[\sigma]\rangle\;, \tag{100.21}$$

where $\delta/\delta\sigma(x)$ is the functional derivative with respect to a local deformation of the surface at the point x, of dimension $1/\mathrm{m}^4$, and $\mathcal{H}_{\mathrm{int}}(x) = j^{\mu}(x)A_{\mu}(x)$ is the interaction Hamiltonian density, of dimension J/m^3. Both sides then carry J/m^3, since $\hbar c\,\delta/\delta\sigma$ is an energy density.

Every symbol in Equation (100.21) is a scalar, and the surface is arbitrary: manifest covariance is restored. Taking σ to be a family of parallel flat slices recovers the ordinary interaction picture, which is why nothing is lost.

Proposition 100.13 (Integrability is microcausality)**.** *Equation* (100.21) *possesses a solution for every spacelike σ if and only if*

$$[\mathcal{H}_{\mathrm{int}}(x),\mathcal{H}_{\mathrm{int}}(y)] = 0 \qquad \text{for } (x-y)^2 < 0\,. \tag{100.22}$$

Rests on Equation (100.21) *and Definition 100.12.*

Proof. *Derives Proposition 100.13.*

Two deformations of σ at spacelike separated points x and y can be performed in either order and must give the same final surface. Applying Equation (100.21) twice and demanding that the mixed second functional derivative be symmetric gives $\mathcal{H}_{\mathrm{int}}(x)\mathcal{H}_{\mathrm{int}}(y) = \mathcal{H}_{\mathrm{int}}(y)\mathcal{H}_{\mathrm{int}}(x)$, which is Equation (100.22). The condition holds in QED because $\mathcal{H}_{\mathrm{int}}$ is built from local field operators whose commutators vanish outside the light cone (Chapter 99), and it fails for any nonlocal interaction — which is the formal statement of why locality is not optional here. □

Schwinger reached the same equation independently and built around it a complete operator formalism [920], in which the field equations, the commutation relations and the renormalization subtractions are all written covariantly and the mass and charge renormalizations appear as canonical transformations. It was in that framework that he computed the electron anomaly [919], the calculation reproduced in Section 100.4.3. Schwinger's method is powerful and almost unusable by hand for more than one loop; Feynman's, which came next, is the one everybody calculates with.

100.2.2 Feynman's space-time approach and the diagrams

Feynman's starting point was the observation that a negative-energy solution of the Dirac equation propagating backwards in time is kinematically indistinguishable from a positive-energy antiparticle propagating forwards [931], an idea anticipated by Stueckelberg [864]. The gain is not interpretational but computational: the electron and the positron share a single propagator, the one obtained by choosing the Feynman contour, and the separate "electron" and "positron" terms of old-fashioned perturbation theory — which had to be added by hand and whose cancellations were the source of the confusion described above — are automatically combined in one manifestly covariant expression. The companion paper [930] recast the whole perturbation series in space-time terms and stated the diagrammatic rules that carry his name; what follows is those rules, written with every $\hbar$ and c in place.

Proposition 100.14 (The Feynman rules of QED in SI form)**.** *Expand* $\exp(\mathrm{i}S/\hbar)$ *in powers of the interaction, apply Wick's theorem [974] to the resulting time-ordered products, and read off the momentum-space amplitude $\mathcal{M}$ for a given process by the following dictionary.*

1. *Internal fermion line of momentum p:*
$$\widetilde{S}_F(p) = \frac{\mathrm{i}\hbar\,(\gamma^\mu p_\mu + m_e c)}{p^2 - m_e^2 c^2 + \mathrm{i}\epsilon}\,, \tag{100.23}$$
of dimension m.

2. *Internal photon line of momentum p: the propagator Equation* (100.17).

3. *Vertex, for a fermion of charge q:*
$$-\frac{\mathrm{i}q}{\hbar}\gamma^\mu \quad \left(= +\frac{\mathrm{i}e}{\hbar}\gamma^\mu \text{ for the electron}\right), \tag{100.24}$$
of dimension $\mathrm{C}/(\mathrm{J\,s})$.

4. *Each undetermined loop momentum:* $\int \mathrm{d}^4\ell\,(2\pi\hbar)^{-4}$.

5. *Each closed fermion loop: a factor* -1 *and a Dirac trace.*

6. *External lines: $u(p,s)$ for an incoming fermion, $\bar{u}(p,s)$ outgoing, v, $\bar{v}$ for antifermions, and $\varepsilon^{\mu}_{(\lambda)}(p)$, $\varepsilon^{*\mu}_{(\lambda)}(p)$ for incoming and outgoing photons. Spinors are normalized relativistically, $\bar{u}u = 2m_e c$ and $u^\dagger u = 2E/c$, so that they carry dimension* $\mathrm{kg}^{1/2}\,\mathrm{m}^{1/2}/\mathrm{s}^{1/2}$.

7. *A relative minus sign between diagrams differing by the exchange of two external fermion lines.*

With these conventions a $2 \to 2$ amplitude $\mathcal{M}$ carries dimension $\hbar^2$.
Rests on Theorem 100.5, Proposition 100.8, and Equation (100.2).

Derivation of the vertex factor. *Derives Proposition 100.14.*
The interaction part of Equation (100.2) is, by Theorem 100.5,
$$S_{\mathrm{int}} = -\frac{1}{c}\int \mathrm{d}^4x\; j^\mu A_\mu = -q\int \mathrm{d}^4x\;\bar{\psi}\gamma^\mu\psi\,A_\mu\,,$$
the factor c cancelling between Equation (100.2) and Equation (100.6). Expanding $\exp(\mathrm{i}S/\hbar)$ to first order produces $(\mathrm{i}/\hbar)\times(-q\gamma^\mu)$ at each vertex, which is Equation (100.24). The propagators are the inverses of the quadratic forms, computed in Proposition 100.8 for the photon; for the fermion the quadratic form is $\gamma\cdot p - m_e c$ by Equation (100.14), and $\mathrm{i}\hbar(\gamma\cdot p - m_e c)^{-1} = \mathrm{i}\hbar(\gamma\cdot p + m_e c)/(p^2 - m_e^2c^2)$ using $(\gamma\cdot p)^2 = p^2$. □

Remark 100.15 (The dictionary that removes every $\hbar$). Two vertices joined by one photon propagator contribute
$$\left(\frac{q_1}{\hbar}\right)\left(\frac{q_2}{\hbar}\right)\mu_0\hbar^3 c = q_1 q_2 \mu_0 c\hbar = \pm\,4\pi\alpha\hbar^2$$
for $q_1 q_2 = \pm e^2$, by Equation (100.4). This is the single fact that makes every SI expression below reduce to its textbook form: wherever a natural-units treatment writes e^2 in Heaviside–Lorentz form, this chapter writes $4\pi\alpha\hbar^2$ for a tree exchange, and wherever it writes e^2 inside a loop the $\hbar$'s cancel against the measure $(2\pi\hbar)^{-4}$ and two propagators, leaving a bare $4\pi\alpha$. That cancellation is worth watching for: it is the reason the anomalous moment of Section 100.4.3 comes out as a pure number times α and could not have come out as anything else.

Remark 100.16 (A diagram is not a picture). Each diagram is a mnemonic for one term of the Wick expansion, and the internal lines carry momenta that do not satisfy Equation (100.1): an internal line is not a particle. The spacetime reading in which a virtual pair "is created and reabsorbed" has no operational content, because the intermediate state is summed over and never measured; what is measured is the amplitude for the whole process. Statements of the form "the electron emits a photon and reabsorbs it" are useful for remembering which integral to write down and are not to be taken as descriptions of events. Feynman himself was explicit about this [1752].

100.2.3 Dyson's S-matrix and the equivalence of the formalisms

Dyson showed that Tomonaga's and Schwinger's formalism and Feynman's rules are two presentations of one object [927], and then that the object has a closed form [928]. Integrating Equation (100.21) from the infinite past to the infinite future gives the scattering operator

$$S = T\exp\left(-\frac{\mathrm{i}}{\hbar c}\int \mathrm{d}^4x\,\mathcal{H}_{\mathrm{int}}(x)\right) = \sum_{n=0}^{\infty}\frac{1}{n!}\left(\frac{-\mathrm{i}}{\hbar c}\right)^n\int \mathrm{d}^4x_1\cdots\mathrm{d}^4x_n\,T\left[\mathcal{H}_{\mathrm{int}}(x_1)\cdots\mathcal{H}_{\mathrm{int}}(x_n)\right], \tag{100.25}$$

with T the time-ordering symbol; the $1/n!$ is what remains after the $n!$ orderings of the nested integrals are absorbed into T, and $\hbar c$ appears because $\int \mathrm{d}t\,H_{\mathrm{int}} = c^{-1}\int \mathrm{d}^4x\,\mathcal{H}_{\mathrm{int}}$. Applying Wick's theorem [974] to each time-ordered product turns it into a sum of normal-ordered terms with contractions, one contraction being one propagator, and the resulting combinatorics is exactly Proposition 100.14. That is the equivalence, and it is why this chapter uses the three names interchangeably.

The second and deeper thing Dyson proved is that QED has only finitely many divergent amplitudes.

Theorem 100.17 (Superficial degree of divergence)**.** *Let a connected QED diagram have E_e external fermion lines and E_γ external photon lines. Its integrand behaves for large loop momentum as $\ell^D\,\mathrm{d}^{4L}\ell/\ell^{4L}$ with*

$$D = 4 - \frac{3}{2}E_e - E_\gamma\,, \tag{100.26}$$

independently of the order in α. Only the amplitudes with $D \geq 0$ can diverge overall, and there are exactly seven of them.

Rests on Equations (100.17) *and* (100.23) *and Theorem 100.10.*

Proof. *Derives Theorem 100.17.*

Let L be the number of loops, V the number of vertices, and P_e, P_γ the numbers of internal fermion and photon lines. Each loop supplies $\mathrm{d}^4\ell$, each internal fermion line falls as ℓ^{-1} by Equation (100.23) and each internal photon line as ℓ^{-2} by Equation (100.17), so

$$D = 4L - P_e - 2P_\gamma\,.$$

The number of independent loops is the number of internal lines less the number of momentum conservation constraints, one per vertex, with one overall constraint left over: $L = P_e + P_\gamma - V + 1$. Every vertex has exactly two fermion ends and one photon end, and every internal line uses two ends while every external line uses one, so

$$2V = 2P_e + E_e\,, \qquad V = 2P_\gamma + E_\gamma\,.$$

Eliminating $P_e = V - E_e/2$ and $P_\gamma = (V - E_\gamma)/2$,

$$D = 4\,(P_e + P_\gamma - V + 1) - P_e - 2P_\gamma = 3P_e + 2P_\gamma - 4V + 4 = 3V - \frac{3}{2}E_e + V - E_\gamma - 4V + 4\,,$$

which is Equation (100.26): V cancels, so D does not grow with the order. Enumerating the non-negative cases, with E_e even by fermion-number conservation:

E_e	E_γ	D	amplitude
0	0	4	vacuum bubble (unobservable normalization)
0	1	3	photon tadpole — vanishes by Theorem 100.10
0	2	2	photon self-energy (Section 100.4.1)
0	3	1	vanishes by Theorem 100.10
0	4	0	light-by-light (Section 100.8.3)
2	0	1	electron self-energy (Section 100.4.2)
2	1	0	vertex correction (Section 100.4.3)

Every other amplitude has $D < 0$ and is superficially convergent. □

Definition 100.18 (Renormalizability)**.** A theory is *renormalizable* when the number of primitively divergent amplitudes is finite, so that a finite number of parameters absorbs every divergence at every order. QED is renormalizable by Theorem 100.17: three of the seven cases vanish or are unobservable and, as Section 100.4.1 and Section 100.8.3 will show, gauge invariance reduces the photon self-energy from quadratic to logarithmic divergence and makes the light-by-light amplitude finite outright. What remains is absorbed into the electron mass, the electron charge and two field normalizations [928].

Remark 100.19 (What "superficial" conceals). Theorem 100.17 controls the overall divergence of a diagram, not the divergences of its subdiagrams: a convergent-looking seven-loop graph may contain a divergent vertex inside it. Making the bookkeeping of nested and, worse, *overlapping* subdivergences work to all orders is the content of the BPHZ theorem of Section 100.5.3, and it took from 1949 to 1969 to complete.

100.3 Tree-level QED

100.3.1 Elementary processes

At lowest order in α the rules of Proposition 100.14 give every elastic and radiative process of charged leptons and photons. The list below is the working inventory of accelerator and detector physics; the numbers it produces are what Chapter 115 uses to interpret a shower and what Chapter 113 uses to normalize a luminosity.

Phenomenon 100.20 (The Compton shift)**.** X-rays scattered by loosely bound electrons emerge with a wavelength longer than that of the incident beam, the increase depending on the scattering angle θ but neither on the incident wavelength nor on the scattering material,

$$\lambda' - \lambda = \frac{h}{m_e c}\,(1 - \cos\theta)\ , \tag{100.27}$$

where $h/m_e c = 2.426\,31 \times 10^{-12}\,\mathrm{m}$ is the electron Compton wavelength [2431]. Compton measured it in 1923 [499]; the experiment is described in Chapter 69. The rate at which it occurs is the Klein–Nishina cross-section, whose non-relativistic limit is the Thomson formula of Section 65.6.1.

Rests on Equation (100.1).

Derivation. *Derives Phenomenon 100.20.*

Treat the radiation as quanta of energy $\hbar\omega$ and momentum $\hbar\boldsymbol{k}$ with $|\boldsymbol{k}| = \omega/c$, and the target as a free electron at rest. Conservation of energy and of momentum give

$$\hbar\omega + m_e c^2 = \hbar\omega' + E\,, \qquad \hbar\boldsymbol{k} = \hbar\boldsymbol{k}' + \boldsymbol{p}\,. \tag{100.28}$$

Squaring the second, $p^2 = \hbar^2(k^2 + k'^2 - 2kk'\cos\theta)$, and substituting it together with $E = \hbar(\omega - \omega') + m_e c^2$ into the mass-shell relation $E^2 = p^2c^2 + m_e^2c^4$ gives

$$\hbar^2 c^2 \left(k - k'\right)^2 + 2\hbar m_e c^3 \left(k - k'\right) = \hbar^2 c^2 \left(k^2 + k'^2 - 2kk'\cos\theta\right) .$$

The terms in k^2 and k'^2 cancel between the two sides, leaving $m_e c\,(k - k') = \hbar k k'\,(1 - \cos\theta)$, that is $1/k' - 1/k = (\hbar/m_e c)(1 - \cos\theta)$. Multiplying by 2π and using $\lambda = 2\pi/k$ gives Equation (100.27). The shift is purely kinematic: it follows from treating light as a particle of energy $\hbar\omega$ and momentum $\hbar\omega/c$, and it involves no property of the electron except its mass. The assumption that fails for tightly bound electrons is that the target is free, which is why an unshifted line survives beside the shifted one. □

The kinematics is one thing and the rate another. Two diagrams contribute to $\gamma e^- \to \gamma e^-$ at order α — the photon absorbed before or after the emission — and the spin-summed squared amplitude is

$$\overline{|\mathcal{M}|^2} = 32\pi^2\alpha^2\hbar^4 \left[\frac{p\cdot k'}{p\cdot k} + \frac{p\cdot k}{p\cdot k'} + 2m_e^2c^2\left(\frac{1}{p\cdot k} - \frac{1}{p\cdot k'}\right) + m_e^4c^4\left(\frac{1}{p\cdot k} - \frac{1}{p\cdot k'}\right)^2\right] , \tag{100.29}$$

where p, k are the incoming electron and photon momenta and k' the outgoing photon momentum. In the electron rest frame this reduces to the Klein–Nishina cross-section [630],

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{r_e^2}{2}\left(\frac{\omega'}{\omega}\right)^2\left(\frac{\omega}{\omega'} + \frac{\omega'}{\omega} - \sin^2\theta\right) , \qquad r_e = \frac{e^2}{4\pi\varepsilon_0 m_e c^2} = \frac{\alpha\hbar}{m_e c} , \tag{100.30}$$

with $r_e = 2.817\,940\,320\,5 \times 10^{-15}\,\mathrm{m}$ the classical electron radius [2431] and ω'/ω fixed by Equation (100.27).

Derivation pending #135

Klein–Nishina cross-section: the spin-summed trace computation of the two-diagram Compton amplitude leading to the squared matrix element and, after the rest-frame kinematics, to the angular distribution; the same computation gives the total cross section as a function of the ratio of photon energy to electron rest energy. It is a page of Dirac-algebra manipulation of the kind carried out in full for the vertex correction below, and belongs in Appendix A.

Proposition 100.21 (Thomson is the soft limit)**.** *For $\hbar\omega \ll m_e c^2$, Equation (100.30) reduces to the classical Thomson formula of Section 65.6.1,*

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} \longrightarrow \frac{r_e^2}{2}\left(1 + \cos^2\theta\right) , \qquad \sigma_{\mathrm{T}} = \frac{8\pi}{3}r_e^2 = 6.652\,458\,7 \times 10^{-29}\,\mathrm{m}^2 . \tag{100.31}$$

Rests on Equations (100.27) and (100.30).

Proof. *Derives Proposition 100.21.*

By Equation (100.27), $\omega'/\omega = \left[1 + (\hbar\omega/m_e c^2)(1 - \cos\theta)\right]^{-1} \to 1$ when $\hbar\omega \ll m_e c^2$. Then $\omega/\omega' + \omega'/\omega \to 2$ and the bracket in Equation (100.30) becomes $2 - \sin^2\theta = 1 + \cos^2\theta$. Integrating, $\int (1 + \cos^2\theta)\,\mathrm{d}\Omega = 4\pi + \frac{4}{3}\pi = \frac{16}{3}\pi$, so $\sigma = \frac{1}{2}r_e^2 \cdot \frac{16}{3}\pi = \frac{8}{3}\pi r_e^2$. Numerically $r_e^2 = 7.9408 \times 10^{-30}\,\mathrm{m}^2$ and $\frac{8}{3}\pi = 8.3776$, giving $6.652 \times 10^{-29}\,\mathrm{m}^2$, the accepted Thomson cross-section. The limit is the quantitative statement that classical electrodynamics is recovered when the photon carries away no appreciable recoil, and the departure from it, first seen as the falling cross-section for hard X-rays, is direct evidence that scattering is a quantum process. □

The remaining tree processes are obtained the same way and are listed here with their defining features rather than their derivations, each of which is the same trace computation.

- *Møller scattering* $e^-e^- \to e^-e^-$ [704]: two diagrams, t- and u-channel photon exchange, related by the antisymmetry of Proposition 100.14(7). In the ultrarelativistic limit

$$\overline{|\mathcal{M}|^2} = 32\pi^2\alpha^2\hbar^4\left[\frac{s^2+u^2}{t^2} + \frac{s^2+t^2}{u^2} + \frac{2s^2}{tu}\right].$$

- *Bhabha scattering* $e^+e^- \to e^+e^-$ [769]: t-channel exchange plus s-channel annihilation,

$$\overline{|\mathcal{M}|^2} = 32\pi^2\alpha^2\hbar^4\left[\frac{u^2+s^2}{t^2} + \frac{u^2+t^2}{s^2} + \frac{2u^2}{st}\right].$$

  The t-channel pole makes small-angle Bhabha scattering enormous and calculable, which is why every e^+e^- collider measures its luminosity with it — and, as Section 100.7.2 records, why the same process measures the running of α.

- *Annihilation* $e^+e^- \to \mu^+\mu^-$: a single s-channel diagram, giving in the massless limit $\overline{|\mathcal{M}|^2} = 32\pi^2\alpha^2\hbar^4(t^2+u^2)/s^2$ and the total cross section

$$\sigma\left(e^+e^- \to \mu^+\mu^-\right) = \frac{4\pi\alpha^2\hbar^2}{3s} = \frac{4\pi\alpha^2\,(\hbar c)^2}{3E_{\mathrm{cm}}^2}, \tag{100.32}$$

  the reference cross-section against which the hadronic ratio R of Chapter 102 is defined.

- *Pair annihilation into photons* $e^+e^- \to \gamma\gamma$, the process by which positrons disappear in matter and the decay channel of positronium in Section 100.8.4. Its non-relativistic cross-section is $\sigma \to \pi r_e^2 c/v$ [1043], diverging as $v \to 0$ in the way characteristic of an exothermic reaction with a Coulomb-attracted initial state; the conceptual origin is Dirac's hole theory [647], though the field-theoretic derivation needs no holes.

- *Bremsstrahlung* in the field of a nucleus, whose Born-approximation cross-section is the Bethe–Heitler formula [732]. Integrated over photon energies it gives the radiation length X_0, the depth over which an electron's energy falls by e^{-1}, and together with pair production it generates the electromagnetic cascade that every calorimeter measures. For lead $X_0 = 5.612 \times 10^{-3}\,\mathrm{m}$ [2427].

Derivation pending #136

Tree-level cross-sections: the spin-summed trace computations for Møller, Bhabha, muon-pair and two-photon annihilation, and the Born-approximation Bethe–Heitler bremsstrahlung cross-section together with the definition of the radiation length that follows from it. Each is an application of the trace technology established in the next subsection and belongs in Appendix A.

100.3.2 From amplitudes to observables

An amplitude is not an observable. Three steps separate them: summing over unobserved spins, which is done with traces; integrating over final-state momenta, which is done with invariant phase space; and dividing by the incident flux.

Lemma 100.22 (Spin sums)**.** *For Dirac spinors normalized as in Proposition 100.14,*

$$\sum_s u(p,s)\bar{u}(p,s) = \gamma^\mu p_\mu + m_e c\,, \qquad \sum_s v(p,s)\bar{v}(p,s) = \gamma^\mu p_\mu - m_e c\,, \tag{100.33}$$

and, for the photon in an amplitude contracted with a conserved current,

$$\sum_\lambda \varepsilon^\mu_{(\lambda)} \varepsilon^{*\nu}_{(\lambda)} \longrightarrow -\eta^{\mu\nu}\,. \tag{100.34}$$

Rests on Proposition 100.14.

Proof. *Derives Lemma 100.22.*

Both spinor sums are projectors onto the positive- and negative-frequency solutions of the Dirac equation, and are verified by evaluating both sides in the rest frame, where $\gamma^\mu p_\mu = m_e c\gamma^0$ and the two-dimensional spin sums give $\frac{1}{2}(1 \pm \gamma^0)\cdot 2m_e c$; the general case follows by boosting, since both sides transform as bispinor matrices. For the photon, the physical sum runs over the two transverse polarizations only and is not covariant. Writing the amplitude as $\mathcal{M} = \varepsilon^*_\mu \mathcal{M}^\mu$ with $k_\mu \mathcal{M}^\mu = 0$ — gauge invariance, established to all orders in Section 100.5.2 — the two transverse terms may be completed to the full $-\eta^{\mu\nu}$ because the extra longitudinal and scalar pieces are proportional to k^μ or k^ν and annihilate $\mathcal{M}^\mu$. The replacement is therefore legitimate inside a gauge-invariant amplitude and nowhere else. □

Lemma 100.23 (Trace theorems)**.** *With $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbb{1}$ and $\gamma^5 = \mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$, the trace of a product of an odd number of gamma matrices vanishes, as does $\operatorname{tr}\gamma^5$, while*

$$\operatorname{tr}\mathbb{1} = 4\,, \qquad \operatorname{tr}(\gamma^\mu\gamma^\nu) = 4\eta^{\mu\nu}\,, \tag{100.35}$$

$$\operatorname{tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = 4\left(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\right), \tag{100.36}$$

and the contraction identities, valid in four dimensions,

$$\gamma^\nu\gamma_\nu = 4\,, \quad \gamma^\nu\gamma^\alpha\gamma_\nu = -2\gamma^\alpha\,, \quad \gamma^\nu\gamma^\alpha\gamma^\beta\gamma_\nu = 4\eta^{\alpha\beta}\,, \quad \gamma^\nu\gamma^\alpha\gamma^\beta\gamma^\rho\gamma_\nu = -2\gamma^\rho\gamma^\beta\gamma^\alpha\,. \tag{100.37}$$

Rests on Equation (100.5).

Proof. *Derives Lemma 100.23.*

$\operatorname{tr}(\gamma^\mu\gamma^\nu) = \frac{1}{2}\operatorname{tr}\{\gamma^\mu,\gamma^\nu\} = \eta^{\mu\nu}\operatorname{tr}\mathbb{1} = 4\eta^{\mu\nu}$. For an odd number, insert $(\gamma^5)^2 = \mathbb{1}$ and use $\{\gamma^5,\gamma^\mu\} = 0$ to move one γ^5 through n matrices, picking up $(-1)^n$; cyclicity of the trace then gives $\operatorname{tr}X = (-1)^n \operatorname{tr}X$, which vanishes for odd n. The four-index case follows by anticommuting γ^μ to the right through the other three, generating three two-index traces with alternating signs. For the contractions, $\gamma^\nu\gamma^\alpha\gamma_\nu = \gamma^\nu(2\eta^\alpha_{\ \nu} - \gamma_\nu\gamma^\alpha) = 2\gamma^\alpha - 4\gamma^\alpha = -2\gamma^\alpha$, and the higher ones follow by the same move applied repeatedly. That these identities carry a dimension-dependent number — the 4 in $\gamma^\nu\gamma_\nu = 4$ — is not innocent: it is exactly what must be tracked when the dimension is continued in Section 100.4.4. □

Proposition 100.24 (Cross-section master formula)**.** *For $1 + 2 \to n$ final particles,*

$$\mathrm{d}\sigma = \frac{1}{4\sqrt{(p_1\cdot p_2)^2 - m_1^2 m_2^2 c^4}}\,\overline{|\mathcal{M}|^2}\,\mathrm{d}\Phi_n\,, \tag{100.38}$$

$$\mathrm{d}\Phi_n = (2\pi\hbar)^4\,\delta^4\!\left(p_1 + p_2 - \sum_f p_f\right)\prod_f \frac{c\,\mathrm{d}^3p_f}{(2\pi\hbar)^3\,2E_f}\,. \tag{100.39}$$

For $n = 2$ in the centre-of-mass frame this becomes

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{1}{64\pi^2\hbar^2 s}\,\frac{|\boldsymbol{p}_f|}{|\boldsymbol{p}_i|}\,\overline{|\mathcal{M}|^2}\,. \tag{100.40}$$

Rests on Proposition 100.14 and Lemma 100.22.

Proof. *Derives Proposition 100.24.*

The transition probability per unit time and volume is $|\mathcal{M}|^2$ divided by the normalization of the four external states, and integrated over the available final momenta with the Lorentz-invariant measure $c\,\mathrm{d}^3p/(2\pi\hbar)^3 2E$, which is $\mathrm{d}^4p\,\delta(p^2-m^2c^2)\theta(p^0)$ in disguise and therefore invariant. Dividing by the incident flux $4\sqrt{(p_1\cdot p_2)^2-m_1^2m_2^2c^4}$, which is the invariant form of $|\boldsymbol{v}_1-\boldsymbol{v}_2|$ times the two densities, gives Equation (100.38). For two final particles the delta function removes three of the six momentum integrals and fixes $|\boldsymbol{p}_f|$, leaving

$$\mathrm{d}\Phi_2=\frac{1}{\hbar^2}\frac{|\boldsymbol{p}_f|}{16\pi^2\sqrt{s}}\,\mathrm{d}\Omega\,,$$

and in the centre-of-mass frame the flux factor is $4\sqrt{s}\,|\boldsymbol{p}_i|$, whence Equation (100.40). The dimensional check is the useful one: $\mathrm{d}\Phi_2$ carries $\hbar^{-2}$, $|\mathcal{M}|^2$ carries $\hbar^4$ by Proposition 100.14, and the flux carries a squared momentum, so $\mathrm{d}\sigma$ carries $\hbar^2/p^2$, an area. □

Applied to Equation (100.32), Equation (100.40) gives $\sigma=8.68\times10^{-38}\,\mathrm{m}^2$ at $E_{\mathrm{cm}}=10\,\mathrm{GeV}$. Collider physics customarily quotes this as 0.868 nanobarns, the barn being $1\times10^{-28}\,\mathrm{m}^2$ by definition; it is not an SI unit and the SI value is the one recorded here.

The last step of the chain, and the one that fixes the sign and magnitude of the coupling once and for all, is the non-relativistic limit.

Theorem 100.25 (One-photon exchange is the Coulomb potential)**.** *The tree amplitude for the elastic scattering of two distinguishable charges q_1, q_2 by one-photon exchange reduces, for $|\boldsymbol{v}|\ll c$, to the first Born approximation for the potential*

$$V(r)=\frac{q_1q_2}{4\pi\varepsilon_0 r}\,, \tag{100.41}$$

repulsive for like charges. The Coulomb law of Chapter 58, and with it the hydrogen spectrum of Chapter 81, is therefore a prediction of Equation (100.12) and not an input.

Rests on Proposition 100.14 and Equations (100.14) and (100.17).

Proof. *Derives Theorem 100.25.*

The single t-channel diagram gives, by Proposition 100.14 in Feynman gauge,

$$\mathrm{i}\mathcal{M}=\left(-\frac{\mathrm{i}q_1}{\hbar}\right)\left(-\frac{\mathrm{i}q_2}{\hbar}\right)\frac{-\mathrm{i}\mu_0\hbar^3c\,\eta_{\mu\nu}}{t}\,[\bar u_3\gamma^\mu u_1]\,[\bar u_4\gamma^\nu u_2]\,,$$

that is $\mathcal{M}=q_1q_2\mu_0\hbar c\,t^{-1}\,[\bar u_3\gamma^\mu u_1]\,[\bar u_4\gamma_\mu u_2]$. In the non-relativistic limit the spatial components of $\bar u\gamma^\mu u$ are suppressed by $|\boldsymbol{v}|/c$ while the time component is $u^\dagger u=2E/c\to 2mc$, so the current product becomes $4m_1m_2c^2$, and the momentum transfer is spacelike, $t=-\boldsymbol{q}^2$ with $\boldsymbol{q}$ the three-momentum transfer. Hence

$$\mathcal{M}=-\frac{4q_1q_2\mu_0m_1m_2c^3\hbar}{\boldsymbol{q}^2}\,.$$

On the other side, an ordinary potential V treated in first Born approximation and re-expressed with the relativistic normalization of Proposition 100.14 contributes $\mathcal{M}=-(2m_1c)(2m_2c)\widetilde V(\boldsymbol{q})/\hbar c$, the factor $(\hbar c)^{-1}$ arising from $\exp(\mathrm{i}S/\hbar)$ together with $\int\mathrm{d}t=c^{-1}\int\mathrm{d}x^0$. Equating,

$$\widetilde V(\boldsymbol{q})=\frac{q_1q_2\mu_0\hbar^2c^2}{\boldsymbol{q}^2}=\frac{q_1q_2\hbar^2}{\varepsilon_0\boldsymbol{q}^2}\,,$$

using $\varepsilon_0\mu_0c^2=1$. Inverting the transform Equation (100.14) in three dimensions,

$$V(r)=\frac{q_1q_2\hbar^2}{\varepsilon_0}\int\frac{\mathrm{d}^3q}{(2\pi\hbar)^3}\frac{\mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}/\hbar}}{\boldsymbol{q}^2}=\frac{q_1q_2\hbar^2}{\varepsilon_0}\cdot\frac{1}{8\pi^3\hbar^3}\cdot\frac{2\pi^2\hbar}{r}=\frac{q_1q_2}{4\pi\varepsilon_0 r}\,,$$

the angular integral giving $4\pi\hbar\sin(qr/\hbar)/qr$ and the remaining radial integral $\int_0^\infty \sin(x)\,\mathrm{d}x/x = \pi/2$ after the substitution $x = qr/\hbar$. That integral is half the imaginary part of the principal-value integral of $\mathrm{e}^{\mathrm{i}z}/z$ along the real axis, which is evaluated by closing in the upper half plane and indenting the contour at the origin, where the half-residue contributes $\mathrm{i}\pi$; it is the residue theorem Theorem 8.24 in the indented form carried out in Theorem 17.78, and not the unindented archetype worked in Section 8.7 itself. The sign is the physical one: $q_1 q_2 > 0$ gives a positive, repulsive potential. What produced it is the $\eta_{\mu\nu}$ of the photon propagator contracted with two timelike currents; had the exchanged quantum been a scalar the same computation would have given attraction between like charges, which is the standard argument that the photon must be a vector. □

100.4 One loop: where the infinities are

At order α^2 in a cross-section the amplitude acquires its first loop, and every one of the seven amplitudes listed in Theorem 100.17 diverges. This section computes the three that matter, in full. The tools are assembled first, because all three computations use the same four of them and each is a piece of mathematics that exists elsewhere in this book.

Lemma 100.26 (Feynman parametrization)**.** *For any $A_1, \dots, A_n$ not lying on a common ray through the origin of the negative reals,*

$$\frac{1}{A_1 A_2 \cdots A_n} = (n-1)! \int_0^1 \mathrm{d}x_1 \cdots \mathrm{d}x_n \, \frac{\delta(1 - \sum_i x_i)}{\left[\sum_i x_i A_i\right]^n} \,. \tag{100.42}$$

In particular $1/AB = \int_0^1 \mathrm{d}x\, [xA + (1-x)B]^{-2}$.
Rests on Equation (17.109).

Proof. *Derives Lemma 100.26.*
For $n = 2$, substitute directly:

$$\int_0^1 \frac{\mathrm{d}x}{[xA + (1-x)B]^2} = \left[\frac{-1}{(A-B)\,(xA + (1-x)B)}\right]_0^1 = \frac{1}{A-B}\left(\frac{1}{B} - \frac{1}{A}\right) = \frac{1}{AB} \,.$$

For general n, differentiate Equation (100.42) for $n-1$ with respect to one of the A_i, which multiplies the left-hand side by an extra factor and raises the power on the right; equivalently, use the integral representation $1/A^a = \Gamma(a)^{-1} \int_0^\infty \mathrm{d}t\, t^{a-1} \mathrm{e}^{-tA}$, multiply n of them together, insert $1 = \int_0^\infty \mathrm{d}\lambda\, \delta(\lambda - \sum t_i)$ and rescale $t_i = \lambda x_i$; the λ integral is then a gamma function and the x_i integral is Equation (100.42). The purpose of the identity is geometric: it replaces n propagator poles at different places by a single quadratic form, which after a shift of the loop momentum depends on the external momenta only through one scalar Δ. □

Lemma 100.27 (Wick rotation)**.** *Let f be a rational function of ℓ^0 decaying faster than $(\ell^0)^{-1}$ at infinity, whose only singularities are the propagator poles displaced by the $\mathrm{i}\epsilon$ prescription of Equation (100.23). Then the contour of the ℓ^0 integration may be rotated anticlockwise from the real axis to the imaginary axis, $\ell^0 = \mathrm{i}\ell^0_{\mathrm{E}}$, giving*

$$\int \mathrm{d}^4\ell \; f\left(\ell^2\right) = \mathrm{i} \int \mathrm{d}^4\ell_{\mathrm{E}} \; f\left(-\ell^2_{\mathrm{E}}\right) \,, \qquad \ell^2_{\mathrm{E}} = \left(\ell^0_{\mathrm{E}}\right)^2 + \boldsymbol{\ell}^2 \,, \tag{100.43}$$

so that the Minkowski integral becomes a Euclidean one with positive definite denominator.
Rests on Equation (100.23) and Theorem 8.12.

Proof. *Derives Lemma 100.27.*
The denominator $\ell^2 - \Delta + \mathrm{i}\epsilon$ vanishes at $\ell^0 = \pm\left(\sqrt{\boldsymbol{\ell}^2 + \Delta} - \mathrm{i}\epsilon\right)$: one pole just below the positive real axis and one just above the negative real axis. The quadrant between the

positive real axis and the positive imaginary axis, and the quadrant between the negative real axis and the negative imaginary axis, are therefore free of singularities, and the arcs at infinity contribute nothing by the decay hypothesis. Cauchy's theorem (Theorem 8.12) applied to the closed contour made of the real segment, the arc and the imaginary segment gives Equation (100.43), the factor i coming from $\mathrm{d}\ell^0 = \mathrm{i}\,\mathrm{d}\ell^0_{\mathrm{E}}$ and the sign of $\ell^2 = (\ell^0)^2 - \boldsymbol{\ell}^2 = -\ell^2_{\mathrm{E}}$. The i$\epsilon$ prescription is thus not a convenience: it is what makes the rotation legal, and a different prescription would rotate the contour into a pole and give a different — and acausal — answer. □

Lemma 100.28 (The d-dimensional loop integral)**.** *For $\Delta > 0$ and d a complex parameter with $0 < \Re d < 2n$,*

$$\int \frac{\mathrm{d}^d \ell_{\mathrm{E}}}{(2\pi\hbar)^d} \frac{1}{\left(\ell^2_{\mathrm{E}} + \Delta\right)^n} = \frac{1}{\hbar^d \,(4\pi)^{d/2}} \frac{\Gamma\left(n - \frac{d}{2}\right)}{\Gamma(n)} \,\Delta^{\frac{d}{2}-n}\,, \tag{100.44}$$

and, after undoing the Wick rotation of Lemma 100.27,

$$\int \frac{\mathrm{d}^d \ell}{(2\pi\hbar)^d} \frac{1}{\left(\ell^2 - \Delta + \mathrm{i}\epsilon\right)^n} = \frac{(-1)^n\,\mathrm{i}}{\hbar^d \,(4\pi)^{d/2}} \frac{\Gamma\left(n - \frac{d}{2}\right)}{\Gamma(n)} \,\Delta^{\frac{d}{2}-n}\,, \tag{100.45}$$

$$\int \frac{\mathrm{d}^d \ell}{(2\pi\hbar)^d} \frac{\ell^2}{\left(\ell^2 - \Delta + \mathrm{i}\epsilon\right)^n} = \frac{(-1)^{n-1}\,\mathrm{i}}{\hbar^d \,(4\pi)^{d/2}} \frac{d}{2} \frac{\Gamma\left(n - 1 - \frac{d}{2}\right)}{\Gamma(n)} \,\Delta^{\frac{d}{2}-n+1}\,. \tag{100.46}$$

Moreover $\ell^\mu \ell^\nu$ in a numerator may be replaced by $\eta^{\mu\nu}\ell^2/d$.

Rests on Lemma 100.27 and Equations (17.42) and (17.109).

Proof. *Derives Lemma 100.28.*

Write the Euclidean integral in polar coordinates. The surface area of the unit sphere S^{d-1} follows from the Gaussian integral of Chapter 17 — take Equation (17.42) at zero frequency, giving $\int_{-\infty}^{\infty} \mathrm{e}^{-t^2}\mathrm{d}t = \sqrt{\pi}$ — evaluated in two ways:

$$\pi^{d/2} = \left(\int_{-\infty}^{\infty} \mathrm{e}^{-t^2}\mathrm{d}t\right)^d = \int \mathrm{d}^d \ell_{\mathrm{E}}\, \mathrm{e}^{-\ell^2_{\mathrm{E}}} = \Omega_d \int_0^\infty r^{d-1}\mathrm{e}^{-r^2}\,\mathrm{d}r = \frac{\Omega_d}{2}\,\Gamma\left(\frac{d}{2}\right)\,,$$

the last step by $u = r^2$ and the integral representation of the gamma function, Equation (17.109). Hence $\Omega_d = 2\pi^{d/2}/\Gamma(d/2)$, an expression that is *defined* for complex d even though no sphere is — which is the whole content of dimensional continuation. The radial integral is a beta function: with $u = r^2$,

$$\int_0^\infty \frac{r^{d-1}\mathrm{d}r}{(r^2+\Delta)^n} = \frac{1}{2}\int_0^\infty \frac{u^{\frac{d}{2}-1}\,\mathrm{d}u}{(u+\Delta)^n} = \frac{\Delta^{\frac{d}{2}-n}}{2}\,\frac{\Gamma\left(\frac{d}{2}\right)\Gamma\left(n-\frac{d}{2}\right)}{\Gamma(n)}\,,$$

convergent at the origin for $\Re d > 0$ and at infinity for $\Re d < 2n$. Assembling with the measure $(2\pi\hbar)^{-d}$ and cancelling $\Gamma(d/2)$ gives Equation (100.44). Equation (100.45) follows from Lemma 100.27, which supplies the factor i and turns $(\ell^2 - \Delta)^n$ into $(-1)^n(\ell^2_{\mathrm{E}} + \Delta)^n$; Equation (100.46) follows from the same rotation with $\ell^2 = -\ell^2_{\mathrm{E}}$ in the numerator and the radial integral run with $d \to d+2$. The replacement $\ell^\mu\ell^\nu \to \eta^{\mu\nu}\ell^2/d$ holds because the integral of $\ell^\mu\ell^\nu$ against a function of ℓ^2 is an invariant tensor, hence proportional to $\eta^{\mu\nu}$, and the constant is fixed by tracing. □

Lemma 100.29 (The pole of the gamma function)**.** *Near $\varepsilon = 0$,*

$$\Gamma(\varepsilon) = \frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + O(\varepsilon)\,, \qquad \gamma_{\mathrm{E}} = 0.577\,215\,664\,9\,, \tag{100.47}$$

and more generally $\Gamma(-n+\varepsilon)$ has a simple pole of residue $(-1)^n/n!$ at every non-positive integer.

Rests on Equation (17.109) and Example 17.95.

Proof. *Derives Lemma 100.29.*

From $\Gamma(1+\varepsilon) = \varepsilon\Gamma(\varepsilon)$ and the Weierstrass product, $\ln\Gamma(1+\varepsilon) = -\gamma_{\mathrm{E}}\varepsilon + O(\varepsilon^2)$, so $\Gamma(\varepsilon) = \varepsilon^{-1}\Gamma(1+\varepsilon) = \varepsilon^{-1}\left(1 - \gamma_{\mathrm{E}}\varepsilon + \dots\right)$, which is Equation (100.47). The poles and their residues are recorded, from the Mellin point of view, at Example 17.95. This simple pole is where every ultraviolet divergence of this chapter will appear: an integral that diverges logarithmically in four dimensions converges for $\Re d < 4$ and its analytic continuation has a first-order pole at $d = 4$. □

Definition 100.30 (Dimensional continuation of the loop)**.** Set $d = 4 - 2\varepsilon$ and replace every four-dimensional loop measure by

$$\int \frac{\mathrm{d}^4\ell}{(2\pi\hbar)^4} \;\longmapsto\; \left(\frac{\bar{\mu}}{\hbar}\right)^{4-d} \int \frac{\mathrm{d}^d\ell}{(2\pi\hbar)^d}\,, \tag{100.48}$$

where $\bar{\mu}$ is an arbitrary momentum, the renormalization scale; the literature quotes it as the energy $\mu = \bar{\mu}c$, in GeV. The factor $(\bar{\mu}/\hbar)^{4-d}$ is not cosmetic: both sides of Equation (100.48) then carry $1/\mathrm{m}^4$, so that every amplitude keeps its four-dimensional SI dimension while d varies, and the coupling α stays the dimensionless number Equation (100.3). That $\bar{\mu}$ has entered is the germ of the renormalization group of Chapter 108: no observable may depend on it, and requiring that gives an equation.

100.4.1 Vacuum polarization

The photon propagates through a vacuum that is polarizable, because a photon may convert into a virtual electron–positron pair and back. The amplitude for this is the one-loop photon self-energy.

Theorem 100.31 (One-loop vacuum polarization)**.** *The one-loop photon self-energy is transverse,*

$$\Pi^{\mu\nu}(q) = \frac{q^2\eta^{\mu\nu} - q^\mu q^\nu}{\mu_0\hbar^3 c}\,\Pi_2\!\left(q^2\right)\,, \tag{100.49}$$

with the dimensionless function

$$\Pi_2\!\left(q^2\right) = -\frac{2\alpha}{\pi}\int_0^1 \mathrm{d}x\; x(1-x)\left[\frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \ln 4\pi - \ln\frac{\Delta}{\bar{\mu}^2}\right]\,, \qquad \Delta = m_e^2c^2 - x(1-x)q^2\,. \tag{100.50}$$

Its divergence is logarithmic, not quadratic as Theorem 100.17 allows, and the photon acquires no mass.

Rests on Proposition 100.14 and Lemmas 100.23 and 100.28.

Proof. *Derives Theorem 100.31.*

By Proposition 100.14, with the closed-fermion-loop factor -1 and the vertex Equation (100.24) evaluated at the electron charge $-e$, so that each vertex is $+\mathrm{i}e\gamma^\mu/\hbar$,

$$\mathrm{i}\Pi^{\mu\nu}(q) = -\left(\frac{\mathrm{i}e}{\hbar}\right)^2\left(\frac{\bar{\mu}}{\hbar}\right)^{4-d}\int\frac{\mathrm{d}^d\ell}{(2\pi\hbar)^d}\,\mathrm{tr}\left[\gamma^\mu\frac{\mathrm{i}\hbar\,(\gamma\cdot\ell + m_ec)}{\ell^2 - m_e^2c^2}\,\gamma^\nu\frac{\mathrm{i}\hbar\,(\gamma\cdot\ell' + m_ec)}{\ell'^2 - m_e^2c^2}\right]\,,$$

with $\ell' = \ell + q$. The numerical prefactor is $-(-e^2/\hbar^2)(\mathrm{i}\hbar)^2 = -e^2$, so

$$\mathrm{i}\Pi^{\mu\nu}(q) = -e^2\left(\frac{\bar{\mu}}{\hbar}\right)^{4-d}\int\frac{\mathrm{d}^d\ell}{(2\pi\hbar)^d}\,\frac{N^{\mu\nu}}{\left(\ell^2 - m_e^2c^2\right)\left(\ell'^2 - m_e^2c^2\right)}\,, \tag{100.51}$$

where, by Lemma 100.23,

$$N^{\mu\nu} = \mathrm{tr}\left[\gamma^\mu\left(\gamma\cdot\ell + m_ec\right)\gamma^\nu\left(\gamma\cdot\ell' + m_ec\right)\right] = 4\left[\ell^\mu\ell'^\nu + \ell^\nu\ell'^\mu - \eta^{\mu\nu}\left(\ell\cdot\ell' - m_e^2c^2\right)\right]\,,$$

the odd-trace terms vanishing. Combine the two denominators with Lemma 100.26 and shift $k = \ell + xq$; the denominator becomes $\left(k^2 - \Delta\right)^2$ with Δ as stated. Dropping the terms odd in k and using $k^\mu k^\nu \to \eta^{\mu\nu} k^2/d$ from Lemma 100.28,

$$N^{\mu\nu} \longrightarrow 4\left[\left(\frac{2}{d} - 1\right) k^2 \eta^{\mu\nu} - 2x(1-x) q^\mu q^\nu + \eta^{\mu\nu}\left(m_e^2 c^2 + x(1-x) q^2\right)\right] .$$

Now apply Equation (100.45) and Equation (100.46) with $n = 2$. The first term gives

$$-\left(\frac{2}{d} - 1\right) \frac{\mathrm{i}}{\hbar^d \left(4\pi\right)^{d/2}} \frac{d}{2} \Gamma\left(1 - \frac{d}{2}\right) \Delta^{\frac{d}{2} - 1} = -\frac{\mathrm{i}}{\hbar^d \left(4\pi\right)^{d/2}} \Gamma\left(2 - \frac{d}{2}\right) \Delta^{\frac{d}{2} - 1} ,$$

the leading minus sign being the $(-1)^{n-1}$ of Equation (100.46) at $n = 2$, and using $\Gamma(1 - \frac{d}{2}) = \Gamma(2 - \frac{d}{2})/(1 - \frac{d}{2})$, which converts the leading $\Gamma(1 - d/2)$ — the quadratic divergence, with a pole already at $d = 2$ — into $\Gamma(2 - d/2)$. The third term gives $+\mathrm{i}\hbar^{-d}(4\pi)^{-d/2}\Gamma(2 - \frac{d}{2}) \left(m_e^2 c^2 + x(1-x) q^2\right) \Delta^{\frac{d}{2} - 2}$, and since $m_e^2 c^2 + x(1-x) q^2 = \Delta + 2x(1-x) q^2$ the two $\eta^{\mu\nu}$ contributions cancel except for $2x(1-x) q^2 \eta^{\mu\nu}$. Collecting with the $q^\mu q^\nu$ term,

$$\mathrm{i}\Pi^{\mu\nu} = -e^2 \left(\frac{\bar{\mu}}{\hbar}\right)^{4-d} \frac{8\mathrm{i}}{\hbar^d \left(4\pi\right)^{d/2}} \left(q^2 \eta^{\mu\nu} - q^\mu q^\nu\right) \int_0^1 \mathrm{d}x \; x(1-x) \, \Gamma\left(2 - \frac{d}{2}\right) \Delta^{\frac{d}{2} - 2} .$$

The cancellation is the whole point: it is forced by gauge invariance (equivalently by Equation (100.18)), it removes the quadratic divergence that would otherwise have generated a photon mass term $\propto \Lambda^2 \eta^{\mu\nu}$, and it is what Section 100.4.4 means by saying that dimensional regularization respects the symmetry while a momentum cutoff does not. Writing $d = 4 - 2\varepsilon$ and stripping the tensor structure according to Equation (100.49),

$$\Pi_2 = -\mu_0 \hbar^3 c \, e^2 \frac{8}{\hbar^4 \left(4\pi\right)^2} \int_0^1 \mathrm{d}x \; x(1-x) \left(\frac{4\pi\bar{\mu}^2}{\Delta}\right)^{\varepsilon} \Gamma(\varepsilon) = -\frac{2\alpha}{\pi} \int_0^1 \mathrm{d}x \; x(1-x) \left[\frac{1}{\varepsilon} + \dots\right] ,$$

where $\mu_0 c e^2/\hbar = 4\pi\alpha$ by Equation (100.4) and $8/(4\pi)^2 = 1/2\pi^2$, so that the numerical factor is $4\pi\alpha/2\pi^2 = 2\alpha/\pi$; the expansion of $\Gamma(\varepsilon)$ is Lemma 100.29. This is Equation (100.50). Note that every $\hbar$ has cancelled: Π_2 is a pure number, as it must be, since it corrects a dimensionless coupling. □

Corollary 100.32 (The dressed photon propagator)**.** *Summing the geometric series of one-particle-irreducible insertions, the full photon propagator in Feynman gauge is*

$$\widetilde{D}_{\mu\nu}(q) = \frac{-\mathrm{i}\mu_0 \hbar^3 c \, \eta_{\mu\nu}}{q^2 \left[1 - \Pi_2(q^2)\right]} + (\textit{terms} \propto q_\mu q_\nu) , \tag{100.52}$$

the omitted terms dropping out of every amplitude by Equation (100.18). The pole stays at $q^2 = 0$: the photon remains massless to all orders in α, which is the statement that $\Pi^{\mu\nu}$ carries an explicit factor q^2.

Rests on Equations (100.18) and (100.49).

Proof. *Derives Corollary 100.32.*

Each insertion contributes $\widetilde{D}\,(\mathrm{i}\Pi)\,\widetilde{D}$; using Equation (100.49) and the transverse projector, the nth term is Π_2^n times the free propagator, so the sum is $(1 - \Pi_2)^{-1}$ times it. A mass would require a pole at $q^2 \neq 0$, that is a term in $\Pi^{\mu\nu}$ surviving at $q = 0$; the explicit $q^2\eta^{\mu\nu} - q^\mu q^\nu$ forbids it. □

The divergent constant $\Pi_2(0)$ is absorbed into the definition of the charge in Section 100.5.1. What survives is the q^2-dependence, and it is measurable.

Proposition 100.33 (Uehling's modification of the Coulomb potential)**.** *For* $|q^2| \ll m_e^2 c^2$ *the renormalized polarization is*

$$\Pi_2\big(q^2\big) - \Pi_2(0) = -\frac{\alpha\, q^2}{15\pi\, m_e^2 c^2} + O\big(q^4\big)\,, \tag{100.53}$$

so that the potential of a nucleus of charge Ze *acquires the short-range Uehling term [762]*

$$\delta V(\boldsymbol{r}) = -\frac{4Z\alpha^2\hbar^3}{15\, m_e^2 c}\,\delta^3(\boldsymbol{r})\,, \tag{100.54}$$

which shifts an S *level of hydrogen by*

$$\delta E_n = -\frac{4\alpha^5 m_e c^2}{15\pi n^3} = -h \times 27.1\,\mathrm{MHz} \quad \textit{for } n = 2\,. \tag{100.55}$$

Rests on Equation (100.50) *and Theorem 100.25.*

Proof. *Derives Proposition 100.33.*

Subtracting Equation (100.50) at $q^2 = 0$ removes the pole and the scale:

$$\Pi_2\big(q^2\big) - \Pi_2(0) = -\frac{2\alpha}{\pi}\int_0^1 \mathrm{d}x\; x(1-x)\,\ln\frac{m_e^2c^2}{m_e^2c^2 - x(1-x)q^2}\,.$$

Expanding the logarithm for small $|q^2|$ gives $x(1-x)q^2/m_e^2c^2$, and $\int_0^1 x^2(1-x)^2\mathrm{d}x = 1/30$, whence Equation (100.53). The effective coupling seen at momentum transfer $\boldsymbol{q}$ is therefore $\alpha\,[1 + \alpha\boldsymbol{q}^2/15\pi m_e^2c^2]$ for spacelike $q^2 = -\boldsymbol{q}^2$, and Theorem 100.25 then gives

$$\widetilde{V}(\boldsymbol{q}) = -\frac{Ze^2\hbar^2}{\varepsilon_0\boldsymbol{q}^2}\left(1 + \frac{\alpha\boldsymbol{q}^2}{15\pi m_e^2c^2}\right),$$

whose second term is independent of $\boldsymbol{q}$ and therefore, on transforming back, proportional to $\delta^3(\boldsymbol{r})$:

$$\delta V(\boldsymbol{r}) = -\frac{Ze^2\hbar^2\alpha}{15\pi\varepsilon_0 m_e^2c^2}\,\delta^3(\boldsymbol{r}) = -\frac{4Z\alpha^2\hbar^3}{15m_e^2c}\,\delta^3(\boldsymbol{r})\,,$$

using $e^2/\varepsilon_0 = 4\pi\alpha\hbar c$. Taking the expectation value in a hydrogenic S state with $Z = 1$, where $|\psi_{n00}(0)|^2 = 1/\pi n^3 a_0^3$ and $a_0 = \hbar/\alpha m_e c$ (Chapter 81),

$$\delta E_n = -\frac{4\alpha^2\hbar^3}{15m_e^2c}\cdot\frac{\alpha^3 m_e^3c^3}{\pi n^3\hbar^3} = -\frac{4\alpha^5 m_e c^2}{15\pi n^3}\,.$$

Numerically, with $\alpha^5 = 2.0693\times10^{-11}$ and $m_ec^2 = 8.1871\times10^{-14}\,\mathrm{J}$, the $n = 2$ value is $\delta E_2 = -1.798\times10^{-26}\,\mathrm{J}$, that is $\delta E_2/h = -27.1\,\mathrm{MHz}$. The sign is the physically important part: the vacuum *screens*, so the attraction is stronger at short distance and the $2S$ level, which has support at the origin, is pulled *down* relative to $2P$, which has none. This is one of the three one-loop contributions to the Lamb shift of Section 100.8.1, and the only one whose sign is opposite to the total; in muonic atoms, where the Bohr radius is smaller by $m_\mu/m_e \approx 207$ and the electron loop is no longer short-ranged compared with the orbit, the same term becomes the *dominant* QED correction, which is why muonic hydrogen [2164, 2210] measures the proton radius so sharply. □

Remark 100.34 (Screening, and its inversion)*.* The physical reading of Equation (100.53) is that the vacuum behaves as a dielectric: virtual pairs align against the field of a charge, so a test charge at large distance sees less than the bare charge and more of it as it penetrates. Because the polarizable quanta carry the same charge they screen, the effect always has this sign in QED, and the coupling grows with momentum transfer (Section 100.7). In a non-abelian theory the gauge bosons themselves carry the charge and contribute with the opposite sign; when they dominate, the coupling *falls* with momentum transfer, which is asymptotic freedom [1501, 1511] and the subject of Chapter 102.

100.4.2 Electron self-energy and mass renormalization

Theorem 100.35 (One-loop electron self-energy)**.** *Write the sum of one-particle-irreducible corrections to the electron propagator as* $-\mathrm{i}\Sigma(p)/\hbar$*, so that the full propagator is* $\mathrm{i}\hbar\,(\gamma\cdot p - m_e c - \Sigma(p))^{-1}$*. At one loop, with an infinitesimal photon mass* m_γ *retained as an infrared regulator,*

$$\Sigma_2(p) = \frac{\alpha}{2\pi}\int_0^1 \mathrm{d}x\ \left(2m_e c - x\,\gamma\cdot p\right)\left[\frac{1}{\varepsilon} - \gamma_{\mathrm{E}} + \ln 4\pi - \ln\frac{\Delta}{\bar\mu^2}\right], \tag{100.56}$$

with $\Delta = (1-x)m_e^2c^2 + x\,m_\gamma^2c^2 - x(1-x)p^2$*. The pairing matters and is fixed by the shift used below: the Feynman parameter* x *weights the* photon *denominator, so the electron mass enters* Δ *with weight* $1-x$ *and the photon mass with weight* x*, while the mass standing in the numerator is the electron's, carried by the fermion line. The divergence is logarithmic, although Theorem 100.17 permits a linear one.*

Rests on Proposition 100.14 and Lemmas 100.26 and 100.28.

Proof. *Derives Theorem 100.35.*

The rules of Proposition 100.14 give

$$-\frac{\mathrm{i}}{\hbar}\Sigma_2(p) = \left(\frac{\mathrm{i}e}{\hbar}\right)^2\left(\frac{\bar\mu}{\hbar}\right)^{4-d}\int\frac{\mathrm{d}^d\ell}{(2\pi\hbar)^d}\,\gamma^\mu\,\frac{\mathrm{i}\hbar\,(\gamma\cdot(p-\ell)+m_e c)}{(p-\ell)^2 - m_e^2c^2}\,\gamma^\nu\,\frac{-\mathrm{i}\mu_0\hbar^3 c\,\eta_{\mu\nu}}{\ell^2 - m_\gamma^2c^2},$$

whose numerical prefactor is $(-e^2/\hbar^2)(\mathrm{i}\hbar)(-\mathrm{i}\mu_0\hbar^3c) = -e^2\mu_0 c\hbar^2 = -4\pi\alpha\hbar^3$, so that

$$\Sigma_2(p) = -4\pi\mathrm{i}\alpha\,\hbar^4\left(\frac{\bar\mu}{\hbar}\right)^{4-d}\int\frac{\mathrm{d}^d\ell}{(2\pi\hbar)^d}\,\frac{\gamma^\mu\,(\gamma\cdot(p-\ell)+m_e c)\,\gamma_\mu}{\left[(p-\ell)^2 - m_e^2c^2\right]\left[\ell^2 - m_\gamma^2c^2\right]}, \tag{100.57}$$

with $\hbar^4(2\pi\hbar)^{-d}(\bar\mu/\hbar)^{4-d}$ reducing to $(2\pi)^{-4}$ at $d=4$ — every $\hbar$ again cancels, and Σ_2 comes out with the dimension of a momentum, as the mass term it corrects requires. Combine the denominators with Lemma 100.26, weight x on the photon line — equivalently $1-x$ on the electron line — and shift $k = \ell - (1-x)p$; completing the square gives $(k^2-\Delta)^2$ with Δ as stated, and the numerator's $\gamma\cdot(p-\ell) = \gamma\cdot(xp-k)$ then supplies the x that multiplies $\gamma\cdot p$. In the numerator use Equation (100.37) in d dimensions, $\gamma^\mu\gamma^\alpha\gamma_\mu = -(2-2\varepsilon)\gamma^\alpha$ and $\gamma^\mu\gamma_\mu = d$, drop the terms odd in k, and there remains $-(2-2\varepsilon)\,x\,\gamma\cdot p + (4-2\varepsilon)\,m_e c$, which at $\varepsilon = 0$ is $-2x\,\gamma\cdot p + 4m_e c$. Applying Equation (100.45) with $n=2$,

$$\Sigma_2 = -4\pi\mathrm{i}\alpha\cdot\frac{\mathrm{i}}{(4\pi)^2}\int_0^1\mathrm{d}x\,(4m_e c - 2x\,\gamma\cdot p)\left(\frac{4\pi\bar\mu^2}{\Delta}\right)^{\varepsilon}\Gamma(\varepsilon),$$

and $4\pi/(4\pi)^2 = 1/4\pi$ together with the factor 2 pulled out of the bracket gives the $\alpha/2\pi$ of Equation (100.56). The logarithm rather than a linear divergence is visible in Equation (100.57) itself: the numerator is linear in ℓ and the denominator quartic, so the would-be linearly divergent piece is odd in the shifted momentum and integrates to zero, leaving a logarithm. □

Corollary 100.36 (Mass renormalization)**.** *The electromagnetic self-interaction shifts the pole of the propagator away from the Lagrangian mass by*

$$\delta m := \frac{1}{c}\,\Sigma_2(\gamma\cdot p = m_e c) = \frac{3\alpha}{4\pi}m_e\left[\frac{1}{\varepsilon} + \dots\right] \ \leftrightarrow\ \frac{3\alpha}{4\pi}m_e\ln\frac{\Lambda^2}{m_e^2c^2} \tag{100.58}$$

in a cutoff scheme with Λ *an upper limit on the loop momentum, so that the pole sits at the measured* m_e *only if the bare mass is* $m_0 = m_e - \delta m$*: the bare electron is* lighter *than the physical one, the difference being the energy stored in its own field. The shift is positive and proportional to* m_e *itself.*

Rests on Equation (100.56).

Proof. *Derives Corollary 100.36.*

On shell, $\gamma \cdot p = m_e c$ and $p^2 = m_e^2 c^2$, so $\Delta \to (1-x)^2 m_e^2 c^2$ when $m_\gamma \to 0$, and Equation (100.56) gives $\Sigma_2 = \frac{\alpha}{2\pi} m_e c \int_0^1 (2-x)\mathrm{d}x \left[\varepsilon^{-1} + \dots\right] = \frac{3\alpha}{4\pi} m_e c \left[\varepsilon^{-1} + \dots\right]$, since $\int_0^1 (2-x)\mathrm{d}x = 3/2$. The correspondence $\varepsilon^{-1} \leftrightarrow \ln\left(\Lambda^2/m_e^2 c^2\right)$ between the two regulators, established in Section 100.4.4, gives the second form. □

Proposition 100.37 (Chiral symmetry protects the electron mass)**.** *Because $\delta m \propto m_e$, the fractional correction*

$$\frac{\delta m}{m_e} = \frac{3\alpha}{2\pi} \ln \frac{\Lambda}{m_e c} \tag{100.59}$$

is small even for Λ at the Planck momentum: with $\Lambda c = 1.22 \times 10^{19}\,\mathrm{GeV}$ and $m_e c^2 = 0.511\,\mathrm{MeV}$ the logarithm is $\ln\left(2.39 \times 10^{22}\right) = 51.5$ and $\delta m/m_e = 0.18$.

Rests on Equation (100.12) and Corollary 100.36.

Proof. *Derives Proposition 100.37.*

Set $m_e = 0$ in Equation (100.12). The Lagrangian is then invariant under the chiral rotation $\psi \mapsto \mathrm{e}^{\mathrm{i}\theta\gamma^5}\psi$, because γ^μ anticommutes with γ^5 while the mass term does not, and the interaction $-j^\mu A_\mu$ is built from γ^μ alone. A symmetry of the classical Lagrangian that survives regularization — and dimensional regularization preserves this one, away from the anomaly of Chapter 105 — forbids the generation of a term that violates it. Hence no mass can be generated when $m_e = 0$, so δm must vanish with m_e, and by dimensional analysis the only remaining possibility is $\delta m \propto m_e \times (\text{logarithm})$. Numerically, $3\alpha/2\pi = 3.484 \times 10^{-3}$ and $51.5 \times 3.484 \times 10^{-3} = 0.179$. The contrast with a scalar field is the whole reason the point is worth making: a scalar mass has no symmetry protecting it, its correction goes as Λ^2 rather than $m \ln \Lambda$, and the resulting sensitivity of the Higgs mass to the cutoff is the naturalness problem recorded in Chapter 104. □

Remark 100.38 (The field-strength constant and the spectral representation). Expanding Σ_2 about the mass shell, $\Sigma_2(p) = c\,\delta m + (\gamma \cdot p - m_e c)\left(Z_2^{-1} - 1\right) + \dots$, defines the field-strength renormalization Z_2, which is also logarithmically divergent and, unlike δm, infrared divergent as $m_\gamma \to 0$ — a first sign of Section 100.6. That Z_2 is the residue of the propagator at its pole, and that $0 < Z_2 \le 1$ with the deficit carried by multiparticle states, is the content of the Källén–Lehmann spectral representation [1003, 1048], which writes the exact two-point function as a positive-weight superposition of free ones. The representation is used in Chapter 109 as a structural fact rather than a perturbative one; neither the representation nor the bound it implies is derived here or there yet.

Derivation pending #137

The field-strength renormalization as a residue, and its bound: the Källén–Lehmann spectral representation of the exact fermion two-point function, obtained by inserting a complete set of eigenstates of the four-momentum and using the spectrum condition; the positivity of the spectral density, which follows because each weight is a squared modulus of a vacuum-to-state matrix element; the isolated one-particle delta whose weight is the field-strength constant, identifying it with the residue of the exact propagator at its pole; and the sum rule from the canonical equal-time anticommutator, which normalizes the total spectral weight to one and hence bounds the constant between zero and one, the deficit being the weight carried by the multiparticle continuum. The subsection of the axiomatic chapter named for this representation is at present a reserved heading, so the derivation is owed there or in Appendix A.

100.4.3 The vertex correction and the anomalous magnetic moment

The third divergent amplitude is the one that made renormalization believable, because after the divergence is removed a finite, parameter-free number remains and it was measured within months.

Definition 100.39 (Form factors)**.** Lorentz invariance, current conservation and parity restrict the exact electromagnetic vertex of an on-shell electron to

$$\bar{u}(p')\,\Gamma^{\mu}(p',p)\,u(p) = \bar{u}(p')\left[\gamma^{\mu}F_1\!\left(q^2\right) + \frac{\mathrm{i}\sigma^{\mu\nu}q_{\nu}}{2m_e c}F_2\!\left(q^2\right)\right]u(p)\,, \tag{100.60}$$

with $q = p' - p$, $\sigma^{\mu\nu} = \frac{\mathrm{i}}{2}[\gamma^{\mu},\gamma^{\nu}]$, and F_1, F_2 dimensionless — the factor $2m_e c$ in the denominator being exactly what makes $\sigma^{\mu\nu}q_{\nu}/2m_e c$ a pure number. At tree level $F_1 = 1$ and $F_2 = 0$.

Lemma 100.40 (Gordon identity)**.** *For on-shell spinors,*

$$2m_e c\,\bar{u}(p')\gamma^{\mu}u(p) = \bar{u}(p')\left[(p+p')^{\mu} + \mathrm{i}\sigma^{\mu\nu}q_{\nu}\right]u(p)\,. \tag{100.61}$$

Rests on Definition 100.39 and Equation (100.5).

Proof. *Derives Lemma 100.40.*

Using $\gamma^{\nu}\gamma^{\mu} = \eta^{\nu\mu} - \mathrm{i}\sigma^{\nu\mu}$, which is the split of a product into its symmetric and antisymmetric parts,

$$2m_e c\,\bar{u}(p')\gamma^{\mu}u(p) = \bar{u}(p')\left(\gamma\cdot p'\,\gamma^{\mu} + \gamma^{\mu}\,\gamma\cdot p\right)u(p)$$

by the Dirac equations $\bar{u}(p')\gamma\cdot p' = m_e c\bar{u}(p')$ and $\gamma\cdot p\,u(p) = m_e c\,u(p)$. Expanding, $\gamma\cdot p'\gamma^{\mu} = p'^{\mu} - \mathrm{i}p'_{\nu}\sigma^{\nu\mu}$ and $\gamma^{\mu}\gamma\cdot p = p^{\mu} - \mathrm{i}p_{\nu}\sigma^{\mu\nu}$, and $\sigma^{\nu\mu} = -\sigma^{\mu\nu}$, so the antisymmetric terms combine into $\mathrm{i}\sigma^{\mu\nu}(p'-p)_{\nu}$. □

Theorem 100.41 (Schwinger)**.** *At one loop the anomalous magnetic moment of the electron is*

$$a_e = F_2(0) = \frac{\alpha}{2\pi} = 1.161\,410\times10^{-3}\,, \tag{100.62}$$

finite, independent of every regulator and of the renormalization scheme, and containing no free parameter beyond α itself [919].

Rests on Definition 100.39, Proposition 100.14, and Lemma 100.40.

Proof. *Derives Theorem 100.41.*

By Proposition 100.14 the one-loop vertex is

$$\frac{\mathrm{i}e}{\hbar}\,\delta\Gamma^{\mu} = \left(\frac{\mathrm{i}e}{\hbar}\right)^3\int\frac{\mathrm{d}^4\ell}{(2\pi\hbar)^4}\,\frac{-\mathrm{i}\mu_0\hbar^3 c\,\eta_{\nu\rho}}{(\ell-p)^2}\,\gamma^{\nu}\,\frac{\mathrm{i}\hbar\,(\gamma\cdot\ell' + m_e c)}{\ell'^2 - m_e^2c^2}\,\gamma^{\mu}\,\frac{\mathrm{i}\hbar\,(\gamma\cdot\ell + m_e c)}{\ell^2 - m_e^2c^2}\,\gamma^{\rho}\,,$$

with $\ell' = \ell + q$. The numerical prefactor is $(-\mathrm{i}e^3/\hbar^3)\,(-\mathrm{i}\mu_0\hbar^3 c)\,(\mathrm{i}\hbar)^2 = e^3\mu_0 c\hbar^2$, so, dividing by $\mathrm{i}e/\hbar$ and using $\mu_0 c e^2/\hbar = 4\pi\alpha$,

$$\delta\Gamma^{\mu} = \frac{-4\pi\mathrm{i}\alpha}{(2\pi)^4}\int\mathrm{d}^4\ell\,\frac{N^{\mu}}{\left[(\ell-p)^2\right]\left[\ell'^2 - m_e^2c^2\right]\left[\ell^2 - m_e^2c^2\right]}\,, \tag{100.63}$$

every $\hbar$ having cancelled between $\hbar^4$ in the prefactor and $(2\pi\hbar)^{-4}$ in the measure. *The answer is already constrained to its final form*: the correction is α times a dimensionless integral over a dimensionless integrand, so $F_2(0)$ can only be α times a pure number.

The numerator, by Equation (100.37), is

$$N^{\mu} = \gamma^{\nu}\,(\gamma\cdot\ell' + m_e c)\,\gamma^{\mu}\,(\gamma\cdot\ell + m_e c)\,\gamma_{\nu} = -2\,\gamma\cdot\ell\,\gamma^{\mu}\,\gamma\cdot\ell' + 4m_e c\,(\ell+\ell')^{\mu} - 2m_e^2c^2\gamma^{\mu}\,.$$

Combine the three denominators by Lemma 100.26 with parameters x on $\ell'^2 - m_e^2c^2$, y on $\ell^2 - m_e^2c^2$ and z on $(\ell - p)^2$, and $x + y + z = 1$. Using $p^2 = p'^2 = m_e^2c^2$ and hence $2p \cdot q = -q^2$, the combined denominator is $(k^2 - \Delta)^3$ after the shift $k = \ell + xq - zp$, with

$$\Delta = -xy\, q^2 + (1 - z)^2\, m_e^2c^2 \,. \tag{100.64}$$

Terms odd in k integrate to zero. The F_2 part of the answer comes entirely from the terms in N^μ proportional to $(p + p')^\mu$, so those are what must be collected. At $k = 0$,

$$\ell = zp - xq = (x + z)\, p - x\, p' \,, \qquad \ell' = zp + (y + z)\, q = -y\, p + (y + z)\, p' \,,$$

using $q = p' - p$. Sandwiching between $\bar u(p')$ and $u(p)$ and using the Dirac equations repeatedly, together with $\gamma \cdot p\, \gamma^\mu \gamma \cdot p = 2p^\mu \gamma \cdot p - m_e^2c^2\gamma^\mu$ and $2p \cdot p' = 2m_e^2c^2 - q^2$, the four cross terms of $-2\,\gamma \cdot \ell\, \gamma^\mu \gamma \cdot \ell'$ reduce to

$$\begin{aligned} &-2(x + z)(-y) \left[2m_e c\, p^\mu - m_e^2c^2\gamma^\mu\right] \\ &-2(x + z)(y + z) \left[2m_e c\, (p + p')^\mu - \left(3m_e^2c^2 - q^2\right)\gamma^\mu\right] \\ &\quad -2(-x)(-y)\; m_e^2c^2\gamma^\mu \\ &\quad -2(-x)(y + z) \left[2m_e c\, p'^\mu - m_e^2c^2\gamma^\mu\right] \,, \end{aligned} \tag{100.65}$$

while the second piece of N^μ contributes $4m_e c\,[2z\, p^\mu + (y + z - x)q^\mu]$. Writing $p^\mu = \frac{1}{2}\,[(p + p')^\mu - q^\mu]$ and $p'^\mu = \frac{1}{2}\,[(p + p')^\mu + q^\mu]$ and collecting the coefficient b of $(p + p')^\mu$,

$$\frac{b}{2m_e c} = (1 - y)y + x(1 - x) - 2(1 - y)(1 - x) + 2z = 3(x + y) + 2z - (x + y)^2 - 2 \,,$$

and with $x + y = 1 - z$ this is $3 - 3z + 2z - (1 - z)^2 - 2 = z - z^2 = z(1 - z)$, so $b = 2m_e c\, z(1 - z)$. By the Gordon identity Equation (100.61) read backwards, $(p + p')^\mu = 2m_e c\,\gamma^\mu - \mathrm{i}\sigma^{\mu\nu}q_\nu$ between the spinors, so the coefficient of $\mathrm{i}\sigma^{\mu\nu}q_\nu/2m_e c$ in N^μ is $-2m_e c\, b = -4m_e^2c^2 z(1 - z)$.

It remains to do the momentum integral. From Lemma 100.26 with $n = 3$ the Feynman combination carries a factor 2, and from Equation (100.45) with $n = 3$, $d = 4$,

$$\frac{1}{(2\pi)^4} \int \mathrm{d}^4k\, \frac{1}{(k^2 - \Delta + \mathrm{i}\epsilon)^3} = \frac{-\mathrm{i}}{32\pi^2\Delta} \,,$$

which is finite: the F_2 part needs no regulator, and this is why a_e is a prediction while F_1 is not. Assembling,

$$\begin{aligned} F_2\left(q^2\right) &= -4\pi\mathrm{i}\alpha \int_0^1 \mathrm{d}x\, \mathrm{d}y\, \mathrm{d}z\; \delta\,(x + y + z - 1)\; 2\left(-4m_e^2c^2 z(1 - z)\right) \frac{-\mathrm{i}}{32\pi^2\Delta} \\ &= \frac{\alpha\, m_e^2c^2}{\pi} \int_0^1 \mathrm{d}x\, \mathrm{d}y\, \mathrm{d}z\; \delta\,(x + y + z - 1)\, \frac{z(1 - z)}{\Delta} \,, \end{aligned} \tag{100.66}$$

the prefactor being that of Equation (100.63), in which every $\hbar$ has already cancelled. At $q^2 = 0$, Equation (100.64) gives $\Delta = (1 - z)^2 m_e^2c^2$, so

$$F_2(0) = \frac{\alpha}{\pi} \int_0^1 \mathrm{d}z \int_0^{1-z} \mathrm{d}y\, \frac{z(1 - z)}{(1 - z)^2} = \frac{\alpha}{\pi} \int_0^1 \mathrm{d}z\, (1 - z) \frac{z}{1 - z} = \frac{\alpha}{\pi} \int_0^1 z\, \mathrm{d}z = \frac{\alpha}{2\pi} \,,$$

the y integral running over the length $1 - z$ of the simplex. Numerically $\alpha/2\pi = 1.161\,410 \times 10^{-3}$. □

Remark 100.42 (What the calculation used and what it did not). Not one regulator appears in the last three lines: F_2 is ultraviolet finite because the $(p+p')^\mu$ terms of the numerator carry no power of the loop momentum. The divergence of the vertex sits entirely in F_1, in the $k^2\gamma^\mu$ term dropped above, and is removed in Section 100.5.1 by the condition $F_1(0)=1$, which says that the charge measured at large distance is the charge that appears in Coulomb's law. That condition is imposed exactly, so F_1 carries no infrared divergence at $q^2=0$: it is 1 there by definition. The infrared divergence of the vertex sits at *nonzero* momentum transfer, where the subtracted one-loop F_1 carries $\ln\left(-q^2/m_\gamma^2c^2\right)$ and blows up as the photon-mass regulator is removed, the more so the larger $-q^2$; it is not a defect of the form factor but of the exclusive quantity it is being asked to give, and it cancels against the emission of soft real photons in Equation (100.80), which is the subject of Section 100.6. F_2 is infrared finite at every q^2, because the soft region is suppressed by the explicit factor $z(1-z)$. The prediction of Equation (100.62) is therefore clean in a way no other one-loop quantity in this chapter is, and it is measured in Chapter 112 to thirteen figures.

100.4.4 Regularization

A divergent integral is not a number and cannot be manipulated. A regulator is a one-parameter deformation of the theory that makes every integral finite, chosen so that the original is recovered in a limit; the divergences then appear as terms that blow up in that limit and are disposed of by Section 100.5.1. Three regulators are used in practice and it is worth saying exactly what each costs.

- *Momentum cutoff.* Restrict $|\ell_{\mathrm{E}}|<\Lambda$. Simple, physically suggestive — Λ looks like the momentum above which the theory is not to be trusted — and *it violates gauge invariance.* A sharp cutoff is not translation invariant in loop momentum, so the shift $k=\ell+xq$ used in Theorem 100.31 is illegal, and the cancellation that made $\Pi^{\mu\nu}$ transverse fails: one finds a residual $\Lambda^2\eta^{\mu\nu}$, that is a photon mass, contradicting Phenomenon 100.7. The term can be removed by hand, and every pre-1972 calculation did so, but subtracting a symmetry violation by hand is exactly the kind of step that cannot be automated to high order.

- *Pauli–Villars.* Subtract from each propagator a copy with a large mass M and the wrong-sign residue [945], so that $1/(\ell^2-m^2c^2)\to 1/(\ell^2-m^2c^2)-1/(\ell^2-M^2c^2)$, which falls as ℓ^{-4} and makes a logarithmically divergent integral converge; $M\to\infty$ at the end. This preserves Lorentz invariance and, in QED, gauge invariance, and it was the standard tool of the 1950s. Its price is that the regulator fields have negative norm, so the regulated theory is not unitary, and that it does not extend cleanly to non-abelian gauge theories.

- *Dimensional regularization.* Continue the number of spacetime dimensions to $d=4-2\varepsilon$ as in Definition 100.30 [1463, 1465]. Nothing in the derivation of Lemma 100.28 required d to be an integer, and the result is an analytic function of d with poles at $d=4,6,\dots$; the four-dimensional divergence is the residue at $d=4$. It preserves Lorentz invariance and gauge invariance exactly, because the continuation touches only the measure and never the symmetry of the Lagrangian, and it makes the algebra shorter. It is what made the renormalization of non-abelian theories tractable [1448] and hence what Chapter 102 and Chapter 104 use throughout.

Proposition 100.43 (The two regulators agree on what is divergent)**.** *For a logarithmically divergent one-loop integral, the substitution*

$$\frac{1}{\varepsilon}-\gamma_{\mathrm{E}}+\ln 4\pi-\ln\frac{\Delta}{\bar{\mu}^2}\quad\leftrightarrow\quad\ln\frac{\Lambda^2}{\Delta} \tag{100.67}$$

maps the dimensionally regularized result onto the cutoff one, up to terms that vanish as $\varepsilon \to 0$ *and* $\Lambda \to \infty$*. Differences of the same quantity at two kinematic points — which is what every observable is — are independent of the choice.*

Rests on Equation (100.44) *and Lemma 100.29.*

Proof. *Derives Proposition 100.43.*

In the cutoff scheme, $\int^{\Lambda} \mathrm{d}^4\ell_{\mathrm{E}}\,(\ell_{\mathrm{E}}^2+\Delta)^{-2} = 2\pi^2 \int_0^{\Lambda} \ell^3 \mathrm{d}\ell\,(\ell^2+\Delta)^{-2} = \pi^2\left[\ln(\Lambda^2/\Delta) - 1 + O(\Delta/\Lambda^2)\right]$; in dimensional regularization the same integral is $\pi^2\left[\varepsilon^{-1} - \gamma_{\mathrm{E}} + \ln 4\pi - \ln(\Delta/\bar{\mu}^2)\right]$ by Equation (100.44) and Lemma 100.29. The two differ by a Δ-independent constant, which is Equation (100.67); and in a difference at two values of Δ the constant cancels together with Λ and $\bar{\mu}$. □

Remark 100.44 (Regularization is bookkeeping, and must leave no trace). A regulator is not a physical hypothesis. Λ is not the energy at which new physics appears, M is not a particle, and ε is not a statement that spacetime has 3.9999 dimensions. The requirement on a calculation is that no observable depend on which regulator was used, and Proposition 100.43 is the one-loop instance of that requirement. The genuinely physical reading of a cutoff — as the scale beyond which the theory is replaced by another — belongs to the effective-field-theory picture of Chapter 108, and is a different statement about a different object. One warning belongs here: dimensional regularization is not innocent for γ^5, which has no d-dimensional definition compatible with all its four-dimensional properties, and the resulting care is unavoidable in the chiral theories of Chapter 101 and Chapter 104. In QED, which uses no γ^5 in its interaction, the problem does not arise.

100.5 Renormalization

Three amplitudes diverge. The claim of renormalization is that the divergences can be absorbed, once and for all, into the definitions of three quantities that were never predicted in the first place — the electron's mass, its charge, and the normalization of the fields — and that after this is done every remaining prediction is finite. Nothing is thrown away: what is thrown away is the pretence that the parameters written in Equation (100.12) were the measured ones.

100.5.1 Counterterms and renormalization constants

Definition 100.45 (Bare and renormalized quantities)**.** Regard the fields and parameters of Equation (100.12) as *bare*, write them ψ_0, A_0^μ, m_0, e_0, and define renormalized ones by

$$\psi_0 = \sqrt{Z_2}\,\psi\,, \qquad A_0^\mu = \sqrt{Z_3}\,A^\mu\,, \qquad m_0 = m_e - \delta m\,, \qquad e_0 = \frac{Z_1}{Z_2\sqrt{Z_3}}\,e\,, \tag{100.68}$$

where Z_1 is defined so that the interaction term takes the same form in renormalized variables and δm is the positive shift of Equation (100.58), so that the sign here is the one forced by Corollary 100.36: the self-interaction adds to the mass, hence the bare mass is the smaller. Writing $Z_i = 1 + \delta_i$, the Lagrangian splits as

$$\begin{aligned}\mathcal{L} = {}& \bar{\psi}\left(\mathrm{i}\hbar c\gamma^\mu\partial_\mu - m_e c^2\right)\psi - \frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu} + ec\,\bar{\psi}\gamma^\mu\psi A_\mu \\ & + \delta_2\,\mathrm{i}\hbar c\,\bar{\psi}\gamma^\mu\partial_\mu\psi - (\delta_2 m_e - Z_2\delta m)\,c^2\bar{\psi}\psi - \frac{\delta_3}{4\mu_0}F_{\mu\nu}F^{\mu\nu} + \delta_1 ec\,\bar{\psi}\gamma^\mu\psi A_\mu\,,\end{aligned} \tag{100.69}$$

the mass counterterm being the whole of $Z_2 m_0 - m_e = \delta_2 m_e - Z_2\delta m$ left over when $-Z_2 m_0 c^2\bar{\psi}\psi$ has $-m_e c^2\bar{\psi}\psi$ removed from it; the first line is the original theory with *measured* parameters and the second a set of *counterterms*, each of which supplies an extra Feynman rule and each of whose coefficients is fixed — order by order in α, and divergent — by a renormalization condition.

Definition 100.46 (On-shell renormalization conditions)**.** The four constants are fixed by requiring that the renormalized parameters be the measured ones:

1. the full electron propagator has its pole at $\gamma\cdot p = m_e c$, with m_e the mass in the mass-shell relation Equation (100.1) — this fixes δm;
2. the residue at that pole is $\mathrm{i}\hbar$, i.e. the same as the free propagator — this fixes δ_2;
3. the full photon propagator has a pole at $q^2=0$ with residue equal to the free one — this fixes δ_3, through $\Pi_2(0)=0$ after subtraction;
4. $F_1(0)=1$, i.e. the charge measured in the long-wavelength limit — in Thomson scattering, or in Coulomb's law by Theorem 100.25 — is e — this fixes δ_1.

At one loop the conditions give counterterms that cancel exactly the divergent parts computed in Theorem 100.31, Theorem 100.35 and Theorem 100.41. For the photon, Equation (100.50) evaluated at $q^2=0$ has divergent part

$$\Pi_2(0)\big|_{\mathrm{div}} = -\frac{2\alpha}{\pi}\int_0^1 \mathrm{d}x\; x(1-x)\,\frac{1}{\varepsilon} = -\frac{\alpha}{3\pi}\,\frac{1}{\varepsilon}\,, \tag{100.70}$$

since $\int_0^1 x(1-x)\mathrm{d}x = 1/6$, and δ_3 is whatever cancels it; δ_1 and δ_2 are likewise proportional to α/ε, equal to each other by Corollary 100.49, and $\delta m = 3\alpha m_e/4\pi\varepsilon + \dots$ by Corollary 100.36. The essential point is not their values but their number. There are four, they are the same four at every order, and Theorem 100.17 guarantees no fifth is ever needed: that is renormalizability (Definition 100.18) and it was Dyson's theorem [928].

Remark 100.47 (What a "physical parameter" means afterwards). After renormalization the symbols m_e and e in Equation (100.69) denote numbers taken from experiment, and the bare ones are formally infinite. This is uncomfortable only if one insists that the bare parameters were meaningful. They were not: no measurement isolates the coupling of a Lagrangian written at infinite momentum. What the theory predicts is every *other* quantity in terms of those two, and the count of the inputs — how many numbers physics has to be told rather than derive — is the subject of the free-parameters appendix, Appendix C.

100.5.2 The Ward–Takahashi identity

Of the four constants, two turn out to be equal, and the equality is not an accident of one-loop arithmetic.

Theorem 100.48 (Ward–Takahashi)**.** *Let $S(p) = \mathrm{i}\hbar\,(\gamma\cdot p - m_e c - \Sigma(p))^{-1}$ be the exact electron propagator and $\Gamma^\mu(p',p)$ the exact vertex function of Equation (100.60), both off shell. Then*

$$q_\mu\,\Gamma^\mu(p+q,p) = \left[\gamma\cdot(p+q) - m_e c - \Sigma(p+q)\right] - \left[\gamma\cdot p - m_e c - \Sigma(p)\right]\,, \tag{100.71}$$

to all orders in α [973, 1132]. In the limit $q\to 0$ this is Ward's identity

$$\Gamma^\mu(p,p) = \frac{\partial}{\partial p_\mu}\left[\gamma\cdot p - m_e c - \Sigma(p)\right]\,. \tag{100.72}$$

Rests on Equations (100.6) and (100.60) and Theorem 100.5.

Proof. *Derives Theorem 100.48.*

Consider the Green function $G^\mu(x;y,z) = \left\langle T\, j^\mu(x)\,\psi(y)\,\bar\psi(z)\right\rangle$ with j^μ the current Equation (100.6). Differentiating, the divergence picks up two contributions: one from $\partial_\mu j^\mu = 0$, which vanishes, and one from differentiating the time-ordering symbol, which produces

equal-time commutators. Using the canonical relation of Chapter 99, $[j^0(x), \psi(y)]\,\delta(x^0 - y^0) = -qc\,\delta^4(x-y)\,\psi(y)$, and similarly for $\bar\psi$ with the opposite sign,

$$\partial_\mu G^\mu(x;y,z) = -qc\left[\delta^4(x-y) - \delta^4(x-z)\right]\left\langle T\,\psi(y)\bar\psi(z)\right\rangle .$$

Fourier transforming with Equation (100.14) turns $\partial_\mu \mapsto -\mathrm{i}q_\mu/\hbar$ on the left and the delta functions into unity on the right, so that

$$q_\mu\, S(p+q)\,\Gamma^\mu(p+q,p)\,S(p) \;\propto\; S(p) - S(p+q)\,,$$

the left-hand side being the amputated vertex reattached to two full propagators. Multiplying by S^{-1} on both sides gives Equation (100.71); the normalization is fixed by comparing the tree-level terms, where $\Gamma^\mu = \gamma^\mu$ and $q_\mu\gamma^\mu = \gamma\cdot(p+q) - \gamma\cdot p$ identically. Equation (100.72) follows by dividing by q and letting $q \to 0$. The only inputs are current conservation, which is Noether's theorem applied to the exact symmetry of Theorem 100.5, and the canonical commutator; neither is perturbative, so the identity holds order by order and also non-perturbatively. □

Corollary 100.49 ($Z_1 = Z_2$, and the universality of charge)**.** *The vertex and field-strength renormalizations of Equation* (100.68) *coincide,*

$$Z_1 = Z_2\,, \qquad \textit{hence} \qquad e_0 = \frac{e}{\sqrt{Z_3}}\,. \tag{100.73}$$

The renormalization of the charge therefore involves only Z_3, which belongs to the photon and knows nothing about the matter field. Consequently the observed charges of the electron, the muon, the tau and the proton are shifted by radiative corrections by the same factor*, and their equality — verified to one part in 10^{21} for the electron and the proton by the neutrality of bulk matter [2427] — survives quantization.*

Rests on Equations (100.68) *and* (100.72) *and Definition 100.46.*

Proof. *Derives Corollary 100.49.*

By Definition 100.46, δ_2 is fixed by the derivative of Σ at the mass shell and δ_1 by $\Gamma^\mu(p,p) = Z_1^{-1}\gamma^\mu$ at $F_1(0) = 1$. Take Equation (100.72) on shell: the right-hand side is $\gamma^\mu - \partial\Sigma/\partial p_\mu$, whose divergent part is $\gamma^\mu(1-\delta_2^{\mathrm{div}})$ by the definition of δ_2, while the left-hand side is $\gamma^\mu(1-\delta_1^{\mathrm{div}})$ by the definition of δ_1. Hence $\delta_1 = \delta_2$ to all orders, so $Z_1 = Z_2$, and Equation (100.68) collapses to Equation (100.73). Proposition 100.6 asserted universality at tree level; this is the statement that it is not destroyed at any order, which is what had to be shown, since Z_1 and Z_2 are separately mass-dependent and only their ratio is not. □

Remark 100.50 (Gauge invariance, current conservation, transversality)*.* The same identity has three further uses in this chapter, all already invoked. It is what makes $q_\mu\mathcal{M}^\mu = 0$ for an external photon, hence what licenses the polarization sum Equation (100.34); it is what makes $\Pi^{\mu\nu}$ transverse, hence what protects Phenomenon 100.7 beyond one loop; and it is what makes the gauge parameter ξ of Equation (100.17) drop out of every observable. In non-abelian theories the corresponding statements are the Slavnov–Taylor identities [1458, 1484], which are more complicated because the gauge-fixing procedure itself introduces the ghost fields of [1347]; they are what makes the proof of renormalizability of Chapter 102 and Chapter 104 possible [1448].

100.5.3 All orders: the BPHZ theorem

One loop is a special case in which every divergence is overall. At higher order a diagram contains divergent *subdiagrams*, and the counterterms generated at lower order must cancel them before the overall divergence is even well defined.

Definition 100.51 (Nested, disjoint and overlapping divergences)**.** Two divergent subdiagrams of a given graph are *disjoint* if they share no line, *nested* if one is contained in the other, and *overlapping* if they share some but not all of their lines. The first two cases are handled by recursion on the containment ordering. The third is not, and it is the reason renormalization to all orders took twenty years: at two loops the electron self-energy already contains two vertex subdiagrams that overlap.

Theorem 100.52 (Bogoliubov–Parasiuk–Hepp–Zimmermann)**.** *Define, recursively, the subtracted integrand* $\bar{R}_G = I_G + \sum_{\gamma \subset G} (\prod \text{counterterms of } \gamma)\, I_{G/\gamma}$ *and* $R_G = (1 - T_G)\,\bar{R}_G$*, where* T_G *is the Taylor expansion in the external momenta to order* $D(G)$ *of Equation* (100.26)*. Then* R_G *is absolutely convergent for every graph* G *of QED [1103, 1331, 1411], and* R_G *is generated by the counterterm Lagrangian Equation* (100.69) *with the four constants of Definition 100.45 alone. Equivalently, Zimmermann's forest formula*

$$R_G = \sum_{F \in \mathcal{F}(G)} \prod_{\gamma \in F} (-T_\gamma)\; I_G \tag{100.74}$$

— the sum running over all forests*, that is all sets of divergent subgraphs that are pairwise nested or disjoint — solves the recursion in closed form. QED is therefore finite to all orders in perturbation theory once* m_e*,* e *and the two field normalizations are fixed.*

Rests on Equations (100.26) *and* (100.69) *and Definition 100.45.*

Derivation pending #138

The Bogoliubov–Parasiuk–Hepp–Zimmermann theorem: the recursive subtraction, the combinatorial proof that the forest formula solves the recursion, and Hepp's sector decomposition establishing absolute convergence of the subtracted integrand, together with the demonstration that overlapping divergences require no counterterm beyond those of the local Lagrangian. This is a long combinatorial argument and belongs in Appendix A; the statement is used here only to license the claim that the four constants suffice at every order.

Remark 100.53 (Why the counterterms are local)*.* The operation T_γ is a Taylor expansion in external momenta, so the counterterm it produces is a *polynomial* in momenta of degree $D(\gamma)$, that is a local operator in position space. This is not a technical remark: it is why a finite number of terms in the Lagrangian can absorb an infinite number of divergent integrals. Had the divergences been non-polynomial in the external momenta, no local counterterm could have removed them and the theory would not have been renormalizable in any useful sense.

100.5.4 Scheme dependence and the meaning of a renormalized parameter

The conditions of Definition 100.46 are one choice among many. A *scheme* is any prescription that fixes the finite parts of the counterterms; the divergent parts are common to all of them.

Definition 100.54 (Two schemes)**.** In the *on-shell* scheme the counterterms are fixed by Definition 100.46, so that m_e is the pole mass and e the Thomson-limit charge. In *minimal subtraction* the counterterms remove only the pole $1/\varepsilon$; in *modified minimal subtraction*, written $\overline{\text{MS}}$, they remove the whole recurring combination

$$\frac{1}{\varepsilon} - \gamma_{\text{E}} + \ln 4\pi\,, \tag{100.75}$$

which by Lemma 100.28 accompanies every pole. The renormalized parameters then depend on the arbitrary scale $\bar{\mu}$ of Definition 100.30: one speaks of the running mass $m_e(\bar{\mu})$ and the running coupling $\alpha(\bar{\mu})$.

Proposition 100.55 (Scheme independence of observables)**.** *Two schemes give the same value for any S-matrix element expressed in terms of measured quantities. They differ only in what the symbols mean.*

Rests on Definitions 100.46 and 100.54.

Proof. *Derives Proposition 100.55.*

Both schemes are related by a finite redefinition $\alpha \mapsto \alpha' = \alpha(1 + c_1\alpha + \dots)$, $m \mapsto m' = m(1 + d_1\alpha + \dots)$ with c_i, d_i finite. An observable computed to order α^n in one scheme, re-expanded in the other's parameters, differs only at order α^{n+1} — that is, by terms of the order that has not been computed. Once the parameters are eliminated in favour of two *measurements*, the prediction for a third quantity is scheme independent at every order at which it is complete. This is the criterion that separates convention from physics in this chapter: α, m_e, ξ, $\bar{\mu}$ and the choice of regulator are conventions; the relation between Equation (100.62) and the Lamb shift is not. □

Remark 100.56 (Two numbers must be measured)*.* Nothing in QED predicts α or m_e. They are two of the free parameters of the Standard Model catalogued in Appendix C, and their values are taken from the CODATA and Particle Data Group compilations [2427, 2431]. Everything else in this chapter is a prediction, which is why the electron anomaly, the Lamb shift and light-by-light scattering are tests rather than fits — and why the several independent routes to α of Section 100.8.4 matter so much: agreement among them is what converts a fitted parameter into a checked one.

100.6 Infrared structure

The divergences of Section 100.4 came from the ultraviolet. QED has a second kind, from the opposite end of the spectrum, and its resolution is physical rather than formal: it says something true about what a detector can measure.

100.6.1 Soft photons and the Bloch–Nordsieck mechanism

Phenomenon 100.57 (No charge is deflected without radiating)**.** Every deflection of a charged particle is accompanied by electromagnetic radiation, and the number of quanta emitted with energy below $\hbar\omega$ grows without bound as $\omega \to 0$: the "elastic" peak recorded in any scattering experiment is therefore not a property of Nature but a statement about the resolution of the apparatus, and every measured cross-section is inclusive over radiation softer than that resolution [1976]. In perturbation theory the same fact appears as an infrared divergence of the elastic amplitude taken by itself [788].

Rests on Equations (100.23), (100.34) and (100.39).

Derivation. *Derives Phenomenon 100.57.*

Let $\mathcal{M}_0$ be the amplitude for a process in which an electron of momentum p is scattered into momentum p', and attach one outgoing photon of momentum k and polarization $\varepsilon_{(\lambda)}$. The photon may be emitted from the outgoing leg or the incoming one. In the first case the electron propagator immediately before emission carries momentum $p' + k$, so by Equation (100.23) it contributes

$$\frac{\mathrm{i}\hbar\,(\gamma\cdot(p'+k)+m_e c)}{(p'+k)^2 - m_e^2c^2} = \frac{\mathrm{i}\hbar\,(\gamma\cdot(p'+k)+m_e c)}{2\,p'\cdot k}\,,$$

using $p'^2 = m_e^2c^2$ and $k^2 = 0$. As $k \to 0$ the denominator vanishes linearly, so this term dominates; in the numerator $\gamma\cdot k$ may be dropped and $(\gamma\cdot p' + m_e c)\,\gamma^\mu \varepsilon^*_\mu u \to 2p'\cdot\varepsilon^*\,u$ by the Dirac equation. The emission from the incoming leg gives the same structure with $p' \to p$

and an opposite sign, because there the propagator carries $p - k$. Hence the amplitude *factorizes*,

$$\mathcal{M}_{\text{soft}} = \mathcal{M}_0 \;\times\; \mathcal{J}^{\mu} \varepsilon_{\mu}^{*} , \qquad \mathcal{J}^{\mu} = q \left(\frac{p'^{\mu}}{p' \cdot k} - \frac{p^{\mu}}{p \cdot k} \right) , \tag{100.76}$$

with $\mathcal{J}^{\mu}$ the eikonal current, of dimension $\mathrm{C\,s/(kg\,m)}$; the whole dependence on the hard process has dropped out. Squaring, summing over the two polarizations with Equation (100.34), and integrating over the photon phase space of Equation (100.39), the expected number of photons emitted is

$$\mathrm{d}\,\langle n \rangle = \frac{\alpha}{4\pi^2} \left[\frac{2\, p \cdot p'}{(p \cdot k)\,(p' \cdot k)} - \frac{m_e^2 c^2}{(p \cdot k)^2} - \frac{m_e^2 c^2}{(p' \cdot k)^2} \right] \frac{\mathrm{d}^3 k}{|\boldsymbol{k}|} , \tag{100.77}$$

which is dimensionless as it must be, the bracket carrying the inverse square of a momentum and $\mathrm{d}^3 k / |\boldsymbol{k}|$ its square. Every term in the bracket scales as $|\boldsymbol{k}|^{-2}$, while $\mathrm{d}^3 k = |\boldsymbol{k}|^2 \,\mathrm{d}\,|\boldsymbol{k}|\,\mathrm{d}\Omega$, so the photon-momentum dependence is exactly

$$\mathrm{d}\,\langle n \rangle = \frac{\mathrm{d}\,|\boldsymbol{k}|}{|\boldsymbol{k}|} \times (\text{a function of angles only}) = \frac{\mathrm{d}\omega}{\omega} \times (\dots) , \tag{100.78}$$

and $\int_0^{\omega_{\max}} \mathrm{d}\omega/\omega$ diverges logarithmically at the lower limit. The number of photons emitted below any energy is infinite; the *energy* they carry, $\int \hbar\omega \,\mathrm{d}\,\langle n \rangle \propto \int \mathrm{d}\omega$, is finite, which is why nothing physical is wrong. The angular integration for an ultrarelativistic deflection through momentum transfer q gives

$$\langle n \rangle = \frac{2\alpha}{\pi} \left(\ln \frac{-q^2}{m_e^2 c^2} - 1 \right) \ln \frac{\omega_{\max}}{\omega_{\min}} , \tag{100.79}$$

the double logarithm of Bloch and Nordsieck [788] and Weinberg [1322]. Since $\langle n \rangle \to \infty$ as $\omega_{\min} \to 0$, the probability of emitting *no* photon at all, which for the Poisson distribution the soft emissions obey is $\mathrm{e}^{-\langle n \rangle}$, is zero. The elastic peak of any real experiment is the set of events in which no photon above the detector threshold was emitted, and it is therefore a property of the threshold. □

Theorem 100.58 (Bloch–Nordsieck cancellation)**.** *The infrared divergence of the virtual correction to the elastic cross-section cancels exactly against the divergence of the real emission cross-section integrated up to the detector resolution E_{res}. Explicitly, with a photon mass m_γ as regulator,*

$$\left| F_1\!\left(q^2\right) \right|^2 = 1 - \frac{\alpha}{\pi}\, \mathcal{B}\!\left(q^2\right) \ln \frac{-q^2}{m_\gamma^2 c^2} + \dots , \qquad \frac{\mathrm{d}\sigma_{\text{real}}}{\mathrm{d}\sigma_0} = + \frac{\alpha}{\pi}\, \mathcal{B}\!\left(q^2\right) \ln \frac{E_{\text{res}}^2}{m_\gamma^2 c^4} + \dots \tag{100.80}$$

with the same function $\mathcal{B}$, so that the sum

$$\mathrm{d}\sigma_{\text{incl}} = \mathrm{d}\sigma_0 \left[1 - \frac{\alpha}{\pi}\, \mathcal{B}\!\left(q^2\right) \ln \frac{-q^2 c^2}{E_{\text{res}}^2} + \dots \right] \tag{100.81}$$

is finite and depends on E_{res}, which is a property of the apparatus. Exponentiating the soft series replaces the bracket by $\exp\left[-(\alpha/\pi)\, \mathcal{B} \ln\left(-q^2 c^2 / E_{\text{res}}^2\right) \right]$, the Sudakov form factor, which vanishes as $E_{\text{res}} \to 0$: a strictly elastic cross-section is not merely divergent, it is zero.

Rests on Phenomenon 100.57 and Equation (100.60).

Derivation pending #139

Bloch–Nordsieck cancellation: the explicit infrared part of the one-loop form factor with a photon mass regulator, the integral of the eikonal emission rate up to the detector resolution, the demonstration that the coefficient functions of the two logarithms are equal and opposite, and the exponentiation of the soft series into the Sudakov form factor. The structure and its physical reading are established above; what is owed is the coefficient function, and it belongs in Appendix A.

Remark 100.59 (The observable is inclusive). The lesson survives its perturbative origin. In QED an exclusive final state containing a definite number of photons is not an observable at all, because states differing by arbitrarily soft quanta are not distinguishable by any apparatus; the physical quantities are sums over degenerate final states. The same statement, with gluons in place of photons, is what makes a *jet* rather than a quark the observable of Chapter 102. It is also, in a different guise, the reason a charged particle has no isolated asymptotic state — the tension with the scattering formalism of Chapter 86, which assumes free asymptotic particles, is real and is one of the foundational loose ends recorded in Chapter 109.

100.6.2 Mass singularities

A second infrared problem appears when a mass is small rather than a momentum. Setting $m_e = 0$ in Equation (100.77) makes the angular integral diverge as well, because a photon emitted exactly collinear with a massless charge costs nothing.

Theorem 100.60 (Kinoshita–Lee–Nauenberg)**.** *Mass singularities of the form* $\ln(m_e^2 c^2/s)$ *cancel in any transition probability summed over all initial and final states degenerate in energy in the massless limit [1232, 1288]. In QED with massive charges the singularities are cut off by the mass and appear as large logarithms rather than divergences; in the massless limit only sufficiently inclusive quantities are finite.*

Rests on Theorem 100.58 and Phenomenon 100.57.

Derivation pending #140

Kinoshita–Lee–Nauenberg theorem: the classification of the singular regions of a Feynman integral in the massless limit — soft and collinear — and the proof that the sum over the degenerate subspace of initial and final states is free of them, together with the counting that shows why an average over degenerate initial states is needed and not only a sum over final ones. It belongs in Appendix A.

Remark 100.61 (Where this reappears). Two consequences are used elsewhere in this part. First, the collinear logarithms that survive when only final states are summed are precisely the ones resummed by the evolution equations of Altarelli and Parisi [1591], which govern the scaling violations measured in Chapter 116. Second, the same structure with colour in place of charge is why the observable of a strong-interaction final state is a jet defined by a resolution parameter, and never a quark: see Chapter 102.

100.7 The running coupling

100.7.1 Gell-Mann–Low and the beta function

Phenomenon 100.62 (The fine-structure constant runs)**.** The strength of the electromagnetic interaction is not one number but a function of the momentum transfer at which

it is measured. At vanishing momentum transfer $\alpha^{-1} = 137.035999\ldots$ [2431], whereas the effective coupling extracted from e^+e^- data at the Z pole, $\sqrt{s}\,c = 91.19\,\mathrm{GeV}$, satisfies $\alpha^{-1} \approx 129$ [2427]. The difference is some six percent, thousands of times any experimental uncertainty. It is measured independently in small-angle Bhabha scattering, in the Z lineshape and in the hadronic contribution to the vacuum polarization, and the three agree.

Rests on Equation (100.52)*, Proposition 100.33, and Definition 100.46.*

Derivation. *Derives Phenomenon 100.62.*

The measured coupling at momentum transfer q is the one that appears in the dressed propagator Equation (100.52): the product of two charges and one photon exchange carries $\alpha/\left[1-\Pi_2(q^2)\right]$ where α is the Thomson-limit value fixed by Definition 100.46. Since the condition there was $\Pi_2(0) = 0$ after subtraction, the effective coupling is

$$\alpha_{\mathrm{eff}}\left(q^2\right) = \frac{\alpha}{1-\left[\Pi_2(q^2)-\Pi_2(0)\right]}\,. \tag{100.82}$$

By Proposition 100.33 the subtracted polarization is

$$\Pi_2(q^2)-\Pi_2(0) = -\frac{2\alpha}{\pi}\int_0^1 \mathrm{d}x\; x(1-x)\ln\frac{m_e^2c^2}{m_e^2c^2 - x(1-x)q^2}\,,$$

and for $-q^2 \gg m_e^2c^2$ the logarithm becomes $\ln\left[m_e^2c^2/\left(-x(1-x)q^2\right)\right]$. With $\int_0^1 x(1-x)\mathrm{d}x = 1/6$ and $\int_0^1 x(1-x)\ln\left[x(1-x)\right]\mathrm{d}x = 2\int_0^1 x(1-x)\ln x\,\mathrm{d}x = 2\left(-\frac{1}{4}+\frac{1}{9}\right) = -\frac{5}{18}$,

$$\Pi_2(q^2)-\Pi_2(0) = \frac{\alpha}{3\pi}\left(\ln\frac{-q^2}{m_e^2c^2} - \frac{5}{3}\right)\,, \tag{100.83}$$

so that the effective coupling *grows* logarithmically with $-q^2$. Numerically, running from $q^2 = 0$ to $-q^2 = m_Z^2c^2$ with only the electron in the loop gives $\ln\left(m_Z/m_e\right)^2 = \ln\left(1.78\times10^5\right)^2 = 24.2$ and $\alpha\left(24.2-5/3\right)/3\pi = 0.0174$, which is the electron's share of the shift. The muon and the tau contribute 0.0092 and 0.0048 by the same formula with their own masses, and the quarks contribute about 0.0276, weighted by squared charge and by three colours and evaluated from data rather than from Equation (100.50) for the reason given below; the total $\Delta\alpha \approx 0.059$ is the observed $\alpha^{-1}(m_Z^2c^2) \approx 129$. The physical reading is Remark 100.34: a probe of higher momentum transfer penetrates further into the polarization cloud and sees a larger charge. □

Proposition 100.63 (The QED beta function)**.** *Defining the running coupling by evaluating Equation* (100.82) *at* $-q^2 = \bar{\mu}^2$*,*

$$\bar{\mu}\,\frac{\mathrm{d}\alpha}{\mathrm{d}\bar{\mu}} = \beta(\alpha) = \frac{2\alpha^2}{3\pi}\sum_f N_c^{(f)}\left(\frac{q_f}{e}\right)^2 + O\left(\alpha^3\right)\,, \tag{100.84}$$

the sum running over the charged fermions with $m_fc^2 \lesssim \bar{\mu}c$ *and* $N_c = 3$ *for quarks,* 1 *for leptons. The sign is positive: QED is not asymptotically free.*

Rests on Equations (100.82) *and* (100.83)*.*

Proof. *Derives Proposition 100.63.*

From Equation (100.83) at one loop, $\alpha(\bar{\mu})^{-1} = \alpha^{-1} - (3\pi)^{-1}\ln\left(\bar{\mu}^2/m_e^2c^2\right)$ for a single unit-charge fermion. Differentiating with respect to $\ln\bar{\mu}$, $-\alpha^{-2}\,\mathrm{d}\alpha/\mathrm{d}\ln\bar{\mu} = -2/3\pi$, which is Equation (100.84). Each additional species contributes an identical loop with e^2 replaced by q_f^2 and multiplied by its number of colours, whence the sum; each decouples below its own mass, which is the decoupling of heavy states [1538], implicit in the mass dependence of Δ in Equation (100.50). The sign is fixed by the fermion loop being a screening medium (Remark 100.34), and it is the opposite of the non-abelian case [1501, 1511]. The systematic apparatus — the Callan–Symanzik equation [1415, 1435], anticipated by Gell-Mann and Low [1038] and, earlier still, by Stueckelberg and Petermann [1028] — is Chapter 108. □

100.7.2 Measured running of α

The running of Equation (100.82) is not a bookkeeping device: it is measured, and it is the cleanest available evidence that renormalization describes something in Nature rather than a way of organizing arithmetic.

- At $q^2 = 0$ the coupling is $\alpha^{-1} = 137.035999177(21)$ [2431], obtained from the electron anomaly and from atom-recoil interferometry (Section 100.8.4).
- Small-angle Bhabha scattering at e^+e^- colliders measures α at spacelike q^2 directly: the t-channel pole of Section 100.3.1 makes the rate large and its QED prediction essentially exact, so a departure of the measured angular distribution from the fixed-coupling prediction *is* the running.
- At the Z pole, $\sqrt{s}\,c = (91.1880 \pm 0.0020)\,\mathrm{GeV}$, the effective coupling is $\alpha^{-1} \approx 128.9$, a shift $\Delta\alpha \approx 0.059$ of which roughly half is leptonic and computable from Equation (100.83) and roughly half hadronic and extracted from measured $e^+e^- \to$ hadrons cross-sections through a dispersion relation [2427].

The hadronic piece deserves a word, because it is where a QED calculation stops being purely perturbative. The contribution of quark loops to Π_2 cannot be computed from Equation (100.50) at low q^2, since the loop momenta are of order the strong-interaction scale. It is instead obtained from data: the analyticity of $\Pi_2(q^2)$ in the cut plane, together with its behaviour at infinity, gives a dispersion relation expressing Π_2 at spacelike q^2 as an integral of its discontinuity across the timelike cut, and the discontinuity is proportional to the measured cross-section for $e^+e^- \to$ hadrons. The contour argument is the one proved in Theorem 17.78, where causality and analyticity alone are shown to relate the real and imaginary parts of a response function, transposed from a function of frequency with a pole on the axis to a function of q^2 with a branch cut; the same technique carries the hadronic contribution to the muon anomaly in Chapter 112.

Derivation pending #141

Hadronic vacuum polarization from data: the once-subtracted dispersion relation for the renormalized polarization function in the cut plane, with the subtraction fixed by the renormalization condition at zero momentum transfer and the convergence of the integral argued from the behaviour of the function at infinity; the optical theorem identifying the discontinuity across the timelike cut with the measured ratio of the annihilation cross section into hadrons to that into muon pairs; and the resulting integral over that measured ratio, which is the number quoted above as the hadronic half of the shift in the coupling at the mass of the Z boson. Only the analyticity input is proved in the treatise, in the Fourier and integral-transforms chapter; the dispersion integral itself is owed, and belongs in Appendix A.

100.7.3 The Landau pole, stated honestly

Proposition 100.64 (Where the one-loop coupling diverges)**.** *Integrating Equation* (100.84) *with only the electron in the loop, the coupling reaches infinity at*

$$\bar{\mu}_{\mathrm{L}} c = m_e c^2 \exp\!\left(\frac{3\pi}{2\alpha}\right) \approx 10^{286}\,\mathrm{eV}\,, \tag{100.85}$$

that is about 10^{277} GeV *[1047].*

Rests on Equation (100.84).

Proof. *Derives Proposition 100.64.*

$\alpha(\bar{\mu})^{-1} = \alpha^{-1} - (3\pi)^{-1} \ln(\bar{\mu}^2/m_e^2c^2)$ vanishes when $\ln(\bar{\mu}^2/m_e^2c^2) = 3\pi/\alpha$, that is at $\bar{\mu} = m_e c \exp(3\pi/2\alpha)$. With $\alpha^{-1} = 137.036$ the exponent is $3\pi \times 137.036/2 = 645.8$, so $\exp(645.8) = 10^{280.4}$, and multiplying by $m_e c^2 = 0.511 \times 10^6$ eV gives Equation (100.85). □

Remark 100.65 (What this does and does not mean). Four things must be said, and the fourth is the one usually omitted.

First, the computation extrapolates a one-loop formula over 280 orders of magnitude in energy, to a regime where the expansion parameter it is built from is of order one. Nothing in perturbation theory licenses that, and the position of the pole is not a prediction of QED in any useful sense.

Second, there is independent, non-perturbative evidence pointing the same way: lattice studies of pure U(1) gauge theory with charged matter find that the continuum limit exists only at zero renormalized coupling — *triviality* — so that a cutoff-free QED would be a free theory. If that is right, QED alone has no continuum limit and the theory is necessarily an effective one with a finite cutoff.

Third, this costs nothing at any accessible energy. The scale Equation (100.85) is larger than the Planck energy 1.22×10^{28} eV by more than 250 orders of magnitude, so the question is academic long before it is physical: some other description takes over first, and the modern reading of a renormalizable theory as a low-energy effective description with a cutoff (Chapter 108) is the honest framing throughout.

Fourth, QED is not a theory on its own. Above the electroweak scale it is a part of the $\mathrm{SU}(2) \times \mathrm{U}(1)$ theory of Chapter 104, whose hypercharge coupling runs differently and whose non-abelian factor runs with the opposite sign. The extrapolation is therefore not merely unjustified but performed on the wrong theory. What survives all four objections is the moral: the statement "$\alpha = 1/137$" is a statement about a measurement at low momentum transfer, and a theory that says nothing about its own ultraviolet completion should not be asked what happens at 10^{286} electronvolts. Programmes that claim to answer such a question — string theory, supersymmetric unification, grand unified theories — have no observational support of the kind this book requires, and are excluded from it for that reason and no other; the position is stated in Chapter 133.

100.8 Precision tests

Everything above is machinery. This section is the reason the machinery is believed.

100.8.1 The Lamb shift

Phenomenon 100.66 (The Lamb shift)**.** In atomic hydrogen the $2S_{1/2}$ and $2P_{1/2}$ levels are not degenerate, although the Dirac equation of Chapter 93 makes them exactly so: the S level lies above the P level by (1057.8298 ± 0.0032) MHz [2331], first resolved by the microwave resonance method of Lamb and Retherford [901]. No rearrangement of the one-particle Dirac theory produces the splitting; it is the first observed consequence of the interaction of a bound electron with the quantized radiation field, and its explanation [897] was the first finite answer extracted from a divergent quantum field theory.

Rests on Theorem 100.35 and Corollary 100.36.

Derivation of the dominant term. *Derives Phenomenon 100.66.*

Bethe's calculation [897] is non-relativistic and treats the electron in the Coulomb field of the proton, coupled to the quantized transverse field of Chapter 99. In the Coulomb

gauge the coupling of an electron of charge $-e$ is, to first order in the vector potential,

$$H' = \frac{e}{m_e}\,\hat{\boldsymbol{p}}\cdot\hat{\boldsymbol{A}}(\boldsymbol{x})\,, \qquad \hat{\boldsymbol{A}}(\boldsymbol{x}) = \sum_{\boldsymbol{k},\lambda}\sqrt{\frac{\hbar}{2\varepsilon_0\omega_k V}}\left(\boldsymbol{\varepsilon}_{(\lambda)}\,a_{\boldsymbol{k}\lambda}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}} + \text{h.c.}\right), \tag{100.86}$$

with $\omega_k = c\,|\boldsymbol{k}|$ and V the quantization volume; the normalization is the one that makes the field energy $\sum \hbar\omega_k\left(n_{\boldsymbol{k}\lambda}+\frac{1}{2}\right)$. Second-order perturbation theory for the state $|n\rangle$ with no photons present, summed over intermediate atomic states $|m\rangle$ and one-photon states, gives

$$\Delta E_n = \sum_m \sum_{\boldsymbol{k},\lambda} \frac{|\langle m;\boldsymbol{k}\lambda|\,H'\,|n;0\rangle|^2}{E_n - E_m - \hbar\omega_k} = \frac{e^2\hbar}{2\varepsilon_0 m_e^2}\sum_m\sum_{\boldsymbol{k},\lambda}\frac{\left|\boldsymbol{\varepsilon}_{(\lambda)}\cdot\boldsymbol{p}_{mn}\right|^2}{\omega_k V\,(E_{nm}-\hbar\omega_k)}\,,$$

writing $E_{nm} = E_n - E_m$ and $\boldsymbol{p}_{mn} = \langle m|\,\hat{\boldsymbol{p}}\,|n\rangle$, and using the dipole approximation $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}} \approx 1$, legitimate because the relevant wavelengths are long compared with the atom. Converting the mode sum, $\sum_{\boldsymbol{k}} \to V(2\pi)^{-3}\int \mathrm{d}^3k$, and using $\sum_\lambda \int \mathrm{d}\Omega\,\left|\boldsymbol{\varepsilon}_{(\lambda)}\cdot\boldsymbol{p}\right|^2 = \frac{8}{3}\pi\,|\boldsymbol{p}|^2$ together with $k^2\mathrm{d}k/\omega = \omega\,\mathrm{d}\omega/c^3$,

$$\Delta E_n = \frac{2\alpha\hbar^2}{3\pi m_e^2 c^2}\sum_m |\boldsymbol{p}_{mn}|^2 \int_0^{\omega_{\max}} \frac{\omega\,\mathrm{d}\omega}{E_{nm}-\hbar\omega}\,, \tag{100.87}$$

where $e^2\hbar/2\varepsilon_0 m_e^2\cdot(3\pi^2c^3)^{-1} = 2\alpha\hbar^2/3\pi m_e^2c^2$ by $e^2/\varepsilon_0 = 4\pi\alpha\hbar c$. The integral diverges linearly, which is the divergence of Theorem 100.35 seen in non-relativistic disguise. Split it:

$$\frac{\omega}{E_{nm}-\hbar\omega} = -\frac{1}{\hbar} + \frac{1}{\hbar}\,\frac{E_{nm}}{E_{nm}-\hbar\omega}\,.$$

The first piece contributes $-\left(2\alpha\hbar/3\pi m_e^2c^2\right)\omega_{\max}\sum_m|\boldsymbol{p}_{mn}|^2 = -\left(2\alpha\hbar\omega_{\max}/3\pi m_e c^2\right)\langle\hat{\boldsymbol{p}}^2/m_e\rangle_n$ by completeness, that is a term proportional to the expectation of the kinetic energy: it is a change in the electron's *mass*, present for a free electron as much as a bound one, and it is removed by the mass renormalization of Corollary 100.36. This subtraction is the whole of Bethe's insight, and it is renormalization performed before anyone had a name for it. What remains is

$$\Delta E_n = \frac{2\alpha}{3\pi m_e^2c^2}\sum_m |\boldsymbol{p}_{mn}|^2\;E_{mn}\;\ln\frac{\hbar\omega_{\max}}{|E_{nm}|}\,,$$

with $E_{mn} = -E_{nm}$, the logarithm arising from $\int^{\omega_{\max}}\mathrm{d}\omega/(E_{nm}-\hbar\omega)$. Bethe cut the integral off at $\hbar\omega_{\max} = m_ec^2$, the energy above which the non-relativistic treatment is meaningless; the covariant calculation [937] later confirmed that this is the right scale and supplied the constant beside the logarithm. Defining the Bethe logarithm by $\ln\langle\Delta E\rangle$ such that the weighted average may be taken outside the sum, the remaining sum is a commutator:

$$\sum_m |\boldsymbol{p}_{mn}|^2\,(E_m-E_n) = \langle n|\,\hat{\boldsymbol{p}}\cdot(H-E_n)\,\hat{\boldsymbol{p}}\,|n\rangle = \frac{1}{2}\,\langle n|\,[\hat{\boldsymbol{p}},[H,\hat{\boldsymbol{p}}]]\,|n\rangle = \frac{\hbar^2}{2}\left\langle\nabla^2V\right\rangle_n\,,$$

using $[H,\hat{\boldsymbol{p}}] = \mathrm{i}\hbar\nabla V$ and $[\hat{p}_j,\mathrm{i}\hbar\partial_jV] = \hbar^2\nabla^2V$. For the Coulomb potential $V = -e^2/4\pi\varepsilon_0 r$ one has $\nabla^2V = (e^2/\varepsilon_0)\,\delta^3(\boldsymbol{r})$, so the sum equals $2\pi\alpha\hbar^3c\,|\psi_n(0)|^2$ and vanishes for every state with $\ell\neq 0$ — which is why the effect separates $2S$ from $2P$ at all. With $|\psi_{n00}(0)|^2 = \alpha^3m_e^3c^3/\pi n^3\hbar^3$ (Chapter 81),

$$\Delta E_{nS} = \frac{4\alpha^5 m_e c^2}{3\pi n^3}\,\ln\frac{m_ec^2}{\langle\Delta E\rangle}\,. \tag{100.88}$$

Numerically, for $n=2$ the prefactor is $4\alpha^5m_ec^2/24\pi = 8.99\times10^{-26}\,\mathrm{J}$, that is $h\times 135.6\,\mathrm{MHz}$; Bethe's estimate $\langle\Delta E\rangle \approx 17.8\,\mathrm{Ry} = 242\,\mathrm{eV}$ gives a logarithm $\ln\left(5.11\times10^5/242\right) = 7.66$

and hence 1040 MHz, against the 1000 MHz Lamb and Retherford had measured. That a divergent theory, subtracted by hand, reproduced a measured microwave frequency to four percent within weeks of the measurement is the event from which the whole of Section 100.5 follows. □

The complete one-loop shift has three pieces, of which the derivation above is the largest:

- the *self-energy* of the bound electron, positive and dominant, Equation (100.88) together with its relativistic completion [937];
- the *vacuum polarization*, negative and small, computed exactly in Proposition 100.33: $-h \times 27.1\,\mathrm{MHz}$, the only piece of the three whose sign is opposite to the total;
- the *vertex* contribution, which at low momentum transfer is the anomalous magnetic moment of Theorem 100.41 acting on the spin–orbit interaction, and is positive.

Modern theory carries the expansion to two loops and beyond and includes the finite size of the proton, whose charge radius enters through the same $\delta^3(\boldsymbol{r})$ structure as Equation (100.54); the comparison with experiment is therefore a simultaneous determination of the proton radius, and the tension between the muonic and electronic determinations that dominated the 2010s is described in Chapter 90.

Derivation pending #142

Lamb shift, covariant completion: the relativistic one-loop self-energy of a bound electron, which supplies the constant accompanying Bethe's logarithm and fixes the cutoff-independence of the result; the binding corrections organized as an expansion in $Z\alpha$; and the finite-nuclear-size term through which the proton charge radius enters the comparison. The non-relativistic leading term and the vacuum-polarization term are derived in full above; this box covers the remainder, and it belongs in Appendix A.

100.8.2 The electron anomalous magnetic moment

Phenomenon 100.67 (The electron is not a pure Dirac particle)**.** The magnetic moment of the electron exceeds the value $g = 2$ that the Dirac equation assigns to a structureless spin-$\frac{1}{2}$ particle. The excess

$$a_e := \frac{g-2}{2} \tag{100.89}$$

is measured in a one-electron quantum cyclotron to a fractional precision of order 10^{-13}, giving $a_e = 0.001\,159\,652\,180\,59 \pm 0.000\,000\,000\,000\,13$ [2419], and the QED series evaluated to tenth order [2190, 2330] reproduces it over the whole range that the independently measured value of α permits. The apparatus is Chapter 112.

Rests on Theorem 100.41 and Definition 100.39.

Derivation. *Derives Phenomenon 100.67.*

The leading term is Theorem 100.41, $a_e = \alpha/2\pi = 1.161\,410 \times 10^{-3}$, derived in full in Section 100.4.3. It already accounts for the measured value to one part in 10^3, and the remainder is the rest of the series. Because the vertex correction was shown there to be α times a dimensionless integral, the whole expansion is a power series in α/π with pure numbers as coefficients,

$$a_e = \sum_{n \geq 1} C_n \left(\frac{\alpha}{\pi}\right)^n + a_e^{\mu,\tau} + a_e^{\mathrm{had}} + a_e^{\mathrm{weak}}\,, \tag{100.90}$$

with, from [2330],

$$C_1 = \tfrac{1}{2}\,, \qquad C_2 = -0.328478965\ldots\,, \quad C_3 = 1.181241456\ldots\,,$$
$$C_4 = -1.912245\ldots\,, \quad C_5 = 6.737(159)\,.$$

These are the mass-independent coefficients $A_1^{(2n)}$ of that reference; the mass-dependent terms are the separate $a_e^{\mu,\tau}$ of Equation (100.90). C_5 is known only numerically, its uncertainty is the error of the numerical integration, and the value quoted supersedes the same group's earlier 6.675(192). C_2 and C_3 are known in closed form; C_4 required the numerical evaluation of 891 diagrams and C_5 of 12 672, and an independent recomputation of the fifth-order term [2343] does not agree with the published value within its quoted uncertainty — a fact recorded here because a single unverified computation would otherwise be load-bearing. The remaining terms are small: muon and tau loops contribute 2.75×10^{-12}, hadronic vacuum polarization and hadronic light-by-light about 1.69×10^{-12}, and the electroweak contribution about 0.03×10^{-12} [2330]. Summing at $\alpha^{-1} = 137.035999177$ reproduces 0.001 159 652 18, in agreement with [2419].

The honest statement of the test requires one more step, and it is not the one usually made. The series is a function of α, so the comparison needs α measured somewhere else. The two best independent determinations, both from photon-recoil interferometry, are

$$\alpha^{-1} = 137.035999046(27)\ \text{(caesium)}\ [2316]\,, \qquad \alpha^{-1} = 137.035999206(11)\ \text{(rubidium)}\ [2363]\,,$$

and they disagree by more than five combined standard uncertainties. Propagating the difference through $a_e = \alpha/2\pi + \ldots$ gives a spread in the predicted a_e of about 1.4×10^{-12}, roughly ten times the experimental uncertainty 1.3×10^{-13} of [2419]. What QED is confirmed to is therefore the precision of its input — about one part in 10^9 of a_e — and not the thirteen figures that the precision of a_e alone would suggest. The arithmetic is carried out in Chapter 112, and the conclusion is worth stating plainly here because the looser claim is repeated everywhere. □

Remark 100.68 (The muon, and why it is the more sensitive probe). The same series with m_e replaced by m_μ gives $a_\mu = \alpha/2\pi + \ldots$ at leading order, since Theorem 100.41 contains no mass. Sensitivity to anything other than QED enters through loops of heavier states, and those contribute in proportion to m_ℓ^2, so the muon is more sensitive than the electron by $(m_\mu/m_e)^2 \approx 4.3 \times 10^4$. The measured value $a_\mu = (116\,592\,059 \pm 22) \times 10^{-11}$ [2368, 2416] is consequently compared against a Standard Model prediction [2353] whose uncertainty is dominated not by QED but by the hadronic vacuum polarization, where a dispersive evaluation from e^+e^- data and a lattice evaluation [2375] do not agree. The status is recorded in Chapter 112; the point for this chapter is that the QED part of a_μ is not in question, and that a discrepancy, if one survives, would be a statement about hadrons or about physics beyond the Standard Model, not about Equation (100.12).

100.8.3 Light-by-light scattering

Phenomenon 100.69 (Light scatters off light)**.** Two photons in vacuum interact. Maxwell's equations are linear and forbid the process outright; in QED it proceeds through a virtual charged loop, and it has been seen in ultraperipheral lead–lead collisions at the LHC, where the coherent photon flux carried by a nucleus of charge Ze is enhanced by Z^2 and brings the tiny cross-section within reach [2277, 2322]. The QED vacuum is therefore a nonlinear optical medium, as the effective Lagrangian of Euler and Heisenberg requires [777].

Rests on Theorems 100.17 and 100.31 and Equation (100.12).

Derivation of the effective Lagrangian and the scale. *Derives Phenomenon 100.69.*

The amplitude is the $E_e = 0$, $E_\gamma = 4$ entry of Theorem 100.17, with superficial degree of divergence $D = 0$: naively logarithmically divergent. It is in fact finite, and for the same reason Theorem 100.31 was only logarithmically divergent — gauge invariance forces each of the four photon legs to appear through its field strength rather than its potential, so the amplitude carries four explicit powers of momentum and the would-be divergence is cancelled. There is accordingly no counterterm for photon–photon scattering, and the process is a parameter-free prediction.

At photon energies well below $m_e c^2$ the electron loop may be integrated out, leaving a local interaction among the field strengths. Lorentz and gauge invariance and the C, P, T symmetry of Section 100.1.4 permit only two independent quartic invariants, and the coefficients follow from expanding the exact one-loop effective action of a constant field [777, 988]:

$$\mathcal{L}_{\mathrm{EH}} = \frac{2\alpha^2 \varepsilon_0^2 \hbar^3}{45\, m_e^4 c^5} \left[\left(E^2 - c^2 B^2 \right)^2 + 7 c^2 \left(\boldsymbol{E} \cdot \boldsymbol{B} \right)^2 \right] . \tag{100.91}$$

The dimensions check: $\varepsilon_0 E^2$ is an energy density, so the bracket with its prefactor ε_0^2 carries $\mathrm{J}^2/\mathrm{m}^6$, and $\hbar^3/m_e^4 c^5$ carries m^3/J, leaving J/m^3 as an addition to Equation (100.12) must. Compare Equation (100.91) with the Maxwell term $\frac{\varepsilon_0}{2}\left(E^2 - c^2 B^2\right)$ for a pure electric field. Their ratio is $4\alpha^2 \varepsilon_0 \hbar^3 E^2 / 45 m_e^4 c^5$, and using $\varepsilon_0 \hbar c / e^2 = 1/4\pi\alpha$ it collapses to

$$\frac{\mathcal{L}_{\mathrm{EH}}}{\mathcal{L}_{\mathrm{Maxwell}}} = \frac{\alpha}{45\pi} \left(\frac{E}{E_{\mathrm{cr}}} \right)^2 , \qquad E_{\mathrm{cr}} = \frac{m_e^2 c^3}{e\hbar} = 1.3233 \times 10^{18}\, \mathrm{V/m} , \tag{100.92}$$

with E_{cr} the Schwinger field [988], at which the work done on an electron over a Compton wavelength equals its rest energy and at which the vacuum becomes unstable against pair creation. Two statements must be kept apart here, because the literature runs them together. E_{cr} is the scale that makes the *expansion parameter* E/E_{cr} of order one, and it is the field at which the weak-field expansion Equation (100.91) stops being an expansion at all, since pair creation sets in with a rate carrying $\exp\left(-\pi E_{\mathrm{cr}}/E\right)$. The two terms of the Lagrangian are *not* equal there: the loop factor $\alpha/45\pi = 5.16 \times 10^{-5}$ makes the ratio that small at $E = E_{\mathrm{cr}}$, and it would reach unity only at $\sqrt{45\pi/\alpha} \approx 139$ times E_{cr}, that is about $1.8 \times 10^{20}\, \mathrm{V/m}$ — a field the theory as written cannot be extrapolated to. Laboratory static fields are some ten orders of magnitude below E_{cr}, which is why the vacuum looks linear.

The corresponding photon–photon cross-section for unpolarized light of energy $\hbar\omega \ll m_e c^2$ in the centre-of-mass frame is

$$\sigma_{\gamma\gamma} = \frac{973}{10125\pi}\, \alpha^4 \left(\frac{\hbar}{m_e c} \right)^2 \left(\frac{\hbar\omega}{m_e c^2} \right)^6 , \tag{100.93}$$

the sixth power of the energy being the direct consequence of the four powers of field strength in Equation (100.91) together with the two-body phase space. The α^4 and the sixth power together make the cross-section utterly negligible for visible light: at $\hbar\omega = 1\,\mathrm{eV}$ it is of order $1 \times 10^{-70}\, \mathrm{m}^2$.

What makes the process observable is a heavy-ion collider. A nucleus of charge Ze passing at small impact parameter carries a coherent electromagnetic field whose equivalent photon flux scales as Z^2, so a photon–photon luminosity in Pb–Pb collisions is enhanced by $Z^4 = 82^4 \approx 4.5 \times 10^7$ over the proton case. ATLAS reported evidence at 4.4 standard deviations [2277] and then observation at 8.2 [2322], with a fiducial cross-section of about $7.8 \times 10^{-36}\, \mathrm{m}^2$ — about 78 nanobarns — consistent with the QED prediction. □

Derivation pending #143

Light-by-light scattering: the explicit four-photon amplitude from a closed charged-fermion loop, the demonstration by gauge invariance that the six box diagrams combine into a finite answer despite a superficial degree of divergence of zero, the expansion of the one-loop effective action of a constant field yielding the coefficients in the Euler–Heisenberg Lagrangian, and the phase-space integration giving the low-energy cross-section. It belongs in Appendix A.

Remark 100.70 (Related nonlinear-vacuum effects and their status). Equation (100.91) also predicts that a strong magnetic field makes the vacuum birefringent, with different refractive indices for light polarized parallel and perpendicular to the field. Laboratory searches using long optical cavities in superconducting magnets have so far produced only upper limits, still above the predicted effect, so this particular consequence is *not* yet observed and must not be listed among the confirmations. Two effects of the same family are: the deflection of a photon in the Coulomb field of a nucleus, which is the same box amplitude with two legs attached to the nucleus, and the radiation reaction and pair-creation phenomena of ultra-intense laser–electron collisions, where evidence for quantum radiation reaction has been reported [2305, 2317]. None of this leaves QED: it is the same Lagrangian Equation (100.12) evaluated where its perturbative expansion in the external field breaks down.

100.8.4 Bound-state QED and the fine-structure constant

Scattering is not the only place QED is tested to many figures. A bound state made only of leptons has no hadronic structure at all, so its spectrum is a pure QED prediction, and the agreement with experiment is limited only by the input value of α and by the order to which the series has been evaluated.

- *Positronium*, the e^+e^- bound state discovered by Deutsch [980]. Its reduced mass is $m_e/2$, so the Bohr formula of Chapter 81 gives binding energies half those of hydrogen, $-\alpha^2 m_e c^2/4n^2$, that is $-6.80\,\mathrm{eV}$ in the ground state. It is unstable: the spin-singlet state annihilates into two photons at the rate $\Gamma_{2\gamma} = \alpha^5 m_e c^2/2\hbar$, a lifetime of 125 ps, while the spin-triplet state cannot decay into two photons — the two-photon system cannot carry $J = 1$ [917, 975] — and goes to three, giving a lifetime longer by roughly $1/\alpha$ times a phase-space factor, of order 140 ns. Both rates and the ground-state hyperfine splitting are calculable to high order and provide a QED test free of any nuclear input.

- *Muonium*, μ^+e^-, likewise purely leptonic. Its ground-state hyperfine interval is measured to $(4\,463\,302\,765 \pm 53)\,\mathrm{Hz}$ [1978], twelve significant figures, and its comparison with theory determines the muon-to-electron mass ratio.

- *Hydrogen*, whose $1S$–$2S$ two-photon transition is known to $(2\,466\,061\,413\,187\,035 \pm 10)\,\mathrm{Hz}$ [2179] and, after transfer over a 920 km fibre link to a caesium fountain, to $(2\,466\,061\,413\,187\,018 \pm 11)\,\mathrm{Hz}$ [2221] — fifteen significant figures, and the most accurately measured transition frequency in physics. Here QED is not the limiting uncertainty: the proton is. The measured frequency determines the Rydberg constant only in combination with the proton charge radius, which enters through a term of the same $\delta^3(\boldsymbol{r})$ form as Equation (100.54), and the discrepancy between the radius extracted from muonic hydrogen [2164, 2210] and the then-accepted electronic value was the proton-radius puzzle. It has since been resolved in favour of the smaller, muonic value by new electronic measurements [2281, 2311, 2331, 2358], and the recommended radius is now $(0.840\,75 \pm 0.000\,64)\,\mathrm{fm}$ [2431]; the experimental account is Chapter 90.

Derivation pending #144

Bound-state QED: the annihilation rates of para- and ortho-positronium quoted above, the ground-state hyperfine splitting of positronium and of muonium, and the systematic expansion of a two-body bound-state energy in powers of α and $\ln\alpha$ that organizes them. The selection rule forbidding a two-photon decay of a $J = 1$ state is cited rather than derived here and is proved in the discrete-symmetry chapter. This box belongs in Appendix A.

Proposition 100.71 (Several roads to α, and why that matters)**.** *The fine-structure constant is not predicted by anything in this book. It is measured, and the value is trustworthy because at least three physically unrelated routes agree:*

1. *from the electron anomaly, by inverting the series Equation (100.90) against the measured a_e of [2419] — a route that assumes QED;*
2. *from photon recoil, $\alpha^2 = (2R_\infty/c)\,(m_{\mathrm{at}}/m_e)\,(h/m_{\mathrm{at}})$, measured by atom interferometry in caesium [2316] and rubidium [2363] — a route that assumes only atomic kinematics and the Rydberg constant;*
3. *from the muonium hyperfine interval [1978] and from bound-state spectroscopy generally.*

The recommended value $\alpha^{-1} = 137.035999177(21)$ [2431] carries an uncertainty inflated to cover the disagreement between the two recoil determinations.

Rests on Phenomenon 100.67 and Equation (100.90).

Proof. *Derives Proposition 100.71.*

Route (i) is Equation (100.90) solved for α; route (ii) is kinematic, since a photon of known frequency transfers a known momentum to an atom of known mass and the resulting recoil frequency shift gives h/m_{at}, from which α follows through the displayed relation with R_∞ and the mass ratio measured independently; route (iii) uses the theoretical expression for the hyperfine interval, which is proportional to α^2 times the magnetic moment ratio. The routes share no systematic error, and two of them do not presuppose the QED series at all. That is what converts α from a parameter fitted to one measurement into a measured constant of Nature, and it is what makes the anomaly a *test* rather than a definition — the distinction insisted on in Remark 100.56. □

Remark 100.72 (A consequence of the 2019 SI for this chapter). Since 2019 the elementary charge e and the Planck constant h have exact defined values, and the speed of light has been exact since 1983. Equation (100.3) then reads $\alpha = \mu_0 c e^2/4\pi\hbar$ with everything on the right exact *except* the magnetic constant μ_0, which is therefore no longer $4\pi \times 10^{-7}\,\mathrm{N/A^2}$ by definition but a measured quantity, $\mu_0 = (1.256\,637\,061\,27 \pm 0.000\,000\,000\,20) \times 10^{-6}\,\mathrm{N/A^2}$ [2431], carrying exactly the fractional uncertainty of α. The experimental content of "α is measured" has been moved, by a change of unit conventions, into a constant that used to be exact. Nothing physical changed; but a reader who takes $\mu_0 = 4\pi \times 10^{-7}$ as exact and then quotes α to ten figures is quoting two mutually inconsistent statements, and the conventions of Chapter 2 are what keep the two apart.

Chapter 101

Weak Interactions

The weak interaction was forced on physics by an anomaly nobody wanted: the electrons emitted in nuclear beta decay come out with a continuous range of energies, although the initial and final nuclei have sharp masses. Everything in this chapter follows from the two responses to that single observation — a new, undetected neutral particle, and a new, extremely short-ranged interaction that does not conserve the quantum numbers the other forces conserve. The chapter runs from Chadwick's spectrum of 1914 to the discovery of the W and Z bosons in 1983, and it is deliberately told in that order, because the weak interaction is the one force whose theoretical structure was extracted almost entirely from experiment: parity violation, the $V - A$ current, universality and the charm quark were each read off measurements before any principle demanded them.

It sits after Chapter 100 because it is where the QED template first fails. Fermi's four-fermion theory is non-renormalizable and violates unitarity at energies of a few hundred GeV; the resolution — a massive intermediate vector boson, and hence a spontaneously broken gauge symmetry — is the subject of Chapter 104, which this chapter exists to motivate. Its immediate neighbours are the parity experiment of Chapter 110, the neutrino-helicity measurement of Chapter 98, the quark-mixing and neutrino-mass material of Chapter 103, and the nuclear phenomenology of Chapter 107. Standard treatments are [1739, 1933]; current values throughout are from [2427].

Conventions are those of Section 100.1.1 without exception: the metric is $\eta_{\mu\nu} = \mathrm{diag}(+1, -1, -1, -1)$, four-momenta are $p^\mu = (E/c, \boldsymbol{p})$ of SI dimension $\mathrm{kg\,m/s}$, the mass shell is $p^2 = m^2c^2$ as in Equation (100.1), so that a propagator denominator reads $p^2 - m^2c^2$ and never $p^2 - m^2$, and the Dirac field carries $1/\mathrm{m}^{3/2}$ by Definition 100.2. Every $\hbar$ and every c is written out. The one place where this chapter's arithmetic differs in appearance from its sources is the Fermi constant, which the literature quotes divided by $(\hbar c)^3$; both forms are given in Definition 101.8 and the difference between them is stated there rather than left to be guessed. Readers coming from the standard references, which drop both constants from every formula, should use the translation rule of Remark 100.4, which is the only place in this part where that convention is discussed.

101.1 The beta-decay crisis

101.1.1 The continuous spectrum

Alpha and gamma emission produce line spectra: a definite parent nucleus and a definite daughter nucleus differ by a definite energy, and the emitted quantum carries it. Beta emission was expected to do the same, and for two decades the experimental record was read as though it did — the sharp *internal-conversion* lines that accompany the beta continuum were mistaken for the primary spectrum, and the continuous background was ascribed to

electrons that had lost energy on their way out of the source.

Chadwick settled the question in 1914 with a magnetic spectrometer read by an ionization chamber rather than by a photographic plate [414]. A plate saturates, and a sharp line on a saturated plate looks like all there is; a counter measures intensity, and Chadwick's counter showed a broad continuous distribution on which the conversion lines sat as small peaks. The primary beta spectrum of radium B and C was continuous.

The escape route left open was that the electron leaves with the full energy and loses part of it in the source or in the surrounding material, so that the missing energy reappears as secondary radiation. Ellis and Wooster closed it by calorimetry [574]. They enclosed a radium-E source in a thick-walled calorimeter that would absorb everything except a neutrino, and measured the heat per disintegration: about 0.35 MeV, against an endpoint near 1 MeV. Had the missing energy been carried by any form of radiation, the calorimeter would have found it. Meitner and Orthmann repeated the measurement with a different calorimeter and a different absolute calibration and obtained the same answer [662], which is what turned a surprising result into an accepted one.

The seriousness of the anomaly is measured by the responses it drew. Bohr was for several years willing to entertain the possibility that energy conservation holds only statistically in nuclear processes — that is, to give up the conservation law rather than postulate an unseen particle. Pauli took the opposite view, and this chapter is the record of his being right; but the point worth keeping is that at the time neither option was obviously the cheaper one.

Phenomenon 101.1 (The beta spectrum is continuous)**.** The electrons emitted in nuclear beta decay do not carry a single energy. They are distributed continuously from zero up to a sharp endpoint fixed by the mass difference of the initial and final nuclei, although both of those masses are sharp [414]. The missing energy is not recovered as secondary radiation: a calorimeter enclosing a radium-E source records a mean energy per disintegration of about 0.35 MeV against an endpoint near 1 MeV [574].

Derivation. *Derives Phenomenon 101.1.*

Suppose the decay had only two products, a daughter nucleus of mass M' and an electron of mass m, and let the parent of mass M be at rest. Momentum conservation makes the two momenta equal and opposite, $\boldsymbol{p}' = -\boldsymbol{p}$, and energy conservation then reads

$$Mc^2 = \sqrt{p^2c^2 + M'^2c^4} + \sqrt{p^2c^2 + m^2c^4}\,. \tag{101.1}$$

The right-hand side is a strictly increasing function of p, so it attains the value Mc^2 for exactly one p: a two-body decay of a state of definite mass yields a *line*, and the electron energy $E = \sqrt{p^2c^2 + m^2c^4}$ is fixed. The observed continuum is therefore, by itself, a proof that at least three bodies share the released energy. Since the daughter and the electron are both detected and account between them for less than the release, the third is not detected: it must be neutral, must interact far more weakly than the electron, and must be light enough to leave the endpoint where the two-body kinematics puts it. That is precisely the particle Pauli proposed in 1930 [665] and Cowan and Reines detected twenty-six years later [1085]. The argument also shows what would have followed had the spectrum been a line with a lower endpoint — energy conservation itself would have been at stake, which is why Bohr was prepared to give it up. □

Remark 101.2 (What the calorimeter measures, quantitatively). The calorimetric result is stronger than "some energy is missing". Write $\langle T_e \rangle$ for the mean electron kinetic energy and T_0 for its endpoint. A three-body decay with a massless third particle distributes the release between electron and neutrino according to the phase-space factor derived in Proposition 101.11; for an allowed transition with $T_0 \approx 1\,\mathrm{MeV}$ that factor gives $\langle T_e \rangle \approx 0.40\,T_0$, and the measured ratio for radium E is about 0.33 [574]. A calorimeter that recorded T_0

per disintegration would have proved the missing energy to be radiation; one that records a third of it proves the energy is carried away by something the calorimeter cannot stop. The residual discrepancy between 0.40 and 0.33 is itself instructive and was not understood until much later: the decay of radium E, that is ^{210}Bi, is first-forbidden and its spectrum is correspondingly softer than the allowed shape. Nothing in the conclusion depends on that refinement — the alternative on offer in 1927 was that the calorimeter should have found the whole release, and it found a third.

101.1.2 Pauli's neutrino

On 4 December 1930 Pauli wrote to a conference at Tübingen he could not attend, addressing the "radioactive ladies and gentlemen" and proposing what he called a "desperate remedy" [665]: a neutral particle of spin $\frac{1}{2}$, obeying the exclusion principle, of mass "of the same order of magnitude as the electron mass" and in any case not larger than about one per cent of the proton mass, emitted together with the electron in every beta decay. He called it the neutron; the name *neutrino* is Fermi's, coined after Chadwick's discovery of the real neutron in 1932 had taken the first name.

The proposal is remarkable for how much it buys at once. Three independent difficulties, which had no reason to be connected, are removed by one hypothesis.

1. *Energy.* The release is shared between two light particles, so the electron energy is continuous with an endpoint at the full release, which is Phenomenon 101.1.

2. *Angular momentum.* Beta decay changes the mass number A by zero, so it changes the number of nucleons not at all and the number of fermions in the nucleus not at all; emitting a single spin-$\frac{1}{2}$ electron would change the total angular momentum of the system by a half-integer, which no rotation can do. A second spin-$\frac{1}{2}$ particle restores integrality.

3. *Statistics.* The nitrogen-14 nucleus was known from the band spectrum of N_2 to be a boson of spin 1. On the proton–electron model of the nucleus, ^{14}N contains 14 protons and 7 electrons, that is 21 fermions, and must be a fermion. The contradiction is what Pauli's letter calls the "wrong statistics".

Proposition 101.3 (The endpoint measures the neutrino mass)**.** *Let a nucleus of mass M at rest decay to a daughter of mass M', an electron of mass m_e and a neutral particle of mass m_ν. Write $Q = (M - M' - m_e)c^2$ for the energy released as kinetic energy. Then the maximum kinetic energy of the electron is*

$$T_e^{\max} = \frac{(Q - m_\nu c^2)\,(2M'c^2 + Q + m_\nu c^2)}{2\,(M'c^2 + m_e c^2 + Q)} = \left(Q - m_\nu c^2\right)\left[1 - \frac{2m_e c^2 + Q - m_\nu c^2}{2M'c^2} + \cdots\right], \tag{101.2}$$

and in the limit $M'c^2 \gg Q$ in which the daughter recoil is negligible, $T_e^{\max} = Q - m_\nu c^2$.

Rests on Equation (101.1).

Proof. *Derives Proposition 101.3.*

The electron takes its greatest energy when the daughter and the neutrino move together, so that the pair may be treated as a single body of mass $M' + m_\nu$ recoiling against the electron. That is a two-body decay, and Equation (101.1) with $M' \to M' + m_\nu$ fixes the electron energy uniquely:

$$E_e^{\max} = \frac{M^2c^4 + m_e^2c^4 - (M' + m_\nu)^2\,c^4}{2Mc^2}\,.$$

Subtract $m_e c^2$ and use $Mc^2 - m_e c^2 = M'c^2 + Q$ to factor the numerator as $(Q - m_\nu c^2)\,(2M'c^2 + Q + m_\nu c^2)$; writing the denominator as $2(M'c^2 + m_e c^2 + Q)$ gives the exact form in Equation (101.2), and expanding in $1/M'c^2$ gives the second. The recoil correction is of relative order $(2m_e c^2 + Q)\,/2M'c^2$ — dominated by the electron mass, not by Q, which is the trap in this expansion — and for tritium ($Q = 18.6\,\mathrm{keV}$, $M'c^2 = 2808\,\mathrm{MeV}$) it is 1.85×10^{-4}, that is 3.4 eV of recoil energy taken by the daughter. That is four times the whole mass sensitivity of Equation (101.23), so it is computed and subtracted rather than neglected. The leading statement is the one that matters here: the endpoint sits a distance $m_\nu c^2$ below the release, so a measured endpoint bounds the neutrino mass without any assumption about the interaction that produced it. □

Pauli's own bound came from exactly this argument applied to the spectra then available, and gave $m_\nu \lesssim m_e$; the modern version of the same measurement, on tritium, gives $m_\nu < 0.8\,\mathrm{eV}/c^2$ [2399], an improvement of six orders of magnitude in the same observable.

Pauli's caution was well judged in one respect. He estimated that his particle, being neutral and weakly coupled, would have a penetrating power far greater than a photon's, and doubted it could ever be observed. That doubt is quantified in Section 101.1.3 and it was very nearly right.

101.1.3 Detection

A particle postulated to explain a missing quantity is a bookkeeping device until it is detected in its own right. The detection reaction is beta decay run backwards,

$$\bar{\nu}_e + p \longrightarrow n + e^+ , \tag{101.3}$$

which has two attractive features: free protons are available in bulk as the hydrogen of water, and the final state carries its own signature in time.

Proposition 101.4 (Threshold of the inverse beta reaction)**.** *Reaction Equation* (101.3) *on a proton at rest requires*

$$E_{\bar{\nu}} \geq \frac{(m_n + m_e)^2\, c^4 - m_p^2 c^4}{2m_p c^2} = 1.806\,\mathrm{MeV}\,. \tag{101.4}$$

Rests on Equation (101.3)*.*

Proof. *Derives Proposition 101.4.*

The invariant $s = (p_{\bar{\nu}} + p_p)^2$ is conserved, and the final state exists only if $\sqrt{s}\,c \geq (m_n + m_e)c^2$, the least energy the pair can have. With the proton at rest and the antineutrino massless, $sc^2 = m_p^2 c^4 + 2m_p c^2 E_{\bar{\nu}}$, and the inequality rearranges to Equation (101.4). Inserting $m_n c^2 = 939.565\,\mathrm{MeV}$, $m_p c^2 = 938.272\,\mathrm{MeV}$ and $m_e c^2 = 0.511\,\mathrm{MeV}$ [2427] gives 1.806 MeV. A fission reactor emits antineutrinos with a spectrum extending to about 8 MeV, so a useful fraction of them are above threshold; this is why the experiment was done at a reactor and not with a natural source. □

The signature is a delayed coincidence. The positron annihilates within nanoseconds against an electron of the target, giving two 511 keV photons back to back; the neutron wanders, thermalizes, and is captured microseconds later on a nucleus with a large capture cross-section — cadmium dissolved in the water — which de-excites by emitting several megaelectronvolts of gamma rays. Two flashes separated by a characteristic time, in the right energy ratio, in a detector shielded against everything else, is a signature no ordinary background reproduces. Cowan, Reines and their collaborators built it at the Savannah River reactor and reported the observation in 1956 [1085, 1097], twenty-six years after Pauli's letter.

Phenomenon 101.5 (The neutrino interacts, and almost never)**.** Free antineutrinos from a reactor induce reaction Equation (101.3) at a rate corresponding to a cross-section of order $10^{-47}\,\mathrm{m}^2$ for a few-MeV antineutrino [1085, 1097]. A block of lead containing that many protons per unit volume would have to be of order a light-year thick to stop half the beam.

Rests on Equation (101.3) *and Proposition 101.4.*

Derivation. *Derives Phenomenon 101.5.*

The cross-section may be predicted from the coupling that Section 101.2.1 extracts from beta decay itself, which is what makes the number a test rather than a fit. At energies far below the mass of the mediating boson the interaction is a contact one, the amplitude is a product of two currents at a point, and by the derivation of Proposition 101.54 — which is performed there in full and is common to every charged-current process of this kind — the cross-section for the nucleon reaction is

$$\sigma\left(\bar{\nu}_e p \to n e^+\right) = \frac{G_F^2\,|V_{ud}|^2\,(1+3\lambda^2)}{\pi\,(\hbar c)^4}\,p_e c\,E_e\,, \tag{101.5}$$

with $E_e = E_{\bar{\nu}} - (m_n - m_p)c^2$ the positron energy, $p_e c = \sqrt{E_e^2 - m_e^2 c^4}$ and $\lambda = g_A/g_V = 1.2754$ the ratio of the axial and vector nucleon couplings measured in neutron decay [2427]; the factor $1 + 3\lambda^2$ is the sum of one Fermi and three Gamow–Teller spin channels, counted in Section 101.2.2. The factor $|V_{ud}|^2 = \cos^2\theta_C = 0.949$ is there because this is a *hadronic* charged current and not a leptonic one: the reaction turns a d quark into a u, and by Equation (101.63) that vertex carries $\cos\theta_C$. Omitting it overstates the rate by five per cent. At $E_{\bar{\nu}} = 3\,\mathrm{MeV}$ this gives $E_e = 1.707\,\mathrm{MeV}$, $p_e c = 1.628\,\mathrm{MeV}$ and

$$\sigma = 2.6 \times 10^{-47}\,\mathrm{m}^2\,,$$

which is the observed order of magnitude. For the penetrating power, lead has $11.34 \times 10^3\,\mathrm{kg/m^3}$ and molar mass $0.2072\,\mathrm{kg/mol}$, hence 3.30×10^{28} nuclei and 2.70×10^{30} protons per cubic metre; the mean free path is

$$\ell = \frac{1}{n\sigma} = \frac{1}{(2.70 \times 10^{30}\,1/\mathrm{m}^3)\,(2.6 \times 10^{-47}\,\mathrm{m}^2)} = 1.4 \times 10^{16}\,\mathrm{m}\,,$$

which is 1.5 yr of travel at the speed of light. The idealization is explicit and is worth stating: a proton bound in a lead nucleus is not a free proton and the reaction on it is not Equation (101.3), so the figure counts protons, not targets. As an order of magnitude for the transparency of matter to neutrinos it is nevertheless the right one, and it is the reason Pauli thought his particle undetectable. □

Two later measurements complete the picture of what a neutrino is. The first is that there is more than one kind. Firing a beam of neutrinos produced in pion decay, $\pi^+ \to \mu^+\nu$, at a spark-chamber detector, Danby and collaborators at the Brookhaven AGS found the reaction products to be muons and never electrons [1223]: the neutrino accompanying a muon makes a muon, not an electron. Since nothing in the kinematics forbids the electron channel — it is in fact the more open of the two — the null result establishes a conserved quantum number distinguishing the two families, which is lepton flavour. The third family's neutrino was observed directly at Fermilab forty years later by the DONUT collaboration, which identified the short kinked track of a tau produced in a nuclear emulsion [2016]. The second completion is the counting: Section 101.6.4 shows that the number of light neutrino species that couple to the Z is three, and that this is measured, not assumed.

101.2 Fermi's theory

101.2.1 The four-fermion interaction

Fermi's 1934 paper [738] is the origin of every equation in this chapter. Its construction is an analogy, and the analogy is with the electromagnetic interaction of Section 100.1. In QED the interaction Lagrangian density is a current contracted with a field, $\mathcal{L}_{\text{int}} = -j^{\mu}A_{\mu}$, and an elastic scattering amplitude is a product of two currents joined by the photon propagator: the interaction is *current–current*, with the two currents at different points and a field carrying the influence between them. Fermi kept the current–current form, kept the vector character of the currents, and threw away the field: his two currents sit at the same spacetime point.

The reasons were empirical. Beta decay had a range too short to measure, and no quantum of the required kind was known; the electron and the neutrino are created in the decay, exactly as a photon is created in an atomic transition, which is what suggested a field theory rather than a rearrangement of pre-existing constituents; and the vector form was the one that reproduced the observed spectrum shape. Nature rejected the paper as "too remote from physical reality". It appeared in *Zeitschrift für Physik* and contains, in the space of a few pages, the coupling constant, the spectrum shape, and the lifetime systematics.

Definition 101.6 (Fermi's interaction)**.** Let $\psi_p, \psi_n, \psi_e, \psi_\nu$ be the Dirac fields of the proton, neutron, electron and neutrino, each of SI dimension $1/\mathrm{m}^{3/2}$ by Definition 100.2. Fermi's interaction is the Lorentz-invariant contact term

$$\mathcal{L}_{\mathrm{F}} = -G\left(\bar{\psi}_p \gamma^{\mu} \psi_n\right)\left(\bar{\psi}_e \gamma_{\mu} \psi_\nu\right) + \text{h.c.}\,, \tag{101.6}$$

in which each factor in parentheses is a *current*, the two are evaluated at the same point x, and G is a constant.

Proposition 101.7 (The Fermi coupling has the dimension of an energy times a volume)**.** *For Equation* (101.6) *to be an energy density,* $\mathrm{J/m^3}$*, the constant* G *must carry*

$$[G] = \mathrm{J\,m^3} = 1/\mathrm{J}^2 \times \left[(\hbar c)^3\right]\,, \tag{101.7}$$

that is, $G/(\hbar c)^3$ *is an inverse squared energy.*
Rests on Equation (101.6) *and Definition 100.2.*

Proof. *Derives Proposition 101.7.*
By Definition 100.2 the bilinear $\bar{\psi}\gamma^{\mu}\psi$ has dimension $1/\mathrm{m}^3$, so the product of two currents carries $1/\mathrm{m}^6$. An energy density is $\mathrm{J/m^3}$. Hence $[G] = \mathrm{J/m^3} \times \mathrm{m}^6 = \mathrm{J\,m^3}$. Since $\hbar c$ has dimension J m, dividing by $(\hbar c)^3$ leaves $1/\mathrm{J}^2$. □

This one line is the most consequential dimensional statement in the chapter. Every coupling in Chapter 100 is dimensionless once expressed as α; Fermi's is not, and cannot be made so. Section 101.7.2 shows that this alone condemns the theory to non-renormalizability, and Section 101.7.1 shows that it also fixes, in advance, the energy at which the theory must fail.

Definition 101.8 (The Fermi constant)**.** The Fermi constant is defined by the muon lifetime through Equation (101.53), and its measured value is

$$\frac{G_F}{(\hbar c)^3} = (1.166\,378\,7 \pm 0.000\,000\,6) \times 10^{-5}/\mathrm{GeV}^2\,, \qquad G_F = 1.435\,85 \times 10^{-62}\,\mathrm{J\,m^3}\,. \tag{101.8}$$

The first form is the one universally quoted, and it is not G_F but G_F divided by the cube of $\hbar c$; the second is G_F itself in SI base units. Confusing them costs a factor $(\hbar c)^3 = 3.1600 \times 10^{-77}\,\mathrm{J^3\,m^3}$, so the distinction is stated here once and relied on thereafter.

Derivation of the conversion. *Derives Definition 101.8.*

$\hbar c = 3.161\,527 \times 10^{-26}\,\mathrm{J\,m}$ from the defined values of $\hbar$ and c, so $(\hbar c)^3 = 3.160\,03 \times 10^{-77}\,\mathrm{J^3\,m^3}$. One gigaelectronvolt is $1.602\,176\,634 \times 10^{-10}\,\mathrm{J}$ exactly, since the elementary charge is fixed by definition since 2019, so $1/\mathrm{GeV}^2 = 3.895\,66 \times 10^{19}/\mathrm{J}^2$. Then

$$G_F = 1.166\,378\,7 \times 10^{-5} \times 3.895\,66 \times 10^{19}/\mathrm{J}^2 \times 3.160\,03 \times 10^{-77}\,\mathrm{J^3\,m^3} = 1.435\,85 \times 10^{-62}\,\mathrm{J\,m^3}\,.$$

Two derived numbers used repeatedly below follow at once: the energy at which the dimensionless combination $G_F E^2/(\hbar c)^3$ reaches unity is

$$E_F = \left(\frac{(\hbar c)^3}{G_F}\right)^{1/2} = 292.8\,\mathrm{GeV}\,, \tag{101.9}$$

and the combination $(\sqrt{2}G_F/(\hbar c)^3)^{-1/2} = 246.2\,\mathrm{GeV}$ is the electroweak scale v that Chapter 104 identifies with the vacuum expectation value of the scalar field. □

Remark 101.9 (Why the customary units are not abandoned here). Editorial rule 3 requires SI, and Equation (101.8) gives it. The reciprocal-squared-energy form is nevertheless retained alongside, for a reason that is physics and not deference: the quantity that controls the size of every weak amplitude is the dimensionless ratio $G_F E^2/(\hbar c)^3$, and quoting $G_F/(\hbar c)^3$ in $1/\mathrm{GeV}^2$ makes that ratio readable at a glance — at $E = 1\,\mathrm{GeV}$ it is 1.17×10^{-5}, at $E = 100\,\mathrm{GeV}$ it is 0.117, and at Equation (101.9) it is one. The bare SI number $1.435\,85 \times 10^{-62}\,\mathrm{J\,m^3}$ conveys none of that. Both are correct; each is quoted where it does work.

The rest of this subsection extracts from Equation (101.6) the two results Fermi's paper is remembered for: the shape of the electron spectrum and the systematics of the lifetime. Both follow from one tool, which is used again in Section 101.4.3 in its relativistic form and is therefore stated here once with its derivation.

Proposition 101.10 (The golden rule)**.** *Let a system be prepared at $t = 0$ in a discrete state $|i\rangle$ of energy E_i and let a time-independent perturbation V connect it to a continuum of final states $|f\rangle$ with density $\rho(E_f)$ states per unit energy. Then, for times long compared with $\hbar/|E_f - E_i|$ over the width of the continuum and short compared with the lifetime, the transition rate is constant and equal to*

$$\Gamma = \frac{2\pi}{\hbar} \sum_f |\langle f|\, V\, |i\rangle|^2\, \delta\left(E_f - E_i\right)\,, \tag{101.10}$$

the sum being an integral $\int \mathrm{d}E_f\, \rho(E_f)$ over the continuum.

Rests on Postulate 77.4.

Proof. *Derives Proposition 101.10.*

To first order in V the amplitude for finding the system in $|f\rangle$ at time t is

$$c_f(t) = -\frac{\mathrm{i}}{\hbar} \int_0^t \mathrm{d}t'\, \langle f|\, V\, |i\rangle\, \mathrm{e}^{\mathrm{i}(E_f - E_i)t'/\hbar} = \langle f|\, V\, |i\rangle\, \frac{1 - \mathrm{e}^{\mathrm{i}\omega_{fi}t}}{\hbar\omega_{fi}}\,,$$

with $\hbar\omega_{fi} = E_f - E_i$. Hence

$$|c_f(t)|^2 = |\langle f|\, V\, |i\rangle|^2\, \frac{4\sin^2\left(\omega_{fi}t/2\right)}{\hbar^2\omega_{fi}^2}\,.$$

The kernel $4\sin^2(\omega t/2)/(\hbar\omega)^2$ has total integral $\int \mathrm{d}\omega\, 4\sin^2(\omega t/2)/(\hbar\omega)^2 = 2\pi t/\hbar^2$ and a width in ω of order $1/t$, so for t large compared with the inverse spread of the continuum it acts as $(2\pi t/\hbar^2)\delta(\omega) = (2\pi t/\hbar)\delta(E_f - E_i)$. Summing over f and dividing by t gives Equation (101.10); the probability grows linearly in t, which is what makes the *rate* well defined and the decay law exponential once the depletion of $|i\rangle$ is fed back in. The result is Dirac's [572]; the name is Fermi's [954], and it is the tool with which he wrote [738]. □

Proposition 101.11 (The allowed beta spectrum)**.** *Let a nucleus decay by an* allowed *transition — one in which the electron and neutrino are emitted in relative s waves, so that the nuclear matrix element does not depend on their momenta. Then the electron energy spectrum is*

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}E_e} \propto F(Z,E_e)\, p_e E_e \,(E_0 - E_e)\sqrt{(E_0-E_e)^2 - m_\nu^2 c^4}\,, \tag{101.11}$$

where E_0 is the total energy available to the lepton pair, $p_e = \sqrt{E_e^2/c^2 - m_e^2 c^2}$, and $F(Z,E_e)$ is the Coulomb correction for the motion of the emitted electron in the field of the daughter nucleus. For $m_\nu = 0$ this reduces to

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}E_e} \propto F(Z,E_e)\, p_e E_e \,(E_0 - E_e)^2\ . \tag{101.12}$$

Rests on Proposition 101.10.

Proof. *Derives Proposition 101.11.*

Apply the golden rule of Proposition 101.10 with two light particles in the final state and the recoiling daughter treated as infinitely heavy, so that it absorbs momentum but no energy. With the matrix element independent of the lepton momenta, the entire energy dependence is the density of final states,

$$\mathrm{d}\rho \propto \mathrm{d}^3p_e\,\mathrm{d}^3p_\nu\,\delta\left(E_0 - E_e - E_\nu\right) = 16\pi^2 p_e^2\,\mathrm{d}p_e\,p_\nu^2\,\mathrm{d}p_\nu\,\delta\left(E_0 - E_e - E_\nu\right)\ ,$$

the angular integrations giving 4π each because an s-wave matrix element is isotropic. Change variables with $p^2\,\mathrm{d}p/\mathrm{d}E = pE/c^2$, valid for either particle, and use the delta function to set $E_\nu = E_0 - E_e$:

$$\frac{\mathrm{d}\rho}{\mathrm{d}E_e} \propto \frac{p_e E_e}{c^2}\cdot\frac{p_\nu E_\nu}{c^2} = \frac{p_e E_e}{c^4}\,(E_0-E_e)\sqrt{(E_0-E_e)^2 - m_\nu^2c^4}\,,$$

where the last step used $p_\nu c = \sqrt{E_\nu^2 - m_\nu^2 c^4}$. That is Equation (101.11). The Coulomb factor is a separate effect: the emitted electron is not a plane wave but a continuum Coulomb wave in the field of the daughter's charge Z, and the rate is proportional to the squared modulus of that wave at the nucleus. Its non-relativistic form is

$$F(Z,E_e) = \frac{2\pi\eta}{1-\mathrm{e}^{-2\pi\eta}}\,, \qquad \eta = \pm\frac{Z\alpha c}{v_e}\,, \tag{101.13}$$

with the upper sign for β^- emission and the lower for β^+, Z being the charge number of the daughter. The sign is the entire physical content of the factor, and the two limits fix it. For β^- the electron is attracted, so $\eta > 0$, and $F \to 2\pi\eta > 1$ as v_e falls: the Coulomb field draws the outgoing wave onto the nucleus and *enhances* the low-energy end of the spectrum. For β^+ the positron is repelled, so $\eta < 0$, and $F \to 2\pi\,|\eta|\,\mathrm{e}^{-2\pi|\eta|} \ll 1$, which is the Gamow barrier factor and *suppresses* the same end. Here α is the fine-structure constant of Equation (100.3) and v_e the electron speed; η is dimensionless, as it must be. □

Proposition 101.12 (Sargent's rule)**.** *For an allowed transition with $E_0 \gg m_e c^2$ and the Coulomb factor neglected, the total rate grows as the fifth power of the energy release,*

$$\Gamma \propto E_0^5\,. \tag{101.14}$$

Rests on Equation (101.12).

Proof. *Derives Proposition 101.12.*

Integrate Equation (101.12) with $F = 1$ and $p_e c \simeq E_e$:

$$\Gamma \propto \int_0^{E_0} E_e^2\,(E_0-E_e)^2\,\mathrm{d}E_e = E_0^5\left(\frac{1}{3}-\frac{1}{2}+\frac{1}{5}\right) = \frac{E_0^5}{30}\,.$$

The fifth power is pure phase space — two particles sharing a release, each contributing a $p^2\mathrm{d}p$ — and it is what Sargent had found empirically in 1933 by plotting the decay constants of the naturally occurring beta emitters against their endpoints on logarithmic axes and obtaining two straight lines of slope five [727]. The two lines, rather than one, are the first appearance in this chapter of a distinction that Section 101.2.2 identifies: allowed and first-forbidden transitions have different matrix elements and therefore different intercepts, but the same slope, because the slope is kinematics. □

Remark 101.13 (Fermi's theory predicted a shape, and was believed because of it). It is worth being explicit about the logic, because it recurs. Equation (101.12) contains no free function: once E_0 is read off the endpoint and Z off the daughter, the entire spectrum is fixed, with the overall normalization the only adjustable number. A theory that merely permitted a continuous spectrum would have explained nothing — the continuum was the datum. Fermi's theory predicted *which* continuum, and the prediction is a one-parameter fit to a curve of several hundred points. That is why the vector form survived until parity violation forced its modification twenty-three years later, and why the modification, when it came, had to preserve the spectrum shape — as Section 101.4.1 shows the $V-A$ form does.

101.2.2 Allowed transitions: Fermi and Gamow–Teller

Fermi's choice of a vector current in Equation (101.6) was one of five possibilities, and Nature uses two of them. The enumeration is fixed by Lorentz invariance and is worth doing, because the same list organizes every experiment in Section 101.4.1 that fixed the interaction empirically.

Proposition 101.14 (There are exactly five bilinear covariants)**.** *The sixteen matrices*

$$\Gamma_i \in \left\{ \mathbb{1},\ \gamma^\mu,\ \sigma^{\mu\nu},\ \gamma^\mu\gamma^5,\ \gamma^5 \right\}, \qquad \sigma^{\mu\nu} = \frac{\mathrm{i}}{2}\left[\gamma^\mu, \gamma^\nu\right], \tag{101.15}$$

form a basis of the complex 4×4 *matrices, and the bilinears* $\bar\psi\Gamma_i\chi$ *built from them transform under the Lorentz group as a scalar (S), a vector (V), an antisymmetric tensor (T), an axial vector (A) and a pseudoscalar (P) respectively. Counting components,* $1+4+6+4+1=16$.

Rests on Lemma 100.23.

Proof. *Derives Proposition 101.14.*

Linear independence: with $\{\gamma^\mu,\gamma^\nu\}=2\eta^{\mu\nu}\mathbb{1}$, every product of gamma matrices reduces to one of Equation (101.15) up to a sign, and the trace relations of Lemma 100.23 give $\operatorname{tr}(\Gamma_i\Gamma_j^{-1})=4\delta_{ij}$ for the sixteen listed matrices, from which $\sum_i c_i\Gamma_i=0$ forces every $c_i=0$. Sixteen independent matrices in a sixteen-dimensional space are a basis. The transformation laws follow from the defining property of the spinor representation, $S^{-1}(\Lambda)\gamma^\mu S(\Lambda)=\Lambda^\mu{}_\nu\gamma^\nu$, established in Chapter 93: $\bar\psi\chi$ is invariant, $\bar\psi\gamma^\mu\chi$ carries one vector index, and so on. That the last two are *pseudo*-quantities is the statement that γ^5 anticommutes with every γ^μ and therefore picks up a sign under the improper transformation P, which is proved in Proposition 101.23. □

The most general Lorentz-invariant contact interaction between two pairs of spin-$\frac12$ fields is then a sum of five terms, one for each covariant, with five complex coefficients — and, once parity is not assumed, ten, since each term may be accompanied by its parity-reflected partner. Determining those ten numbers from experiment is the programme that occupies Sections 101.3 and 101.4.

For nuclear beta decay only two of the five survive, and the reason is angular momentum. In an allowed transition the leptons carry away no orbital angular momentum, so the total change in nuclear spin equals the total spin of the emitted pair, which is 0 or 1.

Proposition 101.15 (Allowed selection rules)**.** *For an allowed transition,*

1. *the S and V couplings emit the lepton pair in a spin singlet, giving* $\Delta J = 0$ *with no change of nuclear parity — the* Fermi *selection rule;*
2. *the T and A couplings emit it in a spin triplet, giving* $\Delta J = 0, \pm 1$ *with no change of parity and with* $0 \to 0$ *forbidden — the* Gamow–Teller *rule [775];*
3. *the P coupling contributes nothing at leading order, its nuclear matrix element being of order* v_{nucleon}/c*.*

The parity of the nucleus cannot change in an allowed transition, because the leptons carry away no orbital angular momentum and the nuclear operators that survive, $\mathbb{1}$ *and* $\boldsymbol{\sigma}$*, are both even under reflection.*

Rests on Proposition 101.14.

Proof. *Derives Proposition 101.15.*

Take the non-relativistic limit of the nucleon current, in which the large components of the nucleon spinors dominate. For the scalar and the time component of the vector, $\bar{\psi}_p \psi_n$ and $\bar{\psi}_p \gamma^0 \psi_n$ both reduce to $\phi_p^\dagger \phi_n$ acting on the two-component nucleon spinors: the operator is the identity in spin space, so the nucleon spin is untouched and by conservation the pair carries spin zero, hence $\Delta J = 0$. For the axial spatial components and the space components of the tensor, $\bar{\psi}_p \gamma^i \gamma^5 \psi_n$ and $\bar{\psi}_p \sigma^{ij} \psi_n$ reduce to $\phi_p^\dagger \sigma^i \phi_n$: the operator is a Pauli matrix, which flips the nucleon spin, so the pair carries spin one and $\Delta J \in \{0, \pm 1\}$. A spin-one pair cannot be emitted in a $0 \to 0$ transition, since there is nothing to absorb its unit of angular momentum. The remaining components — the space part of the vector, the time part of the axial vector and the pseudoscalar — carry an explicit factor of the nucleon velocity in the non-relativistic reduction and are suppressed by $v_{\text{nucleon}}/c \sim 10^{-1}$; they are the leading terms of the *forbidden* transitions.

Parity: in the allowed approximation the lepton wave functions are constants evaluated at the nucleus, so the whole dependence on the nuclear coordinates sits in the two operators just obtained, $\mathbb{1}$ and σ^i, and both are even under spatial reflection — the identity trivially, the Pauli matrix because a spin is an axial vector. A parity-even operator has vanishing matrix element between nuclear states of opposite parity, so the nuclear parity cannot change. The created pair does carry intrinsic parity -1, a fermion and an antifermion having opposite intrinsic parities, but that factor is the same in every beta decay and multiplies every amplitude alike; what distinguishes one transition from another is the orbital factor $(-1)^\ell$, which is $+1$ here and is exactly what changes sign in a first-forbidden transition. □

The decisive datum is that both rules are needed. The decay

$$^6\text{He}\left(0^+\right) \longrightarrow {}^6\text{Li}\left(1^+\right) + e^- + \bar{\nu}_e$$

has $\Delta J = 1$ and is fast, which the Fermi rule forbids outright; the decay $^{14}\text{O}(0^+) \to {}^{14}\text{N}^*(0^+)$ is fast and has $\Delta J = 0$ between two 0^+ states, which the Gamow–Teller rule forbids outright. Gamow and Teller proposed the second coupling in 1936 for exactly this reason [775]: the observed decays do not fit one interaction, and the pair of them is the minimum the data admit.

Definition 101.16 (Comparative half-life)**.** The measured half-life $t_{1/2}$ of a beta transition depends on the energy release through the fifth power of Equation (101.14) and on the nuclear structure through the matrix elements. Dividing out the first isolates the second. Define the dimensionless phase-space integral

$$f\left(Z, E_0\right) = \frac{1}{\left(m_e c^2\right)^5} \int_{m_e c^2}^{E_0} F\left(Z, E\right) \, pc \, E \, \left(E_0 - E\right)^2 \, \mathrm{d}E \,, \tag{101.16}$$

and call $ft_{1/2}$, of dimension s, the *comparative half-life*. A small ft means a fast transition for its energy release, that is a large nuclear matrix element.

Proposition 101.17 (The comparative half-life of an allowed transition)**.** *For an allowed transition,*

$$ft_{1/2} = \frac{K}{G_F^2 \left|V_{ud}\right|^2 \left(\left|M_{\mathrm{F}}\right|^2 + g_A^2 \left|M_{\mathrm{GT}}\right|^2\right)}, \qquad K = \frac{2\pi^3 \hbar \ln 2 \, (\hbar c)^6}{(m_e c^2)^5}, \tag{101.17}$$

where M_{F} and M_{GT} are the Fermi and Gamow–Teller nuclear matrix elements, g_A is the axial coupling of the nucleon and V_{ud} the quark-mixing element of Section 101.5. Numerically

$$\frac{K}{(\hbar c)^6} = 8.120\,276 \times 10^{-7}\ \mathrm{s/GeV^4}, \qquad K = 1.230\,58 \times 10^{-120}\ \mathrm{J^2\,m^6\,s}. \tag{101.18}$$

Rests on Proposition 101.11 and Equations (101.10) and (101.16).

Proof. *Derives Proposition 101.17.*

Collect the factors of Proposition 101.11. The rate is the golden-rule expression Equation (101.10) with the squared coupling $G_F^2 \left|V_{ud}\right|^2$ in front, the nuclear matrix elements squared and summed over the two spin channels with their multiplicities — one for the singlet, three for the triplet, which is the origin of the factor 3 in Equation (101.5) — and the lepton phase space integrated, which is $(m_e c^2)^5 f(Z, E_0)$ by Equation (101.16). Half-life and rate are related by $t_{1/2} = \hbar \ln 2/(\hbar\Gamma) = \ln 2/\Gamma$. Assembling the numerical factors of the two-particle phase space, which are $(2\pi)^{-3}$ per particle from the density of states and $2\pi/\hbar$ from Equation (101.10), leaves $K = 2\pi^3 \hbar \ln 2\,(\hbar c)^6/(m_e c^2)^5$. Its value follows from $\hbar = 6.582\,120 \times 10^{-25}\ \mathrm{GeV\,s}$ and $m_e c^2 = 0.510\,998\,95\ \mathrm{MeV}$:

$$\frac{K}{(\hbar c)^6} = \frac{2\pi^3\,(\ln 2)\,(6.582\,120 \times 10^{-25}\ \mathrm{GeV\,s})}{(5.109\,989\,5 \times 10^{-4}\ \mathrm{GeV})^5} = 8.120\,276 \times 10^{-7}\ \mathrm{s/GeV^4},$$

and multiplying by $(\hbar c)^6 = 9.985\,76 \times 10^{-154}\ \mathrm{J^6\,m^6}$ after converting $1/\mathrm{GeV^4}$ to $1/\mathrm{J^4}$ gives the SI form in Equation (101.18). □

Phenomenon 101.18 (Superallowed decays measure one number)**.** The half-lives, energy releases and branching ratios of the $0^+ \to 0^+$ beta transitions between members of an isospin triplet — ^{10}C, ^{14}O, ^{26m}Al, ^{34}Cl and about a dozen others, spanning a factor of 10^4 in f — yield, after small and calculable corrections for isospin breaking and radiative effects, a single common value

$$\mathcal{F}t = 3072\,\mathrm{s} \tag{101.19}$$

[2427]. Nuclei of different mass, different structure and different lifetime give the same number to a part in 10^4.

Rests on Proposition 101.15 and Equation (101.17).

Derivation. *Derives Phenomenon 101.18.*

A $0^+ \to 0^+$ transition is pure Fermi by Proposition 101.15: the Gamow–Teller operator cannot connect two spinless states. The Fermi operator is the isospin raising or lowering operator, whose matrix element between members of an isospin multiplet is fixed by the algebra and not by the nuclear wave function at all: for a triplet, $\left|M_{\mathrm{F}}\right|^2 = 2$. Hence Equation (101.17) loses every trace of nuclear structure and reduces to

$$\mathcal{F}t = \frac{K}{2G_F^2 \left|V_{ud}\right|^2 (1 + \Delta_R^V)}, \tag{101.20}$$

where Δ_R^V is the transition-independent radiative correction and $\mathcal{F}t$ denotes ft after the small nucleus-dependent corrections have been removed. With $G_F/(\hbar c)^3 = 1.166\,378\,7 \times 10^{-5}/\mathrm{GeV}^2$, $|V_{ud}| = 0.97435$ and $\Delta_R^V = 0.0240$ [2427],

$$\mathcal{F}t = \frac{8.120\,276 \times 10^{-7}\,\mathrm{s/GeV}^4}{2\,(1.166\,378\,7 \times 10^{-5})^2\,(0.97435)^2\,(1.0240)\;1/\mathrm{GeV}^4} = 3070\,\mathrm{s}\,,$$

against the measured 3072 s. The agreement to a part in 10^3 is what turns Equation (101.20) around: read backwards it is the most precise determination of $|V_{ud}|$ available, and hence the first-row test of the unitarity of the mixing matrix in Section 101.5. The constancy of $\mathcal{F}t$ across the multiplet is separately the evidence for the conserved vector current of Section 101.4.2: if the strong interaction renormalized the vector coupling, it would do so differently in a carbon nucleus and an aluminium one, and the fourteen numbers would not agree. □

Away from the superallowed set the same formula is a measurement of nuclear structure rather than of the coupling. Allowed transitions have $\log_{10}(ft/\mathrm{s})$ between about 3 and 6; each unit of forbiddenness — one unit of orbital angular momentum carried by the leptons, costing a factor $(p_e R/\hbar)^2$ in rate, with R the nuclear radius — adds between three and four to the logarithm, which is why ^{40}K lives for 1.25×10^9 yr and ^{6}He for 0.8 s. The systematics belong to Chapter 107; what belongs here is that the ladder exists and is explained, and that the neutron itself sits on the allowed rung with $ft \approx 1.05 \times 10^3$ s, a Fermi and a Gamow–Teller amplitude combining as $|M_\mathrm{F}|^2 + g_A^2\,|M_\mathrm{GT}|^2 = 1 + 3\lambda^2$ with $\lambda = 1.2754$.

101.2.3 The Kurie plot and the neutrino mass

Equation (101.11) is a curve, and curves are hard to compare by eye. Kurie, Richardson and Paxton observed that dividing out the known factors linearizes it [779], turning the comparison of theory with data into the inspection of a straight line — and, more importantly, turning the neutrino mass into a departure from straightness near one end.

Definition 101.19 (Kurie function)**.** For a measured spectrum $\mathrm{d}\Gamma/\mathrm{d}E_e$, the Kurie function is

$$K\,(E_e) = \left[\frac{\mathrm{d}\Gamma/\mathrm{d}E_e}{F\,(Z, E_e)\,p_e E_e}\right]^{1/2} . \tag{101.21}$$

Proposition 101.20 (The Kurie plot is a straight line if and only if the neutrino is massless)**.** *With Equation* (101.11)*,*

$$K\,(E_e) \propto \left[(E_0 - E_e)\,\sqrt{(E_0 - E_e)^2 - m_\nu^2 c^4}\right]^{1/2} , \tag{101.22}$$

which is $E_0 - E_e$ exactly — a straight line meeting the axis at $E_e = E_0$ — if and only if $m_\nu = 0$. For $m_\nu \neq 0$ the line bends downwards and meets the axis vertically at $E_e = E_0 - m_\nu c^2$.

Rests on Equations (101.11) *and* (101.21)*.*

Proof. *Derives Proposition 101.20.*

Substitute Equation (101.11) into Equation (101.21); the factors F, p_e and E_e cancel identically, leaving Equation (101.22). Writing $\epsilon = E_0 - E_e$ for the energy left to the neutrino, the bracket is $\epsilon\sqrt{\epsilon^2 - m_\nu^2 c^4}$, which vanishes at $\epsilon = m_\nu c^2$ rather than at $\epsilon = 0$, and whose derivative there is infinite. Hence the endpoint moves down by $m_\nu c^2$ — which is Proposition 101.3 recovered from the spectrum instead of from the kinematics — and the approach to it becomes vertical. Both features are confined to the last $m_\nu c^2$ of the spectrum, and the fraction of decays falling there is, from Equation (101.12),

$$\frac{\int_{E_0-\Delta}^{E_0} (E_0 - E)^2\,\mathrm{d}E}{\int^{E_0} (E_0 - E)^2\,\mathrm{d}E} \approx \left(\frac{\Delta}{E_0}\right)^3 ,$$

so a neutrino mass of $1\,\mathrm{eV}/c^2$ affects only 2×10^{-13} of the decays of a nucleus with $E_0 = 18.6\,\mathrm{keV}$. That cube is the whole difficulty of the measurement and the whole reason for choosing the smallest available E_0. □

Tritium, $^3\mathrm{H} \to {}^3\mathrm{He} + e^- + \bar{\nu}_e$, is the laboratory of choice on four counts: its release $E_0 = 18.6\,\mathrm{keV}$ is among the smallest known, which maximizes the fraction $(\Delta/E_0)^3$; the transition is superallowed, so the rate is high and the matrix element is structureless; the daughter is a two-electron atom whose final-state excitation spectrum can be computed exactly, which matters because molecular final states smear the endpoint by several electronvolts; and the half-life of 12.3 yr is short enough for a usable source strength and long enough for the source to be stable.

Phenomenon 101.21 (The neutrino mass is smaller than any other fermion mass by six orders of magnitude)**.** The endpoint of the tritium beta spectrum bounds the electron antineutrino mass at

$$m_\nu < 0.8\,\mathrm{eV}/c^2 \qquad (90\,\%\ \text{confidence}) \tag{101.23}$$

[2399]. The next lightest fermion, the electron, has $m_e c^2 = 0.511\,\mathrm{MeV}$: the ratio is below 1.6×10^{-6}.

Rests on Proposition 101.20 and Equation (101.22)*.*

Derivation. *Derives Phenomenon 101.21.*

The bound is Proposition 101.20 applied to a measured spectrum. KATRIN scans the integral spectrum with a magnetic-adiabatic collimation spectrometer of 1 eV resolution, fits the counting rate above a variable retarding potential to the predicted shape convolved with the response function and the calculable molecular final-state distribution, and treats m_ν^2 as the fit parameter — m_ν^2, and not m_ν, because Equation (101.22) depends on the square and because a fit constrained to positive values is biased. The result is consistent with zero, and the interval is converted to the bound Equation (101.23) [2399]. What the experiment measures is strictly an incoherent average, $m_\beta^2 = \sum_i |U_{ei}|^2\, m_i^2$, over the mass eigenstates that make up the electron antineutrino, because the individual masses are far too close together to be resolved as separate kinks; the mixing matrix U is that of Chapter 103. □

The bound is an upper limit, and an upper limit is compatible with zero. That the masses are *not* zero is known from a different kind of experiment entirely — neutrino oscillation, which measures differences of squared masses through an interference phase and is insensitive to the absolute scale. Oscillation gives $|\Delta m_{32}^2| \approx 2.5 \times 10^{-3}\,\mathrm{eV}^2/c^4$ and hence at least one mass above $0.05\,\mathrm{eV}/c^2$; the apparatus and the analysis are Chapter 114 and the theory is Chapter 103. The two measurements are complementary and neither replaces the other: the endpoint bounds the scale from above, oscillation bounds it from below, and the gap between $0.05\,\mathrm{eV}/c^2$ and $0.8\,\mathrm{eV}/c^2$ is where the answer lies.

Remark 101.22 (What a nonzero neutrino mass costs this chapter)*.* Nothing in Section 101.1 or Section 101.2 assumed the neutrino massless. Two later results do, and they are flagged where they occur: the exact identification of chirality with helicity in Proposition 101.32, which acquires a correction of relative size $m_\nu^2 c^4/4E^2$, and the two-component description of Section 101.3.3, which is exact only for a massless field. Both corrections are numerically negligible at any energy at which a neutrino has ever been detected — at $E = 1\,\mathrm{MeV}$ and $m_\nu c^2 = 0.8\,\mathrm{eV}$ the correction is 1.6×10^{-13} — and both are conceptually decisive, because a Standard Model with massless neutrinos has no room for the oscillations that are observed.

101.3 Parity violation

101.3.1 The tau–theta puzzle and the Lee–Yang question

Parity is the operation $P : \boldsymbol{x} \mapsto -\boldsymbol{x}$. Its significance is that it is a symmetry of the Coulomb interaction, of the nuclear force as then understood, and of every optical and spectroscopic selection rule that had ever been checked; atomic states carry a definite parity, and transitions between states of the wrong relative parity are absent to the precision of the measurement. The inference universally drawn was that parity is a symmetry of Nature. The inference is a generalization from two forces to all of them, and nobody had tested it in the third.

Proposition 101.23 (Behaviour of the bilinears under parity)**.** *Under the parity operation, implemented on a Dirac field by $\psi(t,\boldsymbol{x}) \mapsto \gamma^0\psi(t,-\boldsymbol{x})$, the covariants of Proposition 101.14 transform as*

$$\bar\psi\chi \longmapsto +\bar\psi\chi\,, \qquad \bar\psi\gamma^5\chi \longmapsto -\bar\psi\gamma^5\chi\,, \tag{101.24}$$

$$\bar\psi\gamma^\mu\chi \longmapsto +\bar\psi\gamma_\mu\chi\,, \qquad \bar\psi\gamma^\mu\gamma^5\chi \longmapsto -\bar\psi\gamma_\mu\gamma^5\chi\,, \tag{101.25}$$

with the arguments evaluated at the reflected point. Hence a current–current interaction is invariant under P if and only if each of its two currents has a definite and equal parity type: a product $V\times V$ or $A\times A$ is even, and a cross term $V\times A$ is odd.

Rests on Proposition 101.14.

Proof. *Derives Proposition 101.23.*

Use $\gamma^0\gamma^\mu\gamma^0 = \gamma_\mu$ — no sum, and the index is lowered, which is the statement that the time component is unchanged and the space components reverse — together with $(\gamma^0)^2 = \mathbb{1}$ and $\gamma^0\gamma^5\gamma^0 = -\gamma^5$, the last because γ^5 anticommutes with γ^0. Then $\bar\psi\chi = \psi^\dagger\gamma^0\chi \mapsto \psi^\dagger\gamma^0\gamma^0\gamma^0\chi = \bar\psi\chi$, and $\bar\psi\gamma^5\chi \mapsto \psi^\dagger\gamma^0\gamma^0\gamma^5\gamma^0\chi = -\bar\psi\gamma^5\chi$, and similarly for the two vectors. For the last statement, contract two currents: the product of two quantities that both pick up $+1$, or both -1, is invariant, while a product of one of each changes sign. A theory built only from $V\times V$ and $A\times A$ conserves parity; one containing $V\times A$ does not. □

Proposition 101.23 says that a parity-violating interaction is not exotic — it is simply one whose two currents are not both of the same type — and that testing parity means looking for the interference between the even and the odd pieces. Such an interference shows up as a *pseudoscalar* observable: a quantity built from measured vectors that changes sign under reflection, such as $\langle \boldsymbol{J}\rangle \cdot \hat{\boldsymbol{p}}$, the projection of a momentum on a spin. Before 1956 no experiment on a weak process had ever measured one.

What forced the question was a puzzle in the cosmic-ray and accelerator data. Two particles were seen, called at the time θ^+ and τ^+ — the second has nothing to do with the tau lepton, which was discovered twenty years later — decaying as

$$\theta^+ \longrightarrow \pi^+\pi^0\,, \qquad \tau^+ \longrightarrow \pi^+\pi^+\pi^-\,.$$

As the measurements improved, the two came to have the same mass and the same lifetime, to a precision at which a coincidence became absurd. But their decay products have opposite parity.

Proposition 101.24 (The parities of the two final states are opposite)**.** *A state of n pions in relative s waves has parity $(-1)^n$. Hence the $\pi\pi$ final state has parity $+1$ and the $\pi\pi\pi$ final state parity -1, and no single particle of definite parity can decay to both if parity is conserved.*

Rests on Phenomenon 105.5 and Proposition 105.15.

Proof. *Derives Proposition 101.24.*

The pion is a pseudoscalar, $J^P = 0^-$, established from the capture of a negative pion at rest on deuterium: the capture proceeds from an atomic s state to nn, the two neutrons must be in a state antisymmetric overall, and the only such state with $J = 1$ is ${}^3P_1$, of orbital parity -1; equating initial and final parities gives $P_\pi = -1$. The parity of a system of n such particles with no relative orbital angular momentum is the product of the intrinsic parities, $(-1)^n$. For $n = 2$ this is $+1$; for $n = 3$, -1. If the decaying particle has a definite parity P_X and parity is conserved, then $P_X = +1$ from the first mode and $P_X = -1$ from the second, a contradiction. The escape that the three-pion state carries orbital angular momentum, and so is not in relative s waves, is closed by the observed distribution of the three pions over their kinematically allowed region: the density is uniform up to the edges, which is the signature of $\ell = 0$, since any nonzero orbital angular momentum would suppress the configurations in which two pions are collinear. □

The way out was proposed by Lee and Yang in 1956 [1091], and the paper is remarkable less for what it proposed than for what it established first. They surveyed the entire experimental literature of weak decays and found that no measurement had ever been sensitive to a pseudoscalar observable — that the parity invariance of the weak interaction was not a tested fact but an untested assumption inherited from the strong and electromagnetic sectors. Having established that, they listed experiments that could decide, of which the most direct was to align nuclear spins at low temperature and look for a front–back asymmetry in the emitted electrons.

Remark 101.25 (The methodological point). This is worth stating flatly because it recurs throughout physics: a symmetry can hold to extraordinary precision in one interaction and fail completely in another, and the only way to know is to measure it where it matters. The strong and electromagnetic interactions conserve parity, in the second case to a relative precision better than 10^{-8}; the weak interaction violates it maximally. Nothing about the first two facts implies anything about the third, and the inference that was drawn for twenty-five years was a habit, not an argument. The same lesson is recorded for CP in Chapter 105 and for CPT, which unlike the others is a theorem and not an assumption.

101.3.2 Observation

Wu and her collaborators performed the experiment within months [1133]. A thin layer of ^{60}Co was polarized by adiabatic demagnetization of a cerium magnesium nitrate crystal at a few millikelvin, the degree of polarization being monitored by the anisotropy of the gamma rays from the daughter, and the beta electrons counted in an anthracene scintillator whose light was piped out of the cryostat. Reversing the polarizing field reverses $\langle \boldsymbol{J} \rangle$ and so must, if parity holds, leave the counting rate unchanged. It did not: the rate changed by tens of per cent, and the electrons came out preferentially into the hemisphere *opposite* to the nuclear spin. Chapter 110 is the experiment chapter this measurement belongs to. It states the result and proves the parity argument in full; its apparatus, procedure and systematic-check sections — among them the warming curve that shows the asymmetry dying with the polarization — carry their headings and their sources but are not yet written, so the sketch above is for the moment the fuller of the two accounts.

Garwin, Lederman and Weinrich obtained the same conclusion within days by a completely different route [1110]. Stopping positive muons from the decay $\pi^+ \to \mu^+ \nu_\mu$ in carbon and observing the decay positrons, they found the positrons emitted asymmetrically about the muon spin direction — and, since the muons had been polarized by the pion decay itself, the same data show parity violation twice over, once in $\pi \to \mu$ and once in $\mu \to e$. They also measured the muon magnetic moment in the same apparatus by precessing the spin, which is the ancestor of the experiment in Chapter 112.

Phenomenon 101.26 (Parity is violated in weak decays)**.** In the beta decay of polarized ^{60}Co nuclei the electrons are emitted preferentially into the hemisphere opposite to the nuclear spin. The angular distribution has the form

$$W(\theta) \propto 1 + A\,\frac{v}{c}\,\frac{\langle \boldsymbol{J}\rangle \cdot \hat{\boldsymbol{p}}}{|\langle \boldsymbol{J}\rangle|}\,, \tag{101.26}$$

with A negative and of order unity [1133], and the same asymmetry appears twice over in the chain $\pi \to \mu \to e$ [1110]. The apparatus is Chapter 110. No comparable asymmetry occurs in any strong or electromagnetic process.

Rests on Proposition 101.23.

Derivation. *Derives Phenomenon 101.26.*

Under the parity operation a polar vector such as the momentum $\boldsymbol{p}$ reverses while an axial vector such as the angular momentum $\boldsymbol{J}$ does not, so the scalar product $\langle \boldsymbol{J}\rangle \cdot \hat{\boldsymbol{p}}$ appearing in Equation (101.26) is a pseudoscalar and changes sign. The mirror-image experiment therefore predicts $W(\pi - \theta)$ wherever the original predicts $W(\theta)$, and the two disagree unless $A = 0$. A measured $A \neq 0$ is thus in itself a proof that the interaction responsible is not invariant under P: no dynamical input whatever is required, which is why one asymmetry measurement settled a question that decades of spectroscopy had not thought to ask [1091, 1133]. What the further observation $|A| \approx 1$ adds is that the violation is as large as the kinematics permits — the interaction does not merely prefer one handedness, it uses one and ignores the other — and that statement is delivered by Proposition 101.27 below, once the $V - A$ structure of Section 101.4 is in place. □

Proposition 101.27 (The sign and size of the cobalt asymmetry)**.** *For the pure Gamow–Teller transition* $^{60}\mathrm{Co}\,(5^+) \to {}^{60}\mathrm{Ni}\,(4^+)$*, an interaction that emits only left-chiral electrons and right-chiral antineutrinos gives* $A = -1$ *in Equation* (101.26)*: the electrons are emitted opposite to the nuclear spin, with an asymmetry equal in magnitude to the electron's speed in units of* c*.*

Rests on Equation (101.26) *and Propositions 101.32 and 101.34.*

Proof. *Derives Proposition 101.27.*

The transition lowers the nuclear angular momentum by one unit along the polarization axis $\hat{\boldsymbol{z}}$, so the lepton pair must carry away $J_z = +1$: both leptons have their spin projections $+\tfrac{1}{2}$ along $\hat{\boldsymbol{z}}$. Now apply the chirality rule. The antineutrino, being massless to the accuracy of Phenomenon 101.21, has positive helicity exactly by Proposition 101.32, so its spin is along its momentum: with $S_z = +\tfrac{1}{2}$ it must travel along $+\hat{\boldsymbol{z}}$. The electron is emitted in the left-chiral combination, whose helicity expectation value is $-v/c$ by Proposition 101.34; with its spin also along $+\hat{\boldsymbol{z}}$, a negative helicity means momentum along $-\hat{\boldsymbol{z}}$. The electron therefore prefers the hemisphere opposite the nuclear spin, and the preference is complete only in the limit $v \to c$, being diluted by the factor v/c at lower speeds. Writing the distribution as Equation (101.26) identifies $A = -1$ for this transition.

Comparing that with Wu's number requires one factor Equation (101.26) does not contain, and it is worth being careful, because the arithmetic does not otherwise close. The distribution is written for a *fully* polarized ensemble; a real source has a degree of nuclear polarization $f = |\langle \boldsymbol{J}\rangle|\,/J < 1$, and only that fraction of the nuclei contributes to the front–back difference, so the measured counting-rate asymmetry between the two senses of the polarizing field is

$$\varepsilon = \frac{W(0) - W(\pi)}{W(0) + W(\pi)} = A\,\frac{v}{c}\,f\,. \tag{101.27}$$

Wu's electrons had $v/c \approx 0.6$ and the source reached $f \approx 0.6$, giving $|\varepsilon| \approx 0.36$, which is the observed asymmetry of about 0.4. The product $|A|\ v/c$ alone would predict 0.6, half again too large: the polarization factor is not optional, and it is why the experiment had

to measure f independently, from the anisotropy of the daughter's gamma cascade. The same factor supplies the control — the asymmetry disappears as the crystal warms and f decays to zero, on the same time constant as the gamma anisotropy, which is what makes the result an asymmetry and not an instrumental drift [1133]. □

Two further consequences of the same data deserve separate statement.

The first is that charge conjugation is violated as well. If C were a symmetry, the mirror process for antimatter would be obtained by conjugating charges; the $\pi^+ \to \mu^+$ and $\pi^- \to \mu^-$ chains would then show asymmetries of the same sign. They show opposite ones [1110]. What survives is the combination CP: the mirror image of a left-handed neutrino is a right-handed neutrino, which does not exist, but the CP image is a right-handed antineutrino, which does. That CP is itself violated, by a small amount and in a different sector, is the subject of Chapter 105 and Chapter 111.

The second is quantitative and constrains the theory sharply. A parity-violating interaction has, in general, both a P-even and a P-odd part, and the size of the asymmetry measures their relative magnitude. An asymmetry of order unity — not of order 10^{-2}, and not of order 10^{-6} — says that the two parts are of equal size. An interaction whose P-even and P-odd parts are equal is one that couples to a single chirality and not at all to the other. That is the empirical origin of the $V - A$ structure, and it was read off the data in exactly this way.

101.3.3 Neutrino helicity

The most direct statement the parity data suggest is that the neutrino comes in one handedness only. Landau, Lee and Yang, and Salam each proposed independently in 1957 that the neutrino is described by a two-component field — the Weyl equation of Chapter 96 — rather than by a four-component Dirac field with one half of it inert [1118, 1121, 1130]. A two-component field has no mass term available to it and no partner of the opposite handedness, so the proposal makes handedness a defining property rather than a dynamical accident, and it predicts a definite sign which experiment can check.

Checking it means measuring the helicity of a particle that is never detected. Goldhaber, Grodzins and Sunyar found a way [1148]: in the orbital electron capture $^{152m}\mathrm{Eu} + e^- \to {}^{152}\mathrm{Sm}^* + \nu_e$ followed by $^{152}\mathrm{Sm}^* \to {}^{152}\mathrm{Sm} + \gamma$, the photons emitted opposite to the neutrino carry the neutrino's helicity, and their circular polarization can be measured by transmission through magnetized iron. Selecting those photons is done by resonant scattering, which only the ones emitted against the neutrino have enough energy to undergo. Chapter 98 is the experiment chapter for this measurement; it names the decay scheme, the magnetized-iron analyser and the resonant scatterer, and its apparatus and systematic-check sections are still owed. The angular-momentum argument is short enough to give here, and is.

Phenomenon 101.28 (Neutrinos are left-handed)**.** The neutrino emitted in orbital electron capture on $^{152}\mathrm{Eu}$ has negative helicity — its spin points opposite to its momentum — with an uncertainty that leaves no room for an appreciable admixture of the other state [1148]; the antineutrino emitted in beta decay has positive helicity. No right-handed neutrino, and no left-handed antineutrino, has ever been observed to take part in a weak interaction.

Rests on Definition 101.29.

Derivation. *Derives Phenomenon 101.28.*

What has to be established is that the photon the apparatus selects carries the neutrino's helicity, since the photon's circular polarization is the only thing measured. Both steps are angular-momentum bookkeeping along a single axis.

Take $\hat{\boldsymbol{z}}$ along the photon's momentum. The capture $^{152m}\mathrm{Eu}\,(0^-) + e^- \to {}^{152}\mathrm{Sm}^*(1^-) + \nu_e$ proceeds from a K-shell s orbital, so nothing brings orbital angular momentum in, and the

two products leave back to back, the neutrino along $-\hat{\boldsymbol{z}}$ and the recoiling $^{152}\mathrm{Sm}^*$ along $+\hat{\boldsymbol{z}}$. A two-body state collinear with the quantization axis has $L_z = 0$, so along that axis

$$S_z^e = S_z^\nu + J_z^{\mathrm{Sm}^*} . \tag{101.28}$$

Take $S_z^e = -\frac{1}{2}$. A negative-helicity neutrino moving along $-\hat{\boldsymbol{z}}$ has its spin along $+\hat{\boldsymbol{z}}$, that is $S_z^\nu = +\frac{1}{2}$, and Equation (101.28) then forces $J_z^{\mathrm{Sm}^*} = -1$. The excited state decays to a spinless ground state, $^{152}\mathrm{Sm}^*(1^-) \to {}^{152}\mathrm{Sm}\,(0^+) + \gamma$, so the photon carries away the whole of $J_z = -1$; and a photon travelling along $+\hat{\boldsymbol{z}}$ with $J_z = -1$ has helicity -1. Reversing the neutrino's helicity reverses every sign in the chain, so the photon's helicity is not merely correlated with the neutrino's but equal to it.

That fixes the photons emitted *opposite* to the neutrino, and the resonance condition selects exactly those and no others. A photon emitted by a nucleus at rest falls short of the absorption resonance by the recoil energies of emitter and absorber; only a nucleus recoiling towards the emission direction — that is, one whose neutrino went the other way — is moving fast enough for the Doppler shift to make the deficit up, so only those photons scatter resonantly on a $^{152}\mathrm{Sm}$ target. Their circular polarization, measured by transmission through magnetized iron, is therefore the neutrino's helicity, and it came out negative [1148]. The antineutrino statement follows from CP: the CP image of a negative-helicity neutrino is a positive-helicity antineutrino, and CP survives these decays even though C and P separately do not. □

To say what such a measurement establishes, and what it does not, the two notions it is easy to conflate must be separated. They are different in kind: one is a property of a state, the other a property of a field; one is conserved but frame-dependent, the other frame-independent but not conserved; and they coincide only in a limit.

Definition 101.29 (Helicity)**.** The helicity operator for a spin-$\frac{1}{2}$ particle of momentum $\boldsymbol{p}$ is

$$h = \frac{\boldsymbol{\Sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|} , \qquad \boldsymbol{\Sigma} = \begin{pmatrix} \boldsymbol{\sigma} & 0 \\ 0 & \boldsymbol{\sigma} \end{pmatrix} , \tag{101.29}$$

with eigenvalues ± 1. It is the projection of the spin on the direction of motion, and it is a genuine observable: both factors are measurable.

Definition 101.30 (Chirality)**.** The chirality operator is $\gamma^5 = \mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$, with $(\gamma^5)^2 = \mathbb{1}$ and $\{\gamma^5, \gamma^\mu\} = 0$. Its eigenvalues are ± 1 and the associated projectors are

$$P_{\mathrm{L}} = \frac{1}{2}\left(\mathbb{1} - \gamma^5\right) , \qquad P_{\mathrm{R}} = \frac{1}{2}\left(\mathbb{1} + \gamma^5\right) , \tag{101.30}$$

so that $\psi = \psi_{\mathrm{L}} + \psi_{\mathrm{R}}$ with $\psi_{\mathrm{L}} = P_{\mathrm{L}}\psi$. Chirality is a property of the field, defined without reference to any momentum.

Proposition 101.31 (Chirality against helicity)**.** *Chirality is Lorentz invariant but not conserved; helicity is conserved in free motion but not Lorentz invariant. Precisely:*

1. *γ^5 commutes with the generators $\sigma^{\mu\nu}$ of the spinor representation, so P_{L} and P_{R} commute with every Lorentz transformation: chirality is frame-independent.*
2. *A Dirac mass term couples the two chiralities, $\bar\psi\psi = \bar\psi_{\mathrm{L}}\psi_{\mathrm{R}} + \bar\psi_{\mathrm{R}}\psi_{\mathrm{L}}$, so chirality is conserved by the free equation of motion only if $m = 0$.*
3. *h commutes with the free Dirac Hamiltonian, so helicity is conserved in free motion.*
4. *For $m \neq 0$ a particle moves slower than light, so an observer may overtake it; in the overtaking frame $\boldsymbol{p}$ reverses and $\boldsymbol{\Sigma}$ does not, and the helicity changes sign. Helicity is frame-dependent.*

Rests on Definitions 101.29 and 101.30.

Proof. *Derives Proposition 101.31.*

(i) $\sigma^{\mu\nu}$ is a product of two distinct gamma matrices, and γ^5 anticommutes with each, hence commutes with the pair; therefore $[\gamma^5, \sigma^{\mu\nu}] = 0$ and γ^5 commutes with $\exp(-\frac{\mathrm{i}}{4}\omega_{\mu\nu}\sigma^{\mu\nu})$. (ii) $\bar\psi\psi = \bar\psi(P_{\mathrm{L}}+P_{\mathrm{R}})\psi$, and $\bar\psi P_{\mathrm{L}} = \overline{P_{\mathrm{R}}\psi}$ because $\gamma^0\gamma^5 = -\gamma^5\gamma^0$; the diagonal terms therefore vanish and only the cross terms survive. (iii) The free Hamiltonian is $H = c\boldsymbol{\alpha}\cdot\boldsymbol{p} + \beta mc^2$ with $\boldsymbol{\alpha} = \gamma^0\boldsymbol{\gamma}$; a direct computation using $[\Sigma^i, \alpha^j] = 2\mathrm{i}\varepsilon^{ijk}\alpha^k$ and $[\boldsymbol{\Sigma}, \beta] = 0$ gives $[\boldsymbol{\Sigma}\cdot\boldsymbol{p}, H] = 0$. (iv) A boost of speed $u > v$ along $\hat{\boldsymbol{p}}$ sends $\boldsymbol{p} \mapsto -|\boldsymbol{p}'|\,\hat{\boldsymbol{p}}$ while the spin projection on $\hat{\boldsymbol{p}}$ is unchanged, since a boost along an axis does not rotate spin about that axis; hence $h \mapsto -h$. For $m = 0$ no such boost exists and the obstruction disappears. □

The two therefore cannot be the same thing. The following proposition says exactly how close they are, and it is the quantitative content of every statement in this chapter of the form "only left-handed particles participate".

Proposition 101.32 (Chirality and helicity in a state of definite momentum)**.** *Let $u_\lambda(p)$ be a positive-energy Dirac spinor of momentum $\boldsymbol{p}$, energy E and helicity $\lambda = \pm 1$. Then*

$$\frac{|P_{\mathrm{L}}u_\lambda|^2}{|u_\lambda|^2} = \frac{1}{2}\,(1 - \lambda\beta)\,, \qquad \beta = \frac{|\boldsymbol{p}|\,c}{E} = \frac{v}{c}\,. \tag{101.31}$$

In particular, for $\beta \to 1$ the left-chiral projection of a positive-helicity state vanishes as

$$\frac{1}{2}\,(1-\beta) \simeq \frac{m^2c^4}{4E^2}\,, \tag{101.32}$$

so that chirality and helicity agree exactly in the massless limit and to relative accuracy $m^2c^4/4E^2$ otherwise.

Rests on Definition 101.29 and Equation (101.30).

Proof. *Derives Proposition 101.32.*

Work in the Dirac representation, in which $\gamma^5 = \begin{pmatrix} 0 & \mathbb{1} \\ \mathbb{1} & 0 \end{pmatrix}$ in 2×2 blocks. A positive-energy solution of definite helicity is

$$u_\lambda(p) = N \begin{pmatrix} \sqrt{E + mc^2}\,\chi_\lambda \\ \lambda\sqrt{E - mc^2}\,\chi_\lambda \end{pmatrix}\,, \qquad (\boldsymbol{\sigma}\cdot\hat{\boldsymbol{p}})\,\chi_\lambda = \lambda\chi_\lambda\,, \tag{101.33}$$

as follows from the Dirac equation with the lower two components given by $c\,\boldsymbol{\sigma}\cdot\boldsymbol{p}/(E + mc^2)$ times the upper ones and $c\,|\boldsymbol{p}| = \sqrt{(E+mc^2)(E-mc^2)}$. Its norm is $|u_\lambda|^2 = N^2\left[(E+mc^2) + (E-mc^2)\right] = 2N^2E$. Applying $P_{\mathrm{L}} = \frac{1}{2}\begin{pmatrix} \mathbb{1} & -\mathbb{1} \\ -\mathbb{1} & \mathbb{1} \end{pmatrix}$,

$$P_{\mathrm{L}}u_\lambda = \frac{N}{2}\left(\sqrt{E+mc^2} - \lambda\sqrt{E-mc^2}\right)\begin{pmatrix} \chi_\lambda \\ -\chi_\lambda \end{pmatrix}\,,$$

whose squared norm is

$$|P_{\mathrm{L}}u_\lambda|^2 = \frac{N^2}{2}\left(\sqrt{E+mc^2} - \lambda\sqrt{E-mc^2}\right)^2 = N^2\left(E - \lambda\sqrt{E^2 - m^2c^4}\right) = N^2E\,(1-\lambda\beta)\,,$$

using $\lambda^2 = 1$ and $\sqrt{E^2 - m^2c^4} = |\boldsymbol{p}|\,c = \beta E$. Dividing gives Equation (101.31). For the limit, expand $\beta = \sqrt{1 - m^2c^4/E^2} \simeq 1 - m^2c^4/2E^2$. □

Corollary 101.33 (What Goldhaber's experiment measures)**.** *For a neutrino of mass below* $0.8\,\mathrm{eV}/c^2$ *(Phenomenon 101.21) emitted with an energy near* $0.9\,\mathrm{MeV}$*, as in the europium capture, the wrong-helicity admixture in a purely left-chiral coupling is, by Equation* (101.32)*, at most*

$$\frac{m_\nu^2 c^4}{4E^2} < \frac{(0.8\,\mathrm{eV})^2}{4\,(0.9\,\mathrm{MeV})^2} = 2\times 10^{-13}\,.$$

A measurement of the helicity is therefore, to that accuracy, a measurement of the chirality of the coupling — which is the quantity the theory contains and the experiment cannot see directly.

Rests on Phenomenon 101.21 and Equation (101.32)*.*

Proposition 101.34 (The longitudinal polarization of a beta electron)**.** *An interaction that couples only to* ψ_{L} *emits electrons with mean helicity*

$$\langle h\rangle = -\frac{v}{c}\,, \tag{101.34}$$

and positrons with mean helicity $+v/c$*.*

Rests on Equation (101.31)*.*

Proof. *Derives Proposition 101.34.*

By Equation (101.31) the left-chiral projection contains helicity -1 with weight $\frac{1}{2}(1+\beta)$ and helicity $+1$ with weight $\frac{1}{2}(1-\beta)$, and these are the relative probabilities with which the interaction produces the two. Hence $\langle h\rangle = \frac{1}{2}(1-\beta) - \frac{1}{2}(1+\beta) = -\beta$. For the antiparticle the roles of the projectors are exchanged, because the negative-energy spinor v_λ carries the opposite relation between chirality and helicity, and the sign reverses. Equation (101.34) is a prediction with no free parameter: it says that a beta electron of $v/c = 0.5$ is 50 per cent longitudinally polarized and one of $v/c = 0.9$ is 90 per cent polarized, and it is measured directly, by passing the emitted electrons through a polarization-sensitive scatterer. Frauenfelder and collaborators did it for ^{60}Co within months of Wu's result and found the electrons longitudinally polarized, with the predicted sign and a magnitude consistent with $-v/c$ [1108]. It is also what supplies the factor v/c in Equation (101.26), which is therefore not an empirical fudge but the electron mass making itself felt. □

Finally, the same arithmetic explains a rate that would otherwise be inexplicable. The charged pion decays to a muon and not to an electron, although the electronic channel has far more phase space, because the pion is spinless and forces the charged lepton into the helicity that the left-chiral coupling suppresses by $\frac{1}{2}(1-\beta)$; the suppression is governed by the lepton mass and therefore hurts the electron far more than the muon. The derivation and the measured ratio 1.23×10^{-4} are Phenomenon 96.3. It is the sharpest confirmation of Proposition 101.32 available, because it turns a factor of $(m_e/m_\mu)^2$ into a directly counted branching ratio.

101.4 The $V-A$ interaction

101.4.1 Chirality and the left-handed current

Section 101.3 leaves the interaction determined up to ten coefficients, and the observations of maximal asymmetry and of a purely left-handed neutrino determine them. Feynman and Gell-Mann [1144] and, independently and in the same year, Sudarshan and Marshak [1162] proposed that the answer is

$$J^\mu = \bar{\psi}\,\gamma^\mu\left(\mathbb{1}-\gamma^5\right)\chi\,, \tag{101.35}$$

one combination out of the five, with the vector and axial pieces of equal magnitude and opposite sign. Every charged-current process in the Standard Model is built from currents of this form.

Proposition 101.35 (The $V-A$ current is the left-chiral current)**.**

$$\bar{\psi}\gamma^{\mu}\left(\mathbb{1}-\gamma^{5}\right)\chi = 2\,\bar{\psi}_{\mathrm{L}}\gamma^{\mu}\chi_{\mathrm{L}}\,, \tag{101.36}$$

so an interaction built from Equation (101.35) *involves the right-chiral components of the fields not at all.*

Rests on Equations (101.30) *and* (101.35)*.*

Proof. *Derives Proposition 101.35.*

From Equation (101.30), $P_{\mathrm{L}}^{2}=P_{\mathrm{L}}$ and $\gamma^{\mu}P_{\mathrm{L}}=P_{\mathrm{R}}\gamma^{\mu}$, the latter because γ^{5} anticommutes with γ^{μ}. Also $\overline{P_{\mathrm{L}}\psi}=\psi^{\dagger}P_{\mathrm{L}}\gamma^{0}=\bar{\psi}P_{\mathrm{R}}$, using $P_{\mathrm{L}}^{\dagger}=P_{\mathrm{L}}$ and $\gamma^{0}\gamma^{5}=-\gamma^{5}\gamma^{0}$. Hence

$$\bar{\psi}_{\mathrm{L}}\gamma^{\mu}\chi_{\mathrm{L}}=\bar{\psi}P_{\mathrm{R}}\gamma^{\mu}P_{\mathrm{L}}\chi=\bar{\psi}\gamma^{\mu}P_{\mathrm{L}}P_{\mathrm{L}}\chi=\bar{\psi}\gamma^{\mu}P_{\mathrm{L}}\chi=\frac{1}{2}\bar{\psi}\gamma^{\mu}\left(\mathbb{1}-\gamma^{5}\right)\chi\,.$$

The same computation shows that the *scalar* bilinear does the opposite: $\bar{\psi}_{\mathrm{L}}\chi_{\mathrm{L}}=\bar{\psi}P_{\mathrm{R}}P_{\mathrm{L}}\chi=0$, so a chirally projected theory admits vector and axial currents and forbids scalar, pseudoscalar and tensor couplings between fields of the same chirality. Equation (101.35) is therefore not one arbitrary choice among five: it is the only current a theory of purely left-chiral fields can have. □

Proposition 101.36 (Maximal parity violation is exactly $V-A$)**.** *Write a general vector-and-axial current as $\bar{\psi}\gamma^{\mu}(g_V-g_A\gamma^{5})\chi$. Then the P-violating interference between the two, measured by any pseudoscalar observable, is proportional to $g_V g_A$ and the P-conserving part to $g_V^{2}+g_A^{2}$. The ratio of the two is extremal, and equal to unity, if and only if $|g_V|=|g_A|$.*

Rests on Proposition 101.23 and Equation (101.35)*.*

Proof. *Derives Proposition 101.36.*

By Proposition 101.23 the VV and AA terms of the squared amplitude are P-even and the VA cross terms P-odd, and the coefficients are g_V^{2}, g_A^{2} and $2g_Vg_A$ respectively. The asymmetry is therefore $2g_Vg_A/(g_V^{2}+g_A^{2})$, which by the arithmetic–geometric mean inequality is at most 1 in modulus with equality if and only if $g_V=\pm g_A$. The measured asymmetries of Section 101.3.2 are of order unity, which forces the equality, and the observed *sign* — electrons opposite to the nuclear spin, neutrinos left-handed — selects $g_A=+g_V$ in the convention of Equation (101.35), that is $V-A$ and not $V+A$. □

Remark 101.37 (Where the coefficients actually came from)*.* The account above is the logical order, not the historical one. The coefficients were fixed by a decade of experiments on the angular correlation between the electron and the recoiling nucleus, the observable most sensitive to the Lorentz structure and the one that needs no polarization at all. For an allowed transition it has the form

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}\Omega_{e\nu}}\propto 1+a\,\frac{v_e}{c}\cos\theta_{e\nu}\,, \tag{101.37}$$

with $\theta_{e\nu}$ the angle between the electron and antineutrino momenta, inferred in practice from the recoil of the daughter since the antineutrino is not seen. The coefficient a takes a different value for each of the four couplings, so one number decides among them:

coupling	transition type	a
scalar (S)	Fermi	-1
vector (V)	Fermi	$+1$
tensor (T)	Gamow–Teller	$+1/3$
axial (A)	Gamow–Teller	$-1/3$

The values follow from Proposition 101.32 and angular momentum alone; the derivation is Proposition 101.38.

The history is cautionary, and is recorded because the answer was wrong for five years. Feynman and Gell-Mann list the measurements their proposal contradicted — among them a recoil experiment on ^{6}He, a pure Gamow–Teller decay, whose reported correlation favoured tensor over axial — and say in print that they believe those experiments to be wrong [1144]. They were, and the ^{6}He value was later revised to the axial $-1/3$; but the papers reporting and revising it are not in this bibliography, so what is said here rests on Feynman and Gell-Mann's account of them and not on the sources. The lesson is not that theory ran ahead of experiment: it is that one measurement of a small correlation, with an uncontrolled systematic, decided a structural question for five years, and that the theorists who disbelieved it did so on the strength of *other* data — the maximal asymmetries.

Proposition 101.38 (The electron–neutrino correlation coefficients)**.** *For a $V-A$ interaction the coefficient a in Equation* (101.37) *is $+1$ for a Fermi transition and $-1/3$ for a Gamow–Teller transition; for the parity-conjugate choices S and T the signs reverse.*

Rests on Equation (101.37) *and Propositions 101.32 and 101.35.*

Proof. *Derives Proposition 101.38.*

Work in the limit $v_e \to c$, where by Proposition 101.32 the electron emitted by a left-chiral coupling has helicity -1 exactly and the antineutrino has helicity $+1$ exactly; the factor v_e/c in Equation (101.37) is what restores the general case, being the electron's helicity by Equation (101.34). Then the spin of the antineutrino points along its momentum and the spin of the electron points against its own.

A Fermi transition emits the pair in the spin singlet, whose two spins are antiparallel. Let the antineutrino spin be $+\hat{\boldsymbol{z}}$ and the electron spin $-\hat{\boldsymbol{z}}$. The antineutrino momentum is then along $+\hat{\boldsymbol{z}}$ and the electron momentum, being opposite its spin, is also along $+\hat{\boldsymbol{z}}$: the two particles go the same way, $\cos\theta_{e\nu} = +1$, and the distribution is $1 + \cos\theta_{e\nu}$, that is $a = +1$.

A Gamow–Teller transition emits the pair in the spin triplet, and the three substates must be averaged because an unpolarized nucleus populates them equally. For $m = +1$ both spins are $+\hat{\boldsymbol{z}}$; the antineutrino goes along $+\hat{\boldsymbol{z}}$ and the electron along $-\hat{\boldsymbol{z}}$, giving $\cos\theta_{e\nu} = -1$; the same for $m = -1$. The state $m = 0$ is $(|{\uparrow\downarrow}\rangle + |{\downarrow\uparrow}\rangle)/\sqrt{2}$, which is the singlet's partner with antiparallel spins and gives $\cos\theta_{e\nu} = +1$. Averaging, $a = (-1 - 1 + 1)/3 = -1/3$.

Replacing V by S, or A by T, replaces the left-chiral projector on the *electron* by the right-chiral one — this is Proposition 101.35 read backwards, a scalar bilinear connecting opposite chiralities — so the electron's momentum reverses relative to its spin and every sign above flips. The four entries of the table follow. □

Remark 101.39 (Why the spectrum shape did not change)*.* Proposition 101.11 was derived from Fermi's vector coupling and survives its replacement by $V - A$ unaltered, which is why the 1934 spectrum shape remained good evidence after 1957. The reason is that the shape came entirely from phase space, the matrix element being momentum-independent for an allowed transition; and $V - A$, like V, has a momentum-independent allowed matrix element. What changes is the *correlations* — the asymmetry with respect to a polarization, the electron's own polarization, the electron–neutrino angle — none of which anybody had measured before 1956. A theory can be right about everything that has been measured and wrong about its structure, and the way to tell is to measure something else.

101.4.2 Conserved vector current and universality

Two facts about Equation (101.35) are surprising once the strong interaction is remembered. The nucleon is not an elementary field but a bound state of strongly interacting constituents,

so the current a W sees is not the quark current but a dressed object; one would expect the dressing to change the coupling by a factor of order one, and to change it differently for the vector and the axial parts, and differently again for a nucleon and a nucleus. In fact the vector coupling is not renormalized at all, and the axial one is renormalized by only 27 per cent.

Phenomenon 101.40 (The vector coupling is not renormalized)**.** The vector coupling constant extracted from superallowed nuclear beta decay, where the decaying object is a bound state of strongly interacting quarks, agrees with the coupling extracted from muon decay, where nothing strong is involved, once the quark-mixing factor of Section 101.5 is applied. The axial coupling, by contrast, is renormalized to $\lambda = g_A/g_V = 1.2754(13)$ [2427].

Rests on Proposition 100.6 and Phenomenon 101.18.

Derivation. *Derives Phenomenon 101.40.*

The hypothesis that explains the first half is that of Feynman and Gell-Mann [1144]: the weak vector current $V^\mu = \bar\psi_p \gamma^\mu \psi_n$ and the isovector part of the electromagnetic current are three components of one isospin triplet,

$$V_a^\mu = \bar\psi_N \gamma^\mu \frac{\tau_a}{2} \psi_N \,, \qquad a = 1,2,3 \,, \tag{101.38}$$

with the weak charged currents the combinations $V_1^\mu \pm \mathrm{i} V_2^\mu$ and the isovector electromagnetic current V_3^μ. Isospin is a symmetry of the strong interaction, so all three currents are conserved, $\partial_\mu V_a^\mu = 0$, and their charges $T_a = \frac{1}{c}\int \mathrm{d}^3x\, V_a^0$ generate the algebra $[T_a, T_b] = \mathrm{i}\varepsilon_{abc} T_c$.

The argument is now exactly that of Proposition 100.6, transposed. A charge that generates a symmetry algebra takes eigenvalues fixed by the representation theory of that algebra — half-integers, in units set by the commutation relations — and a continuous dynamical effect cannot shift a discrete eigenvalue. The strong interaction commutes with T_a, so it cannot alter the matrix element of V_a^μ between states of definite isospin at zero momentum transfer, any more than the strong interaction alters the electric charge of the proton, which by Proposition 100.6 and the Ward–Takahashi identity of Section 100.5.2 is exactly the positron's. The vector coupling of a nucleon is therefore the same as that of a bare quark, and the constancy of $\mathcal{F}t$ across the superallowed multiplet in Phenomenon 101.18 is the measurement that confirms it: a renormalization that depended on nuclear structure would show up as a spread in those fourteen numbers, and the spread is a part in 10^4.

The axial current is a different matter, because it is *not* conserved: nothing in the strong interaction is invariant under a chiral rotation once the quarks have mass, and, more importantly, the axial symmetry is spontaneously broken. There is accordingly no protection theorem and g_A is renormalized. The measured 27 per cent is small only because the quark masses are small, and its theoretical status belongs to the chiral symmetry of Chapter 102. That the vector coupling is protected and the axial one is not is a structural prediction, and the two measured numbers — 1 and 1.2754 — are the test of it. □

The partial conservation that replaces the exact conservation has a sharp consequence, which is one of the very few quantitative relations in this chapter that connects a weak amplitude to a purely strong one.

Definition 101.41 (The pion decay constant and PCAC)**.** Define f_π by the matrix element of the axial current between the vacuum and a one-pion state,

$$\langle 0 |\, A_a^\mu(0) \,| \pi_b(q) \rangle = \mathrm{i} f_\pi \, \delta_{ab} \, q^\mu \,, \tag{101.39}$$

with $f_\pi c = 92.3\,\mathrm{MeV}$ in the normalization used here [2427], so that f_π has the dimension of a momentum. The hypothesis of a *partially* conserved axial current is that $\partial_\mu A_a^\mu$ is not zero but is proportional to the pion field,

$$\partial_\mu A_a^\mu = f_\pi \left(\frac{m_\pi c}{\hbar} \right)^2 \hbar \, \phi_a \,, \tag{101.40}$$

which is consistent with Equation (101.39) and vanishes in the limit $m_\pi \to 0$: the pion is the almost-Goldstone boson of the broken chiral symmetry.

Proposition 101.42 (Goldberger–Treiman)**.** *Let $g_{\pi N}$ be the pion–nucleon coupling constant measured in strong-interaction scattering and g_A the axial coupling of the nucleon measured in beta decay. Then*

$$f_\pi \, g_{\pi N} = g_A \, m_N c \,, \tag{101.41}$$

up to corrections of order m_π^2/m_N^2.

Rests on Equations (101.39) and (101.40).

Proof. *Derives Proposition 101.42.*

Take the matrix element of $\partial_\mu A_a^\mu$ between two nucleon states of momenta p and p', and evaluate it in two ways.

On the left, use the general decomposition of the axial matrix element consistent with Lorentz invariance and parity,

$$\langle N(p')| \, A_a^\mu \, |N(p)\rangle = \bar u(p') \left[g_A\!\left(q^2\right) \gamma^\mu \gamma^5 + \frac{h_A(q^2)}{m_N c} \, q^\mu \gamma^5 \right] \frac{\tau_a}{2} u(p) \,, \qquad q = p' - p \,, \tag{101.42}$$

with g_A and h_A dimensionless. Contracting with q_μ, and using $\bar u(p')\gamma^\mu q_\mu \gamma^5 u(p) = \bar u(p') \, (\gamma \cdot p' - \gamma \cdot p) \, \gamma^5 u(p) = 2 m_N c \, \bar u(p') \gamma^5 u(p)$ — the Dirac equation applied to each spinor, the sign of the second term flipped by $\gamma^5 \gamma \cdot p = -\gamma \cdot p \, \gamma^5$ so that the two add — gives

$$q_\mu \, \langle N(p')| \, A_a^\mu \, |N(p)\rangle = \left[2 m_N c \, g_A\!\left(q^2\right) + \frac{q^2}{m_N c} h_A\!\left(q^2\right) \right] \bar u(p') \gamma^5 \frac{\tau_a}{2} u(p) \,. \tag{101.43}$$

On the right, use Equation (101.40): the divergence is $f_\pi (m_\pi c/\hbar)^2 \hbar \phi_a$, and the nucleon matrix element of the pion field is the pion propagator times the pion–nucleon vertex, which with the coupling normalized as $\mathcal{L}_{\pi N} = -\mathrm{i} g_{\pi N} \bar\psi_N \gamma^5 \tau_a \psi_N \phi_a$ reads

$$\langle N(p')| \, \hbar \phi_a \, |N(p)\rangle = \frac{2 \hbar \, g_{\pi N}}{q^2 - m_\pi^2 c^2} \, \bar u(p') \gamma^5 \frac{\tau_a}{2} u(p) \cdot \hbar \,.$$

Equating the two expressions and cancelling the common spinor factor,

$$2 m_N c \, g_A\!\left(q^2\right) + \frac{q^2}{m_N c} h_A\!\left(q^2\right) = \frac{2 f_\pi g_{\pi N} \, m_\pi^2 c^2}{q^2 - m_\pi^2 c^2} \,. \tag{101.44}$$

Now set $q^2 = 0$, where the second term on the left vanishes provided h_A has no pole at the origin — which it has not, the pion pole sitting at $q^2 = m_\pi^2 c^2$ — and the right-hand side becomes $-2 f_\pi g_{\pi N}$. Hence $m_N c \, g_A(0) = -f_\pi g_{\pi N}$, which is Equation (101.41) up to the sign convention for $g_{\pi N}$. The mechanism is worth naming: the right-hand side of Equation (101.44) is proportional to m_π^2 and would vanish in the chiral limit, but the pion propagator supplies a compensating $1/m_\pi^2$ at $q^2 = 0$, so the product survives. That is why an exactly conserved axial current would still give a nonzero relation, and why the corrections are of relative order m_π^2/m_N^2 rather than of order one. Numerically, with $f_\pi c = 92.3\,\mathrm{MeV}$, $g_{\pi N} = 13.05$, $m_N c^2 = 938.9\,\mathrm{MeV}$ and $g_A = 1.2754$ [2427],

$$f_\pi c \, g_{\pi N} = 1204\,\mathrm{MeV} \,, \qquad g_A m_N c^2 = 1197\,\mathrm{MeV} \,,$$

agreeing to 0.6 per cent, which is of the expected order $m_\pi^2/m_N^2 \approx 0.02$. The relation is [1147]. What makes it worth the page is that it connects three quantities measured in three different ways — a weak decay rate, a strong scattering length and a leptonic pion decay — and is right to one per cent. □

Phenomenon 101.43 (One coupling governs every charged-current process)**.** The strength of the charged-current interaction extracted from the purely leptonic decay $\mu^- \to e^- \bar{\nu}_e \nu_\mu$, from superallowed nuclear beta decay and from τ decay is one and the same number. The muon lifetime is measured to a part per million, $\tau_\mu = 2.196\,981\,1 \times 10^{-6}\,\mathrm{s}$ [2225], and defines

$$\frac{G_F}{(\hbar c)^3} = 1.166\,378\,7 \times 10^{-5}/\mathrm{GeV}^2 \tag{101.45}$$

[2427]; the same constant reproduces the nuclear rates once the rotation of Section 101.5 is applied to the strangeness-changing part. Universality was read off the data, not imposed: nothing in Fermi's construction required the coupling of a muon and the coupling of a nucleon to agree.

Rests on Equations (101.20) *and* (101.53) *and Phenomenon 101.40.*

Derivation. Derives Phenomenon 101.43.

The three determinations are as follows. Muon decay gives G_F directly by Equation (101.53), with no hadron anywhere in the problem and hence no strong correction beyond the electromagnetic ones. Superallowed nuclear decay gives $G_F\,|V_{ud}|$ by Equation (101.20), and the vector coupling entering it is unrenormalized by Phenomenon 101.40; dividing out $|V_{ud}| = 0.97435$ returns the muon-decay value. Tau decay to $\nu_\tau e \bar{\nu}_e$ is muon decay with a heavier lepton, so Equation (101.53) applies with $m_\mu \to m_\tau$; the predicted partial width, using $m_\tau c^2 = 1776.93\,\mathrm{MeV}$ and the same G_F, reproduces the measured branching fraction of 17.8 % together with the measured lifetime $290.3 \times 10^{-15}\,\mathrm{s}$ [2427]. Three processes whose energy scales differ by a factor 10^4 and whose participants differ in every other respect share one constant. Puppi's observation that the couplings of (μ, ν_μ), (e, ν_e) and (n, p) to one another form a triangle of equal sides, and Konopinski and Mahmoud's version of the same statement [1022], are the origin of the phrase *universal Fermi interaction*; the residual deficit in the strangeness-changing sector, which is what stops the triangle from closing exactly, is Section 101.5. □

101.4.3 Muon decay and the Fermi constant

The muon is the cleanest weak decay in existence. Nothing that feels the strong interaction appears in either the initial or the final state; the final state has three particles, two of which are essentially massless; and the lifetime can be measured by simply counting. It is therefore the process that *defines* G_F, and this subsection carries out the calculation in full.

Definition 101.44 (The effective Lagrangian for muon decay)**.** At energies far below the mass of the W, the decay $\mu^- \to e^- \bar{\nu}_e \nu_\mu$ is governed by the contact interaction

$$\mathcal{L}_\mu = -\frac{G_F}{\sqrt{2}} \left[\bar{\psi}_{\nu_\mu} \gamma^\alpha \left(\mathbb{1} - \gamma^5\right) \psi_\mu\right] \left[\bar{\psi}_e \gamma_\alpha \left(\mathbb{1} - \gamma^5\right) \psi_{\nu_e}\right] + \mathrm{h.c.}\,, \tag{101.46}$$

whose coefficient $G_F/\sqrt{2}$ carries $\mathrm{J\,m^3}$ by Proposition 101.7; the factor $\sqrt{2}$ is a convention, fixed once and for all here, and Section 101.6.1 shows what it becomes when the W is restored. The corresponding invariant amplitude is

$$\mathcal{M} = \frac{G_F}{\sqrt{2}\,\hbar c}\,\mathcal{A}\,, \qquad \mathcal{A} = \left[\bar{u}_{\nu_\mu} \gamma^\alpha \left(\mathbb{1} - \gamma^5\right) u_\mu\right] \left[\bar{u}_e \gamma_\alpha \left(\mathbb{1} - \gamma^5\right) v_{\bar{\nu}_e}\right]\,, \tag{101.47}$$

of SI dimension $\hbar^2$, in agreement with the general statement of Proposition 100.14: the four external spinors contribute a squared momentum, and $G_F/\hbar c$ carries m^2.

Proposition 101.45 (Decay-rate master formula)**.** *For the decay of a particle of energy E_1 into n particles,*

$$\mathrm{d}\Gamma = \frac{c^2}{2E_1}\,\overline{|\mathcal{M}|^2}\,\mathrm{d}\Phi_n\,, \tag{101.48}$$

with the invariant phase space $\mathrm{d}\Phi_n$ *of Equation* (100.39)*. In the rest frame the prefactor is* $1/2m_1$*; in any other frame the rate is smaller by the Lorentz factor* m_1c^2/E_1*, which is time dilation.*

Rests on Equations (100.39) *and* (101.10) *and Proposition 100.14.*

Proof. *Derives Proposition 101.45.*

Quantize in a box of volume V with periodic boundary conditions and normalize each one-particle state to one particle in the box,

$$\psi(x) = \frac{1}{\sqrt{V}}\,\frac{u(p,s)}{\sqrt{2E/c}}\,\mathrm{e}^{-\mathrm{i}p\cdot x/\hbar}\,, \tag{101.49}$$

which is correctly normalized because $u^\dagger u = 2E/c$ by Proposition 100.14, so that $\int_V \mathrm{d}^3x\,\psi^\dagger\psi = 1$; note that the prefactor is dimensionally forced, $1/\mathrm{m}^{3/2}$ on the left and $u/\sqrt{2E/c}$ dimensionless. With $\mathcal{H}_{\mathrm{int}} = -\mathcal{L}_\mu$, which holds because the interaction contains no derivatives, the matrix element between the one-muon state and a three-particle final state is

$$\langle f|\,\mathcal{H}_{\mathrm{int}}\,|i\rangle = \frac{G_F}{\sqrt{2}}\,\frac{1}{V^2}\,\frac{\mathcal{A}}{\prod_{k=1}^{4}\sqrt{2E_k/c}}\;\times V\delta_{\boldsymbol{p}_1,\,\boldsymbol{p}_2+\boldsymbol{p}_3+\boldsymbol{p}_4}\,,$$

the four factors $V^{-1/2}$ coming from the four fields and the factor V from $\int_V \mathrm{d}^3x$, which also enforces momentum conservation as a Kronecker delta. Squaring, using $\delta_{\mathrm{K}}^2 = \delta_{\mathrm{K}}$, and inserting into the golden rule Equation (101.10) with the continuum sum $\sum_f \to \prod_{k=2}^{4} V\mathrm{d}^3p_k/(2\pi\hbar)^3$ and the continuum form of the Kronecker delta, $\delta_{\mathrm{K}} = (2\pi\hbar)^3V^{-1}\delta^3(\boldsymbol{p}_1 - \sum \boldsymbol{p}_f)$, gives

$$\Gamma = \frac{2\pi}{\hbar}\,\frac{G_F^2}{2}\,\frac{c}{2E_1}\int|\mathcal{A}|^2\left[\prod_f \frac{c\,\mathrm{d}^3p_f}{(2\pi\hbar)^3\,2E_f}\right](2\pi\hbar)^3\,\delta^3\!\left(\boldsymbol{p}_1 - \sum_f \boldsymbol{p}_f\right)\delta\!\left(E_1 - \sum_f E_f\right)\,,$$

every power of V having cancelled: V^3 from the three measures against V^{-2} from the squared matrix element and V^{-1} from the delta. Now use $(2\pi\hbar)^4\,\delta^4(p) = (2\pi\hbar)^3\,\delta^3(\boldsymbol{p})\cdot 2\pi\hbar c\,\delta(E)$, so that $2\pi\delta(E)\,(2\pi\hbar)^3\,\delta^3 = (2\pi\hbar)^4\,\delta^4/\hbar c$, to recognize $\mathrm{d}\Phi_3$ of Equation (100.39) entire:

$$\Gamma = \frac{G_F^2}{4\hbar^2E_1}\int|\mathcal{A}|^2\,\mathrm{d}\Phi_3\,.$$

Finally substitute $|\mathcal{A}|^2 = 2\hbar^2c^2\,|\mathcal{M}|^2/G_F^2$ from Equation (101.47), which cancels G_F and $\hbar$ together and leaves Equation (101.48). Nothing in the last two steps used the specific interaction: the coupling and the spinor structure enter only through $\mathcal{M}$, while the factors of V and of $2E/c$ belong to the external legs. Hence the formula holds for any $1 \to n$ decay, which is how it is used again in Section 101.6.4. □

Lemma 101.46 (The spin-summed square)**.** *With the neutrinos massless and the muon spin averaged,*

$$\overline{|\mathcal{A}|^2} = 128\,(p_\mu\cdot p_{\bar\nu_e})\,(p_e\cdot p_{\nu_\mu})\,. \tag{101.50}$$

The muon pairs with the electron antineutrino *and the electron with the* muon neutrino*; the pairing is a consequence of the current structure and not a choice.*

Rests on Equation (100.33) *and Lemma 100.23.*

Proof. *Derives Lemma 101.46.*

Write $\mathcal{A} = L^\alpha M_\alpha$ with $L^\alpha = \bar u_{\nu_\mu}\gamma^\alpha(1-\gamma^5)u_\mu$ and $M_\alpha = \bar u_e\gamma_\alpha(1-\gamma^5)v_{\bar\nu_e}$. Summing over final spins and averaging over the two muon spins, $\overline{|\mathcal{A}|^2} = \tfrac{1}{2}L^{\alpha\beta}M_{\alpha\beta}$ with

$$L^{\alpha\beta} = \mathrm{tr}\left[\gamma\cdot p_{\nu_\mu}\,\gamma^\alpha\left(1-\gamma^5\right)(\gamma\cdot p_\mu + m_\mu c)\,\gamma^\beta\left(1-\gamma^5\right)\right]\,,$$

the spin sums being those of Equation (100.33) and the conjugation using $\gamma^0\left[\gamma^\beta(1-\gamma^5)\right]^\dagger\gamma^0 = \gamma^\beta(1-\gamma^5)$. The mass term drops, because it leaves an odd number of gamma matrices in the trace. Using $(1-\gamma^5)^2 = 2(1-\gamma^5)$ and the trace theorems of Lemma 100.23 together with $\operatorname{tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5) = -4\mathrm{i}\varepsilon^{\mu\nu\rho\sigma}$,

$$L^{\alpha\beta} = 8\left[p^\alpha_{\nu_\mu}p^\beta_\mu + p^\beta_{\nu_\mu}p^\alpha_\mu - \eta^{\alpha\beta}\left(p_{\nu_\mu}\cdot p_\mu\right) + \mathrm{i}\varepsilon^{\rho\alpha\sigma\beta}p_{\nu_\mu\rho}p_{\mu\sigma}\right],$$

and $M_{\alpha\beta}$ is the same expression with $p_{\nu_\mu}\to p_e$ and $p_\mu\to p_{\bar\nu_e}$ and the indices lowered. Abbreviate $P_1 = p_{\nu_\mu}$, $P_2 = p_\mu$, $P_3 = p_e$, $P_4 = p_{\bar\nu_e}$ — numbered rather than lettered, since c is the speed of light throughout this book — and contract.

The symmetric parts contract to

$$\begin{aligned}&64\big[2(P_1\cdot P_3)(P_2\cdot P_4) + 2(P_1\cdot P_4)(P_2\cdot P_3)\\&\quad - 4(P_1\cdot P_2)(P_3\cdot P_4) + 4(P_1\cdot P_2)(P_3\cdot P_4)\big]\\&= 128\left[(P_1\cdot P_3)(P_2\cdot P_4) + (P_1\cdot P_4)(P_2\cdot P_3)\right],\end{aligned}$$

the two trace terms cancelling exactly against the term in which the two metrics meet. The product of the two Levi-Civita terms, using $\varepsilon^{\rho\alpha\sigma\beta}\varepsilon_{\kappa\alpha\lambda\beta} = -2\left(\delta^\rho_\kappa\delta^\sigma_\lambda - \delta^\rho_\lambda\delta^\sigma_\kappa\right)$ and $\mathrm{i}^2 = -1$, contributes

$$128\left[(P_1\cdot P_3)(P_2\cdot P_4) - (P_1\cdot P_4)(P_2\cdot P_3)\right],$$

while the cross terms between a symmetric and an antisymmetric tensor vanish identically. Adding, the $(P_1\cdot P_4)(P_2\cdot P_3)$ pieces cancel and the others double:

$$L^{\alpha\beta}M_{\alpha\beta} = 256\left(p_{\nu_\mu}\cdot p_e\right)\left(p_\mu\cdot p_{\bar\nu_e}\right), \tag{101.51}$$

which halved is Equation (101.50). This is the single most useful identity in weak-interaction physics: any two $V-A$ currents, contracted and summed over spins, collapse to a product of two dot products with the coefficient 256, and the cancellation of the other pairing is what fixes which particle goes with which. □

Lemma 101.47 (The two-neutrino phase space)**.** *For two massless particles sharing a total four-momentum q,*

$$\int \mathrm{d}\Phi_2\; k^\alpha k'^\beta = \frac{1}{96\pi\hbar^2}\left(q^2\eta^{\alpha\beta} + 2q^\alpha q^\beta\right), \tag{101.52}$$

where $\mathrm{d}\Phi_2$ is the two-body element of Equation (100.39) with $k+k'=q$.

Rests on Equation (100.39) and Proposition 100.24.

Proof. *Derives Lemma 101.47.*

The integral is a Lorentz tensor built from q alone, so $I^{\alpha\beta} = Aq^2\eta^{\alpha\beta} + Bq^\alpha q^\beta$. Contract with $\eta_{\alpha\beta}$: since $k^2 = k'^2 = 0$ gives $2k\cdot k' = q^2$, the left side is $\frac12 q^2\Phi_2$ with $\Phi_2 = \int\mathrm{d}\Phi_2$, so $4A + B = \frac12\Phi_2$. Contract with $q_\alpha q_\beta$: $q\cdot k = k'\cdot k = \frac12 q^2$ and likewise $q\cdot k'$, so the left side is $\frac14 q^4\Phi_2$ and $A+B = \frac14\Phi_2$. Hence $A = \Phi_2/12$ and $B = \Phi_2/6$. The total two-body phase space for massless products follows from Proposition 100.24, where $\mathrm{d}\Phi_2 = \hbar^{-2}\left|\boldsymbol{p}_f\right|\mathrm{d}\Omega/16\pi^2\sqrt{s}$ with $|\boldsymbol{p}_f| = \frac12\sqrt{s}$ here, giving $\Phi_2 = 4\pi/32\pi^2\hbar^2 = 1/8\pi\hbar^2$; note that it carries $\hbar^{-2}$, as every element of $\mathrm{d}\Phi$ must. Inserting gives Equation (101.52). □

Theorem 101.48 (The muon decay rate)**.** *Neglecting the electron mass and radiative corrections, the $V-A$ interaction Equation (101.46) gives*

$$\Gamma_\mu = \frac{1}{\tau_\mu} = \frac{1}{192\pi^3\hbar}\left(\frac{G_F}{(\hbar c)^3}\right)^2\left(m_\mu c^2\right)^5 = \frac{G_F^2\left(m_\mu c^2\right)^5}{192\pi^3\hbar\,(\hbar c)^6}, \tag{101.53}$$

and the normalized electron energy spectrum, with $x = 2E_e/m_\mu c^2 \in [0,1]$,

$$\frac{1}{\Gamma_\mu}\frac{\mathrm{d}\Gamma_\mu}{\mathrm{d}x} = 2x^2\,(3-2x)\ . \tag{101.54}$$

Rests on Equations (101.46), (101.48) *and* (101.50).

Proof. *Derives Theorem 101.48.*

Combine Equation (101.48), Equation (101.47) and Equation (101.50):

$$\overline{|\mathcal{M}|^2} = \frac{G_F^2}{2\hbar^2c^2}\cdot 128\,(p_\mu\cdot p_{\bar\nu_e})\,(p_e\cdot p_{\nu_\mu}) = \frac{64G_F^2}{\hbar^2c^2}\,(p_\mu\cdot p_{\bar\nu_e})\,(p_e\cdot p_{\nu_\mu})\ .$$

The two neutrinos are not observed, so integrate over them first. Writing $q = p_\mu - p_e$ for their total four-momentum and using Equation (101.52) with $k = p_{\nu_\mu}$ and $k' = p_{\bar\nu_e}$,

$$\int \mathrm{d}\Phi_2\,(p_\mu\cdot p_{\bar\nu_e})\,(p_e\cdot p_{\nu_\mu}) = p_{e\alpha}p_{\mu\beta}\int \mathrm{d}\Phi_2\,k^\alpha k'^\beta = \frac{q^2\,(p_e\cdot p_\mu) + 2\,(q\cdot p_e)\,(q\cdot p_\mu)}{96\pi\hbar^2}\ .$$

Put the muon at rest, $p_\mu = (m_\mu c, \mathbf{0})$, and neglect the electron mass, $p_e^2 = 0$. Then, writing $y = p_\mu\cdot p_e = m_\mu E_e$,

$$q^2 = m_\mu^2c^2 - 2y\,,\qquad q\cdot p_e = y\,,\qquad q\cdot p_\mu = m_\mu^2c^2 - y\,,$$

so the numerator is $\left(m_\mu^2c^2-2y\right)y + 2y\left(m_\mu^2c^2-y\right) = m_\mu^2E_e\,(3m_\mu c^2 - 4E_e)$. The remaining electron integral is the one-particle element of Equation (100.39) with $\mathrm{d}^3p_e = 4\pi E_e^2\mathrm{d}E_e/c^3$ for a massless electron:

$$\int \frac{c\,\mathrm{d}^3p_e}{(2\pi\hbar)^3 2E_e}\,m_\mu^2E_e\left(3m_\mu c^2 - 4E_e\right) = \frac{4\pi m_\mu^2}{2c^2\,(2\pi\hbar)^3}\int_0^{m_\mu c^2/2} E_e^2\left(3m_\mu c^2 - 4E_e\right)\mathrm{d}E_e\,,$$

the upper limit being the greatest energy an electron can take when the two neutrinos go together against it. The integral is $m_\mu c^2 W^3 - W^4$ with $W = m_\mu c^2/2$, that is $\left(m_\mu c^2\right)^4/16$, and $(2\pi\hbar)^3 = 8\pi^3\hbar^3$, so the electron integral equals $m_\mu^2\left(m_\mu c^2\right)^4/64\pi^2\hbar^3c^2$. Assembling with the prefactor $c^2/2m_\mu c^2$ of Equation (101.48),

$$\Gamma_\mu = \frac{1}{2m_\mu}\cdot\frac{64G_F^2}{\hbar^2c^2}\cdot\frac{1}{96\pi\hbar^2}\cdot\frac{m_\mu^2\left(m_\mu c^2\right)^4}{64\pi^2\hbar^3c^2} = \frac{G_F^2m_\mu\left(m_\mu c^2\right)^4}{192\pi^3\hbar^7c^4}\,,$$

since $64/(2\cdot 96\cdot 64) = 1/192$. Writing $m_\mu = \left(m_\mu c^2\right)/c^2$ and $\hbar^7c^6 = \hbar\,(\hbar c)^6$ gives Equation (101.53). The spectrum Equation (101.54) is the integrand before the last integration: with $E_e = xm_\mu c^2/2$ the integrand is proportional to $E_e^2\,(3m_\mu c^2 - 4E_e) \propto x^2\,(3-2x)$, and $\int_0^1 2x^2(3-2x)\mathrm{d}x = 2\left(1-\frac{1}{2}\right) = 1$ fixes the normalization. □

Remark 101.49 (What the fifth power is). The $\left(m_\mu c^2\right)^5$ in Equation (101.53) is forced and could have been written down without the calculation. Γ has dimension 1/s; the only quantities available are G_F, $m_\mu c^2$, $\hbar$ and c; and $G_F^2/(\hbar c)^6$ carries $1/\mathrm{J}^4$, so exactly four powers of energy are needed to make it dimensionless and a fifth to convert $\hbar^{-1}$ into a rate. What the calculation supplies is the pure number $1/192\pi^3$, and that number is where the $V-A$ structure and the three-body phase space actually live.

The same argument applies to the tau, and it is worth being exact about how much of the answer it supplies. The tau is 16.82 times heavier than the muon [2427], so the fifth power predicts its *partial* width to $e^-\bar\nu_e\nu_\tau$ to be $16.82^5 = 1.35\times10^6$ times the muon's total width. That alone would give the tau a lifetime of $1.63\times10^{-12}\,\mathrm{s}$. The measured lifetime is $2.903\times10^{-13}\,\mathrm{s}$ [2427], shorter by a further factor 5.6, and that factor is not dimensional

analysis: it is $1/\mathcal{B}(\tau^- \to e^-\bar{\nu}_e\nu_\tau) = 1/0.178$, the hadronic and muonic channels open to a tau and closed to a muon. Putting the two together, $2.196\,981\,1\times10^{-6}\,\mathrm{s}\times0.178/1.35\times10^{6} = 2.91\times10^{-13}\,\mathrm{s}$, which is the measurement. The ratio of *total* lifetimes is 7.6×10^{6}, and quoting that as what the fifth power predicts would credit dimensional analysis with a branching fraction it knows nothing about. It is the same fifth power as Sargent's rule Equation (101.14): two light particles sharing a release.

Phenomenon 101.50 (The muon lifetime measures the Fermi constant)**.** The measured positive-muon lifetime is

$$\tau_\mu = (2.196\,981\,1 \pm 0.000\,002\,2)\times10^{-6}\,\mathrm{s} \tag{101.55}$$

[2225], a determination to one part per million from 2×10^{12} recorded decays. Inserted into Equation (101.53), corrected for the electron mass and for the one-loop electromagnetic radiative correction, it yields Equation (101.45); conversely, that value of G_F predicts the lifetime.

Rests on Equations (101.45) *and* (101.53)*.*

Derivation. Derives Phenomenon 101.50.

Evaluate Equation (101.53) with $G_F/(\hbar c)^3 = 1.166\,378\,7\times10^{-5}/\mathrm{GeV}^2$, $m_\mu c^2 = 105.658\,375\,5\,\mathrm{MeV}$ and $\hbar = 6.582\,120\times10^{-25}\,\mathrm{GeV\,s}$:

$$\Gamma_\mu^{\mathrm{tree}} = \frac{(1.166\,378\,7\times10^{-5})^2\,(0.105\,658\,375\,5)^5}{192\pi^3\,(6.582\,120\times10^{-25}\,\mathrm{GeV\,s})}\,1/\mathrm{GeV}^4\,\mathrm{GeV}^5 = 4.5717\times10^{5}/\mathrm{s}\,,$$

that is $\tau = 2.1873\times10^{-6}\,\mathrm{s}$, which is 0.44 per cent below the measurement. Two known corrections account for the difference and for nothing else.

The first is kinematic. Retaining the electron mass multiplies Equation (101.53) by

$$f(z) = 1 - 8z + 8z^3 - z^4 - 12z^2\ln z\,, \qquad z = \frac{m_e^2}{m_\mu^2} = 2.339\times10^{-5}\,, \tag{101.56}$$

whose value here is $f = 0.99981$, a reduction of 1.87×10^{-4}: the electron mass eats into the available phase space, and the effect is second order in m_e/m_μ because the spectrum vanishes quadratically at low x by Equation (101.54).

The second is electromagnetic. The one-loop QED correction to the contact interaction, computed once and for all by the methods of Section 100.4, multiplies the rate by

$$1 + \Delta q\,, \qquad \Delta q = \frac{\alpha\,(m_\mu c^2)}{2\pi}\left(\frac{25}{4} - \pi^2\right) = -4.24\times10^{-3}\,, \tag{101.57}$$

using $\alpha(m_\mu c^2)^{-1} = 135.9$ for the fine-structure constant of Equation (100.3) run to the muon mass by Proposition 100.63. The combination $f(z)\,(1+\Delta q) = 0.99557$ gives

$$\Gamma_\mu = 4.5515\times10^{5}/\mathrm{s}\,, \qquad \tau_\mu = 2.1971\times10^{-6}\,\mathrm{s}\,,$$

against the measured $2.196\,981\,1\times10^{-6}\,\mathrm{s}$: agreement to 4×10^{-5}, which is the accuracy of the two-loop terms not included here and of the fourth digit of $\alpha(m_\mu c^2)$ used above. It is worth being explicit about the logic of the comparison. G_F is *defined* by inverting this calculation, so the agreement of the central values is a tautology; what is not a tautology, and is the actual content, is that the correction factors $f(z)$ and $1+\Delta q$ — computed from the electron mass and from QED, with no adjustable parameter — move the tree-level answer by exactly the 0.44 per cent by which it was wrong. □

Derivation pending #145

Muon decay, the parts not derived here: the phase-space function $f(z)$ of the electron-mass correction, obtained by repeating the phase-space integral of this section with $p_e^2 = m_e^2c^2$ retained; the one-loop electromagnetic correction $[25/4 - \pi^2]$, which is a QED calculation of the kind carried out in the QED chapter but applied to a contact operator; and the spin-dependent decay distribution $x^2[(3-2x) + P_\mu \cos\theta\,(2x-1)]$ obtained by keeping the muon spin projector in place of the average taken in the trace lemma. All three are Appendix A material and all three are quoted with their numerical values in the derivation above.

Definition 101.51 (Michel parameters)**.** The most general local, lepton-number-conserving, four-fermion interaction gives an electron spectrum of the form

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}x} \propto x^2 \left[3\,(1-x) + \frac{2}{3}\rho\,(4x-3) \right], \tag{101.58}$$

together with three further parameters η, ξ and δ governing the electron-mass term and the dependence on the muon polarization [965]. The $V-A$ interaction predicts $\rho = \frac{3}{4}$, $\eta = 0$, $\xi = 1$, $\delta = \frac{3}{4}$.

Phenomenon 101.52 (The muon decay spectrum has the $V-A$ shape)**.** The measured Michel parameters are $\rho = 0.74979(26)$ and $\delta = 0.75047(34)$ [2427], agreeing with the $V-A$ prediction $\frac{3}{4}$ to a few parts in 10^4; measurements with polarized muons bound the admixture of a right-handed charged current at the same level [2170].

Rests on Equations (101.54) *and* (101.58).

Derivation. *Derives Phenomenon 101.52.*

Setting $\rho = \frac{3}{4}$ in Equation (101.58) gives $x^2\left[3 - 3x + \frac{1}{2}(4x-3)\right] = \frac{1}{2}x^2\,(3-2x)$, which is Equation (101.54) up to normalization; so the derived spectrum is the $\rho = \frac{3}{4}$ member of the family and the measurement is a direct test of the Lorentz structure, independent of the rate and therefore independent of G_F. The value $\frac{3}{4}$ is not generic: a scalar or tensor contact interaction gives $\rho = 0$, and a $V+A$ admixture moves ξ away from 1. What the agreement excludes is stated most sharply in the language of left–right symmetric models, where a right-handed W of mass M_2 mixing with the ordinary one shifts $P_\mu \xi\delta/\rho$ below unity; the measured value of that combination is consistent with 1 and bounds the mixing [2170]. □

The last property of the muon that belongs here is a null result, and it is one of the most stringent in physics.

Phenomenon 101.53 (Charged-current lepton flavour is conserved)**.** The decay $\mu^+ \to e^+\gamma$, which conserves electric charge, total lepton number, energy and angular momentum, and which would occur if the muon and the electron differed only in mass, has never been observed. The branching ratio is bounded by

$$\mathcal{B}\left(\mu^+ \to e^+\gamma\right) < 1.5 \times 10^{-13} \qquad (90\,\%\ \text{confidence}) \tag{101.59}$$

from the first dataset of MEG II combined with the full MEG sample; that dataset alone gives $< 7.5 \times 10^{-13}$ [2424].

Rests on Equation (101.46).

Derivation. *Derives Phenomenon 101.53.*

What the bound establishes is that the quantum numbers L_e and L_μ are separately conserved in charged-current processes, and not merely their sum. Were they not, the same W exchange that produces $\mu \to e\nu\bar{\nu}$ would, with the two neutrinos joined into a

loop and a photon attached, produce $\mu \to e\gamma$ at a rate suppressed only by α and by loop factors — of order 10^{-4} of the total, not 10^{-13}. The observed suppression is therefore a statement about the structure of the current and not about the size of a coupling. In the Standard Model with massive neutrinos the amplitude is not exactly zero but is suppressed by $\left(\Delta m_\nu^2 c^4 / M_W^2 c^4\right)^2 \sim 10^{-50}$, an unobservably small number, so any signal at all at the level of Equation (101.59) would be new physics; this is why the search continues. The experiment stops positive muons in a thin target and looks for a positron and a photon, back to back, each of energy $m_\mu c^2/2 = 52.8\,\mathrm{MeV}$, in time coincidence [2424]. □

The crossed version of muon decay is a scattering process, and its cross-section is needed twice below — once in Phenomenon 101.5 and once in Section 101.7.1.

Proposition 101.54 (Inverse muon decay)**.** *For $\nu_\mu e^- \to \mu^- \nu_e$ at centre-of-mass energy E_{cm} large compared with the muon mass, the $V-A$ contact interaction gives an isotropic cross-section*

$$\sigma = \frac{G_F^2 E_{\mathrm{cm}}^2}{\pi\,(\hbar c)^4}\,. \tag{101.60}$$

Rests on Equations (100.40)*,* (101.47) *and* (101.51)*.*

Proof. *Derives Proposition 101.54.*

The amplitude is Equation (101.47) with the external legs crossed, and Equation (101.51) applies unchanged: summing over final spins and averaging over the two electron spins — the neutrino has only one helicity, so nothing is averaged there —

$$\overline{|\mathcal{A}|^2} = \frac{1}{2}\cdot 256\,(p_{\nu_\mu}\cdot p_e)\,(p_\mu \cdot p_{\nu_e}) = 128\cdot\frac{s}{2}\cdot\frac{s}{2} = 32 s^2\,,$$

using $2p_{\nu_\mu}\cdot p_e = s$ for massless incoming particles and the same for the outgoing pair, with $s = E_{\mathrm{cm}}^2/c^2$ a squared momentum in the conventions of Notation 100.1. Then $\overline{|\mathcal{M}|^2} = 16 G_F^2 s^2/\hbar^2 c^2$, and Equation (100.40) with $|\boldsymbol{p}_f| = |\boldsymbol{p}_i|$ gives

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{1}{64\pi^2\hbar^2 s}\cdot\frac{16 G_F^2 s^2}{\hbar^2 c^2} = \frac{G_F^2 s}{4\pi^2\hbar^4 c^2}\,,$$

independent of angle. Multiplying by 4π and writing $s = E_{\mathrm{cm}}^2/c^2$ gives Equation (101.60). The isotropy is not an accident: the contact interaction has no length scale, so it can produce only s-wave scattering, and that fact is what Section 101.7.1 turns against the theory. Applied to a nucleon rather than to an electron, with the vector and axial nucleon couplings inserted, the same calculation gives Equation (101.5): the factor $1+3\lambda^2$ is the one Fermi channel plus the three Gamow–Teller channels of Proposition 101.15, each weighted by its coupling, and the factor $|V_{ud}|^2$ is the quark mixing of Section 101.5, which has no counterpart in the purely leptonic process computed here. □

101.5 Strangeness-changing currents

101.5.1 The strangeness deficit and the Cabibbo rotation

Phenomenon 101.43 is not quite true, and the size of the discrepancy is the subject of this section. When the same G_F that governs muon decay and superallowed nuclear decay is used to predict the rate of a decay that *changes strangeness* — $K^+ \to \mu^+\nu_\mu$ against $\pi^+ \to \mu^+\nu_\mu$, or $\Lambda \to p e^- \bar{\nu}_e$ against neutron decay — the prediction is too large by a factor of about twenty. Universality holds to a per cent for the strangeness-conserving processes and fails by a factor of twenty for the others.

Phenomenon 101.55 (Strangeness-changing decays are suppressed by one angle)**.** Semileptonic decays with $\Delta S = 1$ proceed at roughly one twentieth of the rate predicted by the coupling measured in $\Delta S = 0$ decays; and the deficit of the $\Delta S = 0$ rate below the purely leptonic strength is exactly what is needed to make up the difference. One angle,

$$\theta_C = 12.96^\circ\,, \qquad \sin\theta_C = 0.2243\,, \qquad \cos\theta_C = 0.9745\,, \tag{101.61}$$

accounts for both [1248, 2427].

Rests on Phenomenon 101.43 and Equation (101.20)*.*

Derivation. Derives Phenomenon 101.55.

Cabibbo's hypothesis is that the state entering the hadronic charged current is not the down quark but a rotation of the down-type mass eigenstates,

$$d' = d\cos\theta_C + s\sin\theta_C\,, \tag{101.62}$$

so that the hadronic current is

$$J^\mu_{\text{had}} = \bar\psi_u\gamma^\mu\left(\mathbb{1} - \gamma^5\right)\psi_{d'} = \cos\theta_C\,\bar\psi_u\gamma^\mu\left(\mathbb{1} - \gamma^5\right)\psi_d + \sin\theta_C\,\bar\psi_u\gamma^\mu\left(\mathbb{1} - \gamma^5\right)\psi_s\,, \tag{101.63}$$

and that the *same* G_F multiplies this current and the leptonic one. The two consequences are then not independent. A $\Delta S = 0$ amplitude carries $\cos\theta_C$ and a $\Delta S = 1$ amplitude carries $\sin\theta_C$, so their rates stand in the ratio

$$\frac{\Gamma\left(\Delta S = 1\right)}{\Gamma\left(\Delta S = 0\right)} = \tan^2\theta_C = 0.0530 = \frac{1}{18.9}\,,$$

which is the observed factor of about twenty; and the strangeness-conserving hadronic rate is suppressed relative to the purely leptonic one by $\cos^2\theta_C = 0.9496$, a deficit of about five per cent, which is precisely what Equation (101.20) sees as $|V_{ud}|^2$. The angle is therefore measured twice, in unrelated experiments: from the kaon rates as $\sin\theta_C = |V_{us}| = 0.2243$, and from the superallowed nuclear rates as $\cos\theta_C = |V_{ud}| = 0.97435$. The two determinations satisfy $\sin^2 + \cos^2 = 1$ to about a part in 10^3, and that residual is presently the sharpest unexplained tension in flavour physics; it is recorded, with the current numbers, in Phenomenon 103.7. □

The conceptual step in Equation (101.62) is larger than its algebra suggests, and it is the one that the whole of Chapter 103 elaborates: *the states that couple to the W are not the states of definite mass.* There are two bases for the down-type quarks, one diagonalizing the mass matrix and one diagonalizing the charged-current coupling, and they are related by a rotation. Nothing requires them to coincide, and they do not. Universality is restored not by making the couplings equal but by recognizing that a single coupling is shared out between channels, with the shares summing to one — which is a statement of orthogonality, and therefore the first appearance of the unitarity that Section 101.5.4 turns into a testable constraint.

101.5.2 Selection rules

Equation (101.63) carries two selection rules that were established empirically before it was written and that are among the sharpest tests of the current structure.

Proposition 101.56 (The $\Delta S = \Delta Q$ rule)**.** *A semileptonic decay of hadrons mediated by Equation* (101.63) *satisfies* $\Delta S = \Delta Q$*, where both refer to the hadronic system.*

Rests on Equation (101.63)*.*

Proof. *Derives Proposition 101.56.*

The strangeness-changing part of Equation (101.63) is $\bar{\psi}_u \Gamma \psi_s$, which annihilates an s quark and creates a u. The s quark carries $S = -1$ and charge $-\frac{1}{3}e$; the u carries $S = 0$ and $+\frac{2}{3}e$. Hence $\Delta S = 0 - (-1) = +1$ and $\Delta Q = +\frac{2}{3} - (-\frac{1}{3}) = +1$ in units of e, and the two are equal. The Hermitian conjugate term gives $\Delta S = \Delta Q = -1$. The rule is a prediction and not a convention: it forbids $\Sigma^+ \to n e^+ \nu_e$, which has $\Delta S = +1$ and $\Delta Q = -1$, while allowing $\Sigma^- \to n e^- \bar{\nu}_e$. The forbidden mode is bounded at the 10^{-5} level and the allowed one occurs at 10^{-3} [2427]: two decays of the same multiplet, differing by two orders of magnitude, with the sign of a charge as the only distinction. □

Proposition 101.57 (The $\Delta I = \frac{1}{2}$ rule, and its limits)**.** *The $\Delta S = 1$ current $\bar{\psi}_u \Gamma \psi_s$ carries isospin $\frac{1}{2}$, since u is a member of an isospin doublet and s an isospin singlet. Semileptonic $\Delta S = 1$ decays therefore obey $\Delta I = \frac{1}{2}$ exactly. For* nonleptonic *decays the current–current product contains both $\Delta I = \frac{1}{2}$ and $\Delta I = \frac{3}{2}$, so the rule is not a consequence of the structure; the observed dominance of the first by a factor of about* 20 *in amplitude is a strong-interaction effect and is not explained here.*

Rests on Equation (101.63).

Proof. *Derives Proposition 101.57.*

The isospin assignment is immediate. For the nonleptonic case, the effective operator is a product of two hadronic currents, each of isospin $\frac{1}{2}$ in the $\Delta S = 1$ sector and each of isospin 1 or 0 in the $\Delta S = 0$ sector; combining $\frac{1}{2} \otimes 1$ gives $\frac{1}{2} \oplus \frac{3}{2}$, so both appear with comparable coefficients at the level of the operator. The measurement is the ratio of the two kaon decay amplitudes $K^0 \to \pi^+\pi^-$ and $K^+ \to \pi^+\pi^0$, the second of which is pure $\Delta I = \frac{3}{2}$ because two pions in the $I = 0$ state cannot carry unit charge; the measured ratio of amplitudes is about $1/22$ [2427]. Honesty requires the statement that this factor is a QCD effect — short-distance renormalization of the operators plus long-distance hadronic dynamics — and is not derived in this book; it is the reason the rule is quoted here as an observation with its magnitude, rather than proved. The related but different question of why the operator basis is what it is belongs to Chapter 108. □

Derivation pending #146

The $[\Delta I = 1/2]$ enhancement in nonleptonic strange decays: why the isospin-one-half amplitude dominates the isospin-three-halves one by a factor near twenty, when the current–current operator produces both with comparable coefficients. The explanation combines short-distance operator mixing under the renormalization group with long-distance hadronic matrix elements, so the derivation belongs with the strong-interaction and renormalization-group material rather than here; the measured ratio is quoted with its source above.

101.5.3 The GIM mechanism

Equation (101.62) solves one problem and creates another, and the second is severe. If the state d' couples to the W, it also appears in whatever *neutral* current the theory possesses — and it appears bilinearly.

Proposition 101.58 (A single rotated doublet produces a flavour-changing neutral current)**.** *With the Cabibbo rotation Equation (101.62) and one down-type state d',*

$$\bar{\psi}_{d'} \Gamma \psi_{d'} = \cos^2\theta_C \, \bar{\psi}_d \Gamma \psi_d + \sin^2\theta_C \, \bar{\psi}_s \Gamma \psi_s + \sin\theta_C \cos\theta_C \left(\bar{\psi}_d \Gamma \psi_s + \bar{\psi}_s \Gamma \psi_d \right) , \tag{101.64}$$

whose last term changes strangeness without changing charge, with a coefficient $\sin\theta_C \cos\theta_C = 0.219$ — of the same order as everything else in the theory.

Rests on Equation (101.62).

Proof. *Derives Proposition 101.58.*
Substitute Equation (101.62) and expand. The cross terms are the last bracket. □

Such a term would drive $K^0 \to \mu^+\mu^-$, K^0–$\bar{K}^0$ mixing and $K^+ \to \pi^+\nu\bar{\nu}$ at rates comparable with ordinary weak processes. The measured branching ratio is $\mathcal{B}(K_L \to \mu^+\mu^-) = 6.84 \times 10^{-9}$ [2427], against $\mathcal{B}(K^+ \to \mu^+\nu_\mu) = 0.636$: the neutral mode is suppressed by some eight orders of magnitude relative to the charged one. Equation (101.64) is therefore not merely unobserved but excluded by a very large factor, and something must cancel it.

Theorem 101.59 (Glashow–Iliopoulos–Maiani)**.** *Let the down-type states be rotated by an orthogonal matrix and supplied to* two *up-type partners, so that the two charged-current doublets are*

$$\begin{pmatrix} u \\ d' \end{pmatrix}, \qquad \begin{pmatrix} c \\ s' \end{pmatrix}, \qquad \begin{aligned} d' &= d\cos\theta_C + s\sin\theta_C\,, \\ s' &= -d\sin\theta_C + s\cos\theta_C\,, \end{aligned} \tag{101.65}$$

with c a fourth quark. Then the neutral current is diagonal:

$$\bar{\psi}_{d'}\Gamma\psi_{d'} + \bar{\psi}_{s'}\Gamma\psi_{s'} = \bar{\psi}_d\Gamma\psi_d + \bar{\psi}_s\Gamma\psi_s\,, \tag{101.66}$$

and no flavour-changing neutral current survives at tree level [1423].
Rests on Proposition 101.58 and Equation (101.62).

Proof. *Derives Theorem 101.59.*
The two rotated states are the components of $\psi_{d'} = R\psi_d$ with R the orthogonal matrix of Equation (101.65). Then $\sum_i \bar{\psi}_{i'}\Gamma\psi_{i'} = \bar{\psi}_j \left(R^{\mathsf{T}}R\right)_{jk}\Gamma\psi_k = \bar{\psi}_j\delta_{jk}\Gamma\psi_k$, which is Equation (101.66). Explicitly, the cross terms are $+\sin\theta_C\cos\theta_C$ from d' and $-\sin\theta_C\cos\theta_C$ from s', and they cancel exactly. Nothing about the value of θ_C was used: the cancellation is the orthogonality of the rotation, not a numerical accident, which is why it survives to all orders in θ_C and generalizes without change to the unitary matrix of Section 101.5.4. □

Remark 101.60 (A particle predicted by a null result). Theorem 101.59 is worth pausing on as a piece of scientific reasoning. The input is the *absence* of a process; the output is the existence of a particle. Glashow, Iliopoulos and Maiani proposed the fourth quark in 1970 [1423] on no other evidence, and it was found four years later as the J/ψ resonance.

The cancellation is exact only at zero momentum transfer and only if the two up-type quarks were degenerate. At one loop, in the box diagram that generates K^0–$\bar{K}^0$ mixing, the two contributions differ by the difference of the squared quark masses, and the surviving amplitude is suppressed by $(m_c^2 - m_u^2)\,c^4/\left(M_W c^2\right)^2$ rather than cancelling outright. The measured K_L–K_S mass difference, $\Delta m_K c^2 = 3.484 \times 10^{-12}$ MeV [2427] — a fractional mass splitting of 7×10^{-15}, one of the smallest measured quantities in physics — therefore *bounds the charm mass*, and the bound obtained before the discovery was of order a few GeV/c^2, which is where the charm quark was found. The estimate is due to Gaillard and Lee, whose paper is not in this book's bibliography and is therefore named without a citation rather than cited to a key that does not exist; the mechanism itself is [1423], and the loop calculation belongs to Chapter 103.

101.5.4 Three generations: the CKM matrix

Kobayashi and Maskawa observed in 1973, before the fourth quark had been seen and while the third generation was entirely hypothetical, that the rotation of Equation (101.65) generalizes to N generations as an $N \times N$ unitary matrix, and that the number of *physically meaningful* parameters it contains depends on N in a way that has an observable consequence [1505].

Definition 101.61 (The quark mixing matrix)**.** With three generations the charged-current interaction of the quarks is

$$J^{\mu}_{\text{had}} = \sum_{i,k} \bar{\psi}_{u_i} \gamma^{\mu} \left(\mathbb{1} - \gamma^{5} \right) V_{ik} \, \psi_{d_k} \,, \tag{101.67}$$

where i runs over (u, c, t), k over (d, s, b), and V is the Cabibbo–Kobayashi–Maskawa matrix [1248, 1505]. Its entries are dimensionless pure numbers.

Theorem 101.62 (The mixing matrix is unitary)**.** *V is unitary, $V^{\dagger}V = VV^{\dagger} = \mathbb{1}$.*

Rests on Propositions 5.148 and 5.150.

Proof. *Derives Theorem 101.62.*

V is the matrix relating two orthonormal bases of one three-dimensional complex internal space — the basis of definite mass and the basis that couples to the W — and a change between orthonormal bases is unitary. That the space carries an inner product for which *both* bases are orthonormal is not automatic and is what has to be supplied: it holds because the flavour symmetry acting on the space can be realized by inner-product-preserving operators, which is Proposition 5.150, and because the space then decomposes cleanly, which is Proposition 5.148. Those two propositions are exactly where the licence to write the word "unitary" here comes from, and the argument is set out in Remark 5.152, which states it for this case and records the hypotheses under which each of the two fails. What unitarity buys is set out there as well: two families of relations, the row relations $\sum_k V_{ik} V^{*}_{jk} = \delta_{ij}$ and the column relations $\sum_i V^{*}_{ik} V_{il} = \delta_{kl}$, whose off-diagonal cases are sums of three complex numbers equal to zero and therefore closed triangles in the complex plane. The one that is measured is the subject of Chapter 111. □

Proposition 101.63 (Parameter counting, and why three generations permit CP violation)**.** *An $N \times N$ unitary mixing matrix contains*

$$\frac{N\,(N-1)}{2} \text{ angles} \qquad \text{and} \qquad \frac{(N-1)\,(N-2)}{2} \text{ phases} \tag{101.68}$$

that cannot be removed by redefining the phases of the quark fields. For $N = 2$ there is one angle and no phase, and the interaction is automatically invariant under CP; for $N = 3$ there are three angles and one phase, and CP invariance is violated unless that phase happens to vanish.

Rests on Theorems 101.59 and 101.62 and Equation (101.67).

Proof. *Derives Proposition 101.63.*

A unitary $N \times N$ matrix has N^2 real parameters, of which $N(N-1)/2$ are the angles of the real orthogonal subgroup and the remaining $N^2 - N(N-1)/2 = N(N+1)/2$ are phases. The quark fields may be rephased freely, $\psi_{u_i} \mapsto \mathrm{e}^{\mathrm{i}\alpha_i}\psi_{u_i}$ and $\psi_{d_k} \mapsto \mathrm{e}^{\mathrm{i}\beta_k}\psi_{d_k}$, which changes $V_{ik} \mapsto \mathrm{e}^{\mathrm{i}(\beta_k - \alpha_i)} V_{ik}$ and leaves every other term of the Lagrangian invariant, the mass terms because they are diagonal and the neutral currents because they are diagonal by Theorem 101.59. There are $2N$ such phases, but the overall common phase $\alpha_i = \beta_k$ acts trivially on V, so $2N - 1$ of the phases in V can be removed. The number surviving is $N(N+1)/2 - (2N-1) = (N-1)(N-2)/2$, which with the angles gives Equation (101.68).

For the CP statement, note that the CP conjugate of Equation (101.67) is the same expression with V replaced by V^{*}. If every entry of V can be made real by rephasing, the interaction is CP invariant; if a phase survives, it cannot, and CP is violated. With $N = 2$, $(N-1)(N-2)/2 = 0$: the Cabibbo matrix is real and Equation (101.62) conserves CP however θ_C is chosen. With $N = 3$ one phase survives. Kobayashi and Maskawa's inference [1505] was made in the reverse direction: CP violation had been observed in the neutral kaon system nine years earlier [1274], no two-generation model could accommodate

it without additional structure, and a third generation could. Two of its three quarks were subsequently found. It is one of the few occasions in this chapter on which theory ran ahead of experiment, and it is worth noting that it did so by counting parameters. □

Remark 101.64 (What this chapter does and does not claim about flavour). The measured magnitudes of the mixing elements, the closure of the unitarity triangle, the size of the CP-violating phase and the whole neutrino sector belong to Chapter 103, and the experiments that establish them to Chapter 111 and Chapter 114. What has been established *here* is narrower and prior to all of it: that the charged-current interaction has one universal strength; that the hadronic states it couples are rotations of the mass eigenstates; that the rotation is unitary, with the licence for the word supplied by Remark 5.152; that unitarity is what removes flavour-changing neutral currents; and that the number of surviving parameters, which is pure counting, decides whether CP can be violated at all. Nothing in the list is a fit. Every one of the five statements is a structural consequence of Equation (101.35) plus the observation that the two bases differ.

101.6 Neutral currents and the intermediate bosons

101.6.1 The intermediate vector boson hypothesis

Fermi's contact term was always understood as an approximation. The electromagnetic interaction it was modelled on is not a contact term: two currents are joined by a photon, and the interaction has infinite range because the photon is massless. Yukawa's insight [765], made for the nuclear force, was that the range of an exchange force is set by the mass of what is exchanged.

Proposition 101.65 (Range and mass)**.** *A field ϕ obeying the Klein–Gordon equation with mass M and a static point source produces the potential*

$$V(r) \propto \frac{\mathrm{e}^{-r/R}}{r}\,, \qquad R = \frac{\hbar}{Mc}\,, \tag{101.69}$$

so an interaction of observed range R requires a quantum of mass $M = \hbar/Rc$; equivalently, a momentum transfer q small compared with Mc cannot resolve the exchange and the interaction appears pointlike.

Rests on Equation (101.6).

Proof. *Derives Proposition 101.65.*

The static field equation is $\left(\nabla^2 - (Mc/\hbar)^2\right)\phi = -g\,\delta^3(\boldsymbol{x})$, whose spherically symmetric solution is obtained by writing $\phi = u(r)/r$, giving $u'' = (Mc/\hbar)^2 u$ and hence $u \propto \mathrm{e}^{-Mcr/\hbar}$ for the solution decaying at infinity. In momentum space the same statement is that the propagator is $\left[q^2 + (Mc)^2\right]^{-1}$ in the Euclidean region, which for $q \ll Mc$ is the constant $(Mc)^{-2}$: the propagator loses all memory of the momentum transfer, and the amplitude reduces to a product of two currents at one point, which is Equation (101.6). That is why Fermi's theory works, and it also says exactly how well: the neglected terms are of relative order $q^2/(Mc)^2$. □

The weak interaction has no measurable range, which by Proposition 101.65 means a very heavy quantum; but that argument alone gives only a lower bound. The quantitative statement comes from G_F itself, and requires knowing the coupling of the current to the boson. Glashow supplied the structure in 1961 [1206]: the charged currents $J_1^\mu \pm \mathrm{i}J_2^\mu$ of Equation (101.35) do not close on themselves under commutation but generate a third, *neutral* current, so a gauge theory of the weak interaction must have a group at least as large as SU(2), and once the electromagnetic U(1) is included the smallest possibility is

$\mathrm{SU(2)_L \times U(1)_Y}$. Weinberg [1362] and Salam [1381] completed it with the mechanism that gives the bosons mass, and 't Hooft proved that the result is renormalizable [1448, 1463] — which is what made the whole construction believable, since without that proof it would have been no better off than the theory it replaced. The derivations belong to Chapter 104; what is needed here is the structure of the couplings and their SI dimensions.

Definition 101.66 (The electroweak couplings in SI)**.** Let W_μ^a $(a = 1, 2, 3)$ and B_μ be the gauge fields of $\mathrm{SU(2)_L}$ and $\mathrm{U(1)}_Y$, each of the dimension of the electromagnetic four-potential, V s/m, and let the covariant derivative be

$$D_\mu = \partial_\mu + \frac{\mathrm{i}}{\hbar}\left(g\, W_\mu^a T^a + g'\, B_\mu \frac{Y}{2}\right), \tag{101.70}$$

in exact parallel with Equation (100.9). Then g and g' carry the dimension of *electric charge*, C, and the dimensionless couplings are

$$\alpha_W = \frac{g^2}{4\pi\varepsilon_0\hbar c}, \qquad \alpha' = \frac{g'^2}{4\pi\varepsilon_0\hbar c}, \tag{101.71}$$

built exactly as α is in Equation (100.3). The generators are $T^a = \frac{1}{2}\sigma^a$ acting on left-chiral doublets and zero on right-chiral singlets, and Y is the weak hypercharge.

Proposition 101.67 (The mixing angle and the fermion couplings)**.** *Let the neutral fields be rotated by an angle θ_W,*

$$W_\mu^3 = \cos\theta_W\, Z_\mu + \sin\theta_W\, A_\mu, \qquad B_\mu = -\sin\theta_W\, Z_\mu + \cos\theta_W\, A_\mu. \tag{101.72}$$

Requiring A_μ to couple to the electric charge Q and to nothing else fixes

$$e = g\sin\theta_W = g'\cos\theta_W, \qquad Q = T^3 + \frac{Y}{2}, \tag{101.73}$$

and then Z_μ couples to

$$\frac{e}{\sin\theta_W\cos\theta_W}\left(T^3 - \sin^2\theta_W\, Q\right) = \frac{g}{2\cos\theta_W}\,\gamma^\mu\left(g_V - g_A\gamma^5\right), \tag{101.74}$$

with, for each fermion,

$$g_V = T^3 - 2Q\sin^2\theta_W, \qquad g_A = T^3, \tag{101.75}$$

T^3 being the third component of weak isospin of the fermion's left-chiral *part. Also $\alpha_W = \alpha/\sin^2\theta_W$.*

Rests on Equation (101.70).

Proof. *Derives Proposition 101.67.*

Substituting Equation (101.72) into the neutral part of Equation (101.70), the coefficient of A_μ is $g\sin\theta_W T^3 + g'\cos\theta_W Y/2$. For this to be proportional to a single generator Q — which is what it means for the photon to couple to electric charge — the two coefficients must agree, $g\sin\theta_W = g'\cos\theta_W =: e$, and then the coefficient is $e\,(T^3 + Y/2)$, giving Equation (101.73). The coefficient of Z_μ is $g\cos\theta_W T^3 - g'\sin\theta_W Y/2$, which on eliminating g and g' in favour of e and substituting $Y/2 = Q - T^3$ becomes

$$\frac{e}{\sin\theta_W\cos\theta_W}\left[\cos^2\theta_W T^3 - \sin^2\theta_W\left(Q - T^3\right)\right] = \frac{e}{\sin\theta_W\cos\theta_W}\left(T^3 - \sin^2\theta_W Q\right).$$

Since T^3 acts only on the left-chiral part, write $T^3 \to T^3 P_\mathrm{L} = \frac{1}{2}T^3\,(\mathbb{1} - \gamma^5)$; then $T^3 P_\mathrm{L} - \sin^2\theta_W Q = \frac{1}{2}\left[(T^3 - 2Q\sin^2\theta_W) - T^3\gamma^5\right]$, which with $e/\sin\theta_W = g$ is Equation (101.74) and Equation (101.75). Finally $e = g\sin\theta_W$ squared and divided by $4\pi\varepsilon_0\hbar c$ gives $\alpha = \alpha_W\sin^2\theta_W$. □

Proposition 101.68 (The low-energy limit reproduces Fermi)**.** *Let the charged-current interaction be*

$$\mathcal{L}_{\mathrm{CC}} = -\frac{gc}{2\sqrt{2}}\left[\bar{\psi}_\nu \gamma^\mu \left(\mathbb{1} - \gamma^5\right)\psi_\ell \, W_\mu^+ + h.c.\right], \tag{101.76}$$

and let the W propagator be that of a massive vector field,

$$\widetilde{D}^W_{\mu\nu}(q) = \frac{-\mathrm{i}\mu_0\hbar^3 c}{q^2 - M_W^2c^2 + \mathrm{i}\epsilon}\left(\eta_{\mu\nu} - \frac{q_\mu q_\nu}{M_W^2c^2}\right), \tag{101.77}$$

which is Equation (100.17) with the mass restored. Then for $|q^2| \ll M_W^2c^2$ the exchange of a W between two such currents is indistinguishable from Equation (101.46) with

$$\frac{G_F}{\sqrt{2}} = \frac{g^2\mu_0\hbar^2}{8M_W^2}, \qquad \textit{equivalently} \qquad \frac{G_F}{\sqrt{2}\,(\hbar c)^3} = \frac{\pi\alpha_W}{2\,(M_Wc^2)^2} = \frac{\pi\alpha}{2\sin^2\theta_W\,(M_Wc^2)^2}. \tag{101.78}$$

Rests on Equations (100.17) and (101.46) and Proposition 100.14.

Proof. *Derives Proposition 101.68.*

The vertex factor read off Equation (101.76) by the rule of Proposition 100.14 — expand $\exp(\mathrm{i}S/\hbar)$ with $S = c^{-1}\int \mathrm{d}^4x\,\mathcal{L}$ — is $-\mathrm{i}g\gamma^\mu(\mathbb{1}-\gamma^5)/2\sqrt{2}\hbar$, of the same SI dimension $\mathrm{C}/(\mathrm{J\,s})$ as the QED vertex Equation (100.24), since g is a charge by Definition 101.66. Two vertices joined by Equation (101.77) contribute, in the limit $q^2 \to 0$,

$$\left(\frac{-\mathrm{i}g}{2\sqrt{2}\hbar}\right)^2 \frac{-\mathrm{i}\mu_0\hbar^3 c\,\eta_{\mu\nu}}{q^2 - M_W^2c^2} \;\longrightarrow\; -\frac{\mathrm{i}g^2\mu_0\hbar}{8M_W^2c}\,\eta_{\mu\nu},$$

the $q_\mu q_\nu$ term being dropped because it is contracted with currents of light external fermions, on which it gives a factor $m_\ell c/M_Wc$ squared by the argument of Equation (100.18). The contact interaction Equation (101.46), treated the same way, contributes $-\mathrm{i}G_F/\sqrt{2}\hbar c$ times the same spinor structure. Setting the two equal,

$$\frac{G_F}{\sqrt{2}\,\hbar c} = \frac{g^2\mu_0\hbar}{8M_W^2c},$$

which is the first form of Equation (101.78). For the second, substitute $g^2 = 4\pi\varepsilon_0\hbar c\,\alpha_W$ from Equation (101.71) and $\mu_0 = 1/\varepsilon_0c^2$:

$$\frac{G_F}{\sqrt{2}} = \frac{4\pi\varepsilon_0\hbar c\,\alpha_W\hbar^2}{8M_W^2\varepsilon_0c^2} = \frac{\pi\alpha_W\hbar^3}{2M_W^2c},$$

and dividing by $(\hbar c)^3$ gives $\pi\alpha_W/2\,(M_Wc^2)^2$. The dimensional check is worth doing once: $g^2\mu_0\hbar^2/M_W^2$ carries $\mathrm{C}^2 \times \mathrm{kg\,m/C}^2 \times \mathrm{J}^2\,\mathrm{s}^2/\mathrm{kg}^2 = \mathrm{J\,m}^3$, which is Equation (101.7). □

Remark 101.69 (The problem has moved, not gone). Equation (101.78) contains two unknowns where Fermi's theory had one, and it makes the dimensionful G_F into the ratio of a dimensionless coupling to a mass. That is progress only if the mass is itself explained, and *a massive vector field is not innocent*: the term $\frac{1}{2}M^2W_\mu W^\mu$ is not invariant under the gauge transformation Equation (100.8), and the $q_\mu q_\nu/M^2c^2$ in Equation (101.77) does not fall off at large q, which destroys the power counting of Theorem 100.17 exactly as G_F does. Inserting the boson by hand therefore buys a finite range and loses renormalizability. What buys both is spontaneous breaking of a gauge symmetry, and that is the subject of Chapter 104; 't Hooft's theorems [1448, 1463] are the statement that it works.

101.6.2 Gargamelle and the weak neutral current

The most immediate prediction of Proposition 101.67 is that a fourth current exists, coupling to the Z, which changes neither charge nor flavour. Nothing in Fermi's theory contains such a thing — the observed weak processes all involve a charge change — so its existence or absence was a decisive test.

Proposition 101.70 (The effective neutral-current interaction)**.** *At $|q^2| \ll M_Z^2 c^2$, and given the tree-level relation $M_W = M_Z \cos\theta_W$ of Phenomenon 104.35, the neutral-current interaction of a neutrino with a fermion f is*

$$\mathcal{L}_{\mathrm{NC}} = -\frac{G_F}{\sqrt{2}} \left[\bar{\psi}_\nu \gamma^\alpha \left(\mathbb{1} - \gamma^5\right) \psi_\nu\right] \left[\bar{\psi}_f \gamma_\alpha \left(g_V^f - g_A^f \gamma^5\right) \psi_f\right] , \tag{101.79}$$

with the same *G_F as the charged current and the couplings of Equation (101.75). The neutral-current strength is therefore not a new parameter; the only new number is $\sin^2\theta_W$.*

Rests on Proposition 101.68 and Equations (101.74) and (101.75).

Proof. *Derives Proposition 101.70.*

Repeat the matching of Proposition 101.68 with the Z vertex $-\mathrm{i}g\gamma^\mu(g_V - g_A\gamma^5)/2\hbar\cos\theta_W$ of Equation (101.74) and the Z propagator, which is Equation (101.77) with $M_W \to M_Z$. The effective coefficient is $(g/2\cos\theta_W)^2\,\mu_0\hbar^2/M_Z^2$ times the two current structures. For the neutrino, $T^3 = +\frac{1}{2}$ and $Q = 0$ give $g_V^\nu = g_A^\nu = \frac{1}{2}$ by Equation (101.75), so its factor $\frac{1}{2}(\mathbb{1} - \gamma^5)$ contributes an extra $\frac{1}{2}$. Hence the coefficient is

$$\frac{1}{2} \cdot \frac{g^2 \mu_0 \hbar^2}{4\cos^2\theta_W M_Z^2} = \frac{g^2\mu_0\hbar^2}{8M_W^2} = \frac{G_F}{\sqrt{2}} ,$$

using $M_Z^2\cos^2\theta_W = M_W^2$ and then Equation (101.78). Two independent factors have conspired: the Z is heavier than the W, which weakens the interaction, and it couples more strongly by $1/\cos\theta_W$, which strengthens it by exactly the same amount. That the two cancel is the content of the relation $\rho = 1$ of Equation (104.45), and it is a prediction of the doublet structure of the symmetry breaking rather than a fitted coincidence. □

Proposition 101.71 (Neutrino–electron elastic scattering)**.** *For $E_\nu \gg m_e c^2$, with the squared centre-of-mass energy $E_{\mathrm{cm}}^2 = 2m_e c^2 E_\nu$ for a neutrino of laboratory energy E_ν on an electron at rest,*

$$\sigma\left(\nu_\mu e^- \to \nu_\mu e^-\right) = \frac{G_F^2 E_{\mathrm{cm}}^2}{\pi\left(\hbar c\right)^4}\left(g_L^2 + \frac{g_R^2}{3}\right) , \qquad \sigma\left(\bar{\nu}_\mu e^- \to \bar{\nu}_\mu e^-\right) = \frac{G_F^2 E_{\mathrm{cm}}^2}{\pi\left(\hbar c\right)^4}\left(g_R^2 + \frac{g_L^2}{3}\right) , \tag{101.80}$$

with $g_L = \frac{1}{2}(g_V + g_A) = -\frac{1}{2} + \sin^2\theta_W$ and $g_R = \frac{1}{2}(g_V - g_A) = \sin^2\theta_W$ for the electron. The ratio to the charged-current process Equation (101.60) is $g_L^2 + g_R^2/3$, which for $\sin^2\theta_W = 0.231$ is 0.090.

Rests on Equations (101.60) and (101.79).

Proof. *Derives Proposition 101.71.*

Split the electron current into its chiral parts, $g_V - g_A\gamma^5 = g_L\left(\mathbb{1} - \gamma^5\right) + g_R\left(\mathbb{1} + \gamma^5\right)$, which is the definition of g_L and g_R. The g_L piece is Equation (101.46) with a different coefficient, so Equation (101.60) applies to it directly and gives an isotropic cross-section proportional to g_L^2.

The g_R piece requires one new ingredient, and it is angular momentum rather than algebra. In the centre-of-mass frame let the neutrino move along $+\hat{\boldsymbol{z}}$. It is left-handed, so $S_z^\nu = -\frac{1}{2}$. A left-chiral electron moving along $-\hat{\boldsymbol{z}}$ has its spin along $+\hat{\boldsymbol{z}}$, $S_z^e = +\frac{1}{2}$, so the pair has $J_z = 0$ and can be in a $J = 0$ state: the amplitude may be isotropic, and is. A right-chiral electron moving along $-\hat{\boldsymbol{z}}$ has $S_z^e = -\frac{1}{2}$, so $J_z = -1$ and the state must have $J \geq 1$; the

amplitude is then proportional to the rotation matrix element $d^{1}_{-1,-1}(\theta^{*}) = \tfrac{1}{2}\,(1+\cos\theta^{*})$, which vanishes in the backward direction because a backward scatter would reverse J_z without anything to absorb the two units. Hence

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\cos\theta^{*}} \propto g_L^2 + g_R^2 \left(\frac{1+\cos\theta^{*}}{2}\right)^2 , \tag{101.81}$$

and integrating over $\cos\theta^{*} \in [-1,1]$ gives $2g_L^2$ and $2g_R^2/3$ respectively, which is the factor $g_L^2 + g_R^2/3$ in Equation (101.80) once the normalization is fixed against Equation (101.60). For the antineutrino every helicity reverses, so g_L and g_R exchange roles. Numerically, at $\sin^2\theta_W = 0.231$, $g_L = -0.269$ and $g_R = 0.231$, giving 0.0901 for the neutrino and 0.0775 for the antineutrino, and

$$\sigma\left(\nu_\mu e^- \to \nu_\mu e^-\right) = 1.55{\times}10^{-46}\,\mathrm{m}^2 {\times} \frac{E_\nu}{1\,\mathrm{GeV}}\,, \qquad \sigma\left(\bar\nu_\mu e^- \to \bar\nu_\mu e^-\right) = 1.34{\times}10^{-46}\,\mathrm{m}^2 {\times} \frac{E_{\bar\nu}}{1\,\mathrm{GeV}}\,,$$

which is the size of the signal Gargamelle was looking for. Note that the g_V and g_A enter the two cross-sections in different combinations, so measuring both determines the sign of g_A as well as the value of $\sin^2\theta_W$ — a single measurement would not. □

Phenomenon 101.72 (Neutrinos scatter without becoming charged leptons)**.** A muon neutrino can transfer energy and momentum to matter and leave the apparatus still a neutrino. Both the leptonic channel $\bar\nu_\mu e^- \to \bar\nu_\mu e^-$ [1503] and the hadronic channel $\nu_\mu N \to \nu_\mu X$ [1502] were seen in the Gargamelle bubble chamber as events carrying hadrons or a recoil electron but no outgoing muon, at a rate a substantial fraction of the charged-current rate. Such a current changes neither electric charge nor flavour, and Fermi's theory contains nothing of the kind.

Rests on Propositions 101.70 and 101.71 and Phenomenon 101.5.

Derivation. *Derives Phenomenon 101.72.*

That the process exists at all is Proposition 101.70: a gauge theory containing the observed charged currents cannot avoid a neutral one, because the commutator of the two charged generators is a third generator. That it occurs at the observed *rate* is Proposition 101.71 applied to the leptonic channel Gargamelle actually saw, which was the *antineutrino* one: its predicted cross-section per unit beam energy is $1.34 \times 10^{-46}\,\mathrm{m}^2/\mathrm{GeV}$ at $\sin^2\theta_W = 0.231$, the neutrino channel being the larger of the two at $1.55 \times 10^{-46}\,\mathrm{m}^2/\mathrm{GeV}$. Gargamelle recorded a single such event in the whole exposure, which was the entire leptonic sample and which no background could produce, since an electron recoiling almost exactly along the beam direction with nothing else in the chamber has no other source [1503]. The hadronic channel supplied the statistics: some hundreds of muonless events, with a ratio to the charged-current rate of roughly one to five [1502].

The obstacle was background, and it is worth recording because the signal is defined by an absence. A neutron entering the chamber from the surrounding material produces hadrons and no muon, which is exactly the signature. The argument that settled it was the *spatial distribution*: neutrons are attenuated as they penetrate the liquid, so a neutron-induced sample is concentrated near the walls and falls off with depth, whereas a neutrino-induced sample is uniform because the chamber is transparent to neutrinos by Phenomenon 101.5. The observed distribution was flat. The same reasoning applied to the ratio of muonless to muonful events as a function of position gave a rate that could not be produced by neutrons at any plausible flux. □

Derivation pending #147

The hadronic neutral-current ratio: the prediction for the ratio of neutral-current to charged-current rates on an isoscalar nuclear target, which is what the Gargamelle hadronic sample actually measured. It requires the quark-parton content of the nucleon and the quark neutral-current couplings derived in this section, and therefore belongs with the deep-inelastic material rather than here; the leptonic ratio, which needs nothing beyond this chapter, is derived above.

101.6.3 Discovery of the W and Z

The bosons themselves were produced ten years later. The difficulty was energy: Equation (101.78) predicted masses near $80\,\mathrm{GeV}/c^2$ and $90\,\mathrm{GeV}/c^2$, and no machine reached the required centre-of-mass energy. Rubbia's proposal was to convert the CERN Super Proton Synchrotron into a proton — antiproton collider, which requires no second ring but does require enough antiprotons; van der Meer's stochastic cooling supplied them [1760], by sensing the deviation of a sample of the beam at one point in the ring and applying a correcting kick at another, thereby reducing the phase-space volume of a stored beam — an operation that looks at first sight like a violation of Liouville's theorem and is not, because the feedback system carries away the entropy.

Phenomenon 101.73 (The weak interaction is carried by heavy bosons)**.** Two massive vector particles are produced in $p\bar{p}$ collisions and observed as resonances: the W, as an isolated high-transverse-momentum electron recoiling against missing transverse energy [1710, 1714], and the Z, as a narrow peak in the invariant mass of charged lepton pairs [1711, 1713]. Their masses are

$$M_W c^2 = 80.37\,\mathrm{GeV}\,, \qquad M_Z c^2 = 91.1880\,\mathrm{GeV} \tag{101.82}$$

[2427]. Because these are enormous compared with the energy released in any nuclear decay, the exchange is indistinguishable from a contact interaction at every energy at which beta decay was ever studied.

Rests on Equation (101.78) and Propositions 100.63 and 101.71.

Derivation. *Derives Phenomenon 101.73.*

The masses were predicted before they were measured, from two quantities determined in entirely different experiments. Inverting Equation (101.78),

$$\left(M_W c^2\right)^2 = \frac{\pi\alpha}{\sqrt{2}\sin^2\theta_W}\cdot\frac{(\hbar c)^3}{G_F}\,, \tag{101.83}$$

and inserting $G_F/(\hbar c)^3 = 1.166\,378\,7\times10^{-5}/\mathrm{GeV}^2$ from the muon lifetime, $\alpha^{-1} = 127.95$ at this scale from Proposition 100.63, and $\sin^2\theta_W = 0.2312$ from the neutral-current measurements of Proposition 101.71 and Phenomenon 104.55,

$$\left(M_W c^2\right)^2 = \frac{\pi\,(1/127.95)}{\sqrt{2}\,(0.2312)\,(1.166\,378\,7\times10^{-5})}\,\mathrm{GeV}^2 = 6438\,\mathrm{GeV}^2\,,$$

that is $M_W c^2 = 80.2\,\mathrm{GeV}$, and $M_Z = M_W/\cos\theta_W$ gives $M_Z c^2 = 91.5\,\mathrm{GeV}$. The measured values are Equation (101.82): the tree-level prediction is right to a few parts in a thousand, the residual being the electroweak radiative correction that Section 101.6.4 turns into a measurement in its own right.

Read the other way, the same relation shows why Fermi's contact theory worked so well for so long. Writing $Q^2 = -q^2c^2$ for the squared four-momentum transfer measured as a

squared energy, the exchange contributes the propagator factor $\left[Q^2 + (M_W c^2)^2\right]^{-1}$, and in a nuclear decay Q is a few MeV, so the neglected ratio $Q^2/(M_W c^2)^2$ is of order 10^{-9}. The corresponding range is $\hbar/M_W c = 2.5 \times 10^{-18}\,\mathrm{m}$, a thousandth of the diameter of a proton, which is why no experiment before 1983 had resolved the exchange. Where it must fail is at Q approaching $M_W c^2$, which is the unitarity problem of Section 101.7.1. □

Remark 101.74 (Why the W has no mass peak and the Z does). The difference is kinematic. The Z decays to e^+e^- or $\mu^+\mu^-$, both measured, so the invariant mass of the pair is formed directly and the Z is a peak in it [1711, 1713]. The W decays to a charged lepton and a neutrino, which is not measured, and at a hadron collider the longitudinal balance is unusable because the colliding partons carry unknown longitudinal momenta and most of the debris escapes down the beam pipe. The transverse balance is usable, the initial transverse momentum being zero: the vector sum of the observed transverse momenta, negated, is the neutrino's. The variable that then carries the mass is the transverse mass

$$M_{\mathrm{T}}^2 c^4 = 2 p_{\mathrm{T}}^{\ell} c\, p_{\mathrm{T}}^{\nu} c\,(1 - \cos\Delta\varphi)\ , \tag{101.84}$$

with $\Delta\varphi$ the azimuthal angle between the two. It satisfies $M_{\mathrm{T}} \le M_W$, with equality for a transverse decay, so its distribution has a sharp edge at M_W — a Jacobian peak, from the vanishing of $\mathrm{d}M_{\mathrm{T}}/\mathrm{d}\theta^*$ there — and equivalently the lepton's own transverse-momentum spectrum has an edge at $M_W c/2$. UA1 and UA2 report exactly this: isolated electrons of $p_{\mathrm{T}} \approx 40\,\mathrm{GeV}/c$ against an equal and opposite missing transverse energy [1710, 1714], which is still, forty years later, the operational signature of a neutrino and of anything else that leaves a detector without interacting.

101.6.4 Precision electroweak measurements

Producing the Z in e^+e^- annihilation, where the initial state is known exactly, converts it from a discovery into a metrological instrument. LEP ran at and around the resonance from 1989 to 1995 and recorded some seventeen million Z decays; the combined analysis of the four experiments [2104] fixes M_Z to two parts in 10^5 and every partial width to a fraction of a per cent. One of those measurements counts particles that were never detected.

Proposition 101.75 (Ratios of Z partial widths)**.** *For final-state fermions light compared with the Z,*

$$\frac{\Gamma\left(Z \to f\bar{f}\right)}{\Gamma\left(Z \to f'\bar{f}'\right)} = \frac{N_c^f \left[\left(g_V^f\right)^2 + \left(g_A^f\right)^2\right]}{N_c^{f'} \left[\left(g_V^{f'}\right)^2 + \left(g_A^{f'}\right)^2\right]}\ , \tag{101.85}$$

with $N_c = 1$ for leptons and 3 for quarks. In absolute terms

$$\Gamma\left(Z \to f\bar{f}\right) = \frac{N_c^f}{6\sqrt{2}\pi\hbar}\,\frac{G_F}{(\hbar c)^3}\left(M_Z c^2\right)^3 \left[\left(g_V^f\right)^2 + \left(g_A^f\right)^2\right]\ . \tag{101.86}$$

Rests on Equations (101.48) and (101.74) and Lemma 101.47.

Proof. *Derives Proposition 101.75.*

By Equation (101.48) the width is $(c^2/2M_Z c^2)\int \overline{|\mathcal{M}|^2}\,\mathrm{d}\Phi_2$, and for massless final states $\int \mathrm{d}\Phi_2 = 1/8\pi\hbar^2$ by Lemma 101.47. The squared amplitude, summed over final spins and averaged over the three Z polarizations, involves the trace

$$T^{\mu\nu} = \mathrm{tr}\left[\gamma\cdot p'\,\gamma^\mu\left(g_V - g_A\gamma^5\right)\gamma\cdot p\,\gamma^\nu\left(g_V - g_A\gamma^5\right)\right]\ ,$$

contracted with the polarization sum $\sum_\lambda \varepsilon_\mu^*\varepsilon_\nu = -\eta_{\mu\nu} + q_\mu q_\nu/M_Z^2 c^2$. Moving the first factor $(g_V - g_A\gamma^5)$ rightwards through $\gamma\cdot p$ and then through γ^ν — each passage flipping the sign

of the γ^5 term — collects the two into $(g_V - g_A\gamma^5)^2 = g_V^2 + g_A^2 - 2g_V g_A\gamma^5$. The γ^5 piece produces a Levi-Civita tensor, antisymmetric in $\mu\nu$, which vanishes against the symmetric polarization sum. Hence the entire dependence on the fermion species is the factor $g_V^2 + g_A^2$, together with the colour multiplicity N_c, and Equation (101.85) follows without evaluating anything else. Carrying the remaining common factor through, with the coupling $g/2\cos\theta_W$ of Equation (101.74) re-expressed through Equation (101.78) and $M_W = M_Z\cos\theta_W$, gives Equation (101.86). As a check, for a neutrino $g_V = g_A = \frac{1}{2}$ and Equation (101.86) gives, as an energy width,

$$\hbar\Gamma_{\nu\bar{\nu}} = \frac{(1.166\,378\,7\times10^{-5})\,(91.1880)^3\,(0.5)}{6\sqrt{2}\pi}\,\text{GeV} = 166\,\text{MeV}\,,$$

against the measured 167.2 MeV [2104]: a tree-level formula good to one per cent, the difference being the radiative corrections. Widths are quoted throughout as energies, $\hbar\Gamma$, which is the convention of the source; the rate itself is Γ and carries 1/s. □

Phenomenon 101.76 (There are three light neutrino species)**.** The Z resonance is wider than the sum of its visible decay channels, and the invisible remainder counts the neutrino species light enough for the Z to decay into. The first scan already gave three to within a few per cent [1819]; the final four-experiment combination gives

$$N_\nu = 2.984 \pm 0.008 \tag{101.87}$$

[2104]. A fourth generation with a neutrino lighter than $M_Z c^2/2$ is excluded at more than fifteen standard deviations.

Rests on Equations (101.75) *and* (101.85).

Derivation. *Derives Phenomenon 101.76.*

Measure the total width Γ_Z from the shape of the resonance in $e^+e^- \to$ anything visible, the hadronic width from the hadronic cross-section, and the leptonic width from the lepton-pair cross-sections. The invisible width is the difference, $\Gamma_{\text{inv}} = \Gamma_Z - \Gamma_{\text{had}} - 3\Gamma_{\ell\ell}$. Then

$$N_\nu = \frac{\Gamma_{\text{inv}}}{\Gamma_{\ell\ell}}\left(\frac{\Gamma_{\ell\ell}}{\Gamma_{\nu\bar{\nu}}}\right)_{\text{SM}}\,, \tag{101.88}$$

which is arranged so that the absolute normalization of Equation (101.86) cancels and only the ratio Equation (101.85) is needed. That ratio is pure algebra: for the neutrino $g_V = g_A = \frac{1}{2}$ gives $g_V^2 + g_A^2 = \frac{1}{2}$, while for a charged lepton $T^3 = -\frac{1}{2}$ and $Q = -1$ give, by Equation (101.75), $g_A = -\frac{1}{2}$ and $g_V = -\frac{1}{2} + 2\sin^2\theta_W = -0.0376$ at $\sin^2\theta_W = 0.23122$, so $g_V^2 + g_A^2 = 0.2514$ and

$$\left(\frac{\Gamma_{\nu\bar{\nu}}}{\Gamma_{\ell\ell}}\right)_{\text{SM}} = \frac{0.5}{0.2514} = 1.989\,.$$

The measured ratio is $\Gamma_{\text{inv}}/\Gamma_{\ell\ell} = 5.943\pm0.016$ [2104], whence $N_\nu = 5.943/1.989 = 2.988$, and the full treatment with radiative corrections gives Equation (101.87). The near-cancellation of g_V for the charged lepton — $-\frac{1}{2} + 2(0.231)$ is small because $\sin^2\theta_W$ happens to lie near $\frac{1}{4}$ — is why $\Gamma_{\ell\ell}$ is almost exactly half $\Gamma_{\nu\bar{\nu}}$, and it is a numerical accident with no significance beyond making the arithmetic memorable.

Two caveats belong with the number. It counts only neutrinos with $m_\nu < M_Z/2$ that couple to the Z with standard strength: a heavier or a sterile neutrino is invisible to this measurement, and Chapter 103 records what other evidence says about those. And it is a *counting* measurement whose result is not an integer, 2.984 ± 0.008; the deficit below three is about two standard deviations and is understood as a residual effect in the Bhabha-scattering normalization, which is exactly the kind of statement Chapter 11 is needed to assess. □

The rest of the LEP programme, and the SLC programme beside it, turned the same resonance into a test of the theory's quantum corrections. The weak mixing angle is measured in half a dozen mutually independent ways — from the forward–backward asymmetries of the Z decays, from the left–right asymmetry with a polarized electron beam, from neutrino–nucleon scattering, from parity violation in atomic caesium [1519], and from polarized electron–deuteron scattering [1625], whose apparatus is Chapter 110 — at momentum transfers spanning six orders of magnitude, and one running, scheme-defined angle describes them all [2427]. That consistency, and not any single number, is the measurement. One entry does not fit — a measurement of the W mass sitting several standard deviations from the rest of the electroweak fit — and it is recorded here, because it is unresolved and this is the chapter that owns the quantity. Chapter 133 is not the place to look for it: that chapter collects the observations with no theoretical explanation at all — the flavour hierarchy, the strong CP problem, dark matter, dark energy, the baryon asymmetry — and does not treat the electroweak fit.

101.7 Why Fermi theory had to be replaced

101.7.1 Unitarity violation

Proposition 101.7 said that G_F carries $\mathrm{J\,m^3}$, so that the dimensionless number governing a weak amplitude at energy E is $G_F E^2/(\hbar c)^3$. A dimensionless expansion parameter that grows with energy is a theory with an expiry date, and the date can be computed.

Phenomenon 101.77 (The contact cross-section grows without bound)**.** The measured cross-section for neutrino scattering rises linearly with the beam energy from 1 MeV to several hundred GeV, as Equation (101.60) requires. The linear rise is a statement about a range and not about all energies, and the range is fixed by this chapter's own formulae: Equation (101.60) is the $M_W \to \infty$ limit, and restoring the W propagator of Equation (101.77) damps the growth once the momentum transfer approaches $M_W c$. For a nucleon target $E_{\mathrm{cm}}^2 = 2m_N c^2 E_\nu$, so the linear regime is $E_\nu \ll (M_W c^2)^2/2m_N c^2 = 3.4\,\mathrm{TeV}$; already at the top of the accelerator range, $E_\nu = 350\,\mathrm{GeV}$, the ratio $E_{\mathrm{cm}}^2/(M_W c^2)^2$ has reached 0.10 and the neglect is no longer safe. The departure is itself observed, in the momentum-transfer dependence of deep-inelastic neutrino scattering (Chapter 116).

Rests on Equations (101.60) *and* (101.77) *and Proposition 101.54.*

Derivation. *Derives Phenomenon 101.77.*

This is Proposition 101.54: the cross-section is $G_F^2 E_{\mathrm{cm}}^2/\pi(\hbar c)^4$, and $E_{\mathrm{cm}}^2 = 2m_{\mathrm{target}} c^2 E_{\mathrm{beam}}$ for a fixed target, so σ is proportional to the beam energy. The growth is not a defect of the calculation but a consequence of the dimension of the coupling: with only G_F, $\hbar$, c and E_{cm} available, and σ an area, the answer must be $G_F^2 E_{\mathrm{cm}}^2/(\hbar c)^4$ times a pure number. Restoring the propagator replaces this by $\sigma \propto G_F^2 E_{\mathrm{cm}}^2/\left[1 + E_{\mathrm{cm}}^2/(M_W c^2)^2\right]$, which stops rising once E_{cm} reaches $M_W c^2$ and tends to the constant $G_F^2 (M_W c^2)^2$ instead; the turnover is the direct observation of the propagator, and hence of the W in a scattering experiment rather than as a resonance. □

Theorem 101.78 (The contact theory violates unitarity)**.** *Probability conservation bounds a cross-section proceeding through a single partial wave J by*

$$\sigma_J \le \frac{4\pi\,(2J+1)}{k^2}\,, \qquad k = \frac{|\boldsymbol{p}|}{\hbar} = \frac{E_{\mathrm{cm}}}{2\hbar c} \quad \textit{(massless)}\,, \tag{101.89}$$

that is $\sigma_{J=0} \le 16\pi(\hbar c)^2/E_{\mathrm{cm}}^2$. Equation (101.60) *is pure $J = 0$ and grows as E_{cm}^2, so it breaches the bound at*

$$E_{\mathrm{cm}} = \left(16\pi^2 \frac{(\hbar c)^6}{G_F^2}\right)^{1/4} = 1.04\,\mathrm{TeV}\,, \tag{101.90}$$

and the theory is inconsistent above it.
Rests on Equation (101.60) and Proposition 101.54.

Proof. *Derives Theorem 101.78.*

The bound is the statement that the S-matrix is unitary. Writing the elastic amplitude in partial waves, $f(\theta) = k^{-1}\sum_J (2J+1)a_J P_J(\cos\theta)$, unitarity of $S_J = 1 + 2ia_J$ forces $|a_J| \le 1$, whence $\sigma_J = 4\pi(2J+1)\,|a_J|^2/k^2 \le 4\pi(2J+1)/k^2$; the partial-wave apparatus is that of Chapter 86. That the contact interaction produces only $J=0$ is Proposition 101.54: the cross-section came out isotropic, and an isotropic amplitude is by definition pure s-wave. Setting $G_F^2 E_{\mathrm{cm}}^2/\pi(\hbar c)^4 = 16\pi(\hbar c)^2/E_{\mathrm{cm}}^2$ and solving gives Equation (101.90); with $G_F/(\hbar c)^3 = 1.166\,378\,7\times10^{-5}/\mathrm{GeV}^2$, $E_{\mathrm{cm}}^4 = 16\pi^2/(1.166\,378\,7\times10^{-5})^2\mathrm{GeV}^4$ and $E_{\mathrm{cm}} = 1038\,\mathrm{GeV}$. □

Remark 101.79 (Which number to quote, and why they differ). The scale at which Fermi theory fails is quoted in the literature as anything between 300 GeV and 1 TeV, and the spread is not carelessness: the two ends of the range are different statements.

- Equation (101.90), about 1 TeV, is the energy at which *this particular channel* saturates the $J=0$ bound exactly. It depends on the channel through the spin and colour counting and on the convention for the bound, and moving either shifts it by tens of per cent.
- Equation (101.9), $E_F = \left((\hbar c)^3/G_F\right)^{1/2} = 292.8\,\mathrm{GeV}$, is the energy at which the dimensionless expansion parameter $G_F E^2/(\hbar c)^3$ reaches unity. That is where the perturbative expansion stops converging, which happens before the leading term saturates the bound; it is channel-independent, and it is the number the phrase "a few hundred GeV" refers to.

Both say the same physics: the theory predicts its own replacement, and predicts it at a definite scale. What is remarkable is that the prediction was right — the W was found at $80.4\,\mathrm{GeV}/c^2$, within a factor of a few of E_F, and the Higgs boson at $125\,\mathrm{GeV}/c^2$ (Chapter 113) — and the argument is now the standard template for looking beyond the Standard Model, as Section 101.7.2 records.

Remark 101.80 (The cure, and its cost). Replacing the contact vertex by W exchange cures the growth: by Equation (101.78) the amplitude acquires the factor $(M_W c^2)^2 / \left[Q^2 + (M_W c^2)^2\right]$, so the cross-section stops rising at $Q \sim M_W c^2$ and falls thereafter, and Equation (101.89) is never approached. It does not, however, cure everything: the process $\nu\bar\nu \to W^+W^-$, with longitudinally polarized Ws whose polarization vectors grow as $q^\mu/M_W c$, has an amplitude that again rises with energy, and the cancellation of *that* growth requires the scalar of Chapter 104 and fixes the shape of its couplings. The unitarity argument therefore does not stop at the W; it is what made a Higgs-like state mandatory below about 1 TeV, which is why the LHC was built to that energy and what it found is Chapter 113.

101.7.2 Non-renormalizability and the effective-theory reading

The second failure is not about any particular energy but about the perturbation series itself, and it was diagnosed by Dyson's power counting [928] — the same analysis that established QED to be renormalizable, applied to a different vertex, giving the opposite answer.

Theorem 101.81 (Superficial degree of divergence of the contact theory). *For a connected diagram built from V four-fermion vertices Equation (101.6) with E external fermion lines, the superficial degree of divergence is*

$$D = 4 - \frac{3}{2}E + 2V\,. \tag{101.91}$$

It grows *with the order of perturbation theory, so infinitely many amplitudes diverge and infinitely many counterterms are needed.*

Rests on Equations (100.23), (100.26) *and* (101.6).

Proof. *Derives Theorem 101.81.*

Let L be the number of loops and P the number of internal fermion lines. Each loop contributes $\mathrm{d}^4\ell$ and each internal fermion propagator falls as ℓ^{-1} by Equation (100.23), so $D = 4L - P$. Every vertex has four fermion ends, every internal line uses two and every external line one, giving $4V = 2P + E$; and the number of independent loops is $L = P - V + 1$. Eliminating,

$$D = 4\,(P - V + 1) - P = 3P - 4V + 4 = 3\left(2V - \frac{E}{2}\right) - 4V + 4 = 2V + 4 - \frac{3}{2}E\,,$$

which is Equation (101.91).

The contrast with Equation (100.26) is the whole point. There, $D = 4 - \frac{3}{2}E_e - E_\gamma$ and V cancelled: the degree of divergence is a property of the *amplitude*, not of the order, so only finitely many amplitudes diverge and finitely many parameters absorb them, which is Definition 100.18. Here V does not cancel, and it enters with a positive sign. The four-point function has $E = 4$ and $D = 2V - 2$: convergent at $V = 1$, quadratically divergent at $V = 2$, quartically at $V = 3$, and so on without end. Each new order requires a new counterterm of a new operator structure, and each new counterterm brings a new undetermined constant, so the theory has no predictive power beyond the order at which it is first fitted. □

Corollary 101.82 (The diagnosis is dimensional)**.** *The extra* $2V$ *in Equation* (101.91) *is exactly the* -2 *mass dimension of the coupling, counted once per vertex. A coupling of negative mass dimension is non-renormalizable and a coupling of non-negative mass dimension is not, and no calculation beyond dimensional analysis is required to tell which.*

Rests on Equation (101.91) *and Proposition 101.7.*

Proof. *Derives Corollary 101.82.*

An amplitude of fixed external content has a fixed overall dimension. If a vertex carries a coupling of mass dimension $-\delta$, then V vertices carry $-V\delta$, and the loop integrals must supply $+V\delta$ more powers of momentum to compensate, which is exactly $D \to D + V\delta$. With $\delta = 2$ for G_F this is the $2V$ of Equation (101.91). Conversely the QED coupling $e/\hbar$ has $\delta = 0$ once the $\hbar$'s are counted — which is the content of α being dimensionless, Equation (100.3) — and no such term appears. □

Remark 101.83 (The modern reading: Fermi's theory is not wrong, it is effective)*.* The verdict of Theorem 101.81 was, for thirty years, that Fermi's theory was a stopgap. The modern reading is different, and it is the frame in which every current search for physics beyond the Standard Model is conducted.

Equation (101.6) is the leading term of a systematic expansion. Start from the theory with the W and *integrate out* the heavy field — expand the propagator Equation (101.77) in powers of $q^2/M_W^2c^2$:

$$\frac{1}{q^2 - M_W^2c^2} = -\frac{1}{M_W^2c^2}\left(1 + \frac{q^2}{M_W^2c^2} + \frac{q^4}{M_W^4c^4} + \cdots\right).$$

The leading term is the contact interaction with the coefficient Equation (101.78); the next is a dimension-eight operator with two extra derivatives and two further powers of M_W in the denominator; and so on. The expansion is in E/M_Wc^2, it is systematic, and its accuracy at any energy can be estimated in advance — which is why Fermi's theory reproduces nuclear beta decay with the margin Phenomenon 101.73 computed.

Non-renormalizability is then not a disease but a *measurement*. An operator whose coefficient has mass dimension -2 announces a scale, and that scale is where the description stops: Fermi's coupling announced Equation (101.9), 292.8 GeV, and the W was found at $80.4\,\mathrm{GeV}/c^2$. How such operators mix under a change of scale, and why the leading ones dominate, is Chapter 108.

The same logic now runs in the other direction: the Standard Model is treated as the leading term, and searches are reported as bounds on the coefficients of the higher-dimension operators that could be added to it, equivalently as bounds on a scale Λ. That is how a null result at a collider becomes a quantitative statement, and it is why the failure recorded in this section is now regarded as the most useful thing Fermi's theory ever did.

Remark 101.84 (What this chapter has and has not established). The chapter began with a continuous spectrum and ends with two massive bosons. Everything between was extracted from measurement: the neutrino from kinematics (Phenomenon 101.1), the contact form and the size of the coupling from spectra and lifetimes (Proposition 101.11 and Phenomenon 101.50), the two nuclear couplings from the observed selection rules (Proposition 101.15), the violation of parity from one asymmetry (Phenomenon 101.26), the $V-A$ structure from the size of that asymmetry together with the neutrino helicity (Proposition 101.36 and Phenomenon 101.28), the quark rotation from a deficit in rate (Phenomenon 101.55), a fourth quark from a null result (Theorem 101.59), a third generation from a parameter count (Proposition 101.63), and the neutral current from events with a missing muon (Phenomenon 101.72).

What has *not* been established is why any of it is so. The gauge group was quoted, not derived; the boson masses were matched to G_F, not explained; the mixing angles and the fermion masses are inputs. Those are the business of Chapters 103 and 104 — and, in the case of the mixing parameters, of nobody at present: they are measured numbers with no known origin, recorded as such in Chapter 133 and in the free-parameter count of the appendices.

Chapter 102

Quantum Chromodynamics

Quantum chromodynamics is the gauge theory of colour, and it is the one part of the Standard Model whose defining property — that its elementary fields have never been seen in isolation — makes the evidence for it indirect at every step. This chapter therefore follows the evidence rather than the formalism: the regularities of the hadron spectrum that produced the quark hypothesis, the spin-statistics paradox of the Δ^{++} that forced a threefold colour degree of freedom, the deep inelastic scattering that showed pointlike constituents inside the proton, the three-jet events that made the gluon visible, and the lattice computations that now reproduce the hadron masses from the Lagrangian alone. Only then is the failure to observe a free quark discussed for what it is — a strong empirical regularity supported by a well-tested numerical demonstration, not a theorem.

QCD is the second gauge theory of the part and reuses the entire apparatus of Chapter 100, but two features have no QED analogue and organize everything below. The gluons carry the charge they mediate, so the beta function changes sign: the coupling is weak at short distance — asymptotic freedom, which is why perturbation theory works at all here — and strong at hadronic scales, where it does not, and Chapter 106 together with lattice methods must take over. And the near-masslessness of the lightest quarks gives an approximate chiral symmetry whose spontaneous breaking, not the Higgs mechanism of Chapter 104, supplies about 99 percent of the mass of ordinary matter. Its experimental anchor is Chapter 116; its downstream users are Chapter 107, Chapter 52 and Chapter 49. Standard treatments are [1739, 1933]; data throughout are from [2427].

Units and conventions are those fixed once for the whole part in Section 100.1.1: the metric $\eta_{\mu\nu} = \mathrm{diag}(+1, -1, -1, -1)$ of Notation 100.1, the mass shell $p^2 = m^2c^2$ of Equation (100.1), the action Equation (100.2) carrying an explicit c^{-1}, and $\hbar$ and c written out in every formula. Nothing below is computed in units where they are set to one; Remark 100.4 gives the dictionary for reading this chapter against the literature, which does.

102.1 Hadron spectroscopy and the quark hypothesis

102.1.1 The eightfold way

Between 1947 and 1960 the list of strongly interacting particles grew from a handful to several dozen. The cosmic-ray and accelerator experiments of the period produced the pion, the kaons, the Λ, the Σ and Ξ hyperons and, once the bubble chamber allowed short-lived states to be reconstructed from their decay products, a succession of resonances — the $\Delta(1232)$, the $\Sigma(1385)$, the $\Xi(1530)$, the ρ, the K^*. None of them could be called elementary with a straight face. The response was not to propose constituents but to look for a symmetry, and the symmetry that worked is the one whose group theory is established, as mathematics and with no physics attached, in Section 14.2.2.

Two additive quantum numbers organize the data. The first is *isospin*: the near-equality of the proton and neutron masses, and of the three pion masses, is described by an SU(2) under which (p, n) is a doublet, and its representation theory is that of Chapter 5. The second is *strangeness* S, introduced by Gell-Mann [1017] and independently by Nakano and Nishijima [1024] to account for the fact that the new particles are produced copiously (strong interaction) but decay slowly (weak interaction): S is conserved by the strong interaction and violated by the weak one, so a strange particle can only be produced in pairs and must then wait for a weak decay. Writing the *hypercharge* $Y = B + S$ with B the baryon number, the observed electric charges of every hadron obey

$$\frac{Q}{e} = I_3 + \frac{Y}{2}\,, \tag{102.1}$$

with I_3 the third isospin component. Equation (102.1) is a fact about hundreds of measured charges, not a definition.

The content of the eightfold way, proposed independently by Gell-Mann [1205] and Ne'eman [1216], is that I_3 and Y are the two commuting quantum numbers of a rank-two group, and that the group is SU(3). Proposition 14.50 gives the rank as $\ell = 2$ and the dimension as 8; the two Cartan generators of Definition 14.51 are T_3 and T_8, and the identification with the measured quantum numbers is

$$I_3 = T_3\,, \qquad Y = \frac{2}{\sqrt{3}}\,T_8\,, \tag{102.2}$$

the factor $2/\sqrt{3}$ being fixed once and for all by Equation (14.65). A hadron multiplet is then an irreducible representation, and the weight diagram of that representation — the set of simultaneous eigenvalues of (T_3, T_8), computed as pure mathematics in Equation (14.79) and Equation (14.80) — is a prediction of which charges and strangenesses occur together and how many states there are.

The prediction is sharp and it is met. The eight lightest spin-$\frac{1}{2}$ baryons (p, n, Λ, $\Sigma^{\pm,0}$, $\Xi^{0,-}$) fill the weight diagram of the adjoint representation **8** exactly: six states on a hexagon and two at the centre, which is the count $6 + 2 = 8$ of Remark 14.56. The eight lightest pseudoscalar mesons ($\pi^{\pm,0}$, $K^{\pm}$, K^0, $\bar{K}^0$, η) fill a second copy of the same diagram. The nine lightest spin-$\frac{3}{2}$ baryons known in 1961 fill nine of the ten places of a decuplet, and the tenth place is the subject of Section 102.1.2.

Phenomenon 102.1 (Hadron masses obey an octet mass formula)**.** Within a multiplet the masses are not equal — SU(3) is broken by the strange quark mass — but the breaking is not arbitrary. For the $J^P = \frac{1}{2}^+$ baryon octet the measured masses satisfy the Gell-Mann–Okubo relation [1205, 1240]

$$2\,(M_N + M_\Xi) = 3M_\Lambda + M_\Sigma \tag{102.3}$$

to better than one percent, and for the $J^P = \frac{3}{2}^+$ decuplet the masses are equally spaced in hypercharge to within a few percent.

Rests on Theorem 5.153 and Equations (14.69) *and* (14.70).

Derivation. *Derives Phenomenon 102.1.*

Write the strong Hamiltonian as $H = H_0 + H_1$, with H_0 SU(3)-symmetric and H_1 the symmetry-breaking piece. The breaking comes from the quark mass term of Section 102.3.3, which for $m_u = m_d \neq m_s$ splits into a piece proportional to the identity — absorbed into H_0 — and a piece proportional to λ_8 of Equation (14.65). So H_1 transforms as the eighth component of an octet. Treat it in first-order perturbation theory (Chapter 82), so that the mass shift of a state $|B\rangle$ is $\langle B|H_1|B\rangle$.

By the Wigner–Eckart theorem for SU(3) — the same statement as for SU(2), and proved in the same way from Schur's lemma Theorem 5.153 — the diagonal matrix elements

of an octet operator inside an octet are determined by two reduced matrix elements, because $\mathbf{8} \otimes \mathbf{8}$ contains $\mathbf{8}$ twice (once symmetrically, through d_{abc} of Equation (14.70), and once antisymmetrically, through f_{abc} of Equation (14.69)). Two reduced matrix elements mean two constants, and the only SU(3) scalars that can be built from T_8 and the state's own quantum numbers, to first order, are Y and the isospin Casimir $I(I+1)$ corrected by the trace term $Y^2/4$. Hence

$$M = M_0 + aY + b\left[I(I+1) - \frac{Y^2}{4}\right], \tag{102.4}$$

with M_0, a and b the same for the whole multiplet.

For the octet, (Y, I) is $(1, \frac{1}{2})$ for N, $(0, 0)$ for Λ, $(0, 1)$ for Σ and $(-1, \frac{1}{2})$ for Ξ, so that $I(I+1) - Y^2/4$ equals $\frac{1}{2}$, 0, 2, $\frac{1}{2}$ respectively, and

$$\begin{aligned} M_N &= M_0 + a + \tfrac{1}{2}b\,, & M_\Lambda &= M_0\,, \\ M_\Sigma &= M_0 + 2b\,, & M_\Xi &= M_0 - a + \tfrac{1}{2}b\,. \end{aligned} \tag{102.5}$$

The three unknowns are eliminated from the four masses in one way: $M_N + M_\Xi = 2M_0 + b$ and $3M_\Lambda + M_\Sigma = 4M_0 + 2b$, whence Equation (102.3). Numerically, with the isospin averages $M_N c^2 = 938.92\,\mathrm{MeV}$, $M_\Lambda c^2 = 1115.68\,\mathrm{MeV}$, $M_\Sigma c^2 = 1193.15\,\mathrm{MeV}$ and $M_\Xi c^2 = 1318.29\,\mathrm{MeV}$ [2427],

$$2\,(M_N + M_\Xi)\,c^2 = 4514.4\,\mathrm{MeV}\,, \qquad (3M_\Lambda + M_\Sigma)\,c^2 = 4540.2\,\mathrm{MeV}\,, \tag{102.6}$$

a discrepancy of 25.8 MeV, that is 0.57 % of either side, against a spread of nearly 400 MeV among the masses being related. For the decuplet the states satisfy $I = 1 + Y/2$, so that $I(I+1) - Y^2/4 = 2 + \frac{3}{2}Y$ and Equation (102.4) collapses to a linear function of Y: consecutive isospin multiplets are equally spaced in mass. That is what Section 102.1.2 exploits. □

Remark 102.2 (What the eightfold way did and did not assert). Neither [1205] nor [1216] proposed constituents. The claim was that an approximate SU(3) organizes the spectrum, and the evidence for it was the multiplet structure and Equation (102.3). That the observed multiplets are **1**, **8** and **10** — and never the **3** that generates them — was at the time an unexplained selection rule. It is explained in Section 102.2.1, and its explanation is colour.

102.1.2 The Ω^- prediction and its confirmation

By 1962 the decuplet contained the four Δ states ($Y = 1$, $I = \frac{3}{2}$), the three $\Sigma(1385)$ states ($Y = 0$, $I = 1$) and the two $\Xi(1530)$ states ($Y = -1$, $I = \frac{1}{2}$): nine of ten. The tenth place, $Y = -2$, $I = 0$, was empty. What Equation (102.4) supplies is not merely the existence of a tenth state but every one of its quantum numbers and, through the equal-spacing rule, its mass.

Phenomenon 102.3 (A particle predicted in full and then found)**.** The equal spacing of the decuplet requires a tenth baryon with strangeness $S = -3$, isospin $I = 0$, charge $-e$, spin-parity $\frac{3}{2}^+$ and a mass about 145 MeV above the $\Xi(1530)$, that is close to $1680\,\mathrm{MeV}/c^2$; being below the threshold for any strangeness-conserving strong decay it must decay weakly, and therefore live long enough to leave a macroscopic track. A single bubble-chamber event at Brookhaven displayed exactly such a particle, with mass $(1686 \pm 12)\,\mathrm{MeV}/c^2$ [1270]. The current world average is $(1672.45 \pm 0.29)\,\mathrm{MeV}/c^2$ [2427], within 0.5 % of the prediction.

Rests on Equations (102.1) *and* (102.4).

Derivation. *Derives Phenomenon 102.3.*

Apply Equation (102.4) to the decuplet, where it reduces to $M = \text{const} + \left(a + \frac{3}{2}b\right) Y$ as shown above. The measured spacings between consecutive isospin multiplets of the decuplet are, with modern isospin-averaged masses [2427],

$$M_{\Sigma^*} - M_{\Delta} = 153\,\text{MeV}/c^2\,, \quad M_{\Xi^*} - M_{\Sigma^*} = 149\,\text{MeV}/c^2\,, \quad M_{\Omega} - M_{\Xi^*} = 139\,\text{MeV}/c^2\,, \tag{102.7}$$

equal to within 5 %, which is the accuracy first-order perturbation theory in a breaking of this size deserves. With the masses available in 1962 the first two spacings were about $145\,\text{MeV}/c^2$ each, and extrapolating one further step placed the missing state near $1680\,\text{MeV}/c^2$.

The quantum numbers follow with no freedom at all. The tenth weight of the decuplet sits at $Y = -2$, $I = I_3 = 0$, so Equation (102.1) gives $Q = -e$, and $Y = B + S$ with $B = 1$ gives $S = -3$. The lifetime argument is kinematic: the lightest $S = -3$ combination reachable by a strong decay, which cannot change strangeness, is ΞK, whose threshold is $(1315 + 494)\,\text{MeV}/c^2 = 1809\,\text{MeV}/c^2$ [2427] — above the predicted mass. Every strong channel is therefore closed, the state must decay through the weak interaction of Chapter 101 with $\Delta S = 1$, and its lifetime must be of the order of $10^{-10}\,\text{s}$ rather than the $10^{-23}\,\text{s}$ of its nine partners. That is the difference between a resonance visible only as a bump in a mass distribution and a particle that travels centimetres and is photographed. □

Remark 102.4 (Why this counts for more than a fit). The eightfold way was fitted to the nine known decuplet members; the tenth was not in the data. What was published in advance was a mass, a charge, a strangeness, a spin, a decay mode and an order of magnitude for a lifetime, and all six were confirmed by one event [1270]. A scheme that reproduces n known numbers with n parameters says nothing; a scheme that predicts an unobserved object's entire specification and is then vindicated has been exposed to refutation and has survived. This is the asymmetry between accommodation and prediction argued in Chapter 1, and the Ω^- is the cleanest instance of it in hadron physics.

102.1.3 Quarks

The representations that occur in Nature are **1**, **8** and **10**. None of them is the fundamental **3**, but all of them are built from it: this is the observation of Gell-Mann [1277] and, in a more concretely constituent reading, of Zweig [1301], whose "aces" are the same objects.

Definition 102.5 (Quarks)**.** A quark is a spin-$\frac{1}{2}$ fermion of baryon number $B = \frac{1}{3}$ transforming in the fundamental representation **3** of flavour SU(3). Reading the weights Equation (14.79) through Equation (102.2) assigns to the three states (u, d, s) the quantum numbers

$$\begin{aligned} u:&\quad I_3 = +\tfrac{1}{2}\,, \quad Y = +\tfrac{1}{3}\,, \quad Q = +\tfrac{2}{3}e\,,\\ d:&\quad I_3 = -\tfrac{1}{2}\,, \quad Y = +\tfrac{1}{3}\,, \quad Q = -\tfrac{1}{3}e\,,\\ s:&\quad I_3 = 0\,, \quad\;\; Y = -\tfrac{2}{3}\,, \quad Q = -\tfrac{1}{3}e\,, \end{aligned} \tag{102.8}$$

the charges following from Equation (102.1) and being, for the first time in physics, fractions of the elementary charge. Antiquarks carry the conjugate representation $\bar{\mathbf{3}}$ and the opposite signs.

Proposition 102.6 (Mesons are $q\bar{q}$, baryons are qqq)**.** *The multiplets observed in Section 102.1.1 are exactly those obtained by combining quarks as*

$$\mathbf{3} \otimes \bar{\mathbf{3}} = \mathbf{1} \oplus \mathbf{8}\,, \qquad \mathbf{3} \otimes \mathbf{3} \otimes \mathbf{3} = \mathbf{1} \oplus \mathbf{8} \oplus \mathbf{8} \oplus \mathbf{10}\,. \tag{102.9}$$

Rests on Definition 102.5, Theorem 14.57, and Equation (14.81).

Proof. *Derives Proposition 102.6.*

The first decomposition is Theorem 14.57, proved there both by splitting $\mathrm{End}(\mathbb{C}^3)$ into its trace and traceless parts and by counting weights. For the second, tensor Equation (14.81) once more with **3**, or count directly: $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$ has dimension 27 and decomposes under the symmetric group S_3, which commutes with the SU(3) action, into a totally symmetric part of dimension $\binom{5}{3} = 10$, a totally antisymmetric part of dimension $\binom{3}{3} = 1$, and two copies of a mixed-symmetry part of dimension 8 each; $10 + 1 + 8 + 8 = 27$. Each symmetry class is SU(3)-invariant, and the four pieces are the representations named. Baryon number is additive with $B = \frac{1}{3}$ per quark, so $q\bar{q}$ has $B = 0$ and qqq has $B = 1$, matching mesons and baryons respectively, and Equation (102.1) is reproduced because Q and Y are additive by construction. □

The decuplet is the totally symmetric combination, which is why it contains *uuu*, *ddd* and *sss* — the Δ^{++}, the Δ^{-} and the Ω^{-}. That fact is about to cause trouble.

Phenomenon 102.7 (The nucleon magnetic moments come out right)**.** Treating the nucleon as three quarks in a spatially symmetric ground state, with each quark contributing a Dirac moment inversely proportional to its mass, predicts

$$\frac{\mu_p}{\mu_n} = -\frac{3}{2}\,, \tag{102.10}$$

with no free parameter whatever. The measured ratio is $2.792847/(-1.913043) = -1.45990$ [2431], low by 2.7 %.

Rests on Definition 102.5, Proposition 102.6, and Equation (93.2).

Derivation. *Derives Phenomenon 102.7.*

A Dirac particle of charge $Q_q e$ and mass m_q, with Q_q the dimensionless charge in units of the elementary charge, has magnetic moment $\mu_q = Q_q e\hbar/(2m_q)$, of SI dimension J/T; this is the $g = 2$ result of the Dirac equation (Chapter 93), whose small radiative correction is the subject of Section 100.8.2 and is irrelevant at the accuracy in question here. Write $\hat{\mu} := e\hbar/(2m_q)$ for the common scale, with $m_u = m_d =: m_q$ by isospin symmetry, so that $\mu_u = +\frac{2}{3}\hat{\mu}$ and $\mu_d = -\frac{1}{3}\hat{\mu}$.

The proton is *uud* with total spin $\frac{1}{2}$ and no orbital angular momentum. The spin-flavour wavefunction that is symmetric under exchange of all three quarks — required by Section 102.2.1, and there is exactly one such state with $J = \frac{1}{2}$ — gives, on projecting the magnetic moment operator $\sum_i \mu_i \sigma_z^{(i)}$ onto it,

$$\mu_p = \frac{4\mu_u - \mu_d}{3}\,, \qquad \mu_n = \frac{4\mu_d - \mu_u}{3}\,. \tag{102.11}$$

The combinatorial factors 4 and -1 are the statement that in the symmetric $J = \frac{1}{2}$ state the like pair (uu in the proton) is coupled to spin 1 with weight $\frac{2}{3}$ and the odd quark carries the remaining spin with weight $-\frac{1}{3}$. Substituting, $\mu_p = \hat{\mu}$ and $\mu_n = -\frac{2}{3}\hat{\mu}$, whence Equation (102.10). The unknown m_q has cancelled, which is why the ratio is a prediction and the individual moments are not.

Feeding the measured $\mu_p = 2.792847\,\mu_N$ [2431], with the nuclear magneton $\mu_N = 5.050\,783\,739\,3 \times 10^{-27}\,\mathrm{J/T}$ [2431], back into $\mu_p = e\hbar/(2m_q)$ gives

$$m_q = \frac{m_p}{2.792847} = 5.99 \times 10^{-28}\,\mathrm{kg} = 336\,\mathrm{MeV}/c^2\,, \tag{102.12}$$

almost exactly one third of the nucleon mass. A model in which the nucleon is three objects of mass $m_N/3$ therefore reproduces both the moment ratio and the moment scale. That the number $336\,\mathrm{MeV}/c^2$ has nothing to do with the u and d masses in the Lagrangian, which are $2.16\,\mathrm{MeV}/c^2$ and $4.70\,\mathrm{MeV}/c^2$ [2427], is the first appearance in this chapter of the fact developed in Section 102.8.2: the mass of ordinary matter is not the mass of its quarks. □

Remark 102.8 (The status of the model in 1964). Gell-Mann's paper is explicit that the quarks might be a mathematical device: fractional charge had never been seen, and searches for it were already under way. Zweig, writing at CERN in the same year, took the constituents literally and could not get his paper published in a journal [1301]. The successes above — the multiplet structure, Equation (102.3), Equation (102.10) — are all statements about *symmetry*, and a symmetry can be realized without its generating representation being populated by particles. What converted the scheme into a theory of constituents was the deep inelastic scattering of Section 102.5, which saw the objects directly. The searches for free fractional charge, meanwhile, have never found anything: Section 102.7.3.

102.2 Colour

102.2.1 The statistics paradox

The quark model of Section 102.1.3 works, and it contains a contradiction with a theorem.

Phenomenon 102.9 (The Δ^{++} violates the spin-statistics theorem)**.** The $\Delta^{++}(1232)$ is the lightest baryon of charge $+2e$, with $J^P = \frac{3}{2}^+$, mass $(1232.0 \pm 2.0)\,\mathrm{MeV}/c^2$ and width $(117 \pm 3)\,\mathrm{MeV}$ [2427]. In the quark model its content is uuu: three identical fermions. Being the lightest state of its quantum numbers it has no orbital excitation, so its spatial wavefunction is symmetric; being $J = \frac{3}{2}$ with three spin-$\frac{1}{2}$ constituents, its spin wavefunction in the $J_z = +\frac{3}{2}$ state is $\uparrow\uparrow\uparrow$, also symmetric; and its flavour wavefunction uuu is symmetric. The total wavefunction is therefore symmetric under exchange of any two of three identical fermions, in direct contradiction with the statistics asserted by the spin-statistics theorem, whose proof belongs to the axiomatic chapter.

Rests on Definition 102.5 and Proposition 102.6.

The contradiction is not a technicality that a more careful model might avoid. It is repeated by the Δ^- (ddd) and the Ω^- (sss), and the same symmetric combination is what produced the successful magnetic moments Equation (102.11): the model's failure and its success come from the same wavefunction. Either the spin-statistics theorem fails — and it is a theorem, whose proof belongs to the axiomatic chapter — or a quark carries a quantum number that has not yet been written down.

Greenberg proposed the first escape, replacing Fermi statistics for quarks by *parastatistics* of order three, in which up to three identical quarks may occupy the same state [1278]. Han and Nambu proposed the second, and the one that survived: quarks come in three varieties distinguished by a new exactly conserved quantum number, on which acts a further, exact SU(3) that has nothing to do with the flavour SU(3) of Section 102.1.1 [1309]. The two proposals are related — parastatistics of order three is what an antisymmetrized threefold degeneracy looks like if one refuses to name the degeneracy — but only the second can be gauged, and gauging it is QCD.

Definition 102.10 (Colour)**.** Each quark flavour f carries an additional index $i = 1, 2, 3$ ("red, green, blue"), transforming in the fundamental representation $\mathbf{3}$ of a group $\mathrm{SU}(3)_c$, distinct from and commuting with flavour SU(3) and with the Poincare group. Antiquarks transform in $\bar{\mathbf{3}}$. The generators are the $T_a = \frac{1}{2}\lambda_a$ of Definition 14.51, with the structure constants Equation (14.69) and the normalization $\mathrm{tr}(T_a T_b) = \frac{1}{2}\delta_{ab}$ of Equation (14.66). Colour is dimensionless and is carried by no lepton.

With a colour index available, the Δ^{++} wavefunction is

$$\left|\Delta^{++}, J_z = \tfrac{3}{2}\right\rangle = \frac{1}{\sqrt{6}}\,\epsilon_{ijk}\,\left|u^i\uparrow\right\rangle\left|u^j\uparrow\right\rangle\left|u^k\uparrow\right\rangle\,, \tag{102.13}$$

totally antisymmetric because ϵ_{ijk} is, and the theorem is satisfied. Nothing has been bought cheaply: the same index must now explain why the states it permits are not seen.

Postulate 102.11 (The colour-singlet rule)**.** Every observable asymptotic state is a singlet of $\mathrm{SU}(3)_c$.

Theorem 102.12 (Which quark combinations can be colour singlets)**.** *A state built from m quarks and n antiquarks contains a colour singlet only if $m-n$ is divisible by three. In particular $q\bar{q}$ and qqq each contain exactly one singlet, while qq, $qqq\bar{q}$ and any single quark contain none.*

Rests on Definition 102.10, Theorem 5.153, and Proposition 14.55.

Proof. *Derives Theorem 102.12.*

The centre of SU(3) is the group of the three matrices $\omega^r \mathbb{1}$, $r = 0, 1, 2$, with $\omega = \mathrm{e}^{2\pi\mathrm{i}/3}$; these are unitary, unimodular ($\det(\omega\mathbb{1}) = \omega^3 = 1$) and commute with everything, and no other multiple of the identity is unimodular. On the fundamental $\mathbf{3}$ the element $\omega\mathbb{1}$ acts as multiplication by ω, and on $\bar{\mathbf{3}}$ as multiplication by ω^{-1}. On a tensor product of m copies of $\mathbf{3}$ and n of $\bar{\mathbf{3}}$ it therefore acts as ω^{m-n}, and on the trivial representation it must act as 1. Hence $\omega^{m-n} = 1$, i.e. $3 \mid m-n$. This number, $m-n \bmod 3$, is the *triality*, and it is a representation-theoretic invariant: no equivalence can change it, so the obstruction is absolute and not a matter of which coupling scheme is used.

For the multiplicities: the number of singlets in $V \otimes W$ is $\dim \mathrm{Hom}_G(V^*, W)$, which by Schur's lemma Theorem 5.153 is 1 if W is equivalent to V^* and 0 otherwise. Since $\bar{\mathbf{3}}$ is inequivalent to $\mathbf{3}$ (Proposition 14.55), $\mathbf{3} \otimes \mathbf{3}$ has no singlet, while $\mathbf{3} \otimes \bar{\mathbf{3}}$ has exactly one — as Theorem 14.57 exhibits explicitly, the trace part of a 3×3 matrix. For three quarks, the decomposition Equation (102.9) contains $\mathbf{1}$ once, and the invariant realizing it is ϵ_{ijk}: the unique (up to scale) totally antisymmetric invariant tensor of $\mathrm{SL}(3,\mathbb{C})$, hence of SU(3). □

Corollary 102.13 (The selection rule of the eightfold way)**.** *Combining Postulate 102.11 with Theorem 102.12 and Equation (102.9), the lightest observable hadrons are exactly the flavour multiplets $\mathbf{1} \oplus \mathbf{8}$ from $q\bar{q}$ and $\mathbf{1} \oplus \mathbf{8} \oplus \mathbf{8} \oplus \mathbf{10}$ from qqq: mesons and baryons, and nothing of triality one or two. This is the rule left unexplained in Remark 102.2.*

Rests on Postulate 102.11, Theorem 102.12, and Equation (102.9).

Remark 102.14 (The rule is a postulate here and a consequence later)*.* Postulate 102.11 is stated as a postulate because that is its honest status in this chapter: it is inferred from the observed spectrum and it is not derived from the Lagrangian of Section 102.3.3. The linear potential of Section 102.7.2 makes it plausible — separating a non-singlet pair costs an energy growing without bound — and the lattice computations of Section 102.7.1 exhibit it, but a proof from the continuum theory does not exist. Section 102.7 says so at length rather than disguising the gap.

102.2.2 Counting the colours

Colour was introduced to fix a statistics problem, and a quantum number introduced to fix one problem is worth little until it is measured somewhere else. It is measured in three independent places, all of which count *three*. The counts are independent in the strong sense: they involve different initial states, different interactions and different theoretical inputs, and each would fail by a large factor if N_c were 1.

Phenomenon 102.15 (Three colours, counted in an annihilation ratio)**.** The ratio

$$R := \frac{\sigma(e^+e^- \to \text{hadrons})}{\sigma(e^+e^- \to \mu^+\mu^-)} \tag{102.14}$$

is, away from resonances, nearly independent of energy over wide intervals and steps upward at each new quark threshold. The measured plateaux lie close to 2 below the charm threshold and close to 10/3 between the charm and bottom thresholds [2427]. Both values require three colour states per quark flavour: with one colour they would be 2/3 and 10/9.

Rests on Definition 102.10, Equation (100.32), and Theorem 100.58.

Derivation. *Derives Phenomenon 102.15.*

At leading order both processes proceed through a single virtual photon, so they differ only in the charge of the produced pair and in how many distinct pairs can be produced. The denominator is Equation (100.32), $\sigma(e^+e^- \to \mu^+\mu^-) = 4\pi\alpha^2(\hbar c)^2/3E_{\mathrm{cm}}^2$, computed in Section 100.3.1. For a pointlike spin-$\frac{1}{2}$ particle of electric charge $Q_f e$ — here and throughout, Q_f is the dimensionless charge of flavour f in units of e — created well above its threshold, the same computation applies with the single change $e^2 \to Q_f e^2$ at the production vertex, so the cross-section is that of Equation (100.32) times Q_f^2; and the rates for distinguishable final states add incoherently, so a quark flavour existing in N_c colours contributes N_c times, the electromagnetic vertex being blind to the colour label. Dividing by the muon channel, for which $Q = -1$ and there is one internal state,

$$R = N_c \sum_q Q_q^2 \,, \tag{102.15}$$

the sum running over the flavours light enough to be produced. With $Q_u = Q_c = +\frac{2}{3}$ and $Q_d = Q_s = Q_b = -\frac{1}{3}$ this gives $R = \frac{2}{3}N_c$ for u, d, s, $R = \frac{10}{9}N_c$ once charm opens and $R = \frac{11}{9}N_c$ once bottom opens — that is 2, 10/3 and 11/3 for $N_c = 3$, which is what is measured.

Confinement does not spoil the count. The quarks produced at the photon vertex cannot emerge as free particles, but whatever they do afterwards they end as hadrons with unit probability, so the hadronic total is settled at the moment of pair creation and the long-distance physics cancels in the ratio. This is the same inclusiveness argument that makes Theorem 100.58 work, applied to colour instead of to soft photons.

The residual excess of the data over the integers above is calculable. Gluon emission from the produced pair multiplies Equation (102.15) by $1 + \alpha_s(E_{\mathrm{cm}})/\pi + \ldots$, the first term being the same $\mathcal{O}(\alpha_s)$ real-plus-virtual sum that gives the three-jet rate of Section 102.6.2; at $E_{\mathrm{cm}} = 5\,\mathrm{GeV}$, where $\alpha_s \approx 0.2$, this is a 6 % excess, and it is seen. So R is simultaneously a colour counter at the 10 % level and, once the count is granted, one of the determinations of α_s collected in Section 102.4.2. □

The second count is sharper by a factor of ten in precision, and it is carried out in full in Section 106.7.2 rather than repeated here.

Proposition 102.16 (The neutral pion width counts colours squared)**.** *The two-photon width of the π^0 is fixed by the axial anomaly (Theorem 106.87) to be Equation* (106.103)*,*

$$\Gamma(\pi^0 \to \gamma\gamma) = \left(\frac{N_c}{3}\right)^2 \frac{\alpha^2 \left(m_\pi c^2\right)^3}{64\pi^3 F_\pi^2} \,, \tag{102.16}$$

proportional to N_c^2. For $N_c = 3$ the prediction is $(7.79 \pm 0.14)\,\mathrm{eV}$ [2427, 2431] against the measured $(7.802 \pm 0.117)\,\mathrm{eV}$ [2361]: agreement to 0.2 %. For $N_c = 1$ it would be nine times smaller.

Rests on Theorems 106.87 and 106.89 and Equation (106.103)*.*

Proof. *Derives Proposition 102.16.*

The whole content is the colour factor of the triangle graph. The axial current whose divergence carries the anomaly is the third isospin component, $j_3^{\mu 5} = \frac{1}{2}(\bar{u}\gamma^\mu\gamma^5 u - \bar{d}\gamma^\mu\gamma^5 d)$, and each quark in the loop is weighted by the square of its electric charge and summed over colours, the electromagnetic vertices being colour-blind. The sum is

$$N_c \left[Q_u^2 - Q_d^2\right] = N_c \left(\frac{4}{9} - \frac{1}{9}\right) = \frac{N_c}{3} \,, \tag{102.17}$$

the relative minus sign coming from the isospin structure of the current. The amplitude is proportional to Equation (102.17) and the width to its square, which is Equation (102.16);

the remaining factors — the anomaly coefficient itself, the reduction of the amplitude to the pion decay constant through the partial conservation of the axial current, and the two-body phase space — are derived in Section 106.7.2. The reason this count is sharper than R is that it is a *low-energy* theorem: the anomaly receives no corrections at higher order in α_s (Theorem 106.89), so the only uncertainty is the measured F_π, entering squared. □

Remark 102.17 (Drell–Yan as a third, weaker count). Drell and Yan proposed the production of a massive lepton pair in a hadron–hadron collision through the annihilation of a quark from one hadron with an antiquark from the other [1421]. Colour enters with the opposite sign to R: the annihilating pair must be in a colour-singlet configuration to make a virtual photon, and if the quark and the antiquark are drawn independently from their parents the probability of matching colours is $1/N_c$. The cross-section therefore carries a factor $1/N_c$ multiplying parton densities that, being measured in the deep inelastic scattering of Section 102.5, already contain a sum over N_c colours. The absolute normalization is thus a count. It is a weaker one, because the leading-order prediction is corrected by an $\mathcal{O}(\alpha_s)$ factor of about 1.5 to 2 — the so-called K factor, which is not small — so the measurement tests $N_c = 3$ at the tens-of-percent level rather than the percent level. It is reported here as a consistency check with an independent sign structure, which is what it is, and not as a precision determination.

102.3 The QCD Lagrangian

102.3.1 Yang–Mills theory

Colour, as introduced in Definition 102.10, is a global label. Theorem 100.5 showed what happens when a global phase symmetry is required to hold point by point: an interaction is not chosen but forced. Yang and Mills asked the same question of a non-abelian group [1054], taking isospin as their example, and the answer differs from the abelian one in exactly one respect — the mediating field is charged under the symmetry it mediates.

Notation 102.18 (Colour fields and their SI dimensions). The quark field q_f^i carries a flavour label f and a colour index $i = 1, 2, 3$, and has the dimension $1/\mathrm{m}^{3/2}$ of any Dirac field (Definition 100.2). The eight gauge potentials A_μ^a, $a = 1, \dots, 8$, carry the dimension $\mathrm{V\,s/m}$ of the electromagnetic potential, and the colour charge g_s carries the dimension C of an electric charge. The combination that appears everywhere is

$$\mathcal{A}_\mu := \frac{g_s}{\hbar} A_\mu^a T_a \,, \qquad [\mathcal{A}_\mu] = 1/\mathrm{m} \,, \tag{102.18}$$

which is Equation (106.63). The dimensionless measure of the coupling is

$$\alpha_s := \frac{g_s^2}{4\pi\varepsilon_0 \hbar c} = \frac{\mu_0 c\, g_s^2}{4\pi\hbar} \,, \tag{102.19}$$

the exact analogue of Equation (100.3) and equal to $\hat{g}^2/4\pi$ in the notation of Equation (106.66). That α_s is a pure number is, as for α, a fact and not a convention: g_s^2/ε_0 carries $\mathrm{J\,m}$, exactly as $\hbar c$ does.

Theorem 102.19 (The non-abelian gauge principle)**.** *Require the free quark Lagrangian $\mathcal{L}_0 = \bar{q}(\mathrm{i}\hbar c\,\gamma^\mu \partial_\mu - mc^2)q$, summed over colours, to be invariant under*

$$q(x) \longmapsto U(x)\, q(x) \,, \qquad U(x) = \exp[\mathrm{i}\theta^a(x) T_a] \in \mathrm{SU}(3)_c \,, \tag{102.20}$$

with θ^a arbitrary real functions. Then invariance holds if and only if eight vector fields A_μ^a are introduced, the derivative is replaced by

$$D_\mu := \partial_\mu + \frac{\mathrm{i} g_s}{\hbar} A_\mu^a T_a = \partial_\mu + \mathrm{i}\mathcal{A}_\mu \,, \tag{102.21}$$

and the potentials transform as

$$\mathcal{A}_\mu \longmapsto U\mathcal{A}_\mu U^\dagger + \mathrm{i}\,(\partial_\mu U)\,U^\dagger\,, \tag{102.22}$$

which infinitesimally reads

$$\delta A^a_\mu = -\frac{\hbar}{g_s}\,\partial_\mu\theta^a - f^{abc}\theta^b A^c_\mu\,. \tag{102.23}$$

Rests on Definition 102.10 and Equations (14.67) and (100.8).

Proof. *Derives Theorem 102.19.*

Under Equation (102.20) the derivative picks up an inhomogeneous term, $\partial_\mu q \mapsto U\partial_\mu q + (\partial_\mu U)q$, so $\mathcal{L}_0$ is not invariant. Postulate a matrix field $\mathcal{A}_\mu$ valued in the Lie algebra and define D_μ by Equation (102.21). Demanding $D_\mu q \mapsto U(D_\mu q)$ gives

$$\left(\partial_\mu + \mathrm{i}\mathcal{A}'_\mu\right) Uq = (\partial_\mu U)\,q + U\partial_\mu q + \mathrm{i}\mathcal{A}'_\mu U q \overset{!}{=} U\partial_\mu q + \mathrm{i}U\mathcal{A}_\mu q\,,$$

for all q, whence $\mathrm{i}\mathcal{A}'_\mu U = \mathrm{i}U\mathcal{A}_\mu - (\partial_\mu U)$ and, multiplying on the right by $U^\dagger$, Equation (102.22). Conversely Equation (102.22) makes $\bar q\gamma^\mu D_\mu q$ invariant by the same computation read backwards, so the condition is necessary as well as sufficient.

For the infinitesimal form put $U = \mathbb{1} + \mathrm{i}\theta^a T_a$ and keep first order. The first term of Equation (102.22) gives $\mathcal{A}_\mu + \mathrm{i}\theta^b\,[T_b, \mathcal{A}_\mu]$, and with $[T_b, T_c] = \mathrm{i}f_{bca}T_a$ of Equation (14.67) together with the total antisymmetry of f this is $\mathcal{A}_\mu - (g_s/\hbar)f^{abc}\theta^b A^c_\mu T_a$. The second term gives $\mathrm{i}(\mathrm{i}\partial_\mu\theta^a T_a) = -\partial_\mu\theta^a T_a$. Dividing by $g_s/\hbar$ yields Equation (102.23). For one abelian generator the second term of Equation (102.23) is absent and the first reproduces Equation (100.8) with $\Lambda = -\hbar\theta/g_s$. □

The whole difference between QED and QCD sits in the second term of Equation (102.23): the gluon potential does not merely shift under a gauge transformation, it *rotates* in colour space. It carries colour, and a field that carries the charge it mediates interacts with itself.

Definition 102.20 (The gluon field strength)**.**

$$F^a_{\mu\nu} := \partial_\mu A^a_\nu - \partial_\nu A^a_\mu - \frac{g_s}{\hbar} f^{abc} A^b_\mu A^c_\nu\,, \tag{102.24}$$

of dimension T, equivalently $\mathcal{F}_{\mu\nu} = (g_s/\hbar)F^a_{\mu\nu}T_a = -\mathrm{i}\,[D_\mu, D_\nu]$, which is Equation (106.64).

Proposition 102.21 (Curvature and its transformation law)**.** $\mathcal{F}_{\mu\nu} = -\mathrm{i}\,[D_\mu, D_\nu]$ *holds with Equation (102.24), and under Equation (102.22)*

$$\mathcal{F}_{\mu\nu} \longmapsto U\mathcal{F}_{\mu\nu}U^\dagger\,, \tag{102.25}$$

so that $F^a_{\mu\nu}$ transforms in the adjoint representation **8** *and $F^a_{\mu\nu}F^{a\,\mu\nu}$ is gauge invariant. Unlike Equation (100.11), $F^a_{\mu\nu}$ is itself* not *invariant.*

Rests on Equations (14.66), (102.22) and (102.24).

Proof. *Derives Proposition 102.21.*

Compute the commutator on a quark field:

$$\begin{aligned}[D_\mu, D_\nu] &= \mathrm{i}\,(\partial_\mu\mathcal{A}_\nu - \partial_\nu\mathcal{A}_\mu) - [\mathcal{A}_\mu, \mathcal{A}_\nu] \\ &= \mathrm{i}\frac{g_s}{\hbar}\left(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\right)T_a - \left(\frac{g_s}{\hbar}\right)^2 A^b_\mu A^c_\nu\,\mathrm{i}f_{bca}T_a\,,\end{aligned} \tag{102.26}$$

the derivative terms acting on the quark cancelling between the two orderings. Factoring $\mathrm{i}g_s/\hbar$ and using $f_{bca} = f_{abc}$ gives Equation (102.24). Since $D_\mu \mapsto UD_\mu U^\dagger$ by construction — Equation (102.22) is exactly the statement that $D_\mu q$ transforms like q — the commutator of two such objects transforms as $U\,[D_\mu, D_\nu]\,U^\dagger$, which is Equation (102.25). Finally $F^aF^a \propto \mathrm{tr}(\mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu})$ by Equation (14.66), and a trace of a product of two adjoint objects is invariant by cyclicity — it is the Killing form of Proposition 14.53, which is what makes this the only quadratic invariant available. □

Remark 102.22 (A sign convention, and how to convert). Many texts define $D_\mu = \partial_\mu - \mathrm{i}\mathcal{A}_\mu$ and obtain $F^a_{\mu\nu}$ with $+g_s f^{abc} A^b A^c/\hbar$. The two conventions are related by $g_s \to -g_s$, under which every physical quantity — which depends on g_s only through $\alpha_s \propto g_s^2$, or through an even number of vertices — is unchanged. The convention adopted here is the one that makes Equation (102.21) the literal non-abelian copy of Equation (100.9) and agrees with Notation 106.50, so that formulae may be carried between the three chapters without a sign audit.

Proposition 102.23 (The gluon self-couplings)**.** *The Yang–Mills Lagrangian density*

$$\mathcal{L}_{\mathrm{YM}} = -\frac{1}{4\mu_0} F^a_{\mu\nu} F^{a\,\mu\nu}\,, \tag{102.27}$$

of dimension $\mathrm{J/m^3}$*, contains — besides the free quadratic term — a cubic and a quartic self-interaction of the gauge field,*

$$\begin{aligned}\mathcal{L}_{\mathrm{YM}} = &-\frac{1}{4\mu_0}\left(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\right)\left(\partial^\mu A^{a\nu} - \partial^\nu A^{a\mu}\right)\\ &+\frac{g_s}{2\mu_0\hbar} f^{abc}\left(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\right) A^{b\,\mu} A^{c\,\nu}\\ &-\frac{g_s^2}{4\mu_0\hbar^2} f^{abc} f^{ade} A^b_\mu A^c_\nu A^{d\,\mu} A^{e\,\nu}\,,\end{aligned} \tag{102.28}$$

both proportional to the structure constants Equation (14.69) *and therefore absent in an abelian theory.*

Rests on Equations (14.69)*,* (100.12) *and* (102.24)*.*

Proof. *Derives Proposition 102.23.*

Write $F^a_{\mu\nu} = G^a_{\mu\nu} - (g_s/\hbar) f^{abc} A^b_\mu A^c_\nu$ with $G^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu$ and square, the cross term appearing twice by the symmetry of the contraction. Multiplying by $-1/4\mu_0$ gives Equation (102.28). For an abelian group all f^{abc} vanish and only the first line survives, which is Equation (100.12); the normalization $1/4\mu_0$ is fixed by that limit. Dimensionally F^2/μ_0 carries $\mathrm{T^2\,A^2/N} = \mathrm{J/m^3}$, as in Equation (100.12). □

Remark 102.24 (Yang and Mills's mass problem). A Proca term $(2\mu_0)^{-1}\,(m_g c/\hbar)^2\, A^a_\mu A^{a\,\mu}$, which is the only gluon mass term available and carries $\mathrm{J/m^3}$ as it must, is not invariant under Equation (102.23) — the inhomogeneous piece $\partial_\mu \theta^a$ does not cancel — so gauge invariance forbids a gluon mass, exactly as it forbids a photon mass in Phenomenon 100.7. This was the objection to [1054] at the time: a massless charged vector particle would have been conspicuous, and none was seen. The two known resolutions are different from each other. For the weak interaction the symmetry is spontaneously broken and the gauge bosons acquire mass through the mechanism of Chapter 104. For the strong interaction the gluon really is massless, and the interaction is nevertheless short-ranged because the theory confines (Section 102.7) — a resolution that requires the non-perturbative behaviour of the very self-couplings Equation (102.28) that caused the problem. It took nineteen years.

102.3.2 Gauge fixing, ghosts and the Slavnov–Taylor identities

The quadratic form of Equation (102.28) is singular for the same reason as Equation (100.15): the action does not depend on the gauge direction, so it cannot be inverted there and there is no propagator. In the abelian case the cure of Section 100.1.3 — add $-(\partial\cdot A)^2/2\mu_0\xi$ and proceed — is complete, because the Jacobian accompanying the change of variables is a field-independent constant. In the non-abelian case it is not, and the difference is a new field.

Theorem 102.25 (Gauge fixing needs a determinant)**.** *Fixing the gauge by a condition* $G^a(\mathcal{A}) = 0$ *inside the functional integral of Chapter 106 requires the insertion of the Faddeev–Popov determinant* $\det\left(\delta G^a/\delta\theta^b\right)$ *[1347]. For the covariant condition* $G^a = \partial^\mu A^a_\mu$ *this operator is* $\partial^\mu D_\mu$*, which depends on the gauge field whenever the group is non-abelian; the determinant is therefore not a constant and is represented by a functional integral over a pair of anticommuting scalar fields* c^a*,* $\bar{c}^a$ *in the adjoint representation, the* ghosts*.*

Rests on Theorem 106.52, Equation (102.23)*, and Corollary 106.53.*

Proof. *Derives Theorem 102.25.*

This is Theorem 106.52, proved there; only the group-theoretic input is quoted here. The variation of the gauge condition under Equation (102.23) is $\delta G^a = -(\hbar/g_s)\partial^\mu\left(\delta^{ab}\partial_\mu + (g_s/\hbar)f^{acb}A^c_\mu\right)\theta^b$, whose kernel is the adjoint covariant derivative. The f^{acb} term is absent for an abelian group, which is Corollary 106.53 and the reason the photon needed no ghosts in Section 100.1.3. □

The ghosts are not particles: they are anticommuting scalars, in violation of the spin-statistics theorem, and they may therefore never appear in an asymptotic state. Their function is negative — they cancel the contributions of the unphysical gluon polarizations. A massless vector field has four components and two physical (transverse) polarizations; in a covariant gauge all four propagate, and the timelike and longitudinal ones would spoil the unitarity of the theory. That the ghost loop cancels them exactly is Proposition 106.55, and it is the reason the practical quantization of QCD is the functional one of Chapter 106 rather than the canonical route of Chapter 99.

What survives gauge fixing is a residual global symmetry mixing gauge field and ghosts: the BRST symmetry of Becchi, Rouet and Stora [1518, 1571] and, independently, Tyutin [1564]. Its generator is nilpotent (Theorem 106.57), the physical state space is its cohomology (Definition 106.59), and it is the modern statement of what gauge invariance becomes after the gauge has been fixed. Its practical consequence is a set of identities among renormalization constants, the Slavnov–Taylor identities [1458, 1484], generalizing the Ward–Takahashi identity Theorem 100.48 of the abelian theory. Where the abelian identity gives the single relation $Z_1 = Z_2$ of Corollary 100.49 — charge renormalization is governed by the photon field renormalization alone — the non-abelian identities relate the quark–gluon, three-gluon, four-gluon and ghost–gluon vertex renormalizations to each other, so that the *one* coupling g_s of Equation (102.28) remains one coupling after renormalization. That is not automatic: three vertices renormalized independently would be three couplings, and the theory would lose its predictive content.

Theorem 102.26 (Non-abelian gauge theories are renormalizable)**.** *A Yang–Mills theory with fermions in any representation, quantized with Theorem 102.25, is renormalizable: all ultraviolet divergences are removed to every order by a finite number of counterterms with the same structure as the terms already present [1448, 1463].*

Rests on Theorems 100.17 and 102.25.

Derivation pending #148

Renormalizability of Yang–Mills theory. The proof combines the power-counting theorem, which for a gauge theory in four dimensions gives superficial degree of divergence four minus the number of external lines weighted by their dimension exactly as in the abelian case, with the Slavnov–Taylor identities, which show that the divergent structures allowed by power counting are constrained to be gauge invariant and therefore already present in the Lagrangian. The regularization must respect the gauge symmetry, and dimensional regularization does. This is a long argument of the same shape as the BPHZ theorem of the electromagnetic chapter and belongs beside it in Appendix A.

102.3.3 The Lagrangian and its parameters

Definition 102.27 (The QCD Lagrangian density)**.**

$$\mathcal{L}_{\mathrm{QCD}} = -\frac{1}{4\mu_0} F^a_{\mu\nu} F^{a\,\mu\nu} + \sum_f \bar{q}_f \left(\mathrm{i}\hbar c\, \gamma^\mu D_\mu - m_f c^2 \right) q_f \,, \tag{102.29}$$

with $F^a_{\mu\nu}$ from Equation (102.24), D_μ from Equation (102.21) acting on the colour triplet index, and the flavour sum running over $f = u, d, s, c, b, t$. Both terms carry $\mathrm{J/m^3}$. This is the Lagrangian written down by Fritzsch, Gell-Mann and Leutwyler [1499]. A further gauge-invariant term is allowed and is deferred to Section 102.10.

Proposition 102.28 (The parameters of QCD)**.** *Equation (102.29) contains seven free parameters: the six quark masses and the coupling g_s, equivalently α_s at one reference scale. Nothing else — not the number of gluons, not their couplings to each other, not the relative strength with which any flavour couples to them — is adjustable.*

Rests on Equation (102.29), Proposition 14.50, and Theorem 102.26.

Proof. *Derives Proposition 102.28.*

The gauge sector is fixed by the group: the number of gauge fields is $\dim \mathfrak{su}(3) = 8$ by Proposition 14.50, and the cubic and quartic couplings of Equation (102.28) carry the structure constants Equation (14.69), which are numbers, multiplied by powers of the same g_s that appears in the quark vertex. The quark sector contributes one mass per flavour. That the coupling is the same for every flavour is the non-abelian version of Proposition 100.6: D_μ depends on the matter field only through its colour representation, and every quark is a $\mathbf{3}$. Renormalizability (Theorem 102.26) is what guarantees the count is not enlarged order by order, and the Slavnov–Taylor identities are what keep the three gauge vertices tied to one number. □

Proposition 102.29 (Feynman rules for QCD in SI form)**.** *The rules of Proposition 100.14 carry over with the following replacements and additions, each factor written with its $\hbar$ and c in place.*

1. *Quark propagator: Equation (100.23) times δ_{ij} in colour.*
2. *Gluon propagator: Equation (100.17) times δ^{ab}.*
3. *Quark–gluon vertex:*

$$-\frac{\mathrm{i} g_s}{\hbar} \gamma^\mu \left(T_a\right)_{ij} \,, \tag{102.30}$$

of dimension $\mathrm{C/(J\,s)}$, identical to Equation (100.24) with $q \to g_s T_a$.

Table 102.1: The seven parameters of Equation (102.29). Quark masses are $\overline{\text{MS}}$ values, those of u, d and s quoted at the scale 2 GeV and those of c, b, t at their own mass, in the scheme of Definition 100.54; the scheme dependence is not an uncertainty but part of the definition, because a quark mass is not the pole of a propagator of anything observable. Values from [2427].

Parameter	Value	SI equivalent
m_u	$(2.16 \pm 0.07)\,\text{MeV}/c^2$	$3.85 \times 10^{-30}\,\text{kg}$
m_d	$(4.70 \pm 0.07)\,\text{MeV}/c^2$	$8.38 \times 10^{-30}\,\text{kg}$
m_s	$(93.5 \pm 0.8)\,\text{MeV}/c^2$	$1.667 \times 10^{-28}\,\text{kg}$
m_c	$(1.273 \pm 0.005)\,\text{GeV}/c^2$	$2.269 \times 10^{-27}\,\text{kg}$
m_b	$(4.183 \pm 0.007)\,\text{GeV}/c^2$	$7.457 \times 10^{-27}\,\text{kg}$
m_t	$(172.57 \pm 0.29)\,\text{GeV}/c^2$	$3.0763 \times 10^{-25}\,\text{kg}$
$\alpha_s(m_Z c^2)$	0.1180 ± 0.0009	dimensionless

4. *Three-gluon vertex: from the second line of Equation (102.28), a factor proportional to $(g_s/\hbar\mu_0)f^{abc}$ times a momentum-dependent tensor antisymmetric in the simultaneous exchange of any two legs.*

5. *Four-gluon vertex: from the third line, proportional to $(g_s/\hbar)^2\mu_0^{-1}$ times sums of products $f^{abe}f^{cde}$.*

6. *Ghost propagator and ghost–gluon vertex from Theorem 102.25, with a factor -1 for each closed ghost loop as for a fermion loop.*

Every colour factor is a contraction of the T_a and f^{abc} computed once and for all in Proposition 14.52. The two that occur constantly are

$$(T_aT_a)_{ij} = C_F\,\delta_{ij}\,, \quad C_F = \frac{4}{3}\,, \qquad f^{acd}f^{bcd} = C_A\,\delta^{ab}\,, \quad C_A = 3\,, \tag{102.31}$$

being the quadratic Casimirs Equation (14.77) and Equation (14.78) of the fundamental and adjoint representations, and $\operatorname{tr}(T_aT_b) = T_F\delta_{ab}$ with $T_F = \frac{1}{2}$ from Equation (14.66).

Rests on Proposition 100.14, Equation (102.28), and Theorem 102.25.

Proof. *Derives Proposition 102.29.*

Rules 1–3 are Proposition 100.14 with the substitution $q\gamma^\mu \to g_s\gamma^\mu T_a$ forced by Equation (102.21), together with the observation that the free parts of Equation (102.29) are diagonal in colour; rules 4–6 are read off the interaction terms of Equation (102.28) and of Theorem 102.25 by the same expansion of $\exp(\mathrm{i}S/\hbar)$. For Equation (102.31), T_aT_a commutes with every generator and is therefore a multiple of the identity on the irreducible **3**; Equation (14.77) evaluates the multiple as $4/3$, and Equation (14.78) does the same for the adjoint, where the generators are $-\mathrm{i}f^{abc}$. □

Remark 102.30 (Flavour independence is a prediction, and it is tested). Proposition 102.28 asserts that one number governs the coupling of the gluon to every quark flavour. The claim is testable because α_s is extracted from processes dominated by different flavours: τ decays involve u, d and s; bottomonium spectroscopy involves b; the Z hadronic width involves all five accessible flavours democratically. That these determinations agree after being evolved to a common scale, as Section 102.4.2 records, is a test of flavour independence and not merely a measurement of a number.

102.4 Asymptotic freedom

102.4.1 The sign of the beta function

Remark 100.34 read the running of α as the polarization of a medium: virtual pairs align against an inserted charge, so that a distant probe sees less charge than a close one, and the effective coupling grows with momentum transfer. The reading is literal, and in SI units it can be pushed further than it usually is, because SI keeps the vacuum's electric and magnetic responses as separate named quantities. That separation is what makes the sign of the non-abelian beta function computable by a short argument instead of a two-loop-sized diagram count.

Lemma 102.31 (The vacuum's two responses are reciprocal)**.** *Let the polarization of the vacuum by virtual pairs be described by an effective permittivity ε_{eff} and permeability μ_{eff}. Lorentz invariance of the vacuum requires*

$$\varepsilon_{\text{eff}}\,\mu_{\text{eff}} = \frac{1}{c^2}\,, \qquad \textit{hence} \qquad \frac{\varepsilon_{\text{eff}}}{\varepsilon_0} = \frac{\mu_0}{\mu_{\text{eff}}}\,. \tag{102.32}$$

Consequently a paramagnetic *vacuum, $\mu_{\text{eff}} > \mu_0$, is one with $\varepsilon_{\text{eff}} < \varepsilon_0$: it* anti*screens.*
Rests on Postulate 38.2 and Equation (102.19).

Proof. *Derives Lemma 102.31.*
In a medium of permittivity ε and permeability μ the phase velocity of light is $(\varepsilon\mu)^{-1/2}$. The vacuum, polarized or not, is Lorentz invariant, and by the postulates of Chapter 38 light propagates in it at c in every frame; a medium with $\varepsilon\mu \neq c^{-2}$ would define a rest frame. Hence Equation (102.32). The second form follows from $\varepsilon_0\mu_0 c^2 = 1$, and the statement about signs is immediate. Finally, the coupling measured at a scale is $\alpha_s = g_s^2/\left(4\pi\varepsilon_{\text{eff}}\hbar c\right)$ by Equation (102.19), so $\varepsilon_{\text{eff}} < \varepsilon_0$ means a *larger* effective coupling at long distance and a smaller one at short distance, which is asymptotic freedom. □

The problem is therefore reduced to a magnetostatic one: is the QCD vacuum paramagnetic or diamagnetic? A magnetic response has two sources, and they compete. Orbital motion of a charged particle in a field is diamagnetic — Lenz's law, and Landau diamagnetism. Alignment of an intrinsic magnetic moment with the field is paramagnetic. For a charged particle of spin s and gyromagnetic ratio g the two enter the energy in a fixed ratio, and the following lemma is where the ratio is fixed.

Lemma 102.32 (Landau levels with $g = 2$)**.** *A massless particle of charge q, spin projection s_z along a uniform magnetic field $B\hat{z}$ and gyromagnetic ratio $g = 2$ has energies*

$$E_n^2(p_z) = c^2 p_z^2 + |q|\,\hbar c^2 B\,(2n + 1 + \kappa)\,, \qquad \kappa := -2s_z\,, \quad n = 0, 1, 2, \dots\,, \tag{102.33}$$

each level carrying the degeneracy $|q|\,B/(2\pi\hbar)$ per unit area transverse to the field. The quantity $|q|\,\hbar c^2 B$ has the dimension of a squared energy.
Rests on Equations (93.2) and (102.28).

Proof. *Derives Lemma 102.32.*
For a spinless particle the transverse motion is a harmonic oscillator of frequency $\omega_c = |q|\,c^2 B/E$, whose quantization gives $E^2 = c^2 p_z^2 + (2n+1)\,|q|\,\hbar c^2 B$ — the relativistic Landau problem, obtained by squaring the wave operator so that $\boldsymbol{p}_\perp^2 \to (2n+1)\,|q|\,\hbar B$. A magnetic moment $\boldsymbol{\mu} = g\,(q/2m)\,\boldsymbol{S}$ adds an interaction energy $-\boldsymbol{\mu}\cdot\boldsymbol{B}$, which in the squared equation appears as $-g\,|q|\,\hbar c^2 B s_z$; putting $g = 2$ gives Equation (102.33). That $g = 2$ is the Dirac value for a spin-$\frac{1}{2}$ particle (Chapter 93), and its small radiative correction (Theorem 100.41) is of higher order in the coupling and irrelevant to a one-loop coefficient. That $g = 2$ also for the charged gluons is a property of Equation (102.28): expanding

$-F^a_{\mu\nu}F^{a\,\mu\nu}/4\mu_0$ to second order about a background field produces, besides the covariant Laplacian, exactly the term $-2\mathrm{i}\mathcal{F}_{\mu\nu}$ acting on the vector index of the fluctuation, and a coefficient 2 in front of the field-strength coupling to the spin generator is the statement $g=2$. The degeneracy $|q|\,B/(2\pi\hbar)$ per unit area is the standard one: one state per flux quantum $2\pi\hbar/|q|$. □

Theorem 102.33 (The one-loop coefficient, from a magnetic response)**.** *Let a gauge theory contain species i of spin s_i carrying charge $x_i g_s$ under a chosen Cartan direction, the label i running over all one-particle states (particles and antiparticles counted separately). Then the vacuum behaves as a medium with*

$$\frac{\varepsilon_{\mathrm{eff}}}{\varepsilon_0}=1+\frac{\alpha_s}{24\pi}\,S\,\ln\frac{\Lambda_E^2}{E^2}\,,\qquad S:=\sum_i x_i^2\,(-1)^{2s_i}\sum_{s_z}\Big(1-12s_z^2\Big)\,, \tag{102.34}$$

with Λ_E an ultraviolet cutoff energy and E the energy scale at which the coupling is measured; and consequently

$$\frac{\mathrm{d}\alpha_s}{\mathrm{d}\ln E}=\frac{S}{12\pi}\,\alpha_s^2+O\Big(\alpha_s^3\Big)\,. \tag{102.35}$$

Inside the spin sum the term 1 is the diamagnetic contribution of the orbital motion and the term $-12s_z^2$ the paramagnetic contribution of the magnetic moment.

Rests on Lemmas 102.31 and 102.32 and Equation (102.19).

Proof. *Derives Theorem 102.33.*

Put the vacuum in a uniform field B pointing along the chosen Cartan direction in colour space, so that every field component has a definite charge $x_i g_s$ and the problem is the abelian one of Lemma 102.32. The vacuum energy density is the sum of the zero-point energies of all modes,

$$u=\frac{1}{2}\sum_i(-1)^{2s_i}\frac{|q_i|\,B}{2\pi\hbar}\sum_{s_z}\sum_{n=0}^{\infty}\int_{-\infty}^{\infty}\frac{\mathrm{d}p_z}{2\pi\hbar}\,E_n(p_z)\,, \tag{102.36}$$

the factor $(-1)^{2s}$ being the sign of a fermionic zero-point energy, $-\frac{1}{2}\hbar\omega$ per mode instead of $+\frac{1}{2}\hbar\omega$.

Cut the longitudinal momentum off at $|p_z|\le P$ and write $\varepsilon_n^2=A\,(2n+1+\kappa)$ with $A=|q|\,\hbar c^2 B$. Then

$$\int_{-P}^{P}\frac{\mathrm{d}p_z}{2\pi\hbar}\sqrt{c^2p_z^2+\varepsilon_n^2}=\frac{cP^2}{2\pi\hbar}+\frac{\varepsilon_n^2}{4\pi\hbar c}-\frac{\varepsilon_n^2}{4\pi\hbar c}\ln\frac{\varepsilon_n^2}{4c^2P^2}+O\Big(P^{-2}\Big)\,, \tag{102.37}$$

the first two terms being independent of B and of n in a way that contributes no $B^2\ln B$, and the third being the one that matters. Split $\ln\varepsilon_n^2=\ln A+\ln(2n+1+\kappa)$: the second piece carries no B and produces a term proportional to B^2 with no logarithm, i.e. a renormalization of the field energy and not a running. Keeping the first piece,

$$u_{\ln}=-\frac{1}{2}\sum_i(-1)^{2s_i}\frac{|q_i|\,B}{2\pi\hbar}\cdot\frac{A_i}{4\pi\hbar c}\,\ln\frac{A_i}{4c^2P^2}\sum_{s_z}\sum_{n=0}^{\infty}(2n+1+\kappa)\,. \tag{102.38}$$

The sum over Landau levels diverges and is defined by analytic continuation: writing $2n+1+\kappa=2(n+x)$ with $x=(1+\kappa)/2$, and using the Hurwitz zeta function $\zeta(\sigma,x)=\sum_{n\ge0}(n+x)^{-\sigma}$ continued to $\sigma=-1$, where $\zeta(-1,x)=-\frac{1}{2}\left(x^2-x+\frac{1}{6}\right)$,

$$\sum_{n=0}^{\infty}(2n+1+\kappa)=2\zeta(-1,x)=-\left(x^2-x+\tfrac{1}{6}\right)=\frac{1-3\kappa^2}{12}=\frac{1-12s_z^2}{12}\,, \tag{102.39}$$

using $\kappa = -2s_z$. The two terms of Equation (102.39) are the two magnetic responses: the 1 comes from the $2n+1$ of the orbital motion and the $-12s_z^2$ from the κ of the moment.

Substituting $A_i = |q_i|\,\hbar c^2 B$ into Equation (102.38) and writing $L_i = \ln\left[4c^2P^2/(|q_i|\,\hbar c^2 B)\right]$,

$$u_{\ln} = \frac{cB^2}{16\pi^2\hbar}\sum_i q_i^2(-1)^{2s_i}L_i\sum_{s_z}\frac{1-12s_z^2}{12}\,. \tag{102.40}$$

Comparing with the field energy density $u = B^2/2\mu_{\text{eff}}$ and using Equation (102.32) together with $q_i^2 = x_i^2 g_s^2$ and $g_s^2/(\varepsilon_0\hbar c) = 4\pi\alpha_s$ from Equation (102.19),

$$\frac{\varepsilon_{\text{eff}}}{\varepsilon_0} = \frac{\mu_0}{\mu_{\text{eff}}} = 1 + \frac{\alpha_s}{24\pi}\sum_i x_i^2(-1)^{2s_i}\left[\sum_{s_z}\left(1-12s_z^2\right)\right]L_i\,. \tag{102.41}$$

The species-dependence of L_i is a B-independent additive constant under the logarithm and is therefore a choice of subtraction scheme, not physics: only the coefficient of $\ln B$ is common to all schemes, which is the standard statement that a one-loop beta-function coefficient is scheme-independent (Proposition 100.55). Identifying the energy scale probed by the field, $E^2 \sim g_s\hbar c^2 B$ — the field sets the transverse momentum of the modes — and writing $\Lambda_E = 2cP$, all L_i become $\ln(\Lambda_E^2/E^2)$ up to constants, which is Equation (102.34).

Finally $\alpha_s(E) = g_s^2/\left(4\pi\varepsilon_{\text{eff}}\hbar c\right)$, so $\alpha_s(E)^{-1} = \alpha_s(\Lambda_E)^{-1} + (S/24\pi)\ln(\Lambda_E^2/E^2)$. Differentiating with respect to $\ln E$ gives $-\alpha_s^{-2}\,\mathrm{d}\alpha_s/\mathrm{d}\ln E = -S/12\pi$, which is Equation (102.35). □

Corollary 102.34 (The master formula reproduces QED)**.** *For a single Dirac fermion of unit charge, Equation* (102.35) *gives* $\mathrm{d}\alpha/\mathrm{d}\ln E = 2\alpha^2/3\pi$*, which is Equation* (100.84)*.*

Rests on Equations (100.84)*,* (102.35) *and* (102.39)*.*

Proof. *Derives Corollary 102.34.*

The one-particle states are the fermion and the antifermion, each of charge magnitude e, so $\sum_i x_i^2 = 2$. The statistics factor is $(-1)^{2s} = -1$ and the spin sum over $s_z = \pm\frac{1}{2}$ is $2\left(1 - 12\cdot\frac{1}{4}\right) = -4$. Hence $S = 2\cdot(-1)\cdot(-4) = 8$ and $\mathrm{d}\alpha/\mathrm{d}\ln E = 8\alpha^2/12\pi = 2\alpha^2/3\pi$. The sign is positive — QED screens — and by Equation (102.39) the reason is arithmetical: for $s_z = \pm\frac{1}{2}$ the paramagnetic term $12s_z^2 = 3$ beats the diamagnetic 1, so the electron vacuum is in fact paramagnetic, and it is the Fermi statistics — the minus sign of a fermion loop — that turns the result back into screening. □

Theorem 102.35 (Asymptotic freedom)**.** *For* $\mathrm{SU}(3)_c$ *with* n_f *quark flavours light enough to be excited at the scale considered,*

$$\frac{\mathrm{d}\alpha_s}{\mathrm{d}\ln E} = -\frac{b_0}{2\pi}\,\alpha_s^2 + O\left(\alpha_s^3\right)\,, \qquad b_0 = \frac{11}{3}C_A - \frac{4}{3}T_F n_f = 11 - \frac{2}{3}n_f\,, \tag{102.42}$$

which is negative — the coupling decreases with energy — for every $n_f \le 16$ *[1501, 1511]. Nature supplies* $n_f = 6$*.*

Rests on Theorem 102.33 and Equations (14.80) *and* (102.31)*.*

Proof. *Derives Theorem 102.35.*

Apply Theorem 102.33 twice.

Quarks. A quark flavour is a colour triplet; taking the Cartan direction to be T_3, its three colour states carry charges $x = +\frac{1}{2}, -\frac{1}{2}, 0$, and each is a Dirac field with its own antiparticle. Hence $\sum_i x_i^2 = 2\,\mathrm{tr}\left(T_3^2\right) = 2T_F = 1$ per flavour, the factor 2 counting antiparticles and $T_F = \frac{1}{2}$ being Equation (14.66). With the spin factor $(-1)\times(-4) = +4$ from Corollary 102.34, quarks contribute $S_q = 4n_f$.

Gluons. The gluons form the adjoint $\mathbf{8}$, whose charges under ad_{T_3} are the first components of the roots Equation (14.80), namely ±1, $\pm\frac{1}{2}$, $\pm\frac{1}{2}$ and two zeros, so that $\sum_a x_a^2 = f^{3cd}f^{3cd} =$

$C_A = 3$ by Equation (102.31). Here the charged components already occur in ± pairs — a gluon of charge $+1$ *is* the antiparticle of the one with charge -1 — so no further doubling is applied. A gluon is massless and has two physical polarizations, $s_z = \pm 1$; the unphysical ones are removed by the ghosts of Theorem 102.25, which is where that machinery earns its keep. The statistics factor is $(-1)^2 = +1$ and the spin sum is

$$\sum_{s_z=\pm 1} \left(1 - 12 s_z^2\right) = 2\,(1 - 12) = -22\,, \tag{102.43}$$

so $S_g = 3 \times (-22) = -66$.

Adding, $S = 4n_f - 66 = -6\left(11 - \frac{2}{3}n_f\right) = -6b_0$, and Equation (102.35) becomes Equation (102.42). Restoring the group factors in place of their numerical values, the quark term is $-\frac{4}{3}T_F n_f$ and the gluon term $+\frac{11}{3}C_A$, which is the form used for any gauge group. $b_0 > 0$ requires $n_f < 33/2$, i.e. $n_f \leq 16$. □

Remark 102.36 (Eleven is twelve minus one). The whole of asymptotic freedom is in Equation (102.43). A gluon carries spin 1, so its paramagnetic term is $12 s_z^2 = 12$ against a diamagnetic term of 1: the moment wins by eleven to one, the vacuum is strongly paramagnetic, and by Lemma 102.31 a paramagnetic vacuum antiscreens. The famous 11 of b_0 is literally $12 - 1$. The electron's moment also wins, three to one, but a fermion loop enters with the opposite sign and the result is screening. So the two theories differ not because the gluon is charged in some vague sense, but because *spin one* triples the moment term relative to spin one half while *Bose statistics* declines to flip its sign. This is the contrast Remark 100.34 promised, made quantitative: QED has $S = 8$ per unit-charge fermion and QCD has $S = -66$ from the gluons alone.

Remark 102.37 (What the short calculation costs). Three things in the derivation above are shortcuts, and none of them affects the coefficient. First, the sum Equation (102.39) is divergent and was assigned a value by analytic continuation. A proper-time or dimensional regulator (Definition 100.30) gives the same coefficient of $\ln B$, which is the only quantity used; the finite parts differ and are scheme, as Equation (102.41) already noted. Second, the constant chromomagnetic field is not the true vacuum: the $n = 0$, $s_z = +1$ gluon mode of Equation (102.33) has $E^2 = c^2 p_z^2 - |q|\,\hbar c^2 B$, which is negative for small p_z, so the configuration is unstable and the effective action acquires an imaginary part [1624]. The instability is real physics but it does not touch the real part, which is where the logarithm and hence b_0 live. Third, only the physical gluon polarizations were counted, the unphysical ones being assumed cancelled by ghosts; the gauge-invariant background-field computation does this explicitly and confirms Equation (102.42) [1463, 1501, 1511]. The argument is given in this form because it exhibits the *mechanism* — a competition between two magnetic responses that SI units keep visibly distinct — rather than only the answer.

Definition 102.38 (The scale of QCD)**.** Integrating Equation (102.42) between two energies gives

$$\frac{1}{\alpha_s(E)} = \frac{1}{\alpha_s(E_0)} + \frac{b_0}{2\pi} \ln \frac{E}{E_0}\,, \tag{102.44}$$

so that the pair (α_s, E_0) may be traded for the single energy Λ_{QCD} at which the right-hand side formally vanishes:

$$\alpha_s(E) = \frac{2\pi}{b_0 \ln\left(E/\Lambda_{\mathrm{QCD}}\right)}\,, \qquad \Lambda_{\mathrm{QCD}} = E_0 \exp\!\left[-\frac{2\pi}{b_0 \alpha_s(E_0)}\right]. \tag{102.45}$$

Phenomenon 102.39 (A mass scale from a dimensionless coupling)**.** The Lagrangian Equation (102.29) with the light quark masses set to zero contains no dimensionful parameter whatever: $\hbar$ and c are conversion factors, and α_s is a pure number by Equation (102.19).

Nevertheless the theory it defines has a scale, and the scale is of the observed size: Λ_{QCD} is a few hundred MeV, corresponding to a length $\hbar c/\Lambda_{\mathrm{QCD}}$ of about $1 \times 10^{-15}\,\mathrm{m}$ — the size of a hadron. Almost all of the mass of ordinary matter is set by this number, which appears in no line of the Lagrangian.

Rests on Equations (102.19), (102.29) *and* (102.45).

Derivation. *Derives Phenomenon 102.39.*

This is *dimensional transmutation*, and Equation (102.45) is the whole of it. A statement of the form "$\alpha_s = 0.118$" is meaningless without naming the scale at which it holds, because Equation (102.44) says the number changes with the scale; and a statement of the form "$\alpha_s = 0.118$ at E_0" contains one dimensionless number and one energy. The combination in Equation (102.45) is invariant under changing E_0: differentiating $\ln \Lambda_{\mathrm{QCD}} = \ln E_0 - 2\pi/\left(b_0 \alpha_s(E_0)\right)$ with respect to $\ln E_0$ gives $1 + \left(2\pi/b_0\alpha_s^2\right) \mathrm{d}\alpha_s/\mathrm{d}\ln E_0 = 1 - 1 = 0$ by Equation (102.42). So the theory has exactly one free parameter in its massless limit, and that parameter is an *energy*. The classical scale invariance of the massless Lagrangian is broken by the quantum theory — it is the trace anomaly, the same phenomenon in another guise — and Λ_{QCD} is what the breaking produces. Numerically, taking $E_0 = m_Z c^2 = 91.188\,\mathrm{GeV}$ and $\alpha_s = 0.1180$ [2427] with $n_f = 5$, so that $b_0 = 11 - \frac{10}{3} = \frac{23}{3}$,

$$\Lambda^{(5)}_{\mathrm{QCD}}\Big|_{\text{one loop}} = 91.188\,\mathrm{GeV} \times \mathrm{e}^{-6.945} = 88\,\mathrm{MeV}\,, \tag{102.46}$$

and at four loops in the $\overline{\mathrm{MS}}$ scheme the same data give about 0.21 GeV for five active flavours and about 0.33 GeV for three [2427]. The factor of two between Equation (102.46) and the four-loop value is not a discrepancy: Λ is defined by a truncation of Equation (102.42) and by a scheme, and changes when either changes, whereas α_s at a stated scale does not. That is why the Particle Data Group quotes $\alpha_s(m_Z c^2)$ and not Λ. What is robust, and what Phenomenon 102.39 asserts, is the order of magnitude and the fact that a scale exists at all. □

Remark 102.40 (The scale that no parameter contains). It is worth pausing on what has happened. The proton mass is $938\,\mathrm{MeV}/c^2$; the quark masses in Table 102.1 that build it sum to $9\,\mathrm{MeV}/c^2$. The remaining 99 % is Λ_{QCD}, and Λ_{QCD} is not a parameter of the theory: it is the scale at which a dimensionless coupling, run down from wherever it was measured, becomes of order one. Had $\alpha_s(m_Z c^2)$ been 0.09 instead of 0.118, Equation (102.45) would have put Λ_{QCD} at a few MeV and nucleons would have been a hundred times lighter and a hundred times larger. The exponential in Equation (102.45) is what converts a modest change in a dimensionless number into an enormous change in a mass, and it is the only mechanism in the Standard Model that generates a scale without being given one.

102.4.2 The measured running of α_s

Phenomenon 102.41 (The strong coupling weakens with energy)**.** Determinations of the strong coupling from τ decays, from lattice computation, from deep inelastic scattering, from hadronic event shapes and from Z-pole observables span more than two decades in momentum transfer and fall on one decreasing curve, with

$$\alpha_s(m_Z c^2) = 0.1180 \pm 0.0009 \tag{102.47}$$

at the Z mass [2427]. The strong interaction is therefore weak at short distance and strong at hadronic distances — the opposite of the behaviour established in Chapter 100, and the reason any perturbative calculation of a strong process is possible at all.

Rests on Equations (102.42) *and* (102.44).

Derivation. *Derives Phenomenon 102.41.*

The curve is Equation (102.44) with Equation (102.42), together with the rule that a quark decouples below its own mass — the decoupling theorem [1538] already used in Proposition 100.63 — so that n_f and hence b_0 change at each flavour threshold and α_s is matched continuously across it. Starting from Equation (102.47) and integrating downwards through the b threshold and upwards through the t threshold with the masses of Table 102.1 gives Table 102.2. The prediction is not one number but the shape of a curve over three decades, and the fact that determinations using entirely different physics land on it is the content of the phenomenon. □

Table 102.2: The one-loop running Equation (102.44) evolved from Equation (102.47), with n_f changing at the quark masses of Table 102.1. The last column is the distance $\hbar c/E$ resolved at that energy. The one-loop truncation is accurate to about one percent above 10 GeV and drifts low by roughly a tenth of its value at the τ mass, where the measured α_s is about 0.31 [2427]; this is the expected size of the $O(\alpha_s^3)$ term of Equation (102.42).

E	n_f	$\alpha_s(E)$ one loop	$\hbar c/E$
1.777 GeV ($m_\tau c^2$)	4	0.279	1.1×10^{-16} m
4.183 GeV ($m_b c^2$)	5	0.212	4.7×10^{-17} m
10 GeV	5	0.173	2.0×10^{-17} m
91.188 GeV ($m_Z c^2$)	5	0.1180	2.2×10^{-18} m
1 TeV	6	0.089	2.0×10^{-19} m

The determinations that must agree come from unrelated physics, and listing them is the point.

- *Hadronic τ decays.* The ratio of the τ's hadronic width to its electronic width is the analogue of R at $E = m_\tau c^2 = 1.777\,\text{GeV}$, and is calculable as a series in α_s using the analyticity of the correlator — a contour argument of the kind established in Chapter 8. It is the lowest-energy determination, and therefore the one with the longest lever arm when evolved to $m_Z c^2$.
- *Lattice QCD.* A short-distance quantity computed on the lattice (Section 102.7.1) and matched to its perturbative expansion determines α_s with no experimental input beyond the hadron masses used to set the scale. This class is currently the most precise.
- *Deep inelastic scattering.* The Q^2 dependence of the structure functions of Section 102.5 is governed by α_s through Section 102.5.2; here α_s is measured by a *slope*, not by a rate.
- *Event shapes and jet rates in e^+e^-.* The three-jet fraction of Section 102.6.2 is proportional to α_s at leading order.
- *Electroweak observables at the Z pole.* The hadronic width of the Z carries the factor $1 + \alpha_s/\pi + \dots$ of Phenomenon 102.15, measured at $E = m_Z c^2$ where no evolution is needed at all.

Remark 102.42 (Why the running is the strongest test of QCD). Any theory with one coupling can be made to fit one measurement of that coupling. What cannot be arranged is that five classes of measurement, at energies differing by a factor of five hundred and using different final states, different detectors and different theoretical machinery, agree after being

evolved by Equation (102.44) with a coefficient b_0 that is not adjustable — it is $11 - \frac{2}{3}n_f$, fixed by Theorem 102.35 from the group and the particle content alone. The agreement of the world data with one curve of predicted shape, rather than the value 0.1180 at one point, is the quantitative evidence for QCD. The general renormalization-group apparatus behind the evolution is the subject of Chapter 108; a systematic survey of the determinations is [2142, 2427].

102.5 Deep inelastic scattering and the parton model

102.5.1 Bjorken scaling and partons

Everything so far has been inference from a spectrum. Deep inelastic scattering is different in kind: it is Rutherford's experiment performed on the proton, and what it sees is not a symmetry but an object.

Notation 102.43 (Kinematics of inelastic lepton scattering). An electron of four-momentum k scatters off a proton of four-momentum P and mass M, emerging with k' and leaving an unobserved hadronic system X. Write $q = k - k'$ for the momentum transferred by the virtual photon and

$$Q^2 := -q^2\,, \qquad \nu := \frac{P\cdot q}{M}\,, \qquad x := \frac{Q^2}{2M\nu} = \frac{Q^2}{2P\cdot q}\,, \qquad y := \frac{P\cdot q}{P\cdot k}\,. \tag{102.48}$$

By Notation 100.1 a four-momentum carries kg m/s, so Q^2 carries $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$ and ν, being $P\cdot q/M$, is an *energy*: in the proton rest frame $\nu = E - E'$, the energy lost by the electron. Both x and y are dimensionless, and $0 \le x \le 1$ because $W^2c^2 := (P+q)^2c^2 \ge M^2c^4$ for any hadronic final state. Elastic scattering is $x = 1$; deep inelastic scattering means $Q^2c^2 \gg M^2c^4$ at fixed x.

Definition 102.44 (Structure functions)**.** Lorentz invariance, current conservation and parity restrict the inclusive cross-section, at one-photon exchange, to two independent functions of the two invariants:

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}E'} = \sigma_{\mathrm{Mott}}\left[W_2\left(x,Q^2\right) + 2W_1\left(x,Q^2\right)\tan^2\frac{\vartheta}{2}\right]\,, \tag{102.49}$$

with the Mott cross-section for a structureless target

$$\sigma_{\mathrm{Mott}} = \frac{\alpha^2\left(\hbar c\right)^2\cos^2\left(\vartheta/2\right)}{4E^2\sin^4\left(\vartheta/2\right)}\,, \tag{102.50}$$

of dimension m^2, ϑ the electron scattering angle and E its incident energy. The dimensionless structure functions are

$$F_1\left(x,Q^2\right) := Mc^2W_1\,, \qquad F_2\left(x,Q^2\right) := \nu W_2\,, \tag{102.51}$$

W_1 and W_2 each carrying $1/\mathrm{J}$.

Phenomenon 102.45 (The proton contains pointlike constituents)**.** In inelastic electron–proton scattering at large momentum transfer the cross-section falls far more slowly with Q^2 than the elastic one does, and the structure functions depend, to a good first approximation, only on the dimensionless combination $x = Q^2/2M\nu$ — with Q the momentum transferred, ν the energy transferred and M the proton mass — and not on Q^2 separately [1395, 1397], exactly as Bjorken had predicted from current algebra before the data existed [1393]. The two structure functions are moreover not independent:

$$F_2(x) = 2xF_1(x)\,, \tag{102.52}$$

which the data obey [2427]. Scaling says the target contains constituents that carry no scale of their own; Equation (102.52) says those constituents carry spin $\frac{1}{2}$. The experiment is Chapter 116.

Rests on Definition 102.44 and Equation (102.50).

Derivation. *Derives Phenomenon 102.45.*

Scaling. Suppose the photon, at large Q^2, resolves a time short compared with the time over which the proton's constituents interact with one another, so that it scatters elastically off one of them and the rest are spectators. This is the impulse approximation, and Feynman's name for the constituents is *partons* [1401]. Let the struck parton carry a fraction ξ of the proton's four-momentum, $p = \xi P$, and let it remain on its mass shell after the collision, its mass being ξM in the same approximation. Then

$$(\xi P + q)^2 = \xi^2 M^2 c^2 \quad \Longrightarrow \quad \xi^2 M^2 c^2 + 2\xi\, P\cdot q - Q^2 = \xi^2 M^2 c^2 \quad \Longrightarrow \quad \xi = \frac{Q^2}{2P\cdot q} = x\,. \tag{102.53}$$

So the measured variable x *is* the momentum fraction of the struck constituent: this is what makes x physical rather than a convenient abbreviation. The cross-section is then the incoherent sum over constituents of pointlike elastic cross-sections, each of which is the Mott formula Equation (102.50) times the squared charge, and the only place a scale could enter — a form factor, i.e. a size — is absent by hypothesis. Hence

$$F_2(x) = \sum_q Q_q^2\, x\,[q(x) + \bar{q}(x)]\ , \tag{102.54}$$

with $q(x)\mathrm{d}x$ the number of quarks of flavour q carrying momentum fraction in $\mathrm{d}x$: a function of x alone. Any structure of the constituents themselves would reintroduce a length and destroy the scaling, so scaling is the statement that the constituents are pointlike down to the resolution $\hbar c/Qc$ reached — about $1\times10^{-16}\,\mathrm{m}$ at the original SLAC energies, a tenth of the proton radius $8.4075\times10^{-16}\,\mathrm{m}$ [2431]. The contrast is with elastic scattering, whose cross-section carries the squared dipole form factor and therefore falls as Q^{-12}: the same beam sees a soft object elastically and hard objects inelastically, which is precisely Rutherford's situation.

The Callan–Gross relation. Decompose the virtual photon into its three polarization states in the frame where it moves along $+z$ and the struck parton along $-z$. A massless spin-$\frac{1}{2}$ parton coupling through the vector current $\bar{q}\gamma^\mu q$ conserves helicity, because γ^μ commutes with γ^5 up to a sign that leaves the chiral projectors intact and, for a massless fermion, chirality is helicity. After absorbing the photon the parton moves along $+z$; its helicity is unchanged, so its *spin projection on the z axis* has flipped, $\Delta J_z = \pm1$. Only a transverse photon, $\lambda = \pm1$, can supply that. The longitudinal photon, $\lambda = 0$, therefore cannot be absorbed at all:

$$\sigma_L = 0 \qquad \text{for spin-}\tfrac{1}{2}\text{ partons.} \tag{102.55}$$

Expressing the two cross-sections in terms of the structure functions, the transverse one is proportional to F_1 and the longitudinal to the combination $F_L := F_2 - 2xF_1$ (up to terms of order M^2c^4/Q^2c^2, negligible in the deep inelastic region), so Equation (102.55) is exactly Equation (102.52) [1398]. A spin-0 parton gives the opposite conclusion by the same argument — it has no spin to flip, so only $\lambda = 0$ is absorbed, $\sigma_T = 0$ and $F_1 = 0$ — and the data exclude it decisively: the measured ratio $R_L = \sigma_L/\sigma_T$ is small, as QCD predicts; the experimental write-up belongs to Section 116.4.3. □

Proposition 102.46 (The partons have fractional charge)**.** *Comparing charged-lepton and neutrino deep inelastic scattering on an isoscalar target measures the mean square charge of*

the constituents directly:

$$\frac{F_2^{eN}(x)}{F_2^{\nu N}(x)} = \frac{1}{2}\left[\left(\frac{2}{3}\right)^2 + \left(\frac{1}{3}\right)^2\right] = \frac{5}{18}\,, \tag{102.56}$$

which the data confirm [2427].

Rests on Definition 102.5 and Equation (102.54).

Proof. *Derives Proposition 102.46.*

The photon couples to a quark with strength $Q_q e$, so Equation (102.54) weights each flavour by Q_q^2. The charged weak current of Chapter 101 couples with a strength independent of electric charge, so the corresponding neutrino structure function is $F_2^{\nu N}(x) = x\sum_q [q(x) + \bar{q}(x)]$ with unit weights. On an isoscalar target the u and d distributions enter symmetrically, and the ratio of the two sums is the mean of $(2/3)^2$ and $(1/3)^2$, which is Equation (102.56). Had the constituents carried integer charges the ratio would have been of order unity instead of 0.28. This is a measurement of the charges themselves, independent of the spectroscopy of Section 102.1.3, and it is why neutrino scattering was decisive. □

Phenomenon 102.47 (Half the proton's momentum is electrically neutral)**.** Integrating the measured F_2 over x and dividing out the charge weights gives the total momentum fraction carried by charged constituents,

$$\int_0^1 \mathrm{d}x\; x \sum_q \left[q(x) + \bar{q}(x)\right] \approx 0.5\,, \tag{102.57}$$

so that about half the proton's momentum is carried by something that does not couple to the photon or to the weak current [2427]. The natural candidate is the gauge field itself.

Rests on Equations (102.53), (102.54) and (102.56).

Derivation. *Derives Phenomenon 102.47.*

The momentum of the proton is shared among its constituents by definition, $\int_0^1 \mathrm{d}x\, x \sum_{\text{all}} f_i(x) = 1$, since x is the momentum fraction (Equation (102.53)). The measured left-hand side of Equation (102.57) is obtained from Equation (102.54) together with Equation (102.56), the two providing enough information to separate the charge weights from the distributions; the details of the extraction belong in Section 116.5.2. The deficit is a fact about the data and not an inference: whatever carries the missing half is electrically neutral and weakly inert. In QCD it is the gluon, which appears here for the first time as an experimental necessity rather than a theoretical convenience — and it appeared this way, in the momentum sum rule, before it was seen in the three-jet events of Section 102.6.2. □

102.5.2 Scaling violation and the DGLAP equations

Scaling is not exact, and QCD says exactly how it fails. A quark is not free even at short distance: it can radiate a gluon, and the probability of doing so is not small because the emission is logarithmically enhanced when the gluon is soft or collinear — the same enhancement as the soft photon of Section 100.6.1. Raising Q^2 means resolving a smaller transverse distance, hence seeing emissions that were previously unresolved, hence finding more partons, each carrying less momentum. Structure functions therefore drift: down at large x, up at small x, logarithmically in Q^2.

Proposition 102.48 (Collinear emission and its logarithm)**.** *The probability that a quark of momentum fraction y radiates, leaving a quark of fraction $x = zy$, is*

$$\mathrm{d}\mathcal{P} = \frac{\alpha_s}{2\pi}\, P_{qq}(z)\,\mathrm{d}z\,\frac{\mathrm{d}k_T^2}{k_T^2}\,, \qquad P_{qq}(z) = C_F\left[\frac{1+z^2}{1-z}\right]_+\,, \tag{102.58}$$

with k_T the transverse momentum of the emitted gluon, $C_F = 4/3$ from Equation (102.31), and the plus prescription defined by $\int_0^1 \mathrm{d}z\,[g(z)]_+ f(z) = \int_0^1 \mathrm{d}z\, g(z)[f(z) - f(1)]$. Integrating $\mathrm{d}k_T^2/k_T^2$ up to the resolution Q^2 produces $\ln Q^2$, which is the entire origin of the scaling violation.

Rests on Equations (100.76) and (102.31) and Theorem 100.60.

Proof. *Derives Proposition 102.48.*

Two features are derived here and the third is quoted. The factor $\mathrm{d}k_T^2/k_T^2$ is the collinear singularity of a massless emitter: the propagator of the quark after emission has virtuality $(p-k)^2 \propto -k_T^2/(1-z)$, and the squared amplitude carries its inverse square against a two-body phase space $\propto \mathrm{d}k_T^2$, leaving $\mathrm{d}k_T^2/k_T^2$. It is logarithmic precisely because the emitter is massless, and it is the mass singularity of Theorem 100.60 in its QCD form. The factor $1/(1-z)$ is the soft singularity: as $z \to 1$ the gluon energy goes to zero and the amplitude reduces to the eikonal current Equation (100.76), whose square gives exactly this pole, with C_F replacing the squared electric charge because the emission vertex is T_a and $T_a T_a = C_F \mathbb{1}$. The numerator $1 + z^2$ is the spin structure of the vertex, the two terms being the helicity-conserving and helicity-flip configurations of the emitting quark; it is computed from the same trace technology as Section 100.3.2 [1474, 1591].

The plus prescription is not an extra assumption but a normalization forced by conservation of quark number. The number of quarks of a given flavour minus antiquarks is a conserved charge and cannot change with Q^2, so $\int_0^1 \mathrm{d}z\, P_{qq}(z) = 0$; the unregulated $1/(1-z)$ is not integrable, and the divergence is cancelled by the virtual correction, which lives entirely at $z = 1$. The plus prescription is exactly that cancellation written as a distribution: it subtracts, at $z = 1$, whatever the real emission supplies. Equivalently $[(1+z^2)/(1-z)]_+ = (1+z^2)\,[1/(1-z)]_+ + \frac{3}{2}\delta(1-z)$, and the $\frac{3}{2}$ is the virtual term. □

Theorem 102.49 (The DGLAP evolution equations)**.** *The parton distributions depend on the scale at which they are defined, and the dependence is*

$$\frac{\partial q_i(x,Q^2)}{\partial \ln Q^2} = \frac{\alpha_s(Q^2)}{2\pi} \int_x^1 \frac{\mathrm{d}y}{y} \left[P_{qq}\left(\frac{x}{y}\right) q_i(y,Q^2) + P_{qg}\left(\frac{x}{y}\right) g(y,Q^2) \right], \tag{102.59}$$

together with the companion equation for the gluon distribution involving P_{gq} and P_{gg} [1474, 1591, 1595]. The right-hand side is a multiplicative convolution on $(0,1]$ in the sense of Definition 17.97.

Rests on Proposition 102.48, Equation (102.58), and Definition 17.97.

Proof. *Derives Theorem 102.49.*

A parton of fraction x at resolution $Q^2 + \mathrm{d}Q^2$ is either one that was already there at Q^2, or one produced by an emission from a parton of larger fraction $y > x$ that the coarser resolution could not separate. Multiplying Equation (102.58) by the density of emitters $q_i(y)$, changing variables from z to $x = zy$ at fixed y so that $\mathrm{d}z = \mathrm{d}x/y$, and integrating $\mathrm{d}k_T^2/k_T^2$ over the shell between the two resolutions gives the first term of Equation (102.59). The second term is the same statement for a gluon converting to a quark–antiquark pair, with $P_{qg}(z) = T_F\,[z^2 + (1-z)^2]$. That the kernel depends on x and y only through x/y is a consequence of the collinear factorization: the emission probability knows only the momentum fraction taken, not the absolute momenta. Comparing with Equation (102.63) below identifies the integral as $(P \star q)(x)$ with the Haar measure $\mathrm{d}y/y$ of Definition 17.97, which is the structure that Corollary 102.50 exploits. □

Corollary 102.50 (Moments diagonalise the evolution)**.** *Define the moments of a distribution as in Equation (17.114), $M_N[f] = \int_0^1 f(x) x^N \mathrm{d}x$, so that $N = 0$ counts partons and $N = 1$ is the momentum fraction. For a non-singlet combination — one in which the gluon*

term of Equation (102.59) cancels, for instance $u-d$ or $q-\bar q$ — the evolution becomes an ordinary differential equation for each moment separately,

$$\frac{\mathrm{d}M_N}{\mathrm{d}\ln Q^2}=\frac{\alpha_s(Q^2)}{2\pi}\,\gamma_N\,M_N\,,\qquad \gamma_N:=\int_0^1 \mathrm{d}z\; z^N P_{qq}(z)\,, \tag{102.60}$$

whose solution, using Equation (102.42), is a pure power of the coupling:

$$\frac{M_N\left(Q^2\right)}{M_N\left(Q_0^2\right)}=\left[\frac{\alpha_s(Q^2)}{\alpha_s(Q_0^2)}\right]^{-2\gamma_N/b_0}\,. \tag{102.61}$$

The anomalous dimensions are

$$\gamma_N=C_F\left[\frac{3}{2}-H_N-H_{N+2}\right]\,,\qquad H_m:=\sum_{k=1}^{m}\frac{1}{k}\,, \tag{102.62}$$

with $\gamma_0=0$ and $\gamma_1=-\frac{4}{3}C_F=-\frac{16}{9}$.

Rests on Theorem 102.49, Corollary 17.99, and Equation (102.42).

Proof. *Derives Corollary 102.50.*

Write the convolution of Theorem 102.49 in the form

$$(P\star q)\,(x)=\int_x^1 P(y)\,q\!\left(\frac{x}{y}\right)\frac{\mathrm{d}y}{y}\,, \tag{102.63}$$

which is Equation (17.113): both factors vanish for argument greater than one, so the range is $x\le y\le 1$ and the convolution stays supported on the unit interval. By Corollary 17.99, and ultimately by the Mellin convolution theorem Theorem 17.98, the moments of a multiplicative convolution are the products of the moments, Equation (17.115). Taking M_N of Equation (102.59) therefore turns the integral operator into multiplication by $\gamma_N=M_N[P_{qq}]$, giving Equation (102.60). This is the whole reason the Mellin transform is the right instrument here: it diagonalises dilations, and Equation (102.59) is an equation about how momentum fractions dilate.

To solve, divide Equation (102.60) by Equation (102.42) rewritten as $\mathrm{d}\alpha_s/\mathrm{d}\ln Q^2=-b_0\alpha_s^2/4\pi$ — the factor $\frac{1}{2}$ relative to Equation (102.42) because $\ln Q^2=2\ln Q$. Then $\mathrm{d}\ln M_N/\mathrm{d}\alpha_s=-2\gamma_N/(b_0\alpha_s)$, which integrates to $M_N\propto\alpha_s^{-2\gamma_N/b_0}$ and hence to Equation (102.61).

For Equation (102.62), use the plus prescription:

$$\gamma_N=C_F\int_0^1\mathrm{d}z\,\frac{\left(z^N-1\right)\left(1+z^2\right)}{1-z}\,,$$

the subtraction at $z=1$ making the integrand finite. Split the numerator: $\left(z^N-1\right)+\left(z^{N+2}-z^2\right)$, and write the second bracket as $\left(z^{N+2}-1\right)-\left(z^2-1\right)$. With $\int_0^1\left(z^m-1\right)/(1-z)\,\mathrm{d}z=-H_m$ — immediate from $\left(1-z^m\right)/(1-z)=1+z+\cdots+z^{m-1}$ integrated term by term — this gives $\gamma_N=C_F\left[-H_N-H_{N+2}+H_2\right]$ and $H_2=\frac{3}{2}$, which is Equation (102.62). Checking: $\gamma_0=C_F[\frac{3}{2}-0-\frac{3}{2}]=0$, as quark-number conservation demands, and $\gamma_1=C_F[\frac{3}{2}-1-\frac{11}{6}]=-\frac{4}{3}C_F$. □

Example 102.51 (How fast a moment moves)**.** Take the momentum moment $N=1$ of a non-singlet distribution and evolve from $Qc=10\,\mathrm{GeV}$ to $Qc=100\,\mathrm{GeV}$ with $n_f=5$, so $b_0=23/3$ and the exponent in Equation (102.61) is $-2\gamma_1/b_0=(32/9)\,(3/23)=0.464$. From Table 102.2, α_s falls from 0.173 to 0.116 over that range, a ratio 0.673, so

$$\frac{M_1\left(Q^2\right)}{M_1\left(Q_0^2\right)}=0.673^{0.464}=0.83\,. \tag{102.64}$$

The momentum carried by the valence quarks falls by about a sixth over one decade in Q: a large, slow, logarithmic effect, exactly what distinguishes a scaling violation from a scaling failure.

Remark 102.52 (The prediction is a shape, not a number). QCD does not predict $q(x, Q_0^2)$: the distributions at one scale are non-perturbative and must be measured. What it predicts is their entire Q^2 dependence, with no free parameter beyond α_s. Equation (102.61) makes the point sharply: the ratio of two moments' evolution,

$$\frac{\ln\left[M_N(Q^2)/M_N(Q_0^2)\right]}{\ln\left[M_M(Q^2)/M_M(Q_0^2)\right]} = \frac{\gamma_N}{\gamma_M}\,, \tag{102.65}$$

contains neither α_s nor Λ_{QCD} nor the initial distributions — only the two rational numbers of Equation (102.62). Plotting one moment against another on logarithmic axes must give a straight line of predicted slope, and it does. Global fits to data spanning four orders of magnitude in Q^2 and five in x are described by Equation (102.59) with one coupling; this is the most demanding quantitative test QCD has passed, and its experimental side belongs to Section 116.6.4.

102.5.3 Factorization and parton distributions

Equation (102.54) and Equation (102.59) together contain a claim that goes far beyond deep inelastic scattering: that a hadronic cross-section splits into a part depending on the hard process, which is calculable, and a part depending on the hadron, which is not but is *universal*.

Theorem 102.53 (Collinear factorization)**.** *For an inclusive process with a large scale Q, the cross-section can be written to leading power in Λ_{QCD}/Q as*

$$\sigma = \sum_{i,j} \int \mathrm{d}x_1 \mathrm{d}x_2 \; f_i\left(x_1, \mu_F^2\right) f_j\left(x_2, \mu_F^2\right) \hat{\sigma}_{ij}\left(x_1, x_2, Q^2, \mu_F^2, \alpha_s\right)\,, \tag{102.66}$$

where $\hat{\sigma}_{ij}$ is a partonic cross-section computable as a series in α_s and the f_i are parton distributions that depend on the hadron but not on the process. The arbitrary scale μ_F separating the two is a factorization scale; its μ_F-dependence cancels between the two factors order by order, and $\partial f_i/\partial \ln \mu_F^2$ is Equation (102.59).

Rests on Equations (102.54) and (102.59).

Derivation pending #149

Collinear factorization to all orders. What is available inline is the leading-order statement, which is the impulse approximation together with the observation that the collinear logarithms are universal because they come from the region where the emitted parton is nearly on shell and therefore long-lived compared with the hard collision. The all-orders proof requires showing that the leading regions of the loop momenta are exhausted by hard, collinear and soft subgraphs, that the soft gluons cancel or are absorbed into eikonal lines, and that what remains is the same operator matrix element in every process. That analysis, and the counterexamples at subleading power, belong in Appendix A.

The physical content is that the distributions may be *measured in one process and used in another*. They are extracted from deep inelastic scattering on fixed targets and at HERA, and then used — with the evolution Equation (102.59) carrying them from $Q \sim 10\,\mathrm{GeV}/c$ to $Q \sim 1\,\mathrm{TeV}/c$ — to predict cross-sections at hadron colliders. Every Standard Model rate

measured at the LHC, the Higgs production of Chapter 113 included, is computed with Equation (102.66) and would be unpredictable without it. That the same $f_i(x,\mu_F^2)$ describe electron–proton scattering at 10 GeV and proton–proton collisions at 13 TeV is a test of universality across three decades in scale and two different initial states, and it is the reason Theorem 102.53 is stated as a theorem rather than as a modelling assumption [1817].

Remark 102.54 (What the factorization scale is not). μ_F is not a physical boundary between "inside" and "outside" the proton. It is a subtraction point, exactly like the renormalization scale of Definition 100.54: emissions harder than μ_F are put into $\hat{\sigma}$ and those softer into f_i, and the split is a bookkeeping choice. A complete calculation is μ_F-independent; a calculation truncated at order α_s^n has a residual dependence of order α_s^{n+1}, and varying μ_F by a factor of two is the standard — and admittedly crude — estimate of the missing higher orders. A parton distribution is therefore not a probability density in any scheme-independent sense; it is a scheme-dependent object, and quoting one without its scheme and scale is meaningless.

102.6 Jets and the gluon

102.6.1 Two-jet events and the quark spin

Deep inelastic scattering sees the constituents by their recoil. Electron–positron annihilation makes a pair of them directly, and what the detector records is the closest thing to a photograph of a quark that confinement permits.

Proposition 102.55 (Angular distribution of a produced fermion pair). *For $e^+e^-\to f\bar{f}$ through one virtual photon, with all masses negligible,*

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}=\frac{\alpha^2\,(\hbar c)^2}{4E_{\mathrm{cm}}^2}\,Q_f^2\,N_c^{(f)}\left(1+\cos^2\vartheta\right), \tag{102.67}$$

ϑ being the angle between the outgoing fermion and the beam. A produced spin-0 pair would give $\sin^2\vartheta$ instead.

Rests on Equations (100.32) and (100.40) and Definition 102.10.

Proof. *Derives Proposition 102.55.*

Section 100.3.1 gives the spin-averaged squared amplitude for this process as $\overline{|\mathcal{M}|^2}=32\pi^2\alpha^2\hbar^4\,(t^2+u^2)\,/s^2$. For massless kinematics in the centre-of-mass frame, $t=-\tfrac{1}{2}s\,(1-\cos\vartheta)$ and $u=-\tfrac{1}{2}s\,(1+\cos\vartheta)$, so

$$\frac{t^2+u^2}{s^2}=\frac{1}{4}\left[(1-\cos\vartheta)^2+(1+\cos\vartheta)^2\right]=\frac{1+\cos^2\vartheta}{2}\,.$$

Inserting this into the two-body phase space of Equation (100.40) and multiplying by Q_f^2 for the charge and by N_c for the colour multiplicity gives Equation (102.67); integrating over angles returns Equation (100.32) times the same factors, which is Equation (102.15). The $\sin^2\vartheta$ for scalars follows because a scalar pair produced by a vector current must be in a p-wave with $J_z=0$ along the pair axis, and the corresponding Wigner function is $\sin\vartheta$. □

Phenomenon 102.56 (Hadrons emerge as jets, and some events have three). High-energy e^+e^- annihilation does not produce hadrons isotropically. Most events consist of two back-to-back collimated sprays whose common axis follows the $1+\cos^2\vartheta$ distribution characteristic of a produced spin-$\tfrac{1}{2}$ pair [1548], and a calculable minority are planar events with three distinct sprays [1634]. The energy sharing and the angular correlations of the third spray are those of radiation emitted by a coloured source into a massless spin-one quantum. This is the only direct evidence for the gluon, and it is direct only in the sense that a jet, not a parton, is what a detector records.

Rests on Equations (102.58) and (102.67).

Derivation of the two-jet structure. *Derives Phenomenon 102.56.*

Two facts make a jet. First, the parton pair is produced back to back with energy $E_{\mathrm{cm}}/2$ each, and the angular distribution of the pair axis is Equation (102.67) — an observable that survives hadronization because the subsequent radiation is soft. Second, the radiation *is* soft and collinear: by Equation (102.58) the emission probability is concentrated at small k_T, so the hadrons that materialize share the parton's direction to within an angle of order Λ_{QCD}/E. The transverse momentum inside a jet is therefore bounded by a hadronic scale while its longitudinal momentum grows with the beam energy, and the spray narrows as $1/E$. Hanson and collaborators established this at SPEAR by measuring the sphericity tensor and showing that its principal axis is distributed as $1+\cos^2\vartheta$ [1548]: the axis of a spray of hadrons remembers the spin of a particle that was never observed. □

Remark 102.57 (What a jet has to be to be calculable). A jet is defined by an algorithm, and not every algorithm defines a calculable quantity. Theorem 100.58 and Theorem 100.60 say that infrared and collinear divergences cancel between real and virtual corrections only for observables that are *inclusive* over soft emission and over collinear splitting. An observable is called infrared and collinear safe if it is unchanged by adding a zero-energy particle and by replacing any particle with two collinear ones carrying its total momentum [1611]. The jet algorithms in use are constructed to have that property, and quantities computed from algorithms that lack it are not merely imprecise but divergent order by order. This is the practical content of Theorem 100.60 in QCD, and it is why the comparison of Phenomenon 102.56 with theory compares *jet* rates and never parton rates.

102.6.2 Three-jet events: the gluon

Proposition 102.58 (The three-jet energy distribution). *Let $x_i = 2E_i/E_{\mathrm{cm}}$ be the scaled energies of the quark, antiquark and gluon, so that $x_1+x_2+x_3=2$. Then to first order in α_s*

$$\frac{1}{\sigma_0}\frac{\mathrm{d}^2\sigma}{\mathrm{d}x_1\,\mathrm{d}x_2} = \frac{\alpha_s}{2\pi}\,C_F\,\frac{x_1^2+x_2^2}{(1-x_1)\,(1-x_2)} = \frac{2\alpha_s}{3\pi}\,\frac{x_1^2+x_2^2}{(1-x_1)\,(1-x_2)}\,, \tag{102.68}$$

with σ_0 the two-jet cross-section Equation (102.67) integrated over angles [1668]. Had the emitted quantum been a scalar rather than a vector, the numerator would have been x_3^2.

Rests on Proposition 102.48 and Equations (100.76) and (102.31).

Derivation of the singular structure. *Derives Proposition 102.58.*

The two limits that dominate the rate are derivable from results already established, and they already distinguish a vector from a scalar.

Soft. As $x_3\to 0$ both x_1 and x_2 tend to 1, and the amplitude factorizes into the two-jet amplitude times the eikonal current Equation (100.76) of Section 100.6.1, with the electric charge replaced by g_sT_a and the colour factor $T_aT_a=C_F$ of Equation (102.31). Squaring gives the double pole $[(1-x_1)(1-x_2)]^{-1}$ of Equation (102.68) with numerator 2, which is $x_1^2+x_2^2$ at $x_1=x_2=1$. A scalar emitter has no such factorization: a soft scalar does not couple to the eikonal current at all, because the coupling to a fast fermion line is suppressed by the emitted energy, and $x_3^2\to 0$ in the same limit. The observed events pile up at the soft edge, and that alone excludes a scalar.

Collinear. As $x_1\to 1$ at fixed x_2 the gluon becomes collinear with the antiquark, and Equation (102.68) reduces to $(\alpha_s/2\pi)\,C_F\,(1+x_2^2)\,/\,[(1-x_1)(1-x_2)]$, whose x_2 dependence is the splitting function Equation (102.58) with $z=x_2$ — as it must be, since Proposition 102.48 and Equation (102.68) are two views of the same emission. That the same function $C_F(1+z^2)/(1-z)$ governs scaling violation in Section 102.5.2 and the three-jet rate here is a consistency requirement of the theory and is tested by the agreement of the two determinations of α_s in Section 102.4.2. □

Derivation pending #150

The exact order-α_s three-jet distribution. What is derived inline is the soft and collinear structure, which is where the rate is concentrated and which already excludes a scalar gluon. The full matrix element requires the spin-summed trace over the two interfering diagrams in which the gluon is emitted from the quark and from the antiquark, together with the three-body phase space in the Dalitz variables; and the corresponding statement for a scalar emitter, needed to make the exclusion quantitative rather than qualitative. Both are trace computations of the kind carried out for the electromagnetic processes and belong beside them in Appendix A.

The experimental history is short and decisive. Planar three-jet events were reported by TASSO at PETRA in 1979 [1634] and confirmed within months by the other three experiments at the same machine. The interpretation rests on more than the existence of a third spray: the distribution of energy between the three jets follows Equation (102.68), and the orientation of the three-jet plane relative to the beam — and of the jets within it — is that of a vector quantum and not a scalar. The measurement that established this is the distribution in the Ellis–Karliner angle, the angle between the two most energetic jets in the rest frame of the two least energetic, which is sensitive to the spin of the radiated quantum and insensitive to almost everything else.

Remark 102.59 (Testing the non-abelian structure itself). The existence of a spin-one mediator is not yet the existence of a *non-abelian* one. What distinguishes QCD from an abelian theory of coloured quarks and a neutral gluon is the triple-gluon vertex of Equation (102.28), and that vertex first contributes to a four-jet final state, where a gluon splits into two gluons. The angular correlations among four jets — notably the angle between the planes defined by the two hardest and the two softest jets — depend on the ratio C_A/C_F, which the group theory of Equation (102.31) fixes at 9/4. The LEP experiments measured C_A and C_F from four-jet rates and correlations and found values consistent with 3 and 4/3 at the ten-percent level [2427], with the abelian alternative ($C_A = 0$) excluded by many standard deviations. This is the closest thing to a direct measurement of the gluon self-coupling, and therefore of the mechanism that Theorem 102.35 says produces asymptotic freedom.

102.7 Confinement

102.7.1 Lattice gauge theory

Everything in Sections 102.4 and 102.5 was perturbative and therefore restricted to short distance. Confinement is a long-distance statement, and the only systematic method for it is Wilson's [1537]: define the theory on a Euclidean lattice, where the functional integral is a finite-dimensional ordinary integral, and evaluate it. The construction is carried out in Section 106.5.1 and is not repeated here; what is repeated is what it buys and what it does not.

Three of its results are used throughout this chapter. The link variables Equation (106.79) put the gauge field in the *group* rather than the algebra, so gauge invariance is exact at finite spacing and there is no gauge fixing and no ghost (Proposition 106.67). The Wilson action Equation (106.81) reduces to Equation (102.27) as the spacing goes to zero (Theorem 106.68), with lattice coupling $\beta = 6/\hat{g}^2 = 6/(4\pi\alpha_s)$ for SU(3). And the Wilson loop Definition 106.70 measures the static potential, an area law being equivalent to a linearly rising $V(R)$ (Proposition 106.71).

Theorem 102.60 (Confinement at strong coupling, and what it proves)**.** *For $\beta \ll 1$ the Wilson loop obeys an area law with string tension $\sigma = (\hbar c/a^2)\ln(2N^2/\beta)$, which is Equation* (106.84)*. This is an exact statement about the lattice theory at strong bare coupling. It is* not *a proof of confinement in QCD.*

Rests on Theorems 100.25 and 106.72 and Equation (106.84)*.*

Proof. *Derives Theorem 102.60.*

The area law itself is Theorem 106.72. The second sentence is the point at issue and is established by a counterexample. Compact U(1) lattice gauge theory — lattice electrodynamics — obeys the same strong-coupling area law, by the same plaquette-tiling argument, since that argument uses only the group integration formula $\int \mathrm{d}U\, U = 0$ and never the non-abelian structure. But continuum electrodynamics manifestly does not confine: the Coulomb potential of Theorem 100.25 is measured every day. The resolution is that compact U(1) in four dimensions has a genuine phase transition at intermediate β separating a confining strong-coupling phase from a Coulomb weak-coupling phase, and the continuum limit is taken in the latter. Hence a strong-coupling area law establishes nothing about the continuum theory unless one also knows that no such transition intervenes between $\beta \ll 1$ and the continuum limit $\beta \to \infty$ demanded by Remark 106.69. For SU(3) the absence of a transition is a numerical finding, not a theorem. □

The first such demonstration is Creutz's, for the gauge group SU(2) [1651]. Computing the string tension by Monte Carlo across the region where the strong-coupling expansion fails, he found no discontinuity, and found in addition that σa^2 falls with β at the rate that asymptotic freedom demands for that group — *asymptotic scaling*: the lattice spacing shrinks with the bare coupling exactly as the running of the coupling requires, so that σ expressed in physical units is β-independent. That is the statement that the lattice theory and the asymptotically free continuum theory are the same theory. It is a numerical demonstration to finite accuracy. For SU(3) the same continuity and scaling have since been established on the lattice, most sharply by the spectroscopy computations of [2122], and that is what the honest claim in Section 102.7.3 rests on.

Remark 102.61 (Lattice QCD as a source of numbers)*.* Since Creutz the method has become quantitative. With improved actions, physical quark masses, several lattice spacings extrapolated to zero and several volumes extrapolated to infinity, lattice QCD computes: the light hadron spectrum to about one percent [2122]; the quark masses of Table 102.1, which are *defined* by the lattice or by sum rules since no quark is ever isolated; α_s, currently the most precise determination entering Equation (102.47); decay constants and form factors needed to extract the quark mixing parameters of Chapter 103; the equation of state of hot matter (Section 102.9); and the hadronic vacuum polarization entering the muon anomaly [2375]. What it does not do is prove anything: it is a controlled numerical evaluation of a functional integral with quantified statistical and systematic uncertainties, which is a different epistemic object from a theorem and is treated as such throughout this chapter. Its relationship to the statistical mechanics of Chapter 118 is exact — the Euclidean weight $\mathrm{e}^{-S_E/\hbar}$ is a Boltzmann factor — and the continuum limit is a critical point in the sense of Chapter 123.

102.7.2 The static potential and hadron masses

Phenomenon 102.62 (The static potential rises linearly)**.** The energy of a static colour source and its anticolour separated by r is, over the range $0.2 \times 10^{-15}\,\mathrm{m} \lesssim r \lesssim 1 \times 10^{-15}\,\mathrm{m}$ accessible both to lattice computation and to quarkonium spectroscopy,

$$V(r) = -\frac{C_F\,\alpha_s \hbar c}{r} + \sigma r\,, \qquad \sigma \approx 0.9\,\mathrm{GeV/fm} = 1.4 \times 10^5\,\mathrm{N}\,, \tag{102.69}$$

the first term being the short-distance Coulomb-like exchange with the colour factor $C_F = 4/3$ of Equation (102.31) and the second the confining term. The string tension σ is a force, and it is about fourteen tonnes weight.

Rests on Equations (14.77) *and* (102.31) *and Proposition 106.71.*

Derivation of the two terms and a numerical test. *Derives Phenomenon 102.62.*

The Coulomb term is one-gluon exchange between a colour source in $\mathbf{3}$ and one in $\bar{\mathbf{3}}$ coupled to a singlet. The colour factor is $\langle T_a \otimes T_a \rangle_{\mathbf{1}} = \frac{1}{2}\left[C_2(\mathbf{1}) - 2C_2(\mathbf{3})\right] = -C_F$, using $C_2(\mathbf{1}) = 0$ and Equation (14.77); the sign is attraction, and the magnitude is $4/3$ times the electromagnetic case with $\alpha \to \alpha_s$. Note that the same computation for a $\mathbf{3} \otimes \mathbf{3}$ pair coupled to $\bar{\mathbf{3}}$ gives $-C_F/2$, attractive but weaker, and for the symmetric $\mathbf{6}$ gives $+C_F/4$, repulsive: colour singlets are the most tightly bound configurations available, which is Postulate 102.11 made plausible.

The linear term is not derived here — it is measured on the lattice and inferred from the spectrum — but it has a check that costs one page and is worth doing, because it connects Equation (102.69) to a completely independent body of data. Model the confining flux as a relativistic string of tension σ with massless ends rotating rigidly at the speed of light. If the string has total length $2R$, the transverse speed at distance r from the centre is $v = cr/R$, and

$$E = 2\int_0^R \frac{\sigma \, \mathrm{d}r}{\sqrt{1 - r^2/R^2}} = \pi\sigma R\,,$$
$$J = \frac{2}{c^2}\int_0^R \frac{\sigma \, v \, r \, \mathrm{d}r}{\sqrt{1 - r^2/R^2}} = \frac{2\sigma}{cR}\int_0^R \frac{r^2 \mathrm{d}r}{\sqrt{1 - r^2/R^2}} = \frac{\pi\sigma R^2}{2c}\,, \tag{102.70}$$

using $\int_0^1 u^2(1-u^2)^{-1/2}\mathrm{d}u = \pi/4$. Eliminating R and writing $E = Mc^2$ and $J = \hbar j$,

$$j = \frac{M^2 c^3}{2\pi\sigma\hbar}\,, \tag{102.71}$$

a linear *Regge trajectory*: spin proportional to squared mass, with a slope fixed by the string tension alone. The name records Regge's poles in complex angular momentum [1174]; that the observed hadronic trajectories are in fact linear is an empirical statement about the spectrum, tested on the ρ data below [2427]. Numerically, $\sigma = 1.442 \times 10^5\,\mathrm{N}$ gives $j = 0.896$ for $Mc^2 = 1\,\mathrm{GeV}$: by Equation (102.71) the slope of j in the squared rest energy $(Mc^2)^2$ is $1/(2\pi\sigma\hbar c) = 3.49 \times 10^{19}/\mathrm{J}^2$, that is $0.896/\mathrm{GeV}^2$ in the customary units. The measured ρ trajectory — $\rho(775)$ with $j = 1$, $a_2(1320)$ with $j = 2$, $\rho_3(1690)$ with $j = 3$ [2427] — has slope $0.882/\mathrm{GeV}^2$ between the first two states and $0.895/\mathrm{GeV}^2$ between the second and third. Agreement to about one percent, from a string tension measured in an entirely different way, and with no adjustable parameter: the linearity of Equation (102.69) and the linearity of the observed meson trajectories are the same fact. □

Remark 102.63 (Quarkonium as the short-distance probe). Charmonium and bottomonium are non-relativistic bound states of heavy quarks and therefore sample Equation (102.69) at small r, where the Coulomb term dominates. Their spectra test the potential directly. The signature fact is that the spacing between the ground state and the first radial excitation is nearly the same in the two systems — $0.589\,\mathrm{GeV}/c^2$ for $\psi(2S) - J/\psi(1S)$ and $0.563\,\mathrm{GeV}/c^2$ for $\Upsilon(2S) - \Upsilon(1S)$ [2427], with $m_{J/\psi}c^2 = 3.0969\,\mathrm{GeV}$ and $m_\Upsilon c^2 = 9.4604\,\mathrm{GeV}$ — although the reduced masses differ by a factor of three. A pure Coulomb potential would give spacings scaling as the reduced mass; a pure linear potential would give them scaling as $m^{-1/3}$; the observed mass-independence is what an intermediate, roughly logarithmic, potential produces, and Equation (102.69) is exactly such a potential over the relevant range.

Phenomenon 102.64 (Almost none of the proton's mass comes from quark masses)**.** The proton mass is $938.272\,\mathrm{MeV}/c^2$, while the current masses of its three valence quarks sum to

less than $10\,\mathrm{MeV}/c^2$ [2427] — about one percent of the total. The remainder is the energy of the gluon field and of the confined motion of the quarks. That this is not an evasion is shown by computation: lattice evaluations of the light hadron spectrum, taking as input only the quark masses and the coupling, reproduce the measured masses at the percent level [2122].

Rests on Phenomenon 102.39 and Equations (102.29) *and* (106.81).

Derivation. *Derives Phenomenon 102.64.*

The arithmetic is immediate from Table 102.1: $2m_u + m_d = 9.02\,\mathrm{MeV}/c^2$ against $938.272\,\mathrm{MeV}/c^2$, so 99 % of the mass is not quark mass. What has to be explained is not the deficit but the *presence* of a scale at all, and that is Phenomenon 102.39: in the limit $m_u, m_d \to 0$ the Lagrangian Equation (102.29) contains no dimensionful parameter, yet the quantum theory generates Λ_{QCD} through Equation (102.45), and every mass in the spectrum is a pure number times $\Lambda_{\mathrm{QCD}}/c^2$. The proton mass is therefore predicted up to that one overall scale, which is fixed by measuring any single hadron mass; everything else is then a prediction with no freedom.

Turning that into numbers is a computation and not a derivation, and the distinction is worth keeping. The lattice programme [2122] proceeds by: choosing the bare quark masses and β; computing hadron correlators by Monte Carlo evaluation of Equation (106.81) with dynamical quarks; setting the scale by matching one measured quantity, so that a is known in metres; tuning the light quark masses by matching two more, typically m_π and m_K; extrapolating to zero spacing, to infinite volume and, where necessary, to the physical light quark masses; and then *predicting* the remaining spectrum. Three inputs, and the masses of the nucleon, the Δ, the Λ, the Σ, the Ξ and the Ω come out right to a few percent. That is the strongest single piece of evidence that Equation (102.29) is the correct theory of the strong interaction, and it is the reason this chapter can call confinement an observed regularity of a known Lagrangian rather than a mystery. □

102.7.3 No free quark has ever been observed

Phenomenon 102.65 (No free quark has ever been observed)**.** No particle carrying a fractional electric charge has been detected in any experiment. Millikan-type searches for residual fractional charge in bulk matter set limits below 10^{-20} fractionally charged particles per nucleon in the best samples [1992], and accelerator and cosmic-ray searches are likewise null [2427]. The positive counterpart of this null result is that the potential energy between a static colour source and its anticolour grows linearly with their separation instead of falling off, so that pulling them apart creates a new pair rather than liberating a colour charge.

Rests on Equations (102.12) *and* (102.69).

Derivation of the string-breaking mechanism. *Derives Phenomenon 102.65.*

Take Equation (102.69) at face value and try to separate a quark from an antiquark. At separation r the stored energy is σr, and it grows without bound. But the vacuum is not empty: as soon as σr exceeds the energy needed to create a light quark–antiquark pair, roughly twice the constituent mass Equation (102.12), it is energetically favourable for the flux tube to break, the new pair capping the two broken ends. The critical separation is

$$r_{\mathrm{break}} \approx \frac{2m_q c^2}{\sigma} = \frac{2 \times 0.336\,\mathrm{GeV}}{0.9\,\mathrm{GeV/fm}} \approx 0.7 \times 10^{-15}\,\mathrm{m}\,, \tag{102.72}$$

which is smaller than a hadron. So the attempt to isolate a quark produces, at a separation of less than one hadron radius, two hadrons instead: what would have been a free colour source is always screened by a newly created one before it can be separated. This is why the null results above are expected, and it is also why they cannot be strengthened into an observation of the mechanism: the mechanism predicts precisely that nothing anomalous is ever seen. □

Derivation pending #151

Confinement: no analytic derivation from the continuum Lagrangian exists, and none should be implied. What is available is Wilson's area law for the loop expectation value, exact in the strong-coupling lattice expansion, together with the numerical demonstration that the lattice theory joins continuously onto the asymptotically free continuum. Closing the gap between those two statements is an open problem, not an exercise.

Remark 102.66 (The honest status of confinement). Three statements must be kept apart, and conflating them is the commonest overclaim in expositions of QCD. *(i)* No free quark has been observed. This is an experimental fact, Phenomenon 102.65. *(ii)* The lattice theory confines at strong coupling. This is a theorem, Theorem 102.60, and by the compact-U(1) counterexample given in its proof it does not by itself say anything about the continuum theory. *(iii)* Continuum SU(3) Yang–Mills theory has a mass gap and confines. This is neither observed directly nor proved. It is supported by numerical evidence of high quality — the asymptotic scaling first demonstrated for SU(2) [1651] and the SU(3) spectrum of [2122] — and it is one of the recognized open problems of mathematical physics, recorded as such in Chapter 133. This chapter asserts (i) and (ii) and reports (iii) as well supported and unproved.

102.8 Chiral symmetry and its breaking

102.8.1 The chiral limit

Table 102.1 contains a striking accident. The masses of the two lightest quarks, $2.16\,\mathrm{MeV}/c^2$ and $4.70\,\mathrm{MeV}/c^2$, are of the order of one percent of Λ_{QCD}, which is the only other scale in the theory. To that accuracy they may be set to zero, and the resulting theory has a symmetry that the real one nearly has.

Proposition 102.67 (The chiral symmetry of massless quarks)**.** *Write $q = q_L + q_R$ with the projectors $P_{L,R} = \tfrac{1}{2}\left(\mathbb{1} \mp \gamma^5\right)$. In Equation (102.29) the gauge coupling is diagonal in chirality and the mass term is not:*

$$\bar{q}\mathrm{i}\hbar c\gamma^\mu D_\mu q = \bar{q}_L \mathrm{i}\hbar c\gamma^\mu D_\mu q_L + \bar{q}_R \mathrm{i}\hbar c\gamma^\mu D_\mu q_R\,, \qquad \bar{q}mc^2 q = c^2\left(\bar{q}_L m q_R + \bar{q}_R m q_L\right)\,. \tag{102.73}$$

Hence for n_f massless flavours the Lagrangian is invariant under independent unitary rotations of the left- and right-handed fields,

$$\mathrm{SU}(n_f)_L \times \mathrm{SU}(n_f)_R \times \mathrm{U}(1)_V \times \mathrm{U}(1)_A\,, \tag{102.74}$$

of which $\mathrm{U}(1)_V$ is baryon number and $\mathrm{U}(1)_A$ is destroyed by the axial anomaly of Theorem 106.87.

Rests on Equations (102.21) and (102.29) and Theorem 106.87.

Proof. *Derives Proposition 102.67.*

γ^5 anticommutes with every γ^μ, so $P_L\gamma^\mu = \gamma^\mu P_R$ and $\bar{q}_L\gamma^\mu q_R = q^\dagger P_L\gamma^0\gamma^\mu P_R q = q^\dagger\gamma^0 P_R\gamma^\mu P_R q = 0$ because $P_R\gamma^\mu P_R = \gamma^\mu P_L P_R = 0$; the cross terms in the kinetic piece therefore vanish, which is the first half of Equation (102.73). For the mass term the same algebra keeps only the cross terms, since $\bar{q}_L q_L = 0$. The covariant derivative Equation (102.21) contains no γ^5 and acts only on colour, so it commutes with the flavour rotations $q_L \to U_L q_L$, $q_R \to U_R q_R$; with the mass matrix set to zero nothing else connects the two chiralities, giving Equation (102.74). Splitting $\mathrm{U}(n_f) = \mathrm{SU}(n_f) \times \mathrm{U}(1)$ on each side and recombining the two U(1)s into vector ($U_L = U_R$) and axial ($U_L = U_R^\dagger$) combinations names the last

two factors. The vector one is the conservation of baryon number. The axial one is not a symmetry of the quantum theory at all: the measure of the functional integral is not invariant under it, which is Theorem 106.87, and the classical current has an anomalous divergence proportional to the gluon topological density. □

Phenomenon 102.68 (The spectrum has no parity doublets)**.** If $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$ were realized in the ordinary way — as a symmetry of the states as well as of the Lagrangian — every hadron would have a partner of equal mass and opposite parity. It does not. The lightest vector meson is the $\rho(775)$ with $J^{PC} = 1^{--}$ and its chiral partner the $a_1(1260)$ with 1^{++}, some $455\,\mathrm{MeV}/c^2$ heavier; the nucleon at $939\,\mathrm{MeV}/c^2$ with $J^P = \frac{1}{2}^+$ has as its partner the $N(1535)$ with $\frac{1}{2}^-$, some $596\,\mathrm{MeV}/c^2$ heavier [2427]. Meanwhile the *vector* subgroup $\mathrm{SU}(2)_V$ — ordinary isospin — is realized in the usual way, the proton and neutron differing by $1.3\,\mathrm{MeV}/c^2$, one part in seven hundred [2427].

Rests on Proposition 102.67 and Equation (102.74)*.*

Derivation. Derives Phenomenon 102.68.

If a symmetry generator Q annihilates the vacuum then it commutes with the Hamiltonian and maps energy eigenstates to degenerate energy eigenstates. The axial generators Q_5^a change parity, because the axial current is a pseudovector; so $Q_5^a\,|h\rangle$ would be a state of the same mass and opposite parity to $|h\rangle$, for every hadron. The splittings quoted are not small corrections to such a degeneracy: they are of order Λ_{QCD}, which is the largest scale available, whereas the explicit breaking by the quark masses is of order 7 MeV. Symmetry breaking by the Lagrangian cannot produce an effect a hundred times its own size. Hence the axial generators do *not* annihilate the vacuum, while the vector ones evidently do — the isospin multiplets are degenerate to the accuracy at which electromagnetic and $m_d - m_u$ effects enter. The symmetry is spontaneously broken, in the pattern

$$\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R \longrightarrow \mathrm{SU}(2)_V\,. \tag{102.75}$$

□

102.8.2 Dynamical symmetry breaking

Definition 102.69 (The quark condensate)**.** The order parameter of Equation (102.75) is the vacuum expectation value

$$\langle \bar{q} q \rangle = \langle \bar{q}_L q_R + \bar{q}_R q_L \rangle \neq 0\,, \tag{102.76}$$

of SI dimension $1/\mathrm{m}^3$ by Definition 100.2: it is a number density, and it is negative.

The mechanism was identified by Nambu and Jona-Lasinio [1215] by explicit analogy with superconductivity. In the BCS theory of superconductivity, treated in the condensed-matter part of this book, an arbitrarily weak attraction between electrons destabilizes the Fermi sea and produces a condensate of pairs, and with it a gap: an excitation that was massless acquires a mass generated by the interaction rather than written into the Hamiltonian. Replace electron pairs by quark–antiquark pairs and the gap by a quark mass, and Equation (102.76) is the same statement. A massless quark propagating through a vacuum full of $\bar{q}q$ pairs acquires an effective mass, the *constituent* mass Equation (102.12) of about $336\,\mathrm{MeV}/c^2$ — a hundred times its Lagrangian mass, and manufactured entirely by the interaction.

Theorem 102.70 (Goldstone)**.** *Let j_a^μ be a conserved current of a symmetry that does not annihilate the vacuum, in the sense that some local operator Φ has $\langle [Q_a, \Phi] \rangle \neq 0$ with $Q_a = c^{-1} \int \mathrm{d}^3x\, j_a^0$. Then the theory contains a massless one-particle state $|\pi_a\rangle$ with $\langle 0 | j_a^\mu | \pi_a \rangle \neq 0$ [1207].*

Rests on Phenomenon 102.68 and Equation (102.75)*.*

Proof. *Derives Theorem 102.70.*

Write $v = \langle [Q_a, \Phi(0)] \rangle \neq 0$ and insert a complete set of states between the operators:

$$v = \frac{1}{c} \int \mathrm{d}^3x \sum_n \left[\left\langle 0|j_a^0(x)|n \right\rangle \langle n|\Phi(0)|0\rangle - \langle 0|\Phi(0)|n\rangle \left\langle n|j_a^0(x)|0 \right\rangle \right] .$$

Translation invariance gives $\langle 0|j_a^0(x)|n\rangle = \langle 0|j_a^0(0)|n\rangle \, \mathrm{e}^{-\mathrm{i}p_n \cdot x/\hbar}$, so the integral over d^3x produces $(2\pi\hbar)^3\delta^3(\boldsymbol{p}_n)$: only states of zero three-momentum contribute. For those the remaining x dependence is $\mathrm{e}^{-\mathrm{i}E_n t/\hbar}$, and therefore

$$v = \frac{(2\pi\hbar)^3}{c} \sum_{n,\, \boldsymbol{p}_n = 0} \left[\left\langle 0|j_a^0|n \right\rangle \langle n|\Phi|0\rangle \, \mathrm{e}^{-\mathrm{i}E_n t/\hbar} - \text{c.c. term} \right] .$$

But Q_a is time independent, because $\partial_\mu j_a^\mu = 0$ and the spatial part integrates to a surface term; so v cannot depend on t. Since $v \neq 0$, at least one term must survive, and a surviving term must have $E_n = 0$ at $\boldsymbol{p}_n = 0$. A state with zero energy at zero momentum is a massless particle, and by construction it has a non-vanishing matrix element with the current. Its quantum numbers are those of the current: for the axial current A_a^μ, which is a pseudovector, the state must be a pseudoscalar, since $\langle 0|A_a^\mu|\pi_b\rangle$ can only be proportional to p^μ and p^μ is the only vector available for a spinless state. Applying this to Equation (102.75): three generators are broken — $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$ has six and $\mathrm{SU}(2)_V$ has three — so there are three massless pseudoscalars, an isotriplet. □

Remark 102.71 (Where the mass of ordinary matter comes from). Chapter 104 is often described as explaining the origin of mass. It does not explain the origin of *our* mass. The Higgs mechanism supplies the Lagrangian quark masses of Table 102.1, which contribute $9\,\mathrm{MeV}/c^2$ of the proton's $938.272\,\mathrm{MeV}/c^2$. The remaining 99 % is supplied by Equation (102.76) and Phenomenon 102.39: a dimensionless coupling that runs, a scale generated by that running, and a vacuum that condenses. Two different mechanisms, in two different sectors, and the one that matters for the mass of a table is the strong one.

102.8.3 The pion as a pseudo-Goldstone boson

Phenomenon 102.72 (The pion is anomalously light)**.** The lightest hadron is far lighter than the rest of the spectrum: $m_{\pi^\pm}c^2 = 139.570\,\mathrm{MeV}$ and $m_{\pi^0}c^2 = 134.977\,\mathrm{MeV}$, against 775 MeV for the ρ and 938 MeV for the nucleon [2427]. The gap is not a small effect to be absorbed into a fit; it is a factor of five or six, and it is specific to the pseudoscalar triplet. Furthermore it is m_π^2, and not m_π, that is proportional to the light quark masses, so that the pion alone becomes massless when those masses are set to zero.

Rests on Theorem 102.70, Phenomenon 102.68, and Definition 102.69.

Derivation. *Derives Phenomenon 102.72.*

Theorem 102.70 supplies three massless pseudoscalars in the limit $m_u = m_d = 0$, and Phenomenon 102.68 identifies the broken symmetry as the one whose Goldstone bosons they are. The pions are those states, made massive only by the explicit breaking. It remains to find how their mass depends on the breaking, and the answer is the Gell-Mann–Oakes–Renner relation [1370]:

$$\left(m_\pi c^2\right)^2 F_\pi^2 = -\left(m_u + m_d\right) c^2 \, \langle \bar{q}q \rangle \, (\hbar c)^3 \, , \tag{102.77}$$

where F_π is the pion decay constant of Equation (106.103), an energy, and every factor is written so that both sides carry (energy)^4: $\langle \bar{q}q \rangle$ carries $1/\mathrm{m}^3$ by Definition 102.69 and $(\hbar c)^3$ converts it.

The derivation is a Ward identity. The divergence of the isotriplet axial current, exact in QCD, is $\partial_\mu A_a^\mu = (m_u + m_d)\, c\, P_a$ with $P_a = \mathrm{i}\bar{q}\gamma^5\tau_a q$ the pseudoscalar density; it vanishes in

the chiral limit, which is Proposition 102.67. Take its matrix element between the vacuum and a one-pion state. The left-hand side is fixed by the definition of the decay constant, $\langle 0|A^\mu_a|\pi_b(p)\rangle = \mathrm{i}F_\pi p^\mu \delta_{ab}/c$, so that $\langle 0|\partial_\mu A^\mu_a|\pi_b\rangle = F_\pi \left(m_\pi c\right)^2 \delta_{ab}/\hbar c$ on using $p^2 = m_\pi^2 c^2$. The right-hand side is $\left(m_u + m_d\right) c \langle 0|P_a|\pi_b\rangle$, and the remaining matrix element is related to the condensate by the same chiral rotation that produced the Goldstone boson: acting with the broken charge on the pseudoscalar density returns the scalar density, so $\langle 0|P_a|\pi_b\rangle$ is proportional to $\langle \bar{q}q\rangle / F_\pi$. Assembling the factors gives Equation (102.77). The structural point survives any bookkeeping: m_π^2, not m_π, is linear in the quark masses, because the quark mass enters the Lagrangian linearly and the pion mass enters the Lagrangian squared. □

Example 102.73 (Two numbers out of the relation)**.** *The condensate.* Insert $m_{\pi^0} c^2 = 134.977\,\mathrm{MeV}$, $F_\pi = 92.07\,\mathrm{MeV}$ from $f_\pi = (130.2 \pm 1.2)\,\mathrm{MeV}$, and $\left(m_u + m_d\right) c^2 = 6.86\,\mathrm{MeV}$ [2427] into Equation (102.77). Writing $-\langle \bar{q}q\rangle \left(\hbar c\right)^3 = \Sigma^3$ with Σ an energy,

$$\Sigma = \left[\frac{\left(m_\pi c^2\right)^2 F_\pi^2}{\left(m_u + m_d\right) c^2}\right]^{1/3} = 282\,\mathrm{MeV}\,, \qquad \langle \bar{q}q\rangle = -2.9 \times 10^{45}/\mathrm{m}^3\,, \tag{102.78}$$

about three quark–antiquark pairs per cubic femtometre, and of the order of Λ_{QCD} as Phenomenon 102.39 requires — there being nothing else for it to be made of. Lattice and sum-rule determinations of the condensate agree with Equation (102.78) at the ten-percent level [2427], which is the accuracy the leading order of the chiral expansion deserves.

A ratio with no condensate in it. Equation (102.77) extended to three flavours gives $\left(m_K c^2\right)^2 F_K^2 = -\left(m_d + m_s\right) c^2 \langle \bar{q}q\rangle \left(\hbar c\right)^3$ for the K^0, so that in the limit $F_K \to F_\pi$ the condensate cancels:

$$\frac{m_{K^0}^2}{m_{\pi^0}^2} = \frac{m_d + m_s}{m_u + m_d} = \frac{4.70 + 93.5}{2.16 + 4.70} = 14.3\,, \tag{102.79}$$

against the measured $(497.611/134.977)^2 = 13.6$ [2427]: agreement to 5 %. The neutral mesons are used because the charged ones carry an electromagnetic self-energy that Equation (102.77) does not describe. This is a genuine test, because the quark masses entering it are determined elsewhere — on the lattice and from sum rules — and not fitted to the meson masses.

Remark 102.74 (Chiral perturbation theory, and the ninth meson)*.* Equation (102.77) is the first term of a systematic expansion. Because the pions are the light degrees of freedom at low energy, and because their interactions are constrained by the broken symmetry to vanish as the momenta go to zero, one may write an effective Lagrangian for the pion field alone, organized in powers of momenta and quark masses: chiral perturbation theory [1647, 1737]. It is an effective field theory in the sense developed in the renormalization-group chapter, with a finite number of measurable constants at each order, and it predicts pion–pion scattering lengths, form factors and mass ratios to a few percent.

The pseudoscalar octet has eight members and the Goldstone count for $\mathrm{SU}(3)_L \times \mathrm{SU}(3)_R \to \mathrm{SU}(3)_V$ is eight, so the η' is one too many. It is not a Goldstone boson of $\mathrm{U}(1)_A$, because $\mathrm{U}(1)_A$ is not a symmetry: the anomaly of Theorem 106.87 destroys it, with the gluon topological density of Section 106.6.2 on the right-hand side of the divergence equation. Weinberg's observation [1565] is that if $\mathrm{U}(1)_A$ *had* been a spontaneously broken symmetry the ninth pseudoscalar would have had to weigh at most $\sqrt{3} m_\pi$, about $234\,\mathrm{MeV}/c^2$; the η' weighs $957.78\,\mathrm{MeV}/c^2$ [2427]. Its heaviness is therefore evidence for the anomaly, and through it for the topological structure that Section 102.10 is about.

102.9 QCD under extreme conditions

Asymptotic freedom implies that matter compressed or heated far enough must eventually become a gas of quarks and gluons: at short distances the coupling is weak, and raising the

temperature or the density reduces the mean separation. The transition is not a prediction of perturbation theory — it happens at $\alpha_s \sim 1$ — but of the lattice, and it has been looked for in heavy-ion collisions.

Phenomenon 102.75 (Hadronic matter deconfines when heated)**.** Lattice computation of QCD at finite temperature shows a rapid but smooth rise of the energy density, by a factor of order ten over a narrow range of temperature centred on $k_B T_c \approx 155\,\mathrm{MeV}$, that is

$$T_c \approx \frac{155\,\mathrm{MeV}}{k_B} = 1.8 \times 10^{12}\,\mathrm{K}\,, \tag{102.80}$$

some 10^5 times the temperature at the centre of the Sun. It is a crossover, not a phase transition with a discontinuity. Above it the degrees of freedom are those of quarks and gluons rather than of hadrons.

Rests on Theorem 102.35 and Definition 102.10.

Derivation of the size of the jump. *Derives Phenomenon 102.75.*

The energy density of an ideal ultrarelativistic gas is the standard blackbody result, generalized to g internal states and to fermions by Fermi–Dirac counting:

$$\varepsilon = g_{\mathrm{eff}}\,\frac{\pi^2\,(k_B T)^4}{30\,(\hbar c)^3}\,, \qquad g_{\mathrm{eff}} = g_B + \frac{7}{8}\,g_F\,, \tag{102.81}$$

the factor $7/8$ being the ratio of the Fermi to the Bose integral $\int_0^\infty x^3 \mathrm{d}x/(\mathrm{e}^x \pm 1)$. Counting: a gluon has 8 colours and 2 polarizations, so $g_B = 16$; a quark flavour has 3 colours, 2 spins, and particle and antiparticle, so $g_F = 12$ per flavour and $g_F = 36$ for the three light flavours. Hence $g_{\mathrm{eff}} = 16 + \frac{7}{8}\cdot 36 = 47.5$. Below the transition the degrees of freedom are three pions, $g_{\mathrm{eff}} = 3$. The ratio is nearly sixteen, and that factor — not the precise value of T_c — is what the lattice sees as a steep rise in ε/T^4.

Numerically at $k_B T = 155\,\mathrm{MeV}$, Equation (102.81) gives $\varepsilon \approx 1.2\,\mathrm{GeV}$ per cubic femtometre, that is

$$\varepsilon \approx 1.9 \times 10^{35}\,\mathrm{J/m^3}\,, \tag{102.82}$$

against about $0.4\,\mathrm{GeV}$ per cubic femtometre inside a nucleon at rest. The lattice value near T_c is some tens of percent below the ideal-gas limit Equation (102.81), and the deficit does not go away quickly as the temperature rises: the medium is not a weakly coupled gas, which is exactly what the heavy-ion data below also say. □

The experimental programme is the collision of heavy nuclei at relativistic energies, and its conclusion after the first five years at RHIC [2068] rests on two observations that point the same way.

Jet quenching. A parton produced in a hard scattering inside the collision volume must traverse the medium before fragmenting into the jet of Section 102.6. If the medium is coloured it radiates gluons and loses energy. The observable is the suppression of high transverse-momentum hadrons relative to the same quantity in proton–proton collisions scaled by the number of binary collisions, and it is large — a factor of about five in central gold–gold collisions — while being absent in deuteron–gold collisions, which excludes an initial-state explanation.

Elliptic flow. A non-central collision has an almond-shaped overlap region. If the matter produced behaves as a fluid, the pressure gradients are larger along the short axis and the final momentum distribution is anisotropic in a way that remembers the initial geometry. The measured anisotropy is large and is described by relativistic hydrodynamics with a shear viscosity to entropy density ratio close to the smallest values known for any fluid. The conclusion of [2068] was accordingly not “a weakly coupled quark–gluon gas has been

made" but "a strongly coupled, nearly ideal liquid has been made", which was not what the perturbative picture had led anyone to expect and is the reason the result mattered.

Two further regimes are treated elsewhere. Cold dense quark matter is the possible interior of a neutron star and belongs to Chapter 49. And the whole universe passed through Equation (102.80) downwards at an age of a few microseconds, converting a quark–gluon plasma into hadrons; that is the cosmological quark–hadron transition, and it is the last epoch before the nucleosynthesis of Chapter 52.

102.10 The strong CP problem

Definition 102.27 deferred one term, and it is the only known defect of the theory.

Proposition 102.76 (QCD permits one more term)**.** *Gauge invariance, Lorentz invariance, locality and renormalizability permit, besides Equation* (102.29)*, the term*

$$\mathcal{L}_\theta = \theta\hbar\, q(x) \propto \theta\, \frac{g_s^2}{\hbar} \sum_a \boldsymbol{E}^a \cdot \boldsymbol{B}^a \,, \tag{102.83}$$

with $q(x)$ the gluon topological charge density of Definition 105.43 and θ a dimensionless number, and nothing else. The term violates P and CP (Proposition 105.44), and only the combination $\bar\theta = \theta + \arg\det M_q$ of Equation (105.111) *is physical, because a chiral rotation of the quark fields shifts θ through the anomaly of Theorem 106.87.*

Rests on Equation (102.29)*, Definition 105.43, and Theorem 100.17.*

Proof. *Derives Proposition 102.76.*

Power counting (Theorem 100.17) allows operators of mass dimension at most four. The gauge-invariant, Lorentz-invariant operators of dimension four that can be built from $F^a_{\mu\nu}$ are $F^a_{\mu\nu}F^{a\,\mu\nu}$, already in Equation (102.29), and $\epsilon^{\mu\nu\rho\sigma}F^a_{\mu\nu}F^a_{\rho\sigma}$, which is Equation (102.83); from the quark fields they are the kinetic and mass terms. There is no other. The identification of Equation (102.83) with the topological density, its periodicity in θ, and its origin in the vacuum structure are Corollary 106.84 and Section 106.6.2. The statement that only $\bar\theta$ is observable is Equation (105.111): it ties the gluon sector to the phases of the quark mass matrix, which come from a different sector of the Standard Model altogether. □

Phenomenon 102.77 (The neutron has no measurable electric dipole moment)**.** Every symmetry of QCD permits a term in the Lagrangian proportional to $F\tilde F$; it violates P and CP, and it would give the neutron a permanent electric dipole moment along its spin. None is seen. The best measurement is consistent with zero and bounds $|d_n| < 1.8\times10^{-28}\,e\,\mathrm{m}$ at 90 percent confidence [2346], which forces the coefficient of the permitted term below about 10^{-10}. Nothing in the theory explains why a term it allows should be absent to that accuracy.

Rests on Propositions 102.76 and 105.45 and Equation (105.112)*.*

Derivation. *Derives Phenomenon 102.77.*

The step that converts a measured bound on a dipole moment into a bound on a Lagrangian parameter is the chiral estimate Equation (105.112), derived in Proposition 105.45: $d_n \approx \bar\theta \times 1.6\times10^{-37} - -6.4\times10^{-37}\,\mathrm{C\,m}$, the parametric form following from the requirement that the answer vanish with the quark masses — because a massless quark makes θ unobservable by the chiral rotation of Proposition 102.76 — and the coefficient from a chiral loop. Combining with the ultracold-neutron measurement [2346] gives $\left|\bar\theta\right| \lesssim 10^{-10}$, which is Equation (105.113). The uncertainty of the estimate is a factor of a few, which is why the bound is quoted as an order of magnitude. □

Remark 102.78 (A fine-tuning puzzle, honestly labelled). Nothing is inconsistent. $\bar{\theta} = 0$ is a perfectly good value of a parameter, and QCD with $\bar{\theta} = 0$ describes every measurement in this chapter. What is peculiar is that $\bar{\theta}$ is an angle, periodic with period 2π, assembled from the gluon sector and the phases of the Yukawa couplings of Chapter 104, which are otherwise of order one and which supply the large CP violation of Chapter 105; and the two contributions cancel to ten decimal places. That is a fine-tuning puzzle, not a contradiction, and this book records it as such.

The best-known proposal promotes $\bar{\theta}$ to a dynamical field whose potential is minimized at zero [1609], which predicts a light pseudoscalar particle [1630]. No such particle has been detected in any search to date. In the terms of this book that makes it a proposal and not physics, and the strong CP problem is carried forward unresolved to Chapter 133. It is worth noting what would settle it: detecting the particle, or measuring a nonzero neutron electric dipole moment, which would show $\bar{\theta} \neq 0$ and remove the puzzle by removing its premise.

Chapter 103

Flavour Physics and Neutrinos

Flavour is the part of the Standard Model that nothing explains. The gauge structures of Chapter 100, Chapter 101 and Chapter 102 follow from one principle applied to three groups; the existence of three copies of every fermion, their wildly disparate masses, and the two mixing matrices that relate the states of definite mass to the states that couple to the W are pure measurement. This chapter assembles that measurement. It is also where the treatise's editorial rule bites hardest: flavour is the richest source of proposals without evidence, and what is recorded below is what has been seen — quark mixing, CP violation in three meson systems, and neutrino oscillation — together with an explicit statement of what has not.

The chapter follows Chapter 102 because the hadronic states whose decays carry the information are QCD bound states, and it feeds Chapter 111 and Chapter 114, the two chapters that carry the decisive experimental programmes; the first is still a skeleton of reserved headings and the second is written in part, so where a measurement is owed to one of them this chapter says so. Neutrino oscillation is the only laboratory result that the Standard Model as originally written does not accommodate, since it requires neutrino mass; that makes this chapter the natural bridge to Chapter 133, and its cosmological consequences — the matter–antimatter asymmetry — connect to Chapter 48. Standard treatments are [1739, 1933, 2106]; all quoted values are from [2427] unless another source is named, and every constant is the CODATA 2022 recommendation [2431].

Two pieces of scaffolding are inherited rather than rebuilt. The kinematic and dimensional conventions — metric signature, the mass-shell relation $p^2 = m^2c^2$, the SI dimension carried by a field and by a coupling — are those fixed in Section 100.1.1, and are used here without restatement. The *origin* of the quark mixing matrix, as the residual misalignment between the basis in which the Yukawa couplings are diagonal and the basis in which the charged current is diagonal, is derived in Theorem 104.38 from the Higgs couplings of Chapter 104; Equation (104.48) is the biunitary diagonalization that produces it. This chapter starts from that result and asks what the matrix actually is.

Remark 103.1 (Reading this chapter against the natural-units literature). Every reference cited below writes its formulae with $\hbar = c = 1$, and this book does not: editorial rule 3 requires SI throughout, so $\hbar$ and c appear in every equation and in every intermediate step here. The dictionary is mechanical, and is given once so that a reader can move between the two. A quantity quoted in the literature as an energy to the power n becomes, in SI, that energy divided by the appropriate power of $\hbar c$: a length is $\hbar c/E$, a time is $\hbar/E$, a squared mass is E^2/c^4. The numerical bridge is

$$\hbar c = 1.973\,269\,8 \times 10^{-7}\,\mathrm{eV\,m} = 3.161\,526\,8 \times 10^{-26}\,\mathrm{J\,m}\,, \qquad \hbar = 6.582\,119\,6 \times 10^{-16}\,\mathrm{eV\,s}\,. \tag{103.1}$$

Two conventions deserve naming because they recur. The Fermi constant is universally quoted as $G_F/(\hbar c)^3 = 1.166\,378\,7 \times 10^{-5}/\mathrm{GeV}^2$, which is not G_F; the constant itself is

$G_F = 1.435\,85 \times 10^{-62}\,\mathrm{J\,m^3}$, as Definition 101.8 sets out. And a neutrino squared-mass splitting is quoted as Δm^2 in eV^2 when the quantity meant is $\Delta m^2 c^4$, an energy squared. Both usages are retained below *with the powers of $\hbar$ and c written out*, because the derivations are carried out in SI and not translated into it afterwards. No derivation in this chapter takes place inside this remark.

103.1 The discovery of new quantum numbers

103.1.1 V particles

In October 1946 Rochester and Butler exposed a cloud chamber in a magnetic field to the cosmic radiation at sea level and, in some five thousand photographs, found two in which a track forked without any incoming charged particle at the vertex [903]. The first showed a neutral object decaying into two oppositely charged particles — the forked "V" that named the class — and the second a charged object changing direction with the emission of something neutral. Neither could be a scattering: momentum conservation at the vertex failed unless an unseen neutral particle was created, and the reconstructed mass of the decaying object, about $500\,\mathrm{MeV}/c^2$ in the neutral case, matched nothing then known. The cosmic-ray context, and the instrumental history that made such an exposure possible, belong to Chapter 115.

What made the new particles a problem rather than merely a discovery was a mismatch of time scales, and it is worth putting numbers on it because the whole of flavour physics grows out of that mismatch.

Phenomenon 103.2 (Copious production, slow decay)**.** The new particles are produced in nucleon–nucleon and pion–nucleon collisions with cross sections of hadronic size, of order $1 \times 10^{-30}\,\mathrm{m^2}$, which is the strength of the strong interaction; yet they decay with lifetimes of order $1 \times 10^{-10}\,\mathrm{s}$, which is thirteen to fourteen orders of magnitude longer than a strong decay of the same energy release. The Λ^0 is the cleanest case: its measured width is $2.515 \times 10^{-15}\,\mathrm{GeV}$, corresponding to

$$\tau_\Lambda = \frac{\hbar}{\Gamma_\Lambda} = \frac{6.582\,119\,6 \times 10^{-16}\,\mathrm{eV\,s}}{2.515 \times 10^{-6}\,\mathrm{eV}} = 2.62 \times 10^{-10}\,\mathrm{s}\,, \tag{103.2}$$

against $\tau_\Delta = \hbar/\Gamma_\Delta = 5.6 \times 10^{-24}\,\mathrm{s}$ for the $\Delta(1232)$, a genuine strong decay of comparable energy release [2427].

Rests on Equation (101.53).

Derivation. *Derives Phenomenon 103.2.*

The natural time scale for a decay driven by the interaction that also binds the hadron is the time light takes to cross it, $R/c = 1 \times 10^{-15}\,\mathrm{m}/c = 3.3 \times 10^{-24}\,\mathrm{s}$, and τ_Δ is within a factor of two of it: the Δ decays as fast as it can. The ratio $\tau_\Lambda/\tau_\Delta = 4.7 \times 10^{13}$ therefore cannot be absorbed into phase space, which varies as a power of the energy release and can account for two or three orders of magnitude at most, nor into a centrifugal barrier, which for the observed spins is absent. The only available conclusion is that the interaction responsible for the decay is not the interaction responsible for the production. Comparing τ_Λ with the muon lifetime $2.197 \times 10^{-6}\,\mathrm{s}$ and allowing for the fifth-power dependence of Equation (101.53) on the energy release identifies the decay interaction as the weak one.

The inference is then sharp. *Something* is conserved by the interaction that makes these particles and violated by the interaction that destroys them. That is the whole content of the next subsection, and it is the template for every conserved flavour quantum number in this chapter: exact for two of the three forces, broken by the third. □

A second regularity sharpened the puzzle: the new particles are never produced singly. A π^- striking a proton yields $\Lambda^0 + K^0$ but never $\Lambda^0 + \pi^0$, although the latter is energetically far easier. Pais named this *associated production*, and it is exactly what a conserved additive quantum number, carried with opposite sign by the two partners, would produce.

103.1.2 Strangeness

Definition 103.3 (Strangeness)**.** Strangeness S is an additive quantum number, integer valued, assigned to each hadron so that the electric charge satisfies

$$Q = e\left(I_3 + \frac{B+S}{2}\right), \tag{103.3}$$

with I_3 the third component of isospin and B the baryon number. It is conserved by the strong and electromagnetic interactions and violated by the weak interaction, which changes it by at most one unit in a single transition.

The assignment was made independently by Gell-Mann [1017] and by Nakano and Nishijima [1024], from the observed production and decay patterns alone, several years before any dynamical picture existed. Equation (103.3) is the same relation that reappears in Equation (102.1) as a statement about quark content and, in a wider form, in Equation (104.13) as a statement about the hypercharge of an electroweak multiplet. Its three appearances are one relation seen at three depths.

Proposition 103.4 (Associated production follows from conservation)**.** *If S is conserved by the strong interaction and the initial state of a collision of ordinary matter has $S = 0$, then strange particles can only be produced in pairs of opposite strangeness, and the lightest strange hadron of each sign is stable against strong decay.*

Rests on Definition 103.3 and Phenomenon 103.2.

Proof. *Derives Proposition 103.4.*

Additivity and conservation give $\sum_{\text{final}} S = 0$, so a final state containing one particle with $S = -1$ must contain another with $S = +1$; a final state $\Lambda^0\pi^0$ with $S = -1$ is forbidden however much phase space favours it, which is what is seen. For the second statement, let h be the lightest hadron with $S = -1$. A strong decay must conserve S, so its products together carry $S = -1$; but every hadron with $S = -1$ is at least as heavy as h, and any accompanying non-strange hadron has positive mass, so no such final state is open. The decay must therefore proceed through an interaction that violates S, and by Phenomenon 103.2 that interaction is weak. Applying the argument to Λ^0 ($S = -1$) and to K^+ ($S = +1$) accounts for the long lifetimes of both. □

Example 103.5 (Reading the charge formula)**.** The K^+ is an isodoublet member with $I_3 = +\frac{1}{2}$, $B = 0$; Equation (103.3) then requires $S = +1$. Its antiparticle K^- has $S = -1$, so K^+ and K^- are *not* members of one isodoublet, and the neutral kaons K^0 ($S = +1$) and $\bar{K}^0$ ($S = -1$) are distinct particles rather than one self-conjugate state — the fact that makes the whole of Section 103.5 possible. The Λ^0 is an isosinglet, $I_3 = 0$, $B = 1$, $Q = 0$, hence $S = -1$. The Ω^-, with $I_3 = 0$, $B = 1$, $Q = -e$, requires $S = -3$: three units of a quantum number that the weak interaction can shed only one at a time, which is why it decays in a cascade and why its lifetime is long even by strange standards. That prediction, and its confirmation, are Phenomenon 102.3.

In quark language, settled two decades later, S counts the strange quarks with a sign: $S = -(n_s - n_{\bar{s}})$, the minus sign an accident of the convention fixed before quarks were

known. The same construction repeats for every heavy flavour: charm C, bottom $\tilde{B}$ and top T are defined so that Equation (103.3) generalizes to

$$Q = e\left(I_3 + \frac{B + S + C + \tilde{B} + T}{2}\right), \tag{103.4}$$

and each is conserved by the strong and electromagnetic interactions and violated by the weak. Strangeness is not a special quantum number; it is the first member of a family, and the family is the subject of this chapter.

Remark 103.6 (What was and was not explained). Definition 103.3 is a classification, not a mechanism. It says that some quantity is conserved by two forces and violated by the third; it does not say why, nor how much the violation is, nor why the violating amplitude should be the same size as the one that governs nuclear beta decay. Those questions were answered — the first two by Section 103.2.1, the third only partly, and the deepest of them not at all — and the honest summary is that a selection rule was found in 1953 and the number controlling it was measured in 1963.

103.2 Quark mixing

103.2.1 The Cabibbo angle

By 1963 the weak interaction had a universal strength: the coupling extracted from muon decay and from nuclear beta decay agreed to within a few per cent, which is Phenomenon 101.43 — stated there over muon decay, superallowed nuclear beta decay and τ decay, the third of which came much later. Strangeness-changing decays did not fit. The semileptonic decay $\Lambda^0 \to p\, e^- \bar{\nu}_e$ proceeds at some five per cent of the rate that the same universal coupling predicts, and $K^+ \to \pi^0 e^+ \nu_e$ likewise. There were two ways to read this: either universality is approximate and the weak interaction has a separate, weaker, strangeness-changing piece, or universality is exact and the strength is *shared* between the two channels.

Cabibbo took the second reading [1248], and it is the conceptual step on which everything below rests: *the state that couples to the W is not a state of definite mass.*

Phenomenon 103.7 (Strangeness-changing decays are suppressed, by one angle)**.** Semileptonic decays that change strangeness proceed at roughly one twentieth of the rate of their strangeness-conserving counterparts, and a single rotation angle accounts for the whole of the deficit. The measured magnitudes of the first-row mixing elements are

$$|V_{ud}| = 0.973\,67 \pm 0.000\,32\,, \qquad |V_{us}| = 0.2243 \pm 0.0008\,, \qquad |V_{ub}| = 0.003\,82 \pm 0.000\,20\,, \tag{103.5}$$

obtained from superallowed nuclear beta decay, from kaon decays and from semileptonic B decays respectively [2427]. They satisfy $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 1$ to about a part in 10^3, with a residual deficit of a few standard deviations that is at present the sharpest unexplained departure from the Standard Model anywhere in flavour physics.

Rests on Phenomenon 101.43 and Definition 103.3.

Derivation. *Derives Phenomenon 103.7.*

Cabibbo's hypothesis is that the down-type state entering the charged current is a rotation of the mass eigenstates, $d' = d\cos\theta_C + s\sin\theta_C$, carrying the same overall coupling G_F as the leptonic current [1248]. A strangeness-conserving amplitude then acquires a factor $\cos\theta_C$ and a strangeness-changing one a factor $\sin\theta_C$, so their rates stand in the ratio $\tan^2\theta_C$ and the two effects are not independent: the suppression of the second is precisely the deficit of the first against the leptonic strength, which is what restores universality. Reading $\sin\theta_C = |V_{us}|$ from Equation (103.5) gives $\theta_C = 12.96°$ and hence $\cos\theta_C = 0.9745$,

which is $|V_{ud}|$ to within one part in a thousand — one angle, measured twice over in unrelated processes. The global fit quoted later as $\theta_{12} = 13.00^\circ$ in Equation (103.22) is the same angle: the 0.04° between the two is the difference between the direct kaon determination of $|V_{us}|$ used here and the fitted $\lambda = 0.225\,01$ used there, and nothing else. The rate ratio it predicts, $\tan^2\theta_C = 0.0530$, is the observed factor of about twenty. That the squares sum to unity is the two-generation case of the unitarity discussed in Section 103.4.3; that they sum to unity only to a part in 10^3 is a measurement, not an approximation, and it is recorded here rather than smoothed away. □

The arithmetic behind the last sentence is worth doing explicitly, because the number it produces is the one genuinely open experimental anomaly in quark flavour physics today.

Proposition 103.8 (First-row unitarity deficit)**.** *With the values of Equation* (103.5)*,*

$$\Delta_{\mathrm{CKM}} := |V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.998\,36 \pm 0.000\,72\,, \tag{103.6}$$

which is below unity by 2.3 *standard deviations.*
Rests on Equation (103.5)*.*

Proof. *Derives Proposition 103.8.*
$|V_{ud}|^2 = 0.948\,033$, $|V_{us}|^2 = 0.050\,310$ and $|V_{ub}|^2 = 1.46 \times 10^{-5}$, summing to $0.998\,358$. The uncertainty propagates as $\delta\Delta = 2\left[(|V_{ud}|\,\delta|V_{ud}|)^2 + (|V_{us}|\,\delta|V_{us}|)^2\right]^{1/2}$, the V_{ub} term being negligible, which gives $2\left[(3.12\times10^{-4})^2 + (1.79\times10^{-4})^2\right]^{1/2} = 7.2\times10^{-4}$. Hence $1 - \Delta_{\mathrm{CKM}} = 1.64\times10^{-3} \pm 7.2\times10^{-4}$, a deficit of 2.3σ. □

Remark 103.9 (How to read a two-sigma deficit honestly)*.* The significance of Equation (103.6) depends on which determination of $|V_{us}|$ is used — the value from $K \to \pi e\nu$ and the value from the ratio of $K \to \mu\nu$ to $\pi \to \mu\nu$ differ by about 2σ between themselves — and on the radiative corrections applied to superallowed nuclear beta decay, which were revised in the late 2010s and are what moved this quantity from agreement to tension. Quoted significances between 2σ and 3σ therefore all appear in the literature and all are defensible. What is not defensible is either extreme: calling it a discovery, or suppressing it. Unitarity of the first row is a prediction with no free parameters, the measurement is at the level of one part in 10^3, and it does not currently come out right. This treatise records that, and records equally that the most likely resolution is a systematic effect in one of the two inputs.

103.2.2 GIM and the prediction of charm

Cabibbo's rotation solves the charged-current problem and creates a neutral-current one, which Proposition 101.58 states: the same rotated field d' appears bilinearly in any neutral current, and its cross terms change strangeness with a coefficient $\sin\theta_C\cos\theta_C = 0.219$, of ordinary size. Nature says otherwise.

Phenomenon 103.10 (There are no flavour-changing neutral currents)**.** The neutral weak current does not change quark flavour. A flavour-changing neutral coupling of ordinary strength would make $K_L \to \mu^+\mu^-$ comparable in rate with $K^+ \to \mu^+\nu_\mu$; the measured branching fractions are 6.84×10^{-9} and 0.636 respectively [2427], a suppression by eight orders of magnitude, and the mass differences of the neutral kaon and B systems are correspondingly tiny. The suppression is not a numerical accident of one channel: no tree-level neutral flavour transition has ever been observed in any system, in any generation.
Rests on Theorems 101.59 and 104.38.

Derivation. *Derives Phenomenon 103.10.*
The tree-level statement is Theorem 101.59, proved there for two generations and extended to three in Theorem 104.38(ii): the neutral-current coefficient depends only on

T^3 and Q, hence is the same for every generation, hence is proportional to the identity in generation space, and $U^\dagger \mathbb{1} U = \mathbb{1}$ for any unitary U. Nothing survives the rotation to the mass basis. This is the Glashow–Iliopoulos–Maiani mechanism [1423], and it is a consequence of unitarity together with the requirement that every fermion of a given charge and chirality sit in a complete weak multiplet. The two hypotheses are what a search for flavour-changing neutral currents actually tests.

At tree level the cancellation is exact and the observed rate would be zero, which is also wrong. The measured 6.84×10^{-9} is small but not absent, and it is produced at one loop, where the cancellation is only partial. That calculation is Theorem 103.11 below, and it is where the mechanism stops being an algebraic identity and starts predicting a number. □

The one-loop statement is the important one historically, because it converts a null result into a mass.

Theorem 103.11 (GIM suppression at one loop)**.** *Let $A(m_i)$ be the amplitude for a flavour-changing neutral process, computed with a single up-type quark of mass m_i circulating in the loop, and let $\lambda_i = V_{id}V_{is}^*$ be the associated product of mixing factors. Then the physical amplitude is*

$$A = \sum_{i=u,c,t} \lambda_i A(m_i)\,, \qquad \sum_i \lambda_i = 0\,, \tag{103.7}$$

so any part of $A(m_i)$ that is independent of m_i cancels identically. Expanding A in the small parameter $x_i = m_i^2 c^4 / \left(M_W c^2\right)^2$ leaves

$$A \simeq A'(0) \sum_i \lambda_i \frac{m_i^2 c^4}{\left(M_W c^2\right)^2}\,, \tag{103.8}$$

so the surviving amplitude is suppressed by the ratio of a squared mass difference *of the internal quarks to the squared W mass. A flavour-changing neutral amplitude therefore measures the mass of the heaviest quark circulating in the loop whose mixing factor λ_i is not itself negligible.*

Rests on Theorem 101.62.

Proof. *Derives Theorem 103.11.*

The sum rule $\sum_i \lambda_i = \sum_i V_{id}V_{is}^* = \delta_{ds} = 0$ is the (d,s) column relation of Theorem 101.62. Write $A(m_i) = A(0) + A'(0)x_i + O(x_i^2)$, where the expansion is legitimate for $m_i c^2 \ll M_W c^2$ and where $A(0)$ is by construction independent of i. Then

$$A = A(0)\sum_i \lambda_i + A'(0)\sum_i \lambda_i x_i + \ldots = A'(0)\sum_i \lambda_i x_i + \ldots\,,$$

which is Equation (103.8). Two remarks fix its meaning. First, the cancellation is not a fine tuning: it is the statement that the loop, evaluated with degenerate internal masses, is a flavour-diagonal operator, and the mixing matrix cannot rotate a multiple of the identity into anything else. Second, the surviving term is a *difference*, since $\sum_i \lambda_i = 0$ allows m_i^2 to be shifted by any constant; writing the sum over the first two generations alone gives $\lambda_c \left(m_c^2 - m_u^2\right) c^4$, and the mass of the light quark drops out of everything. □

Example 103.12 (The charm mass from the kaon mass difference)**.** The K_L–K_S mass difference is generated by the box diagram in which two W bosons and two internal up-type quarks convert K^0 into $\bar{K}^0$. Keeping the charm term of Equation (103.8), which dominates for a system built from d and s quarks, the short-distance contribution is

$$\Delta m_K c^2 = \frac{G_F^2}{6\pi^2 \left(\hbar c\right)^6} f_K^2 c^4 B_K \left(m_K c^2\right) \left(m_c c^2\right)^2 \left|V_{cd}V_{cs}^*\right|^2\,, \tag{103.9}$$

where $f_K = 155.7\,\mathrm{MeV}/c^2$ is the kaon decay constant and $B_K = 0.717$ the lattice matrix element of the four-quark operator [2427], computed by the methods of Section 102.7.1. The dimensions balance as follows: $G_F/(\hbar c)^3$ carries $1/\mathrm{J}^2$, so its square carries $1/\mathrm{J}^4$, and the five remaining factors — $f_K^2 c^4$, $m_K c^2$ and $(m_c c^2)^2$ — supply J^5, leaving an energy, which is what $\Delta m_K c^2$ is. Inserting $G_F/(\hbar c)^3 = 1.166\,378\,7 \times 10^{-5}/\mathrm{GeV}^2$, $m_K c^2 = 497.611\,\mathrm{MeV}$, $|V_{cd}V_{cs}| = \sin\theta_C \cos\theta_C = 0.2186$ and $m_c c^2 = 1.273\,\mathrm{GeV}$ gives

$$\Delta m_K c^2\big|_{\text{charm box}} = 1.54 \times 10^{-6}\,\mathrm{eV}\,, \tag{103.10}$$

against the measured $\Delta m_K c^2 = 3.484 \times 10^{-6}\,\mathrm{eV}$, a fractional mass splitting of 7.0×10^{-15} and one of the smallest quantities ever measured [2427]. The box accounts for 44% of it; the short-distance QCD correction raises this to about 60% and the remainder is long-distance, that is, two-pion and other hadronic intermediate states that no short-distance expansion reaches.

Run backwards, before the charm quark was known, the same formula bounds its mass: saturating the observed Δm_K with the box requires $m_c c^2 \approx 1.9\,\mathrm{GeV}$, and requiring merely that the box not *exceed* the measurement gives an upper bound of the same order. Gaillard and Lee obtained a few GeV/c^2 by this argument in 1974 [1527]. The particle was found that November at $3.097\,\mathrm{GeV}/c^2$, which for a bound state of two charm quarks is exactly where a $1.5\,\mathrm{GeV}/c^2$ quark puts it.

Derivation pending #152

The short-distance two-W box amplitude for the kaon mass difference. What is carried out inline is the GIM structure of the internal sum, the dimensional check of every factor, and the numerical evaluation; the loop integral itself — the box function in its limit of internal mass small against the W mass, together with the reduction of the four-quark operator to the decay constant and the bag parameter — is not derived here and belongs in Appendix A.

Remark 103.13 (A particle predicted by a null result, quantified). Remark 101.60 records the structure of the inference: the input is the absence of a process and the output is the existence of a particle. Example 103.12 is what makes it a *measurement* rather than a hunch. The absence of $K_L \to \mu^+\mu^-$ at ordinary strength requires the mechanism; the smallness of Δm_K, which is not zero, then fixes the scale of the particle the mechanism needs. Glashow, Iliopoulos and Maiani proposed the fourth quark in 1970 on the first fact [1423]; the second gave its mass four years later, months before it was found. The same logic, applied to B^0–$\bar{B}^0$ mixing in 1987, gave the top mass a decade before the top was observed: see Section 103.5.3.

103.2.3 The November revolution

On 11 November 1974 two groups announced the same particle. At Brookhaven, Ting's group measured e^+e^- pairs from p + Be collisions and found a peak at $3.1\,\mathrm{GeV}/c^2$ whose width was consistent with the apparatus resolution and nothing more [1515]. At SPEAR, Richter's group scanned the e^+e^- annihilation cross section and found it rise by two orders of magnitude over a few MeV of beam energy [1516]. The particle is now written J/ψ, with

$$m_{J/\psi}c^2 = (3.096\,900 \pm 0.000\,006)\,\mathrm{GeV}\,, \qquad \Gamma_{J/\psi} = (92.6 \pm 1.7)\,\mathrm{keV} \tag{103.11}$$

[2427]. It is the width that mattered.

Phenomenon 103.14 (A hadronic resonance three orders too narrow)**.** The J/ψ lies far above the threshold for decay into ordinary hadrons and carries the quantum numbers of

the photon, so nothing forbids it from decaying strongly. Yet its width is 92.6 keV, against 149 MeV for the $\rho(770)$ and 4.25 MeV for the $\phi(1020)$ [2427] — narrower than the ρ by a factor 1.6×10^3 and than the ϕ by a factor 46.

Rests on Theorem 105.9 and Phenomenon 102.41.

Derivation. *Derives Phenomenon 103.14.*

The three resonances differ in one respect: how their valence quarks can reach the final state. The ρ is $u\bar{u}$ and $d\bar{d}$, and its decay $\rho \to \pi\pi$ can proceed with both valence quarks carried into the final-state hadrons, one $q\bar{q}$ pair being created from the vacuum. The ϕ is $s\bar{s}$; its dominant decay $\phi \to K\bar{K}$ likewise carries both valence quarks through, but only just, the phase space being 32 MeV, and its decay to three pions — which requires the $s\bar{s}$ pair to annihilate — is suppressed despite the far larger phase space. The J/ψ is $c\bar{c}$ below the threshold for a pair of charmed mesons, so *every* decay to light hadrons requires the c and $\bar{c}$ to annihilate.

That is the rule of Okubo [1263], Zweig [1301] and Iizuka [1333]: a decay whose quark-line diagram falls apart into two disconnected pieces is suppressed. Stated as an empirical rule it explains the ϕ; stated dynamically it explains the J/ψ and the size of the suppression. The disconnected diagram requires at least three gluons, because one gluon carries colour and cannot make a colour singlet, and two gluons cannot make a state of odd charge conjugation (Theorem 105.9 is the same argument for photons). The rate is therefore of order α_s^6 evaluated at a scale set by the charm mass, and by Phenomenon 102.41 that coupling is already small: $\alpha_s\,(m_c c^2) \approx 0.35$, so $\alpha_s^6 \approx 1.8 \times 10^{-3}$ against a light-quark process running at $\alpha_s \approx 1$. Asymptotic freedom, discovered the year before, is what turns an empirical rule into a number of the right order. □

The interpretation was settled within months by three further facts. The system has radial and orbital excitations with the spacings of a non-relativistic two-body bound state, treatable by the methods of Chapter 82 and testing the static potential of Equation (102.69) directly, as Remark 102.63 sets out. Above 3.73 GeV the annihilation cross section rises to a new plateau, consistent with the opening of a channel with one unit of a new quantum number in each of two final-state hadrons — open charm. And the ratio R of Phenomenon 102.15 steps up by 4/3, which is $3 \times (2/3)^2$: three colours of a quark of charge $+\frac{2}{3}e$. The fourth flavour predicted by Example 103.12 was there, with the charge the GIM mechanism required.

103.3 Three generations

103.3.1 Kobayashi and Maskawa

In 1973, with three quarks known and a fourth conjectural, Kobayashi and Maskawa asked what it would take for the weak interaction to violate CP [1505]. The answer is a counting argument and nothing else, which is what makes it remarkable.

The counting is carried out twice in this book, in Proposition 101.63 and in Theorem 105.25: an $N \times N$ unitary matrix carries $N(N-1)/2$ angles and $(N-1)(N-2)/2$ phases that survive rephasing of the quark fields. It is not repeated here. What belongs here is the consequence and the inference.

Proposition 103.15 (Why the counting forbids CP violation at $N = 2$)**.** *For $N = 2$ the mixing matrix can be brought to real orthogonal form by rephasing, and the charged-current interaction is then invariant under CP; for $N = 3$ one phase survives and CP invariance holds only if that phase is 0 or π.*

Rests on Equations (101.67), (101.68) and (105.16).

Proof. *Derives Proposition 103.15.*

Under CP the charged-current term of Equation (101.67) maps to itself with $V \mapsto V^*$ (Equation (105.16) gives the transformation of the bilinear). If V can be made real by a rephasing that leaves the rest of the Lagrangian invariant, then $V = V^*$ in that basis and the interaction is CP symmetric. Equation (101.68) with $N = 2$ gives $(N-1)(N-2)/2 = 0$ surviving phases, so the Cabibbo matrix is real and CP is conserved however θ_C is chosen; with $N = 3$ one phase survives and cannot be removed, so $V \neq V^*$ in any basis unless the phase is a multiple of π. □

Remark 103.16 (The size of the inference). The measurement that forced this was a single branching ratio of 2×10^{-3} [1274]. From it, and from the requirement that the theory be renormalizable and its gauge structure unchanged, Kobayashi and Maskawa concluded that two further quarks exist. Both were found: the bottom in 1977 [1597] and the top in 1995 [1891, 1892]. It is worth being precise about what was and was not predicted. The *number* three was predicted, as a minimum. The masses were not, and are still not predicted by anything. What the counting delivers is that the observation of CP violation is, on the stated hypotheses, a measurement of the number of generations — and the completely independent measurement of that number from the Z width, Phenomenon 103.22, agrees with it.

Two alternatives existed in 1973 and both are now excluded. A right-handed charged current with a complex coupling could violate CP with two generations, and is excluded by the helicity measurements of Section 101.3.3 and by the direct violation of Section 103.5.2; a superweak interaction acting only in the mixing could violate CP with two generations, and is excluded by $\varepsilon'/\varepsilon \neq 0$. The Kobayashi–Maskawa mechanism is not merely the simplest surviving option, it is the only one of the three that survived.

103.3.2 The tau lepton

In 1975 Perl's group at SPEAR reported events of the form $e^+e^- \to e^\pm\mu^\mp +$ missing energy, with no other charged particle and no photon [1556]. Two features made them a discovery rather than a background. The final state violates electron and muon number separately unless at least two unobserved neutral particles are present; and the events appear only above a threshold near 3.6 GeV in the total energy, which is the signature of pair production of a new particle of mass about $1.8\,\mathrm{GeV}/c^2$.

Phenomenon 103.17 (A third charged lepton)**.** There exists a charged lepton of mass $m_\tau c^2 = (1776.93 \pm 0.09)\,\mathrm{MeV}$ and lifetime $\tau_\tau = 2.903 \times 10^{-13}\,\mathrm{s}$ [2427], with its own neutrino, whose charged-current interaction has the same strength and the same $V - A$ structure as the electron's and the muon's.

Rests on Equation (101.53).

Derivation. *Derives Phenomenon 103.17.*

The universality claim is testable to a fraction of a per cent by one number, and the test is the cleanest in the whole of flavour physics because it involves no hadrons at all. Equation (101.53) gives the rate of a purely leptonic charged-current decay,

$$\Gamma\left(\ell \to \ell' \nu \bar{\nu}\right) = \frac{G_F^2 \left(m_\ell c^2\right)^5}{192\pi^3 \hbar \left(\hbar c\right)^6} f\left(\frac{m_{\ell'}^2}{m_\ell^2}\right), \qquad f(x) = 1 - 8x + 8x^3 - x^4 - 12x^2 \ln x\,, \tag{103.12}$$

whose fifth power of the mass is the dominant factor. Since the τ has hadronic decay channels as well, the prediction is for the *branching fraction*

$$\mathcal{B}\left(\tau \to e \nu \bar{\nu}\right) = \frac{\tau_\tau}{\tau_\mu} \left(\frac{m_\tau}{m_\mu}\right)^5 \frac{f\left(m_e^2/m_\tau^2\right)}{f\left(m_e^2/m_\mu^2\right)}\,. \tag{103.13}$$

Inserting $\tau_\tau = 2.9034 \times 10^{-13}\,\mathrm{s}$, $\tau_\mu = 2.196\,981\,1 \times 10^{-6}\,\mathrm{s}$, $m_\tau c^2 = 1776.93\,\mathrm{MeV}$ and $m_\mu c^2 = 105.658\,375\,5\,\mathrm{MeV}$, so that $(m_\tau/m_\mu)^5 = 1.3453 \times 10^6$ and the phase-space ratio is 1.00019, gives $\mathcal{B} = 0.1778$. The measured value is $\mathcal{B}(\tau \to e\nu\bar{\nu}) = 0.1782(4)$ [2427]. Agreement to two parts in a thousand, over a factor 1.3×10^6 in rate, is what "the same coupling" means quantitatively; expressed as a coupling ratio, g_τ/g_μ differs from unity by less than 2×10^{-3}. □

Derivation pending #153

The phase-space function $f(x) = 1 - 8x + 8x^3 - x^4 - 12x^2 \ln x$ for a purely leptonic charged-current decay with a massive *daughter lepton. The muon-decay rate inherited from the weak-interactions chapter is derived there only for a massless daughter, where $f(0) = 1$; the massive case is the one used above, and the three-body phase-space integral that produces it belongs in Appendix A.*

The τ neutrino was assumed for a quarter of a century and observed directly only in 2000, by the DONUT experiment, which recorded four ν_τ charged-current interactions producing a short track with a kink — the τ decaying within a millimetre of its production point [2016]. Its appearance in an oscillated beam, which is a different measurement, came in 2015 [2247] and belongs to Chapter 114.

Remark 103.18 (The tau as an instrument). The τ is the only lepton heavy enough to decay into hadrons, and that makes it a laboratory for two things this book measures elsewhere. Its hadronic branching fraction, compared with the leptonic one, gives α_s at a scale of 1.78 GeV — the lowest scale at which the coupling is extracted — and the running of that value up to $M_Z c^2$ is one of the entries in Table 102.2. Its decays into $\pi\pi$ measure the same hadronic vacuum polarization that limits the Standard Model prediction of the muon anomaly, which belongs to Section 112.6.3. Neither use was anticipated when the particle was found.

103.3.3 The bottom quark

Lederman's group at Fermilab measured the mass spectrum of muon pairs produced in 400 GeV proton–nucleus collisions and found a structure near $9.5\,\mathrm{GeV}/c^2$ standing above a smooth continuum [1597]. It resolved into the $\Upsilon(1S)$ and $\Upsilon(2S)$, with $m_\Upsilon c^2 = (9.460\,40 \pm 0.000\,10)\,\mathrm{GeV}$ and $\Gamma_\Upsilon = (54.0 \pm 1.3)\,\mathrm{keV}$ [2427]: the same signature as the J/ψ — a resonance far too narrow for a strong decay — one flavour further up.

Three consequences organize the rest of this chapter.

First, bottomonium and charmonium together test the static potential of Equation (102.69) in a way neither can alone. The reduced masses differ by a factor of about three, yet the spacing between the ground state and the first radial excitation is nearly the same in the two systems, $0.589\,\mathrm{GeV}/c^2$ against $0.563\,\mathrm{GeV}/c^2$; Remark 102.63 draws out why only an intermediate, roughly logarithmic, potential does that.

Second, the bottom quark is the one heavy flavour that forms mesons with a *long* lifetime on the scale of a modern detector. A B meson lives $1.52 \times 10^{-12}\,\mathrm{s}$, so at the energies of an asymmetric-energy collider it travels a few hundred micrometres before decaying — far enough to separate its decay vertex from the production point with a silicon detector, and hence to tag which of the two mesons produced in an event decayed first. That single instrumental fact is what makes the time-dependent measurements of Section 103.5.3 possible; without it the CP asymmetry integrates to a much smaller number.

Third, the mixing of the third generation to the first two is small — the b quark *is* the third generation, and what is small is its coupling out of it. The direct determinations are $|V_{cb}| = 0.0408 \pm 0.0014$ and $|V_{ub}| = 0.003\,82 \pm 0.000\,20$ (Table 103.1), and that smallness is

why B mesons live as long as they do. The lifetime and the mixing element are the same measurement seen twice.

103.3.4 The top quark

The top quark was expected from 1977, when the b was found with weak isospin $-\frac{1}{2}$ and therefore in need of a partner, and was not observed until 1995. In between it was measured indirectly, which is the part of the story that belongs to a treatise of evidence.

Phenomenon 103.19 (The top mass was known before the top was seen)**.** Electroweak radiative corrections depend on the top mass quadratically, through the correction $\Delta\rho$ to the ρ parameter of Equation (104.52), and the LEP precision data therefore determined m_t before any top quark was produced. The value inferred from the fit in 1994 was $(178 \pm 20)\,\mathrm{GeV}/c^2$; the direct measurements published the following year gave $(176 \pm 13)\,\mathrm{GeV}/c^2$ [1892] and $(199 \pm 30)\,\mathrm{GeV}/c^2$ [1891], and the current world average is $m_t c^2 = (172.57 \pm 0.29)\,\mathrm{GeV}$ [2427].
Rests on Equation (104.52), Proposition 104.43, and Theorem 104.40.

Derivation. *Derives Phenomenon 103.19.*

The mechanism is Proposition 104.43: a doublet whose two members have different masses breaks the custodial symmetry of Theorem 104.40, and the resulting shift in the ratio of W and Z self-energies grows as the squared mass splitting, $\Delta\rho \propto (m_t^2 - m_b^2)\,c^4$. Because the dependence is quadratic rather than logarithmic, a measurement of the Z lineshape and asymmetries at the per-mille level of Section 104.6.3 pins m_t to about ten per cent. That is a real prediction and it was confirmed: the indirect and direct values agree within their uncertainties, which is a test of the loop structure of the theory and not merely of its tree-level content. The same fit subsequently bounded the Higgs mass, whose contribution is only logarithmic and therefore far weaker — and that bound too was confirmed, in Phenomenon 104.59. □

Two properties of the top are peculiar to it and both follow from its mass.

Proposition 103.20 (The top decays before it hadronizes)**.** *The top width is* $\Gamma_t = 1.42\,\mathrm{GeV}$ *[2427], so its lifetime is*

$$\tau_t = \frac{\hbar}{\Gamma_t} = \frac{6.582\,119\,6 \times 10^{-16}\,\mathrm{eV\,s}}{1.42 \times 10^{9}\,\mathrm{eV}} = 4.6 \times 10^{-25}\,\mathrm{s}\,, \tag{103.14}$$

which is shorter than the time $\hbar/(\Lambda_{\mathrm{QCD}}) \approx 3.3 \times 10^{-24}\,\mathrm{s}$ *that QCD needs to dress a colour charge into a hadron. The top therefore never forms a bound state.*
Rests on Equations (102.45) and (103.1) and Phenomenon 102.65.

Proof. *Derives Proposition 103.20.*

$\Lambda_{\mathrm{QCD}} \approx 0.2\,\mathrm{GeV}$ by Equation (102.45), and the hadronization time is the inverse of that energy in the sense of Equation (103.1), $\hbar/0.2 \times 10^{9}\,\mathrm{eV} = 3.3 \times 10^{-24}\,\mathrm{s}$: seven times Equation (103.14). The width itself scales as m_t^3, since $t \to bW$ is a two-body decay into a real W with the top mass setting both the coupling's phase space and the longitudinal polarization enhancement, so the inequality gets stronger with mass and is a statement about the top specifically. The consequences are experimental and considerable: the top's spin information survives into its decay products, unrandomized by hadronization, and the object reconstructed in a detector is a bare colour triplet in flight — never, by Phenomenon 102.65, an asymptotic state. □

Remark 103.21 (A Yukawa coupling of one). By Theorem 104.38 the coupling of a fermion to the Higgs field is $\hat{y}_f = \sqrt{2}\,m_f c^2/E_v$ with $E_v = 246.22\,\mathrm{GeV}$, so

$$\hat{y}_t = \frac{\sqrt{2} \times 172.57\,\mathrm{GeV}}{246.22\,\mathrm{GeV}} = 0.991\,,$$

a dimensionless number equal to one within its uncertainty, while the electron's is 2.9×10^{-6}. Table 104.2 lists the full range. No principle in the Standard Model relates them, and that the largest of them sits at unity is the kind of fact that looks like a clue and has never been cashed as one. It is listed as open in Section 133.1.

103.3.5 How many generations

Phenomenon 103.22 (There are exactly three light neutrino species)**.** The part of the width of the Z resonance that no observed final state accounts for counts the neutrino species light enough for the Z to decay into them. Combining the scans of the four LEP experiments,

$$N_\nu = 2.984 \pm 0.008 \tag{103.15}$$

[2104]: two standard deviations below three, and more than a hundred standard deviations below four. The count was already unambiguous in the first scan taken [1819]. Any further neutrino must therefore be heavier than $m_Z c^2/2$ or must not couple to the Z at all.

Rests on Equation (101.75).

Derivation. *Derives Phenomenon 103.22.*

The invisible width is the total width minus the sum of the widths into observed final states, and the species count is that quantity divided by the width into one neutrino pair. The latter is not measured; it is computed, and the computation is short.

By Equation (101.75) the Z couples to a fermion f through vector and axial couplings

$$g_V^f = T_f^3 - 2Q_f \sin^2\theta_W\,, \qquad g_A^f = T_f^3\,, \tag{103.16}$$

and the partial width of a vector boson of mass M_Z into a pair of fermions light compared with it is

$$\Gamma\left(Z \to f\bar{f}\right) = N_c^f \,\frac{G_F\left(M_Z c^2\right)^3}{6\pi\sqrt{2}\,\hbar\,(\hbar c)^3}\left[\left(g_V^f\right)^2 + \left(g_A^f\right)^2\right], \tag{103.17}$$

N_c^f being 3 for quarks and 1 for leptons. The dimensional check is worth doing once: $G_F/(\hbar c)^3$ carries $1/\mathrm{J}^2$, multiplying it by an energy cubed leaves an energy, and the remaining $\hbar^{-1}$ converts that energy into a rate — so Equation (103.17) is 1/s, and $\hbar\Gamma$ is the width in energy units usually quoted.

For a neutrino, $T^3 = +\frac{1}{2}$ and $Q = 0$, so $g_V = g_A = \frac{1}{2}$ and the bracket is $\frac{1}{2}$:

$$\hbar\Gamma\left(Z \to \nu\bar{\nu}\right) = \frac{G_F\left(M_Z c^2\right)^3}{12\pi\sqrt{2}\,(\hbar c)^3} = \frac{1.166\,378\,7 \times 10^{-5}/\mathrm{GeV}^2 \times (91.1880\,\mathrm{GeV})^3}{12\pi\sqrt{2}} = 165.9\,\mathrm{MeV}\,, \tag{103.18}$$

the full one-loop value being 167.2 MeV. For a charged lepton, $T^3 = -\frac{1}{2}$ and $Q = -1$, so with $\sin^2\theta_W = 0.2312$ — the $\overline{\mathrm{MS}}$ value at the scale $M_Z c^2$ [2427], the fourth digit being meaningless without that scheme and that scale, which is why Equation (104.62) quotes the same quantity to three figures — the bracket is $(-0.0376)^2 + \left(-\frac{1}{2}\right)^2 = 0.2514$ and $\hbar\Gamma_{\ell\ell} = 83.4\,\mathrm{MeV}$, against the measured $(83.985 \pm 0.086)\,\mathrm{MeV}$ [2104] — the 0.7% shortfall being exactly the radiative correction the tree-level formula omits. The count is then

$$N_\nu = \frac{\Gamma_{\mathrm{inv}}}{\Gamma_{\ell\ell}}\left(\frac{\Gamma_{\ell\ell}}{\Gamma_{\nu\nu}}\right)_{\mathrm{SM}}, \qquad \left(\frac{\Gamma_{\nu\nu}}{\Gamma_{\ell\ell}}\right)_{\mathrm{SM}} = 1.9912\,, \tag{103.19}$$

the tree-level version of which is $0.5/0.2514 = 1.9888$, differing from the full value by one part in a thousand. With the measured $\Gamma_{\mathrm{inv}} = (499.0 \pm 1.5)\,\mathrm{MeV}$ and $\hbar\Gamma_{\ell\ell} = (83.985 \pm 0.086)\,\mathrm{MeV}$ [2104], the ratio is $499.0/83.985 = 5.942$, and dividing by 1.9912 gives $N_\nu = 2.984$, which is Equation (103.15).

The residual 2σ deviation from three deserves a word, because it is not a hint of a fourth neutrino. It is comparable with the radiative corrections just displayed, and the largest of those enters not the widths but the *luminosity*: the t-channel photon exchange in small-angle Bhabha scattering, which is what LEP counted to normalize every cross section. A re-analysis of that effect published in 2019 — not in this book's bibliography, and therefore named without a citation rather than cited to a key that does not exist — raised the central value to 2.996 ± 0.007. The measurement counts three, and the apparent tension was an artefact of the normalization, not of the neutrino sector. □

Derivation pending #154

The tree-level partial width of the Z into a fermion pair. The formula is stated above with its dimensional check and then used to count the neutrino species; its derivation from the neutral-current Lagrangian — the squared matrix element summed over final and averaged over initial polarizations, times the two-body phase space — is not carried out here and belongs in Appendix A.

Remark 103.23 (What the count does and does not exclude). Equation (103.15) counts neutrinos that are *active* — coupling to the Z with the standard strength — and *light*, meaning $m_\nu c^2 < M_Z c^2/2$. A fourth neutrino evading both conditions is not excluded by it, and the searches for one, with their null results, belong to Section 114.6.4, which reserves them. What the count does exclude is a fourth *generation* of the observed kind, since a fourth charged lepton would come with a light active partner. An independent bound of the same strength comes from primordial nucleosynthesis, where the expansion rate at freeze-out — and hence the neutron-to-proton ratio frozen into the light elements — depends on the number of relativistic species. The light-element floor itself is Phenomenon 48.10; that phenomenon states the abundances as a one-parameter family in the baryon-to-photon ratio and does not yet extract a species count from them, so the nucleosynthesis determination of the number of neutrinos is owed to Chapter 48 rather than held there. It agrees with Equation (103.15), which is what makes the number three a fact about Nature rather than about the Z.

And it is a fact without an explanation. Nothing in the Standard Model fixes the number of generations; three is measured, twice, by completely different means, and predicted by nothing. It is listed in Section 133.1.

103.4 The CKM matrix

103.4.1 Structure and parametrization

Definition 103.24 (The CKM matrix)**.** $V_{\mathrm{CKM}} = U_u^\dagger U_d$ is the unitary 3×3 matrix of Theorem 104.38 relating the down-type states that couple to the W to the down-type states of definite mass,

$$\begin{pmatrix} d' \\ s' \\ b' \end{pmatrix} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} \begin{pmatrix} d \\ s \\ b \end{pmatrix} . \tag{103.20}$$

Its entries are dimensionless. Four of its nine complex entries are physically independent: three angles and one phase, by Equation (101.68).

The convention that the matrix acts on the down-type states rather than the up-type ones is arbitrary and universal; it makes V_{CKM} the object appearing in Equation (101.67). Two parametrizations are in use, and each is right for a different purpose.

Definition 103.25 (Standard parametrization)**.** With $c_{ij} = \cos\theta_{ij}$, $s_{ij} = \sin\theta_{ij}$ and one phase δ,

$$V = \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13} \end{pmatrix} . \tag{103.21}$$

The three angles may be taken in the first quadrant and δ in $[0, 2\pi)$ without loss of generality.

Derivation of the form. *Derives Definition 103.25.*

Write $V = R_{23}(\theta_{23})\,\Phi(\delta)\,R_{13}(\theta_{13})\,\Phi(-\delta)\,R_{12}(\theta_{12})$, where R_{ij} is a real rotation in the ij plane and $\Phi(\delta) = \mathrm{diag}(1, 1, e^{i\delta})$. Any unitary 3×3 matrix can be brought to this form because such a matrix has 9 real parameters — the CKM matrix is unitary with no determinant condition imposed, so the count is that of U(3) and not of SU(3), which has 8 — of which 3 are the angles of the SO(3) subgroup and 6 are phases, and 5 of the phases are removed by rephasing the quark fields, per Proposition 101.63. Multiplying out the five factors gives Equation (103.21). The placement of δ is a convention: any rephasing moves it around the matrix without changing a single observable, since every observable is a rephasing invariant of the type of Equation (105.77). That the phase can be attached to V_{ub}, the smallest element, is what makes the standard parametrization convenient and what makes CP violation small even though δ is of order unity. □

The measured angles are

$$\theta_{12} = 13.00^\circ\,, \qquad \theta_{23} = 2.40^\circ\,, \qquad \theta_{13} = 0.21^\circ\,, \qquad \delta = 65.7^\circ\,, \tag{103.22}$$

[2427]: a strong hierarchy in the angles and a phase of ordinary size. These four numbers are not independent of the four quoted below — they are the same measurement in the other parametrization, and Remark 103.27 carries out the conversion, because a book that quoted both from separate compilations would sooner or later quote two values of one quantity. The hierarchy in the angles is the content of that second parametrization.

Definition 103.26 (Wolfenstein parametrization)**.** Set $\lambda = s_{12}$, $A\lambda^2 = s_{23}$ and $A\lambda^3(\rho - i\eta) = s_{13}e^{-i\delta}$. Then to third order in λ,

$$V = \begin{pmatrix} 1 - \tfrac{1}{2}\lambda^2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1 - \tfrac{1}{2}\lambda^2 & A\lambda^2 \\ A\lambda^3(1 - \rho - i\eta) & -A\lambda^2 & 1 \end{pmatrix} + O\left(\lambda^4\right) , \tag{103.23}$$

with the measured values [2427]

$$\lambda = 0.225\,01 \pm 0.000\,68\,, \quad A = 0.826 \pm 0.017\,, \quad \bar\rho = 0.1591 \pm 0.0094\,, \quad \bar\eta = 0.3523 \pm 0.0076\,, \tag{103.24}$$

where $\bar\rho + i\bar\eta = (\rho + i\eta)\left(1 - \tfrac{1}{2}\lambda^2\right) + O(\lambda^4)$ are the convention-independent combinations that survive to higher order [1733].

Derivation. *Derives Definition 103.26.*

Expand Equation (103.21) with $s_{12} = \lambda$, $s_{23} = A\lambda^2$, $s_{13}e^{-i\delta} = A\lambda^3(\rho - i\eta)$ and $c_{ij} = 1 - \tfrac{1}{2}s_{ij}^2 + \ldots$, keeping terms to $O(\lambda^3)$ in each entry. The $(1,1)$ entry is $c_{12}c_{13} = 1 - \tfrac{1}{2}\lambda^2 + O(\lambda^4)$, the $(1,2)$ entry is $s_{12}c_{13} = \lambda + O(\lambda^5)$, and the $(2,1)$ entry is $-s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} = -\lambda + O(\lambda^6)$, so the upper-left 2×2 block is a rotation through the Cabibbo angle up to $O(\lambda^4)$. The $(3,1)$ entry is $s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} = A\lambda^3 - A\lambda^3(\rho + i\eta) = A\lambda^3(1 - \rho - i\eta)$ to this order, which is the entry carrying the interesting phase. Note that the expansion is not a mathematical approximation imposed for convenience: λ^2 is 0.0506 and λ^4 is 2.6×10^{-3}, so the hierarchy is a property of the measured matrix. □

Remark 103.27 (The standard angles are the apex, converted). Equation (103.22) and Equation (103.24) are one measurement in two coordinate systems, and this book takes the apex as primary because every closure test below is drawn in the $(\bar\rho,\bar\eta)$ plane. Inverting Definition 103.26 with $\rho+\mathrm{i}\eta = (\bar\rho+\mathrm{i}\bar\eta)\left(1-\tfrac{1}{2}\lambda^2\right)^{-1}$ gives $s_{12}=\lambda$, so $\theta_{12}=13.003°$; $s_{23}=A\lambda^2=4.182\times10^{-2}$, so $\theta_{23}=2.397°$; and $s_{13}=A\lambda^3\sqrt{\rho^2+\eta^2}=3.732\times10^{-3}$, so $\theta_{13}=0.2138°$. Note that this uses the *unbarred* pair; the third-order expansion of Example 103.28 uses the barred pair and gets 3.64×10^{-3} for the same quantity, which is the 2.5% discussed there. The phase is fixed by the same relation: $s_{13}\mathrm{e}^{-\mathrm{i}\delta}=A\lambda^3(\rho-\mathrm{i}\eta)$ has the argument of $\bar\rho-\mathrm{i}\bar\eta$, the positive rescaling dropping out, so

$$\delta=\arctan\frac{\bar\eta}{\bar\rho}=\arctan\frac{0.3523}{0.1591}=65.70°\,. \tag{103.25}$$

That is the same arithmetic that produces the angle γ in Phenomenon 103.31, which is why the two agree to within a twentieth of a degree: reconstructing the exact unitary matrix from $(\theta_{12},\theta_{23},\theta_{13},\delta)$ and evaluating $\gamma=\arg(-V_{ud}V_{ub}^*/V_{cd}V_{cb}^*)$ as in Equation (103.31) gives 65.66°, a difference of 0.04° which is the $O(\lambda^4)$ residue. A reader consulting an older compilation will meet $\delta\approx68°$; that number belongs with an earlier apex, and quoting it beside Equation (103.24) would put two mutually inconsistent phases in one chapter.

Example 103.28 (What the λ expansion costs)**.** Four combinations follow from Equation (103.24) once the expansion is truncated at third order:

$$|V_{cb}|=A\lambda^2=0.826\times(0.22501)^2=4.182\times10^{-2}\,, \tag{103.26}$$

$$|V_{ub}|=A\lambda^3\sqrt{\bar\rho^2+\bar\eta^2}=3.64\times10^{-3}\,, \tag{103.27}$$

$$|V_{td}|=A\lambda^3\sqrt{(1-\bar\rho)^2+\bar\eta^2}=8.58\times10^{-3}\,, \tag{103.28}$$

$$J=A^2\lambda^6\bar\eta=3.12\times10^{-5}\,. \tag{103.29}$$

The corresponding numbers from the global fit [2427] — that is, from the exact parametrization of Equation (103.21), not from the expansion — are 4.182×10^{-2}, 3.69×10^{-3}, 8.57×10^{-3} and 3.08×10^{-5}, the last being Equation (105.78).

It is essential to say what this does and does not test. $(\lambda,A,\bar\rho,\bar\eta)$ is a reparametrization of the same four degrees of freedom as $(\theta_{12},\theta_{23},\theta_{13},\delta)$, so nothing here is a test of the CKM matrix, and Equation (103.26) is not a test at all: Definition 103.26 *defines* $A\lambda^2=s_{23}$ and $|V_{cb}|=s_{23}c_{13}$ exactly, so the agreement of the two printed digit for digit is an identity, differing only by $c_{13}=1-7\times10^{-6}$. What the remaining three lines measure is the error of the truncation, and that error is predicted in advance. Writing $\bar\rho,\bar\eta$ in place of ρ,η changes a quantity by a relative $\lambda^2/2=2.5\%$, which is exactly the size of the $O(\lambda^5)$ terms the third-order parametrization drops. In Equations (103.27) and (103.29) the apex coordinates enter directly and the full 2.5% is available; in Equation (103.28) they enter as $1-\bar\rho$, where the same shift is only 0.5%; and in Equation (103.26) they do not enter at all. The line that should be exact is exact, the line that should be accurate to 0.5% is accurate to 0.1%, and the two that should be wrong by up to 2.5% are wrong by 1.4% and 1.3%. The expansion is therefore usable wherever a per-cent statement is wanted, and must be abandoned wherever it is not — which is why every closure test below is stated in terms of the exact matrix.

The genuine test, against numbers that were *not* inputs to the fit, is against the direct determinations of Table 103.1: $|V_{cb}|=0.0408\pm0.0014$ against 4.182×10^{-2} is 0.7σ, $|V_{ub}|=0.003\,82\pm0.000\,20$ against 3.64×10^{-3} is 0.9σ, and $|V_{td}|=0.0086\pm0.0002$ against 8.58×10^{-3} is 0.1σ. Those three comparisons carry the physics; the four lines above carry only the arithmetic of the expansion.

103.4.2 Measured magnitudes

Every element is measured, most of them more than once and by methods sharing no systematics. Table 103.1 collects them with the process each comes from.

Table 103.1: Magnitudes of the CKM elements and the processes that measure them [2427]. The values are the direct determinations, not the outputs of the global unitarity fit, so that the closure tests of Section 103.4.3 are tests. The uncertainty on $|V_{cb}|$ and $|V_{ub}|$ is enlarged over the fit value to cover the inclusive–exclusive tension discussed in the text.

Element	Magnitude	Principal determination
$\lvert V_{ud}\rvert$	$0.973\,67 \pm 0.000\,32$	superallowed $0^+ \to 0^+$ nuclear beta decay; free neutron decay
$\lvert V_{us}\rvert$	0.2243 ± 0.0008	$K \to \pi\ell\nu$ form factor; ratio of $K \to \mu\nu$ to $\pi \to \mu\nu$; hadronic τ decay
$\lvert V_{ub}\rvert$	$0.003\,82 \pm 0.000\,20$	inclusive and exclusive $B \to X_u\ell\nu$
$\lvert V_{cd}\rvert$	0.221 ± 0.004	charm production in neutrino scattering; $D \to \pi\ell\nu$
$\lvert V_{cs}\rvert$	0.975 ± 0.006	$D \to K\ell\nu$; $D_s \to \ell\nu$; W decay to charm
$\lvert V_{cb}\rvert$	0.0408 ± 0.0014	inclusive and exclusive $B \to X_c\ell\nu$
$\lvert V_{td}\rvert$	0.0086 ± 0.0002	B^0–$\bar{B}^0$ oscillation frequency (loop)
$\lvert V_{ts}\rvert$	0.0415 ± 0.0009	B_s–$\bar{B}_s$ oscillation frequency (loop)
$\lvert V_{tb}\rvert$	1.014 ± 0.029	single top production cross section (tree)

Three features of the table matter more than the numbers.

The third row is measured at one loop and at tree level, and the two agree. $|V_{td}|$ and $|V_{ts}|$ come from oscillation frequencies, which are box diagrams of the kind computed in Example 103.12, and therefore assume the loop content of the Standard Model. $|V_{tb}|$ comes from single top production, which is a tree-level charged-current process and assumes nothing of the sort. Consistency between them is a statement that no unknown particle is circulating in the box.

The determination of $|V_{cb}|$ *and* $|V_{ub}|$ *is not settled.* Two methods exist for each. The *inclusive* method sums over all charmed (or charmless) final states and uses an operator product expansion in $1/m_b$; the *exclusive* method measures one channel, $B \to D^*\ell\nu$ or $B \to \pi\ell\nu$, and requires a lattice form factor at the kinematic point of interest. For $|V_{cb}|$ the two differ by about 2 to 3 standard deviations, inclusive high; for $|V_{ub}|$ by a similar amount, again inclusive high. The discrepancy has persisted for two decades, has narrowed as lattice calculations improved without disappearing, and is almost certainly a problem of hadronic theory rather than of the electroweak sector — but it is not resolved, and the enlarged uncertainties in Table 103.1 are an acknowledgement of that rather than a measurement.

Nothing in the table is predicted. Four numbers, and the overall scale of the quark masses, are inputs of the Standard Model. The tests of the next subsection are tests of the *relations* among the nine entries, not of their values.

103.4.3 Unitarity triangle

Unitarity of a 3×3 matrix gives six orthogonality relations between distinct columns or rows. Each is a statement that three complex numbers sum to zero, hence that they close a triangle in the complex plane. Four of the six triangles are extremely flat — one side is smaller than the others by two powers of λ or more — and *two* have all three sides of the

same order. Building the matrix from Equation (103.24) and taking the ratio of the shortest side to the longest gives, for the three column relations (d,s), (d,b), (s,b), the values 0.002, 0.387, 0.020, and for the three row relations (u,c), (u,t), (c,t), the values 0.001, 0.403, 0.046. The (d,b) column triangle, whose sides are all of order $A\lambda^3$, is the one universally called *the* unitarity triangle and is the one defined below; the (u,t) row triangle is if anything marginally less degenerate and has the same area by Proposition 103.30. It is not drawn separately because it carries almost the same information: its angles, computed from the same matrix, are 91.60°, 64.63° and 23.77° against 91.60°, 65.66° and 22.74° for the column triangle, so the largest angle is common to both and the other two differ at $O(\lambda^2)$.

Definition 103.29 (The unitarity triangle)**.** The relation between the first and third columns of Equation (103.20),

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0\,, \tag{103.30}$$

has three terms of order $A\lambda^3$. Dividing through by $V_{cd}V_{cb}^*$ normalizes the middle side to unit length and puts the triangle's base on the real axis from $(0,0)$ to $(1,0)$; the apex is then at $(\bar\rho,\bar\eta)$. Its interior angles are

$$\alpha = \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right)\,,\quad \beta = \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right)\,,\quad \gamma = \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right)\,, \tag{103.31}$$

and $\alpha+\beta+\gamma=\pi$ identically.

Proposition 103.30 (Area and the Jarlskog invariant)**.** *The unnormalized triangle of Equation (103.30) has area $J/2$, with J the Jarlskog invariant of Definition 105.26; all six unitarity triangles have the same area. CP is violated if and only if that area is non-zero.*

Rests on Equations (103.30) and (105.77) and Proposition 105.27.

Proof. *Derives Proposition 103.30.*

For three complex numbers $z_1+z_2+z_3=0$, the triangle they close has area $\frac{1}{2}\,|\mathrm{Im}\,(z_1 z_2^*)|$, since the cross product of the two vectors z_1 and $-z_3 = z_1+z_2$ is $\mathrm{Im}\,(z_1\overline{z_1+z_2}) = \mathrm{Im}\,(z_1 z_2^*)$. With $z_1 = V_{ud}V_{ub}^*$ and $z_2 = V_{cd}V_{cb}^*$ this is $\mathrm{Im}\,(V_{ud}V_{ub}^*V_{cd}^*V_{cb})$, which is a Jarlskog quartet and therefore equals $\pm J$ by Equation (105.77). Since Equation (105.77) makes every quartet equal up to sign, and each of the six relations produces one, all six triangles have area $J/2$. A degenerate triangle — three collinear complex numbers — has $J=0$ and by Proposition 105.27 conserves CP. That the area is a rephasing invariant while the individual angles are not is the reason J, and not δ, is the physical measure of CP violation. □

The triangle is now measured many times over, and the measurements are independent in a strong sense: they use different decays, different detectors, and different parts of the theory.

Phenomenon 103.31 (The unitarity triangle closes)**.** The three angles of Equation (103.31) are measured separately, each from a CP asymmetry in a different class of B decay, with results [2427]

$$\alpha = 85^\circ\,,\qquad \beta = 22.2^\circ\,,\qquad \gamma = 66^\circ\,, \tag{103.32}$$

and the two sides, from $|V_{ub}/V_{cb}|$ and from the ratio of B_s to B_d oscillation frequencies, are measured separately again. All of them meet, within uncertainties, at one apex.

Rests on Definition 103.29 and Equations (103.24) and (103.31).

Derivation. *Derives Phenomenon 103.31.*

Two checks, one of the angles and one relating angles to sides.

First the angles. Equation (103.32) sums to $173^\circ \pm 6^\circ$, consistent with 180° at 1.2 standard deviations; and the constraint $\alpha+\beta+\gamma=\pi$ is an identity of Definition 103.29,

not an input to any of the three measurements. That the three numbers, extracted from $B \to \pi\pi$ and $\rho\rho$, from $B \to J/\psi K_S$, and from $B \to DK$ respectively, sum correctly is a non-trivial test.

Now the apex. Definition 103.29 places it at $(\bar\rho, \bar\eta)$, so

$$\tan\beta = \frac{\bar\eta}{1-\bar\rho}\,, \qquad \tan\gamma = \frac{\bar\eta}{\bar\rho}\,.$$

Inserting Equation (103.24) gives $\beta = 22.7°$, hence $\sin 2\beta = 0.713$, and $\gamma = 65.7°$. The directly measured values are $\sin 2\beta = 0.70 \pm 0.02$, from the time-dependent asymmetry in $B^0 \to J/\psi K_S$ [2005, 2010], and $\gamma = 66° \pm 3°$, from interference between $b \to c$ and $b \to u$ amplitudes in $B \to DK$. Both agree. The first of them is the sharper statement, because $\sin 2\beta$ is measured to three per cent in a tree-dominated decay whose theoretical uncertainty is below one per cent — and it agrees with a value obtained from Δm_d, Δm_s, ε_K and $|V_{ub}/V_{cb}|$, that is from three loop processes and one tree process, none of them a CP asymmetry.

What is being tested is the following. There are four parameters. The observables listed number well over a dozen. Any one of them could have landed outside the region the others define, and that would have falsified the hypothesis that a single phase in a unitary matrix accounts for all CP violation in the quark sector. None has. The global fits [2074] quantify the agreement, and the residual freedom in the apex is now a few per cent in each coordinate. □

Remark 103.32 (Where the closure is weakest). Three qualifications keep Phenomenon 103.31 honest. The angle α carries a 5° uncertainty dominated by the hadronic "penguin" amplitudes that must be subtracted from $B \to \pi\pi$, which is theory, not statistics. The side $|V_{ub}/V_{cb}|$ inherits the inclusive–exclusive tension of Section 103.4.2, and the two choices move the apex by about one standard deviation. And the first-row relation Δ_{CKM} of Equation (103.6), which is the most precisely measured unitarity statement of all, is the one that does not come out right. The correct summary is that the triangle closes at the few-per-cent level and the first row does not close at the 10^{-3} level; both are measurements and both are recorded.

103.5 Neutral meson mixing and CP violation

103.5.1 Neutral kaon mixing

A neutral meson carrying a flavour quantum number has an antiparticle distinct from itself, and the weak interaction, which does not conserve that quantum number, connects the two. The system is then a two-state quantum system with decay, and its behaviour is the most sensitive interferometer physics possesses.

Definition 103.33 (Neutral-meson mixing)**.** Let P^0 and $\bar P^0$ be a neutral meson and its antiparticle, distinguished by a flavour quantum number conserved by the strong interaction. In the two-dimensional subspace they span, the effective time evolution is

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\begin{pmatrix} a \\ \bar a \end{pmatrix} = \left(\mathsf{M}c^2 - \frac{\mathrm{i}\hbar}{2}\Gamma\right)\begin{pmatrix} a \\ \bar a \end{pmatrix}\,, \tag{103.33}$$

with M and Γ Hermitian 2×2 matrices, the first carrying kg and the second 1/s. The eigenvalues of the non-Hermitian matrix in brackets define two states of definite mass and width, split by Δm and $\Delta\Gamma$, and the two dimensionless ratios

$$x := \frac{\Delta m\, c^2}{\hbar\bar\Gamma}\,, \qquad y := \frac{\Delta\Gamma}{2\bar\Gamma}\,, \qquad \bar\Gamma := \tfrac{1}{2}\left(\Gamma_1 + \Gamma_2\right)\,, \tag{103.34}$$

decide whether mixing is observable: $x \ll 1$ and $y \ll 1$ means the meson decays before it can oscillate.

The derivation of Equation (103.33) from the Weisskopf–Wigner treatment of an unstable state, the constraints that CPT invariance and CP invariance impose on M and Γ, and the explicit diagonalization are Proposition 105.22 and Proposition 105.23; they are not repeated here. What belongs here is the physics the four measured systems display.

Table 103.2: The four neutral-meson systems, with the mixing parameters of Equation (103.34) [2427]. Only the strange system has $y \approx 1$, because only there is a decay channel open to one CP eigenstate and closed to the other; only the charm system has $x \ll 1$, because there the GIM suppression of Theorem 103.11 runs over down-type quarks, whose masses are all small.

System	Quarks	x	y	Heaviest quark in the box
K^0–$\bar{K}^0$	$d\bar{s}$	0.946	0.997	charm (top suppressed by mixing)
D^0–$\bar{D}^0$	$c\bar{u}$	0.0041	0.0065	bottom
B^0–$\bar{B}^0$	$d\bar{b}$	0.770	0.001	top
B_s–$\bar{B}_s$	$s\bar{b}$	27.0	0.062	top

Gell-Mann and Pais saw the essential point in 1955, before any of it was measured [1067]. If CP were conserved, the states of definite mass and lifetime would be the CP eigenstates

$$|K_1\rangle = \frac{1}{\sqrt{2}}\left(\left|K^0\right\rangle - \left|\bar{K}^0\right\rangle\right), \qquad |K_2\rangle = \frac{1}{\sqrt{2}}\left(\left|K^0\right\rangle + \left|\bar{K}^0\right\rangle\right), \tag{103.35}$$

with $CP = +1$ and -1 respectively in the phase convention of Equation (105.45). The two-pion final state has $CP = +1$ and the three-pion state $CP = -1$ (Equation (105.47)), and the three-pion channel has almost no phase space — $m_K c^2 - 3m_\pi c^2 = 83\,\mathrm{MeV}$ against 219 MeV for two pions. So K_1 should decay fast and K_2 slowly. The prediction was of a *new particle*, of the same mass and opposite CP, and it was found: the measured lifetimes are

$$\tau_S = 8.954 \times 10^{-11}\,\mathrm{s}, \qquad \tau_L = 5.116 \times 10^{-8}\,\mathrm{s}, \qquad \frac{\tau_L}{\tau_S} = 571, \tag{103.36}$$

which is Equation (105.48).

Proposition 103.34 (The mass difference is measured as a phase)**.** *A beam that is pure K^0 at $t = 0$ contains, at proper time t, a $\bar{K}^0$ component of probability*

$$P\left(K^0 \to \bar{K}^0\right)(t) = \frac{1}{4}\left[\mathrm{e}^{-\Gamma_S t} + \mathrm{e}^{-\Gamma_L t} - 2\mathrm{e}^{-(\Gamma_S+\Gamma_L)t/2}\cos\frac{\Delta m_K c^2 t}{\hbar}\right], \tag{103.37}$$

so Δm_K is read off an interference pattern in time, not from a mass measurement. This is why $\Delta m_K c^2 = (3.484 \pm 0.006) \times 10^{-6}\,\mathrm{eV}$ is known to three significant figures although it is a fraction 7.0×10^{-15} of the kaon mass itself.

Rests on Definition 103.33, Equation (103.35)*, and Proposition 101.56.*

Proof. *Derives Proposition 103.34.*

Write $|K^0\rangle = (|K_L\rangle + |K_S\rangle)/\sqrt{2}$ and $\left|\bar{K}^0\right\rangle = (|K_L\rangle - |K_S\rangle)/\sqrt{2}$, which inverts Equation (103.35) up to the CP-violating admixture of order 2×10^{-3} that is neglected here and restored in Section 103.5.2. Each mass eigenstate evolves with its own phase and its own damping, $|K_i(t)\rangle = \mathrm{e}^{-\mathrm{i}m_i c^2 t/\hbar}\mathrm{e}^{-\Gamma_i t/2}|K_i\rangle$, so

$$\left\langle \bar{K}^0 \middle| K^0(t)\right\rangle = \frac{1}{2}\left(\mathrm{e}^{-\mathrm{i}m_L c^2 t/\hbar - \Gamma_L t/2} - \mathrm{e}^{-\mathrm{i}m_S c^2 t/\hbar - \Gamma_S t/2}\right),$$

whose squared modulus is Equation (103.37). The strangeness of the beam at time t is measured directly, by the sign of the charged lepton in a semileptonic decay: the rule $\Delta S = \Delta Q$ (Proposition 101.56) says a K^0 gives ℓ^+ and a $\bar{K}^0$ gives ℓ^-. Counting the two charges as a function of decay position along a beam line therefore traces Equation (103.37), and the cosine's period measures Δm_K. With $x = \Delta m_K c^2/\hbar\bar{\Gamma} = 0.946$ from Table 103.2, roughly one oscillation occurs per lifetime, which is the optimum: much less and there is no interference, much more and it averages away. □

Remark 103.35 (Regeneration). A beam of K_L, purified by letting the K_S component die away, recovers a K_S component on passing through matter. The mechanism is that the strong interaction sees K^0 and $\bar{K}^0$, not K_L and K_S: the $\bar{K}^0$ can convert a nucleon's quark content in ways the K^0 cannot, so the forward scattering amplitudes f and $\bar{f}$ differ. Writing $|K_L\rangle \propto |K^0\rangle + \left|\bar{K}^0\right\rangle$, the transmitted beam is $f\,|K^0\rangle + \bar{f}\left|\bar{K}^0\right\rangle \propto \left(f+\bar{f}\right)|K_L\rangle + \left(f-\bar{f}\right)|K_S\rangle$, so the regenerated amplitude is proportional to $f-\bar{f}$ and vanishes only if the strong interaction is blind to strangeness, which it is not. The effect, Equation (105.64), is the single largest background to the measurement of Section 103.5.2 and had to be eliminated by evacuating the decay volume.

103.5.2 Discovery of CP violation

Phenomenon 103.36 (The long-lived kaon decays to two pions)**.** The neutral kaon system contains a short-lived state decaying to two pions and a long-lived state, some six hundred times longer lived, decaying to three. In a beam allowed to travel far enough that the short-lived component has died away, a small fraction of the surviving decays are nevertheless to $\pi^+\pi^-$: the branching fraction is about 2×10^{-3} [1274, 2427]. The experiment belongs to Chapter 111.

Rests on Definition 103.33 and Equations (103.35) *and* (105.47).

Derivation. Derives Phenomenon 103.36.

The pion has intrinsic parity -1, so a state of two pions with relative orbital angular momentum L has parity $(-1)^2(-1)^L = (-1)^L$; the kaon has spin zero, so $L = 0$ and the parity is $+1$. Charge conjugation exchanges π^+ with π^-, which for $L = 0$ is the identity, so the state also has $C = +1$. The two-pion state is therefore an eigenstate of CP with eigenvalue $+1$. The three-pion state available to the same system has, by the same counting together with the small energy release that suppresses non-zero orbital angular momenta, $CP = -1$. If CP were a symmetry of the decay interaction the two final states would be reached from two orthogonal kaon states, and whichever state decays to three pions could never decay to two. That one and the same long-lived state does both is thus a direct proof that CP is not conserved [1274]. What the argument does not settle is where the violation sits — in the mixing that defines the long-lived state, or in the decay amplitude itself. Separating them required the measurement of ϵ'/ϵ a generation later, and only that measurement excluded a superweak interaction acting solely on the mixing. □

The separation is parametrized by two complex numbers. The CP-violating admixture in the mixing is ε, defined by Equation (105.54); the CP violation in the decay amplitude itself is ε', defined through the two isospin amplitudes of the two-pion final state by Equation (105.72). The measured values are

$$|\varepsilon| = (2.228 \pm 0.011) \times 10^{-3}\,, \qquad \mathrm{Re}\left(\frac{\varepsilon'}{\varepsilon}\right) = (1.66 \pm 0.23) \times 10^{-3}\,, \tag{103.38}$$

the first from the ratio of K_L to K_S two-pion rates and the second from the double ratio of charged to neutral two-pion modes in the two beams — a quantity constructed precisely so that detector acceptance and beam normalization cancel (Proposition 105.24). The

result was established independently by NA48 [1973] and KTeV [1965] after two decades of measurements that disagreed with each other.

Remark 103.37 (What $\varepsilon' \neq 0$ excluded). Wolfenstein's superweak hypothesis [1300] proposed a new $\Delta S = 2$ interaction acting only in the mass matrix, which would produce $\varepsilon \neq 0$ and $\varepsilon' = 0$ exactly. It fits the 1964 measurement perfectly, requires no third generation, and survived for thirty-five years. Equation (103.38) killed it: ε'/ε is small but non-zero at more than seven standard deviations, so CP violation occurs in the decay amplitude and not only in the mixing. This is the point at which the Kobayashi–Maskawa mechanism ceased to have a live competitor. The Standard Model prediction for ε'/ε is a difference of two large and partially cancelling hadronic contributions and remains uncertain at the level of tens of per cent; what the measurement establishes is the *sign and existence* of direct CP violation, not a precision test.

103.5.3 B mixing and the B factories

In 1987 the ARGUS collaboration at DESY, studying $\Upsilon(4S)$ decays to $B\bar{B}$ pairs, counted events in which both B mesons decayed semileptonically with leptons of the *same* sign [1787]. Same-sign dileptons require one of the two mesons to have changed into its own antiparticle. The measured ratio of same-sign to opposite-sign pairs was $r = 0.21$, and the consequence was immediate and unwelcome.

Proposition 103.38 (Time-integrated mixing probability)**.** *For a system with $y \approx 0$, the probability that a meson born as P^0 decays as $\bar{P}^0$, integrated over all decay times, is*

$$\chi = \frac{x^2}{2\,(1+x^2)}\,, \qquad \textit{so} \qquad r = \frac{\chi}{1-\chi} = \frac{x^2}{2+x^2}\,. \tag{103.39}$$

ARGUS's $r = 0.21$ therefore gives $x_d = 0.73$.

Rests on Equations (103.34) *and* (103.37).

Proof. *Derives Proposition 103.38.*

From Equation (103.37) with $\Gamma_L = \Gamma_S = \Gamma$, the mixed and unmixed probabilities are $\tfrac{1}{2}\mathrm{e}^{-\Gamma t}\left[1 \mp \cos\left(\Delta m\, c^2 t/\hbar\right)\right]$. Using $\int_0^\infty \mathrm{e}^{-\Gamma t}\mathrm{d}t = \Gamma^{-1}$ and $\int_0^\infty \mathrm{e}^{-\Gamma t}\cos\omega t\,\mathrm{d}t = \Gamma/\left(\Gamma^2+\omega^2\right)$ with $\omega = \Delta m\, c^2/\hbar = x\Gamma$, and normalizing by the total Γ^{-1},

$$\chi = \frac{1}{2}\left(1 - \frac{1}{1+x^2}\right) = \frac{x^2}{2\,(1+x^2)}\,.$$

Solving $r = \chi/(1-\chi) = 0.21$ for x gives $x^2 = 2r/(1-r) = 0.532$, hence $x = 0.73$. □

Example 103.39 (The top mass from B mixing)**.** The box diagram generating Δm_d is the one of Example 103.12 with the external quarks d and b, and by Theorem 103.11 it is dominated by the heaviest internal quark, which for a b-flavoured meson is the top. The amplitude is no longer in the regime $m_i \ll M_W$, so the full loop function is needed:

$$\Delta m_d c^2 = \frac{G_F^2\left(M_W c^2\right)^2}{6\pi^2\left(\hbar c\right)^6}\,\eta_B\left(m_B c^2\right)\left(f_B\sqrt{B_B}\,c^2\right)^2 |V_{tb}V_{td}^*|^2\, S_0(x_t)\,, \tag{103.40}$$

with $x_t = \left(m_t c^2\right)^2/\left(M_W c^2\right)^2$, $\eta_B = 0.55$ the short-distance QCD factor, and

$$S_0(x) = x\left[\frac{1}{4} + \frac{9}{4\,(1-x)} - \frac{3}{2\,(1-x)^2}\right] - \frac{3x^3\ln x}{2\,(1-x)^3}\,,$$

which reduces to $S_0(x) \to x$ for $x \ll 1$, recovering Equation (103.8). With $m_t c^2 = 172.57\,\text{GeV}$ and $M_W c^2 = 80.369\,\text{GeV}$ one has $x_t = 4.61$ and $S_0 = 2.52$; inserting $f_B\sqrt{B_B}\,c^2 = 210\,\text{MeV}$, $m_B c^2 = 5.2797\,\text{GeV}$ and $|V_{td}| = 8.57 \times 10^{-3}$ gives

$$\Delta m_d c^2 = 3.51 \times 10^{-4}\,\text{eV}\,, \tag{103.41}$$

against the measured $3.336 \times 10^{-4}\,\text{eV}$ — five per cent, which is the accuracy of the lattice input.

In the dimensionless variable of Equation (103.34), with $\tau_B = 1.519 \times 10^{-12}\,\text{s}$, Equation (103.41) corresponds to $x_d = \Delta m_d c^2 \tau_B/\hbar = 0.81$, against the measured 0.770 of Table 103.2 — the same five per cent, now carried into the quantity ARGUS actually reported.

Now run it backwards to 1987. With $m_t c^2 = 30\,\text{GeV}$, the value then expected, $S_0 = 0.129$ and Equation (103.41) falls by a factor 19.5, giving $x_d = 0.042$ against the 0.73 that ARGUS measured. The hadronic inputs were poorly known in 1987, but not by a factor of eighteen in a squared amplitude, and the conclusion drawn at once was that the top quark is far heavier than anyone had supposed.

Read with today's inputs, ARGUS's number becomes a determination of the top mass, and it is worth doing the inversion rather than asserting its result. Since $\Delta m_d \propto S_0(x_t)$ with everything else held fixed, ARGUS's $x_d = 0.73$ requires $S_0 = 2.5226 \times 0.73/x_d^{\text{ref}}$, where x_d^{ref} is whatever the rest of the formula produces today. Anchoring on the formula itself, $x_d^{\text{ref}} = 0.81$, gives $S_0 = 2.27$, hence $x_t = 4.03$ and $m_t c^2 = 161\,\text{GeV}$; anchoring instead on the *measured* $x_d^{\text{ref}} = 0.770$, which removes the five-per-cent lattice offset, gives $S_0 = 2.39$, hence $x_t = 4.30$ and $m_t c^2 = 167\,\text{GeV}$. The two bracket the answer: ARGUS's mixing rate says $m_t c^2$ is between about 160 GeV and 170 GeV, against the 172.57 GeV eventually measured, eight years before the top was produced — the second time in this chapter that a loop measured a quark that could not yet be made. The gap between the two anchors is the honest uncertainty of the inference, and it is far smaller than the uncertainty the hadronic inputs carried in 1987; the 1987 statement was correctly made as an inequality, and only today's lattice numbers turn it into a measurement.

Derivation pending #155

The loop function $S_0(x)$ and the B-meson box amplitude for the mass difference. Both are stated above and then used twice to weigh the top quark, so the derivation is load-bearing: the box integral for an internal mass comparable with the W mass, whose value is S_0, is not carried out here and belongs in Appendix A.

Proposition 103.40 (The mixing ratio measures a ratio of CKM elements)**.** *Taking the ratio of Equation (103.40) for the B_s and B_d systems, the loop function, the QCD factor and the W mass cancel exactly, leaving*

$$\frac{\Delta m_s}{\Delta m_d} = \frac{m_{B_s}}{m_{B_d}}\,\xi^2\left|\frac{V_{ts}}{V_{td}}\right|^2, \qquad \xi := \frac{f_{B_s}\sqrt{B_s}}{f_{B_d}\sqrt{B_d}}\,. \tag{103.42}$$

The lattice quantity $\xi = 1.208$ is a ratio *of decay constants, in which most of the systematic uncertainty of the individual calculations cancels; this is what makes Equation (103.42) the best determination of $|V_{td}/V_{ts}|$.*

Rests on Equation (103.40).

Proof. *Derives Proposition 103.40.*

Divide Equation (103.40) by its B_s counterpart; every factor independent of the light spectator quark cancels. Inverting with the measured oscillation frequencies $\Delta m_d c^2/\hbar =$

$5.069 \times 10^{11}/\mathrm{s}$ and $\Delta m_s c^2/\hbar = 1.7765 \times 10^{13}/\mathrm{s}$ [2202, 2427], that is $\Delta m_d c^2 = 3.336 \times 10^{-4}\,\mathrm{eV}$ and $\Delta m_s c^2 = 1.169 \times 10^{-2}\,\mathrm{eV}$,

$$\left|\frac{V_{td}}{V_{ts}}\right| = \left[\frac{\Delta m_d}{\Delta m_s}\,\frac{m_{B_s}}{m_{B_d}}\right]^{1/2} \xi = \left[\frac{1}{35.05} \times 1.0165\right]^{1/2} \times 1.208 = 0.206\,,$$

against $8.6 \times 10^{-3}/4.15 \times 10^{-2} = 0.207$ from the individual entries of Table 103.1. Note the units. The literature quotes these as angular frequencies $\Delta mc^2/\hbar$ in 1/ps — 0.5069/ps and 17.765/ps — while this book quotes the energy splitting Δmc^2 in eV. The conversion is $\hbar = 6.582\,119\,6 \times 10^{-16}\,\mathrm{eV\,s}$, so 1/ps corresponds to $6.582 \times 10^{-4}\,\mathrm{eV}$, and the ratio the derivation uses is of course the same either way. □

The asymmetric-energy B factories were built for one measurement. An $\Upsilon(4S)$ produced at rest decays to a $B\bar{B}$ pair almost at rest, and the two mesons travel some 30 µm before decaying — too little to separate. Colliding beams of unequal energy gives the pair a Lorentz boost along the beam axis, stretching the separation to a few hundred micrometres, which a silicon vertex detector resolves. The time between the two decays is then measurable, and with it the time-dependent asymmetry of Equation (105.81).

Phenomenon 103.41 (Large CP violation in the B system)**.** In $B^0 \to J/\psi\, K_S$ the time-dependent decay-rate asymmetry between mesons tagged at production as B^0 and as $\bar{B}^0$ is an oscillation of amplitude

$$S_{J/\psi K_S} = \sin 2\beta = 0.70 \pm 0.02\,, \tag{103.43}$$

observed independently by BaBar [2010] and Belle [2005] in 2001. The effect is of order unity, against 2×10^{-3} in the kaon system, and it agrees with the value predicted from measurements containing no CP asymmetry at all.

Rests on Proposition 105.28 and Equations (103.31) *and* (103.40).

Derivation. Derives Phenomenon 103.41.

Proposition 105.28 gives the asymmetry as $S_f \sin(\Delta m_d c^2 t/\hbar) - C_f \cos(\Delta m_d c^2 t/\hbar)$ with $S_f = 2\,\mathrm{Im}\,\lambda/\left(1 + |\lambda|^2\right)$ and $\lambda = (q/p)\left(\bar{\mathcal{A}}_f/\mathcal{A}_f\right)$. For $f = J/\psi K_S$ three things conspire to make this clean. The decay $b \to c\bar{c}s$ is dominated by a single tree amplitude, so $\left|\bar{\mathcal{A}}/\mathcal{A}\right| = 1$ to within a per cent and $C_f \approx 0$; the mixing phase q/p is, from the box of Equation (103.40), twice the phase of $V_{tb}^* V_{td}$; and the K^0–$\bar{K}^0$ mixing in the final state contributes twice the phase of $V_{cs}^* V_{cd}$. Collecting,

$$\lambda = \mathrm{e}^{-2\mathrm{i}\beta}\,, \qquad \beta = \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right)\,,$$

which is exactly the angle of Equation (103.31); hence $S = \sin 2\beta$ with no hadronic quantity anywhere in the relation. That is the whole reason the measurement is decisive: the hadronic matrix elements cancel between the two interfering paths because both end in the same final state.

Why is the effect a thousand times larger than in the kaon? Because CP violation requires interference between two amplitudes of comparable size and different weak phase. In the kaon, the CP-violating amplitude is a small admixture in a state dominated by CP-conserving physics, so the asymmetry carries the small factor ε. In $B^0 \to J/\psi K_S$ the two interfering paths — decay without mixing, and decay after mixing — have *equal* magnitude by construction, since $|q/p| = 1$ and $|\lambda| = 1$, so the asymmetry is the full sin of the phase difference. Nothing is small except the phase, and the phase is not small. □

Mixing in the B_s system, with $x_s = 27$, oscillates twenty-seven times per lifetime and required a detector with picosecond decay-time resolution; it was resolved at the Tevatron and measured precisely at LHCb, which also observed CP violation in B_s decays [2202]. The value of Δm_s enters Equation (103.42) and is one of the constraints on the apex in Phenomenon 103.31.

103.5.4 Charm and the present picture

The charm system was the last to yield. By Theorem 103.11, a D^0 box runs over d, s and b quarks, all light compared with M_W, so the GIM suppression is severe and x and y are of order 10^{-3} (Table 103.2); the CP-violating part is suppressed further by the small mixing factor $|V_{cb}V_{ub}| \sim 1.5 \times 10^{-4}$.

Phenomenon 103.42 (CP violation in charm decays)**.** The difference of CP asymmetries between $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ is

$$\Delta A_{CP} = A_{CP}\left(K^+K^-\right) - A_{CP}\left(\pi^+\pi^-\right) = (-15.4 \pm 2.9) \times 10^{-4}\,, \tag{103.44}$$

non-zero at 5.3 standard deviations [2323]. With it, CP violation is established in all three quark systems in which it can occur.

Rests on Theorem 103.11 and Definition 103.25.

Derivation. *Derives Phenomenon 103.42.*

Taking the difference of two asymmetries rather than either alone is what makes the measurement possible: production asymmetries between D^0 and $\bar{D}^0$ in pp collisions, and detection asymmetries between positive and negative tracks, are common to the two final states and cancel in the difference, while the CP-odd parts do not, since U-spin relates the two channels with opposite sign. The residual is then a genuine asymmetry between a decay and its conjugate. Its magnitude, 1.5×10^{-3}, is of the order the Kobayashi–Maskawa phase predicts once the small mixing factor and the interference with the dominant Cabibbo-favoured amplitude are accounted for — but the hadronic matrix elements of charm decays are not calculable to better than a factor of a few, so the correct statement is that the observation is *consistent with* the Standard Model and does not test it sharply. □

Remark 103.43 (One phase, everything measured)*.* It is worth stating plainly what Section 103.5 has established. Every CP-violating observable measured in the quark sector — ε and ε' in the kaon, $\sin 2\beta$, γ and α in the B mesons, the B_s asymmetries, and Equation (103.44) in charm — is described by the single phase of Definition 103.25, whose rephasing-invariant measure is $J = 3.08 \times 10^{-5}$. Four parameters, well over a dozen independent measurements, one consistent solution. The places where the description is least sharply tested are those where hadronic matrix elements dominate the uncertainty: ε'/ε, the charm asymmetry just quoted, and the angle α. The places where it is sharply tested — $\sin 2\beta$, γ, the ratio $\Delta m_s/\Delta m_d$ — are those where the hadronic physics cancels.

103.5.5 What CP violation cannot yet explain

Phenomenon 103.44 (The universe contains matter and almost no antimatter)**.** No astrophysical concentration of antimatter is observed, and the baryon density inferred from primordial nucleosynthesis agrees with the one inferred from the acoustic peaks of the microwave background on a baryon-to-photon ratio

$$\eta = \frac{n_B - n_{\bar{B}}}{n_\gamma} = (6.12 \pm 0.04) \times 10^{-10} \tag{103.45}$$

[2348]. Generating such an asymmetry from a symmetric initial state requires baryon-number violation, violation of C and of CP, and a departure from thermal equilibrium [1358]. The

CP violation established in Phenomenon 103.36 is genuine but quantitatively far too small — by eleven powers of ten — to produce η.

Rests on Phenomenon 103.36, Theorem 105.41, and Proposition 105.42.

Derivation. *Derives Phenomenon 103.44.*

The three Sakharov conditions are derived as Theorem 105.41 and the value of η from $\Omega_b h^2$ as Proposition 105.42; neither is repeated. What is needed here is the size of the effect the CKM phase can produce, and the argument is dimensional.

By Proposition 105.27, all CP violation in the quark sector is proportional to the invariant $\det\left[M_u M_u^\dagger c^4, M_d M_d^\dagger c^4\right]$, which carries J multiplied by the six squared-mass differences of Equation (105.79) and has SI dimension J^{12}. Any asymmetry generated at a temperature T is a pure number, so it can depend on that invariant only through the dimensionless ratio Equation (105.106), and evaluating it with the running quark masses at $k_B T \approx 100\,\mathrm{GeV}$, where the baryon-number-violating processes are active, gives Equation (105.107),

$$d_{CP} \approx 2 \times 10^{-21}\,, \tag{103.46}$$

to be compared with $\eta = 6.1 \times 10^{-10}$: the ratio $\eta / d_{CP} = 3 \times 10^{11}$, a shortfall of eleven orders of magnitude, and detailed calculations [1882] do not improve it. The reason is structural. CP violation in this theory requires all six quark masses to be distinct, and at 100 GeV five of the six are negligible against the temperature, so the effect is suppressed by twelve powers of small mass ratios. The phase is of order unity; the masses kill it.

The third Sakharov condition fails as well, and independently. A departure from equilibrium requires the electroweak transition to be first order, and for the measured Higgs mass of Equation (104.66) it is not: it is a smooth crossover, as Remark 104.65 records. Two of the three conditions are therefore not met by the Standard Model with its measured parameters. The origin of Equation (103.45) is unknown, and this treatise says so; it is carried to Section 133.5. □

Remark 103.45 (Why this is stated as a failure and not as a puzzle solved). Mechanisms that would generate the observed asymmetry exist in outline — heavy Majorana neutrinos decaying out of equilibrium, a first-order transition driven by additional scalars — and none has any experimental support. They are named in Section 133.5 and in Section 103.7.4 as hypotheses without evidence, which is what they are. What is *measured* is Equation (103.45), and what is *calculated* is Equation (103.46); the eleven orders of magnitude between them are one of the few places where the Standard Model is known, from laboratory numbers plus one cosmological observation, to be incomplete.

103.6 Lepton flavour and neutrino mixing

103.6.1 The PMNS matrix

Pontecorvo asked in 1957 whether the neutral-kaon phenomenon of Section 103.5.1 has a leptonic analogue [1127, 1159]. His original proposal was $\nu \leftrightarrow \bar{\nu}$ oscillation, which is not what happens; but the idea that a neutral particle produced in a weak interaction need not be a state of definite mass, and can therefore convert into another, is exactly what happens. The correct form was written by Maki, Nakagawa and Sakata in 1962 [1237], the year the second neutrino flavour was established [1223]: flavour states are superpositions of mass states, and the superposition matrix plays for leptons the role V_{CKM} plays for quarks.

Definition 103.46 (The PMNS matrix)**.** In the basis in which the charged-lepton mass matrix is diagonal, the neutrino flavour states are

$$|\nu_\alpha\rangle = \sum_{i=1}^{3} U_{\alpha i}^{*}\, |\nu_i\rangle\,, \qquad \alpha \in \{e, \mu, \tau\}\,, \tag{103.47}$$

with U unitary and dimensionless. Written in the parametrization of Equation (103.21) with angles $\theta_{12}, \theta_{23}, \theta_{13}$ and Dirac phase δ_{CP}, it carries in addition a diagonal factor

$$U = U^{(\text{Dirac form})} \times \operatorname{diag}\left(1, \mathrm{e}^{\mathrm{i}\alpha_{21}/2}, \mathrm{e}^{\mathrm{i}\alpha_{31}/2}\right) , \tag{103.48}$$

present if and only if the neutrinos are Majorana particles.

Proposition 103.47 (Majorana phases do not affect oscillation)**.** *The two phases α_{21}, α_{31} of Equation (103.48) cancel from every oscillation probability, and from every process in which lepton number is conserved. No oscillation experiment, however precise, can determine whether the neutrino is a Dirac or a Majorana particle.*

Rests on Definition 103.46 and Equation (103.48).

Proof. *Derives Proposition 103.47.*

Every oscillation amplitude has the structure $\sum_i U_{\beta i} \mathrm{e}^{-\mathrm{i}\varphi_i} U^*_{\alpha i}$, in which each index i appears once on U and once on U^*. Under Equation (103.48), $U_{\alpha i} \mapsto U_{\alpha i} \mathrm{e}^{\mathrm{i}\alpha_{i1}/2}$ for every α, so the product $U_{\beta i} U^*_{\alpha i}$ acquires $\mathrm{e}^{\mathrm{i}\alpha_{i1}/2} \mathrm{e}^{-\mathrm{i}\alpha_{i1}/2} = 1$. The same cancellation occurs in any amplitude with one neutrino line entering and one leaving, that is, in any lepton-number-conserving process. It fails only where two neutrino lines are contracted with each other, which requires a Majorana propagator and violates lepton number by two units — the process of Section 103.7.2, and the reason that is the only practical test.

The counting is worth recording. For N Dirac neutrinos the phase count is $(N-1)(N-2)/2$, as for quarks, because the neutrino fields may be rephased. For N Majorana neutrinos a rephasing $\nu_i \to \mathrm{e}^{\mathrm{i}\phi}\nu_i$ is forbidden — it would multiply the Majorana mass term $\overline{\nu^c}\nu$ by $\mathrm{e}^{2\mathrm{i}\phi}$ — so only the charged-lepton fields may be rephased, $N-1$ of those phases being usable, and the surviving count is $N(N-1)/2$: three phases for $N = 3$, one Dirac and two Majorana. □

Phenomenon 103.48 (Lepton mixing is large)**.** The magnitudes of the PMNS entries are, from the global fit to all oscillation data [2356, 2427],

$$|U| \approx \begin{pmatrix} 0.82 & 0.55 & 0.15 \\ 0.46 & 0.50 & 0.73 \\ 0.33 & 0.67 & 0.67 \end{pmatrix} , \tag{103.49}$$

against the near-diagonal $|V_{\mathrm{CKM}}|$ of Table 103.1. Two of the three lepton mixing angles are of order tens of degrees; all three quark mixing angles are small.

Rests on Definition 103.46 and Equations (103.21) and (103.22).

Derivation. *Derives Phenomenon 103.48.*

Equation (103.49) follows by inserting the measured $\sin^2\theta_{12} = 0.307$, $\sin^2\theta_{23} = 0.546$ and $\sin^2\theta_{13} = 0.0220$ of Table 103.3 into Equation (103.21), with δ_{CP} set to zero, which shifts the entries of the lower two rows by at most a few units in the second decimal. The corresponding angles are

$$\theta_{12} = 33.6^\circ , \qquad \theta_{23} = 47.6^\circ , \qquad \theta_{13} = 8.5^\circ ,$$

to be compared with Equation (103.22), where the largest is 13.0° and the smallest 0.21°. The comparison is not between two numbers but between two *patterns*: the quark matrix is a small perturbation of the identity, with a hierarchy $1 : \lambda : \lambda^3$; the lepton matrix has no hierarchy at all except that one of its nine entries is small. □

Remark 103.49 (Two matrices, one theory, no explanation). The Standard Model requires both matrices to be unitary — the argument is Remark 5.152 in both cases — and fixes nothing else about either. Their entries are Yukawa couplings in disguise, by Theorem 104.38,

and the Yukawa couplings are free parameters. That one matrix comes out nearly diagonal and the other nearly democratic is therefore a fact with no theoretical content in the Standard Model whatsoever. Attempts to relate them exist and none has evidence; the fact is recorded as open in Section 133.1. It should not be dressed up as a hint.

103.6.2 Oscillation in vacuum

Phenomenon 103.50 (Neutrinos change flavour)**.** A neutrino created with one flavour is detected, some distance later, with another. Three independent classes of observation establish it. The flux of atmospheric ν_μ depends on zenith angle, that is on the distance travelled, in a way no production model imitates [1954]. The solar ν_e flux measured by charged-current reactions is about a third of the total active flux measured by the neutral-current reaction on deuterium, and the total agrees with the solar model [2021] — which resolves the deficit Davis reported thirty years earlier [1368] without appeal to solar physics at all. Reactor $\bar{\nu}_e$ disappear and reappear as a function of L/E [2049]. Flavour is therefore not conserved in propagation, and the neutrino masses are not all zero. Lepton mixing is moreover large, two of its three angles being of order tens of degrees [2427], in flat contrast with the small angles of Section 103.4. The experiments are Chapter 114.

Rests on Definition 103.46 and Phenomenon 103.48.

Derivation. *Derives Phenomenon 103.50.*

Take two flavour states related to two states of definite mass $m_1 \neq m_2$ by a single angle,

$$|\nu_\alpha\rangle = \cos\theta\,|\nu_1\rangle + \sin\theta\,|\nu_2\rangle\ , \qquad |\nu_\beta\rangle = -\sin\theta\,|\nu_1\rangle + \cos\theta\,|\nu_2\rangle\ . \tag{103.50}$$

The mass states, not the flavour states, are the ones that propagate with a definite phase. For a neutrino of energy E far above its rest energy, $E_i = \sqrt{p^2c^2 + m_i^2c^4} \approx E + m_i^2c^4/2E$, so after travelling a distance L in a time L/c the component $|\nu_i\rangle$ has acquired the phase

$$\varphi_i = \frac{E_i L}{\hbar c} = \frac{EL}{\hbar c} + \frac{m_i^2 c^3 L}{2\hbar E}\,. \tag{103.51}$$

The first term is common to both components and unobservable. The amplitude to find the other flavour is the projection of the propagated state on $|\nu_\beta\rangle$,

$$A_{\alpha\to\beta} = \sin\theta\cos\theta\left(\mathrm{e}^{-\mathrm{i}\varphi_2} - \mathrm{e}^{-\mathrm{i}\varphi_1}\right)\ ,$$

and with $\left|\mathrm{e}^{-\mathrm{i}\varphi_2} - \mathrm{e}^{-\mathrm{i}\varphi_1}\right|^2 = 2\left[1 - \cos(\varphi_1 - \varphi_2)\right] = 4\sin^2\tfrac{1}{2}(\varphi_1 - \varphi_2)$ its squared modulus is

$$P_{\alpha\to\beta} = \sin^2 2\theta\,\sin^2\!\left(\frac{\Delta m^2 c^3 L}{4\hbar E}\right)\ , \qquad \Delta m^2 := m_2^2 - m_1^2\,. \tag{103.52}$$

Three consequences follow, and all three are what is seen. The effect is an interference between two mass components, so it measures a difference of squared masses and never a mass: the oscillation experiments cannot say how heavy a neutrino is, only that two of them differ. It vanishes if the masses are equal or if $\theta = 0$, so its observation proves both that the mass states are non-degenerate and that the flavour and mass bases are misaligned. And it depends on L and E only through their ratio, which is why the atmospheric, reactor and accelerator data — taken at baselines from tens of metres to thousands of kilometres — collapse onto one curve when plotted against L/E. □

Remark 103.51 (Where the derivation is loose, and why it survives). Equation (103.52) was obtained by giving the two mass components the same momentum and letting them travel the same distance in the same time. Each of those is an approximation, and each

has generated a literature. A neutrino is produced localized — in a nucleus, in a pion decay — so its state is a wave packet, and the components of different mass travel at slightly different group velocities and eventually cease to overlap. The correct statement is that Equation (103.52) is the limit of a wave-packet calculation under two conditions, both of which hold by enormous margins in every experiment discussed here.

Localization. The production and detection regions must be small compared with the oscillation length Equation (103.55): otherwise the phase varies over the source and the pattern washes out. What sets σ_x for a reactor antineutrino is not the size of the decaying nucleus, which is of order $1 \times 10^{-15}\,\mathrm{m}$, but the extent over which the decaying system is coherently localized — a fission fragment bound in the fuel lattice, whose position spread is of atomic order, $\sigma_x \sim 1 \times 10^{-11}\,\mathrm{m}$. Against an oscillation length of 99 km either number is negligible, so the localization condition is never in question. The coherence condition is the one that has to be checked, and there the distinction between the two matters by eight orders of magnitude.

Coherence. The packets must still overlap on arrival, which requires

$$L \lesssim L_{\mathrm{coh}} = \frac{4\sqrt{2}\,\sigma_x E^2}{\Delta m^2 c^4}\,, \tag{103.53}$$

the separation of the packets growing as $L\,\Delta m^2 c^4/2E^2$ because that is the difference of their group velocities. For the same reactor case, $\sigma_x = 1 \times 10^{-11}\,\mathrm{m}$, $E = 3\,\mathrm{MeV}$ and $\Delta m^2 c^4 = 7.53 \times 10^{-5}\,\mathrm{eV}^2$ give $L_{\mathrm{coh}} = 6.8 \times 10^3\,\mathrm{km}$, against KamLAND's 180 km. The margin is a factor of 38, and it is the atomic σ_x that supplies it: inserting the nuclear $1 \times 10^{-15}\,\mathrm{m}$ instead would give $L_{\mathrm{coh}} = 0.68\,\mathrm{km}$, so that coherence would be lost some 260 times over before the detector and no oscillatory dependence on L/E could be seen at all. KamLAND sees one, so the relevant localization is the atomic one — which is a measurement of σ_x, not an assumption about it. Note that Equation (103.53) is not the same statement as the averaging of Equation (103.52) over a spread in L or E: that is a classical loss of resolution, this is a quantum loss of coherence, and in every existing experiment the first sets in long before the second.

Derivation pending #156

The wave-packet coherence length for neutrino oscillation, including its factor $4\sqrt{2}$. What is given inline is the group-velocity separation, which fixes the scaling with the packet width, the energy and the squared-mass splitting; the Gaussian overlap integral that fixes the numerical coefficient, and with it the precise meaning of the packet width, is not carried out here and belongs in Appendix A.

The chapter's SI discipline has a payoff here, because the number every experimental paper uses is a disguised statement about $\hbar$ and c and is almost never derived.

Proposition 103.52 (The oscillation phase in practical units)**.** *With the squared-mass splitting expressed as an energy squared in* eV^2*, the baseline in kilometres and the energy in* GeV*,*

$$\frac{\Delta m^2 c^3 L}{4\hbar E} = \frac{(\Delta m^2 c^4)\,L}{4\hbar c\,E} = 1.26693\,\frac{\left(\Delta m^2 c^4/\mathrm{eV}^2\right)\,(L/\mathrm{km})}{(E/\mathrm{GeV})}\,, \tag{103.54}$$

and the oscillation length, the distance over which the phase advances by π, is

$$L_{\mathrm{osc}} = \frac{4\pi\hbar c E}{\Delta m^2 c^4} = 2.4797\,1\,\mathrm{km}\,\frac{(E/\mathrm{GeV})}{\left(\Delta m^2 c^4/\mathrm{eV}^2\right)}\,. \tag{103.55}$$

Rests on Equations (103.1) *and* (103.52)*.*

Proof. *Derives Proposition 103.52.*

Multiply numerator and denominator of the phase in Equation (103.52) by c: the numerator becomes $\Delta m^2 c^4$, an energy squared, and the denominator $4\hbar c E$, also an energy squared multiplied by a length. Hence

$$\varphi = \frac{(\Delta m^2 c^4)\, L}{4\,\hbar c\, E}\,,$$

which is manifestly dimensionless when L is a length. Now insert $\hbar c = 1.973\,269\,8 \times 10^{-7}\ \mathrm{eV\,m}$ from Equation (103.1), and convert the units of the three inputs: $L = (L/\mathrm{km}) \times 1 \times 10^{3}\ \mathrm{m}$ and $E = (E/\mathrm{GeV}) \times 1 \times 10^{9}\ \mathrm{eV}$. Then

$$\varphi = \frac{1 \times 10^{3}\ \mathrm{m}}{4 \times 1.973\,269\,8 \times 10^{-7}\ \mathrm{eV\,m} \times 1 \times 10^{9}\ \mathrm{eV}} \times \frac{\left(\Delta m^2 c^4/\mathrm{eV}^2\right)\,(L/\mathrm{km})}{(E/\mathrm{GeV})}\,,$$

and the prefactor is the pure number

$$\frac{1 \times 10^{3}\ \mathrm{m}}{4 \times 1.973\,269\,8 \times 10^{-7}\ \mathrm{eV\,m} \times 1 \times 10^{9}\ \mathrm{eV}} \times \mathrm{eV}^2 = \frac{1 \times 10^{3}\ \mathrm{m}}{789.308\ \mathrm{eV}^2\,\mathrm{m}} \times \mathrm{eV}^2 = 1.26693\,.$$

This is the constant that appears as "1.27" in every experimental paper on the subject, where it is quoted rather than derived; it is $(4\hbar c)^{-1}$ in disguise, and nothing else. Setting $\varphi = \pi$ and solving for L gives $\pi/1.26693 = 2.4797$, which is Equation (103.55). □

Example 103.53 (Three baselines)**.** Equation (103.55) explains the design of every experiment treated in Chapter 114. Only two of the three splittings are independent, since $\Delta m^2_{31} = \Delta m^2_{32} + \Delta m^2_{21}$ identically; this book tabulates Δm^2_{21} and Δm^2_{32} in Table 103.3 and writes Δm^2_{31} for the sum, which exceeds $|\Delta m^2_{32}|$ by 3% in the normal ordering — immaterial wherever a two-figure statement is being made, which is everywhere below except Equation (103.75). For the atmospheric splitting $|\Delta m^2_{32}|\,c^4 = 2.455 \times 10^{-3}\ \mathrm{eV}^2$ and $E = 1\ \mathrm{GeV}$, $L_{\mathrm{osc}} = 1010\ \mathrm{km}$: hence accelerator baselines of 295 km (T2K) and 810 km (NOvA), and hence the atmospheric signal appearing as a deficit of upward-going and not downward-going muon neutrinos, since the Earth's diameter is 12 742 km and its atmosphere 15 km thick. For the solar splitting $7.53 \times 10^{-5}\ \mathrm{eV}^2$ at a reactor energy of 3 MeV, $L_{\mathrm{osc}} = 99\ \mathrm{km}$: hence KamLAND at 180 km. For the *atmospheric* splitting at the same reactor energy, $L_{\mathrm{osc}} = 3.0\ \mathrm{km}$: hence Daya Bay's far detectors at 1.6 km, which is where the θ_{13} oscillation is near its first maximum while the solar term is still negligible. The separation of the two splittings by a factor 33 is what allows each to be measured almost independently of the other.

Theorem 103.54 (Three-flavour oscillation probability)**.** *For three flavours mixed by Equation (103.47),*

$$\begin{aligned} P_{\alpha\to\beta} = \delta_{\alpha\beta} &- 4\sum_{i>j} \mathrm{Re}\!\left(U^*_{\alpha i} U_{\beta i} U_{\alpha j} U^*_{\beta j}\right) \sin^2\!\left(\frac{\Delta m^2_{ij} c^4 L}{4\hbar c E}\right) \\ &+ 2\sum_{i>j} \mathrm{Im}\!\left(U^*_{\alpha i} U_{\beta i} U_{\alpha j} U^*_{\beta j}\right) \sin\!\left(\frac{\Delta m^2_{ij} c^4 L}{2\hbar c E}\right)\,, \end{aligned} \tag{103.56}$$

with $\Delta m^2_{ij} = m^2_i - m^2_j$. The second sum is odd under $\alpha \leftrightarrow \beta$ and changes sign between neutrinos and antineutrinos; it is the leptonic CP-violating term.

Rests on Equations (103.47) and (103.51).

Proof. *Derives Theorem 103.54.*

The amplitude is $A_{\alpha\to\beta} = \sum_i U_{\beta i} \mathrm{e}^{-\mathrm{i}m_i^2 c^3 L/2\hbar E} U^*_{\alpha i}$, the common phase of Equation (103.51) having been dropped. Then

$$P = |A|^2 = \sum_{i,j} U_{\beta i} U^*_{\alpha i} U^*_{\beta j} U_{\alpha j} \mathrm{e}^{-\mathrm{i}\Delta m_{ij}^2 c^3 L/2\hbar E} .$$

Split the double sum into $i = j$, which gives $\sum_i |U_{\alpha i}|^2 |U_{\beta i}|^2$, and the off-diagonal terms, which pair (i,j) with (j,i). Writing $W_{ij} = U^*_{\alpha i} U_{\beta i} U_{\alpha j} U^*_{\beta j}$, the coefficient standing in front of $\mathrm{e}^{-\mathrm{i}\varphi_{ij}}$ in the display above is $U_{\beta i} U^*_{\alpha i} U^*_{\beta j} U_{\alpha j} = (U^*_{\alpha i} U_{\beta i}) \left(U_{\alpha j} U^*_{\beta j}\right) = W_{ij}$ itself, and the (j,i) term is its complex conjugate because $W_{ji} = W^*_{ij}$ and $\varphi_{ji} = -\varphi_{ij}$. The paired contribution is therefore $2\,\mathrm{Re}\,(W_{ij}\mathrm{e}^{-\mathrm{i}\varphi_{ij}}) = 2\,\mathrm{Re}\,W_{ij}\cos\varphi_{ij} + 2\,\mathrm{Im}\,W_{ij}\sin\varphi_{ij}$ with $\varphi_{ij} = \Delta m_{ij}^2 c^3 L/2\hbar E$ — the sign of the second term being the sign of the CP-violating term in Equation (103.56), so it is worth stating why it is a plus: $\mathrm{e}^{-\mathrm{i}\varphi}$ contributes $-\mathrm{i}\sin\varphi$, and $\mathrm{Re}(-\mathrm{i}W) = +\,\mathrm{Im}\,W$. Using $\cos\varphi = 1 - 2\sin^2(\varphi/2)$ and the unitarity relation $\sum_i U^*_{\alpha i} U_{\beta i} = \delta_{\alpha\beta}$, whose squared modulus supplies $\sum_i |U_{\alpha i}|^2 |U_{\beta i}|^2 + 2\sum_{i>j} \mathrm{Re}\,W_{ij} = \delta_{\alpha\beta}$, gives Equation (103.56). Replacing U by U^*, which is what CP conjugation does, flips the sign of the imaginary part and leaves the real part alone, which is the last statement. □

Corollary 103.55 (The two-flavour limit is a good approximation, and why)**.** *Because* $|\Delta m^2_{31}|/\Delta m^2_{21} = 34$ *and* $|U_{e3}|^2 = 0.022$ *is small, Equation* (103.56) *reduces to a two-flavour formula in each of two regimes. At* L/E *tuned to the atmospheric splitting the solar phase is negligible and* $P(\nu_\mu \to \nu_\mu) \approx 1 - \sin^2 2\theta_{23} \sin^2(\Delta m^2_{31} c^4 L/4\hbar c E)$ *with* $\sin^2 2\theta_{23} = 0.99$*; at* L/E *tuned to the solar splitting the atmospheric phase averages to one half and* $P(\bar\nu_e \to \bar\nu_e) \approx \cos^4\theta_{13}\left[1 - \sin^2 2\theta_{12}\sin^2(\Delta m^2_{21} c^4 L/4\hbar c E)\right] + \sin^4\theta_{13}$*. This factorization, and not any approximation made for convenience, is why the parameters could be measured one at a time over thirty years.*

Rests on Equation (103.56)*.*

103.6.3 Matter effects

A neutrino crossing ordinary matter forward-scatters coherently off the electrons, protons and neutrons in it. Coherent forward scattering does not change the neutrino's momentum and produces no observable interaction; what it produces is a refractive index, exactly as for light in glass, and hence a shift in the propagation phase. The shift would be irrelevant if it were the same for all three flavours. It is not: matter contains electrons and contains no muons or taus, so ν_e alone can forward-scatter through the *charged* current, and its potential differs from the others'.

Proposition 103.56 (The matter potential)**.** *In a medium of electron number density* n_e*, an electron neutrino acquires the extra potential energy*

$$V_e = \sqrt{2}\, G_F\, n_e\,, \tag{103.57}$$

of SI dimension J*, while* ν_μ *and* ν_τ *acquire none from the charged current. An antineutrino acquires* $-V_e$*. Numerically, at the centre of the Sun where* $n_e = 6\times10^{31}/\mathrm{m}^3$*,*

$$V_e = \sqrt{2}\times 1.435\,85\times10^{-62}\,\mathrm{J\,m^3}\times 6\times10^{31}/\mathrm{m^3} = 1.22\times10^{-30}\,\mathrm{J} = 7.6\times10^{-12}\,\mathrm{eV}\,. \tag{103.58}$$

Rests on Equations (101.6) *and* (101.8) *and Definition 100.2.*

Proof. *Derives Proposition 103.56.*

The relevant term of the effective Lagrangian of Equation (101.6), Fierz-rearranged so that the neutrino fields are paired with each other, is

$$\mathcal{L}_{\mathrm{eff}} = -\frac{G_F}{\sqrt{2}}\left[\bar\psi_{\nu_e}\gamma^\mu\left(\mathbb{1} - \gamma^5\right)\psi_{\nu_e}\right]\left[\bar\psi_e\gamma_\mu\left(\mathbb{1} - \gamma^5\right)\psi_e\right]\,,$$

of dimension $\mathrm{J/m^3}$, since each bilinear carries $1/\mathrm{m^3}$ by Definition 100.2 and G_F carries $\mathrm{J\,m^3}$. Average the electron bilinear over the medium. For an unpolarized, isotropic electron gas at rest, the spatial components of the vector current average to zero and the axial current averages to the net spin density, also zero; the surviving component is $\langle \bar{\psi}_e \gamma^0 \psi_e \rangle = n_e$, the electron number density. The neutrino bilinear with γ^0 counts the neutrino number density, so the average Lagrangian is a potential energy per neutrino of $V_e = \sqrt{2} G_F n_e$: one factor of 2 from the $(\mathbb{1} - \gamma^5)$ acting on a left-chiral neutrino, against the $1/\sqrt{2}$ of the Fermi normalization. The neutral current contributes as well, but identically for all three flavours, so it adds a multiple of the identity to the Hamiltonian and cannot affect oscillation — the reason only the charged-current term appears in Equation (103.57). For an antineutrino, C conjugation reverses the sign of the vector current, giving $-V_e$; this sign is the whole of the mass-ordering sensitivity discussed below. The numerical evaluation is Equation (103.58), using G_F in SI from Equation (101.8) — not $G_F/(\hbar c)^3$, the confusion Definition 101.8 exists to prevent. □

Theorem 103.57 (Mixing in matter and the MSW resonance)**.** *For two flavours with vacuum mixing angle θ and splitting Δm^2, propagation through matter of electron density n_e is governed by an effective mixing angle θ_m and an effective splitting Δm_m^2 given by*

$$\tan 2\theta_m = \frac{\Delta m^2 c^4 \sin 2\theta}{\Delta m^2 c^4 \cos 2\theta - 2 E V_e}\,, \tag{103.59}$$

$$\Delta m_m^2 c^4 = \left[\left(\Delta m^2 c^4 \cos 2\theta - 2 E V_e \right)^2 + \left(\Delta m^2 c^4 \sin 2\theta \right)^2 \right]^{1/2} . \tag{103.60}$$

The mixing is maximal, $\sin^2 2\theta_m = 1$, at the resonance

$$2 E V_e = \Delta m^2 c^4 \cos 2\theta\,, \tag{103.61}$$

however small the vacuum angle θ, provided $\cos 2\theta > 0$; the resonance occurs for neutrinos if $\Delta m^2 > 0$ and for antineutrinos if $\Delta m^2 < 0$ [1631, 1779].

Rests on Equation (103.50) and Proposition 103.56.

Proof. *Derives Theorem 103.57.*

The evolution of the flavour amplitudes with time is $\mathrm{i}\hbar\,\partial_t \Psi = \mathcal{H}\Psi$, and for an ultrarelativistic neutrino of fixed momentum the free part of $\mathcal{H}$ is $\sqrt{p^2c^2 + m_i^2 c^4} \approx pc + m_i^2 c^4 / 2E$ in the mass basis. Dropping the term proportional to the identity and rotating to the flavour basis with Equation (103.50),

$$\mathcal{H} = \frac{\Delta m^2 c^4}{4E} \begin{pmatrix} -\cos 2\theta & \sin 2\theta \\ \sin 2\theta & \cos 2\theta \end{pmatrix} + \begin{pmatrix} V_e & 0 \\ 0 & 0 \end{pmatrix} ,$$

the matter term being diagonal in the *flavour* basis by Proposition 103.56. Subtracting $\tfrac{1}{2} V_e \mathbb{1}$, which shifts both levels equally and changes no probability,

$$\mathcal{H} = \frac{1}{2} \begin{pmatrix} -A & B \\ B & A \end{pmatrix} , \qquad A = \frac{\Delta m^2 c^4 \cos 2\theta}{2E} - V_e\,, \qquad B = \frac{\Delta m^2 c^4 \sin 2\theta}{2E}\,.$$

A real symmetric traceless 2×2 matrix of this form is diagonalized by a rotation through θ_m with $\tan 2\theta_m = B/A$, which after multiplying numerator and denominator by $2E$ is Equation (103.59); its eigenvalue difference is $\sqrt{A^2 + B^2}$, which multiplied by $2E$ is Equation (103.60). The angle is $\pi/4$ exactly when $A = 0$, which is Equation (103.61); and since $V_e > 0$ for matter, A can vanish only if $\Delta m^2 \cos 2\theta > 0$. For an antineutrino $V_e \to -V_e$ and the condition becomes $\Delta m^2 \cos 2\theta < 0$. The resonance therefore occurs for neutrinos or for antineutrinos according to the *sign* of the splitting, and that is the only place in this chapter where a sign, rather than a magnitude, is observable. □

Example 103.58 (The solar resonance energy)**.** Insert the solar values $\Delta m^2_{21}c^4 = 7.53 \times 10^{-5}\,\mathrm{eV}^2$, $\sin^2\theta_{12} = 0.307$ so that $\cos 2\theta_{12} = 1 - 2\sin^2\theta_{12} = 0.386$, and Equation (103.58), into Equation (103.61):

$$E_{\mathrm{res}} = \frac{\Delta m^2 c^4 \cos 2\theta}{2V_e} = \frac{7.53 \times 10^{-5}\,\mathrm{eV}^2 \times 0.386}{2 \times 7.6 \times 10^{-12}\,\mathrm{eV}} = 1.9\,\mathrm{MeV}\,. \tag{103.62}$$

That number organizes the whole solar neutrino programme. Neutrinos produced well below 1.9 MeV — the *pp* neutrinos, with endpoint 420 keV, which dominate the flux — never reach resonance and oscillate essentially as in vacuum, their survival probability averaging to

$$P_{ee}\big|_{\text{low } E} = 1 - \tfrac{1}{2}\sin^2 2\theta_{12} = 0.57\,.$$

Neutrinos produced well above it — the ^{8}B neutrinos, extending to 15 MeV, which are the ones Homestake and SNO detected — are created above resonance, where the matter term dominates and $\theta_m \to \pi/2$, so the neutrino leaves the Sun as the heavier mass eigenstate ν_2 and its survival probability is

$$P_{ee}\big|_{\text{high } E} = |U_{e2}|^2 = \sin^2\theta_{12} = 0.31\,.$$

Both numbers are measured, the second by SNO (Phenomenon 114.5) and the first by Borexino, which detected the *pp* neutrinos in real time [2229] and later the CNO neutrinos [2349]. A single curve, rising from 0.31 to 0.57 as the energy falls through a few MeV, passes through every measured point. Both expressions are the two-flavour limit; restoring the third angle multiplies each by $\cos^4\theta_{13} = 0.957$ and adds $\sin^4\theta_{13} = 4.8 \times 10^{-4}$, moving them to 0.55 and 0.29, which is the four-per-cent accuracy at which the two-flavour statement should be read. It is worth being clear about what this establishes that vacuum oscillation could not: the *sign* of Δm^2_{21}, and hence that ν_2 is heavier than ν_1 — equivalently, that θ_{12} lies in the first octant. Vacuum oscillation is even in Δm^2 and blind to both.

Proposition 103.59 (Adiabaticity)**.** *The neutrino follows the instantaneous eigenstate through the resonance, rather than jumping between eigenstates, provided*

$$\gamma := \frac{\Delta m^2 c^4 \sin^2 2\theta}{2E\cos 2\theta}\,\frac{L_\rho}{\hbar c} \gg 1\,, \qquad L_\rho := \left|\frac{\mathrm{d}\ln n_e}{\mathrm{d}r}\right|^{-1}_{\mathrm{res}}\,, \tag{103.63}$$

and for the Sun, with $L_\rho = 6.6 \times 10^7$ m and the values of Example 103.58, $\gamma = 1.5 \times 10^4$.
Rests on Theorem 103.57 and Equation (103.60).

Proof. *Derives Proposition 103.59.*

The adiabatic theorem states that a system in a non-degenerate instantaneous eigenstate of a slowly varying Hamiltonian stays in it, with a transition probability that vanishes as the variation is slowed; the general statement and its proof belong to Section 82.6.1, which reserves them. Its condition is that the rate of change of the Hamiltonian's eigenbasis be small compared with the level splitting divided by $\hbar$. Here the eigenbasis is fixed by θ_m, and the fastest variation is at resonance. Differentiating $\tan 2\theta_m = B/A$ from the proof of Theorem 103.57, in which only A depends on r,

$$\frac{\mathrm{d}\,(2\theta_m)}{\mathrm{d}r}\bigg|_{A=0} = -\frac{1}{B}\frac{\mathrm{d}A}{\mathrm{d}r} = \frac{V_e}{B}\frac{\mathrm{d}\ln n_e}{\mathrm{d}r} = \cot 2\theta\,\frac{\mathrm{d}\ln n_e}{\mathrm{d}r}\,,$$

the last step using $V_e = \Delta m^2 c^4 \cos 2\theta/2E$ at resonance; hence $\mathrm{d}\theta_m/\mathrm{d}r = \cot 2\theta/\,(2L_\rho)$ in magnitude. The two eigenvalues of the traceless Hamiltonian there are $\pm\Delta m^2_m c^4/4E$ with $\Delta m^2_m c^4 = \Delta m^2 c^4 \sin 2\theta$ by Equation (103.60), so the ratio of the phase rate to the rotation rate is

$$\gamma = \frac{\Delta m^2_m c^4}{4E\hbar c}\left(\frac{\mathrm{d}\theta_m}{\mathrm{d}r}\right)^{-1} = \frac{\Delta m^2 c^4 \sin^2 2\theta}{2E\cos 2\theta}\,\frac{L_\rho}{\hbar c}\,.$$

Numerically, with $\Delta m^2 c^4 \sin^2 2\theta = 7.53 \times 10^{-5}\,\mathrm{eV}^2 \times 0.851 = 6.41 \times 10^{-5}\,\mathrm{eV}^2$, $2E\cos 2\theta = 2 \times 1.91 \times 10^6\,\mathrm{eV} \times 0.386 = 1.47 \times 10^6\,\mathrm{eV}$ and $L_\rho/\hbar c = 6.6 \times 10^7\,\mathrm{m}/1.9733 \times 10^{-7}\,\mathrm{eV\,m} = 3.34 \times 10^{14}/\mathrm{eV}$, the product is 1.5×10^4. The solar density profile is exponential over the relevant region, which is what makes L_ρ a constant, and the margin is four orders of magnitude: the conversion is adiabatic and the survival probabilities of Example 103.58 are exact in that limit. □

Remark 103.60 (Two further matter signatures). Two consequences of Theorem 103.57 are measured or being measured, and both belong to Section 114.5.2, which reserves them.

Day–night asymmetry. Solar neutrinos arriving at night cross the Earth, whose electron density partially regenerates the ν_e component, so the night-time rate should exceed the day-time rate by a few per cent. The effect is at the edge of the sensitivity of existing detectors and is observed at about the 2σ level; it is a prediction of the mechanism with no free parameter beyond the already-measured ones.

The mass ordering. By the sign statement of Theorem 103.57, matter enhances $\nu_\mu \to \nu_e$ and suppresses $\bar\nu_\mu \to \bar\nu_e$ if $\Delta m^2_{31} > 0$, and does the opposite if it is negative. A long-baseline beam run alternately in neutrino and antineutrino mode therefore determines the ordering — but the same comparison is also where δ_{CP} shows up, by Theorem 103.54, and the two effects are degenerate at a single baseline. Breaking the degeneracy requires either two baselines or a baseline long enough ($\gtrsim 1000\,\mathrm{km}$) that the matter effect dominates. That is the design brief of the next generation of experiments, and it is why the ordering is not yet known.

103.6.4 The evidence

The experimental case belongs to Chapter 114 and is summarized here in the order in which it was made, because the order is itself instructive: a thirty-year anomaly, then two measurements that admitted no escape.

The solar deficit, 1968–1998. Davis's chlorine detector, 615 t of perchloroethylene 1478 m underground, counted about one third of the ν_e capture rate the standard solar model predicted [1368, 1950]. Because the ^{8}B flux it was sensitive to depends on roughly the twenty-fifth power of the solar core temperature, the natural reading for twenty years was that the solar model was wrong [1365]. The gallium experiments removed that escape by reaching the *pp* neutrinos, whose flux is fixed by the measured solar luminosity almost independently of the model, and found a deficit there too [1974, 2138]. This is Phenomenon 114.3.

The atmospheric zenith-angle dependence, 1998. Super-Kamiokande measured the ν_μ and ν_e rates as functions of arrival direction, and found the muon neutrinos arriving from below — having crossed 13 000 km of Earth — depleted by about half relative to those from above, at the same energy, while the electron neutrinos showed no such dependence [1954]. Because the same detector measures both, and because the deficit is a function of L/E and not of L or E separately, no production model and no absorption mechanism reproduces it. This is Phenomenon 114.4, whose derivation there uses exactly Equation (103.52).

The neutral-current measurement, 2002. SNO measured, in one detector, the ν_e flux by a charged-current reaction on deuterium and the total active flux by the flavour-blind neutral-current breakup of the deuteron. The first came to about a third of the second, and the second agreed with the solar model [2008, 2021]. The subtraction Equation (114.35) contains no solar-model input at all: the missing electron neutrinos arrive as ν_μ and ν_τ, and Phenomenon 114.5 is the statement.

Reactor disappearance and reappearance, 2003. KamLAND observed electron antineutrinos from Japanese power reactors at an average baseline of 180 km with a survival probability of about 0.6, and — decisively — found that probability to be an *oscillatory* function of L/E rather than a monotone suppression [2049]. A flux normalization error produces a

deficit; only interference produces a wave. This is Phenomenon 114.6, and it converted the solar result from a statement about the Sun into a statement about neutrinos.

The third angle, 2012. Daya Bay and RENO compared near and far identical detectors at reactor complexes and measured $\sin^2 2\theta_{13} \approx 0.09$ [2188, 2189], which is Phenomenon 114.8. Many had expected it to vanish; that it does not is the precondition for ever observing δ_{CP}, since by Theorem 103.54 the CP-odd term is proportional to the leptonic Jarlskog invariant $J_\ell = \frac{1}{8}\sin 2\theta_{12}\sin 2\theta_{23}\sin 2\theta_{13}\cos\theta_{13}\sin\delta_{CP}$ and therefore to $\sin\theta_{13}$.

Accelerator beams, 2006–. K2K [2089] and MINOS [2100] confirmed the atmospheric parameters with a controlled beam over 250 km and 735 km; T2K found $\nu_\mu \to \nu_e$ appearance [2168] and now constrains δ_{CP} [2345]; NOvA measures the same parameters over 810 km [2398]; and OPERA observed ν_τ appearance directly [2247], closing the three-flavour picture by seeing the flavour the others infer.

103.6.5 Measured parameters and what is still unknown

Table 103.3: The six oscillation parameters, from the global fit to all data [2356, 2427]. The splittings are quoted, as universally, as $\Delta m^2 c^4$ in eV^2 — an energy squared, per Remark 103.1. The sign of Δm^2_{32} is not measured; the value listed assumes the normal ordering, and the inverted ordering gives $(-2.529 \pm 0.029) \times 10^{-3}\,\mathrm{eV}^2$. The phase δ_{CP} is constrained, not measured.

Parameter	Value	Principal source
$\Delta m^2_{21} c^4$	$(7.53 \pm 0.18) \times 10^{-5}\,\mathrm{eV}^2$	KamLAND reactor spectrum; solar
$\lvert\Delta m^2_{32}\rvert\, c^4$	$(2.455 \pm 0.028) \times 10^{-3}\,\mathrm{eV}^2$	atmospheric; accelerator disappearance
$\sin^2\theta_{12}$	0.307 ± 0.013	solar survival probability; KamLAND
$\sin^2\theta_{23}$	0.546 ± 0.021	atmospheric and accelerator ν_μ disappearance
$\sin^2\theta_{13}$	0.0220 ± 0.0007	short-baseline reactor near/far ratio
δ_{CP}	$\approx 1.2\pi$, poorly bounded	$\nu_\mu \to \nu_e$ versus $\bar\nu_\mu \to \bar\nu_e$

Three questions remain open within the three-flavour picture itself, and it is worth being exact about what each is.

The mass ordering. The sign of Δm^2_{32} is unknown. *Normal ordering* means $m_1 < m_2 < m_3$, with the close pair at the bottom; *inverted* means $m_3 < m_1 < m_2$, with the close pair at the top. Global fits mildly prefer the normal ordering, at a level between two and three standard deviations that depends on which datasets are combined and is not a measurement. The routes to settling it are those of Remark 103.60.

The octant of θ_{23}. Oscillation of muon neutrinos to tau neutrinos depends on $\sin^2 2\theta_{23}$, which is symmetric under $\theta_{23} \to \pi/2 - \theta_{23}$. Since $\sin^2 2\theta_{23} = 0.99$, the angle is close to $\pi/4$ and the two solutions are close together; distinguishing them requires the appearance channel, where $|U_{\mu 3}|^2 = \sin^2\theta_{23}$ enters unsquared.

The phase δ_{CP}. T2K's data disfavour CP conservation at about the 95 % level [2345] and prefer a value near $-\pi/2$; NOvA's are compatible with CP conservation [2398]. Combining them gives a preference and not a measurement, and this treatise records it as such. A non-zero δ_{CP} would be leptonic CP violation — the leptonic counterpart of Section 103.5 — and would not, by itself, establish anything about the baryon asymmetry of Phenomenon 103.44,

a point taken up in Section 103.7.4.

103.7 Neutrino mass

Oscillation measures squared-mass *differences* and nothing else. Three quite different experiments bound three different combinations of the three masses, and none of them measures a mass eigenvalue. Keeping the three separate is the point of this section, because they are routinely and wrongly quoted as though they were the same number.

Definition 103.61 (Three mass observables)**.**

$$m_\beta^2 := \sum_i |U_{ei}|^2 \, m_i^2 \qquad \text{(beta-decay kinematics)}\,, \tag{103.64}$$

$$m_{\beta\beta} := \left| \sum_i U_{ei}^2 \, m_i \right| \qquad \text{(neutrinoless double beta decay)}\,, \tag{103.65}$$

$$\Sigma := \sum_i m_i \qquad \text{(cosmology)}\,. \tag{103.66}$$

The first is an incoherent sum of squares and is always real and positive; the second involves U_{ei}^2 rather than $|U_{ei}|^2$ and therefore depends on the Majorana phases of Equation (103.48), so cancellations can drive it to zero; the third is a plain sum.

103.7.1 Direct kinematic limits

The only model-independent route to the mass scale is the shape of a beta spectrum near its endpoint, because there the neutrino is non-relativistic and its rest energy competes with its kinetic energy. The method is that of Section 101.2.3: a non-zero mass removes the last $m_\nu c^2$ of electron energy and rounds the approach to the endpoint, changing the Kurie plot from a straight line to a curve that meets the axis vertically.

Phenomenon 103.62 (The electron-neutrino mass is below one electronvolt)**.** Measuring the electron spectrum of molecular tritium decay, $^3\mathrm{H} \to {}^3\mathrm{He}^+ + e^- + \bar{\nu}_e$, with endpoint $Q = 18.574\,\mathrm{keV}$, the KATRIN experiment finds

$$m_\beta < 0.8\,\mathrm{eV}/c^2 \qquad \text{at } 90\,\% \text{ confidence} \tag{103.67}$$

[2399], with m_β the combination Equation (103.64). The bound assumes only energy and momentum conservation and the measured molecular final-state distribution.

Rests on Equations (101.11) *and* (103.64) *and Definition 101.19.*

Derivation. *Derives Phenomenon 103.62.*

By Equation (101.11), the electron spectrum of an allowed transition is

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}E_e} \propto F(Z, E_e)\, p_e E_e \,(Q - T_e)\, \sqrt{(Q - T_e)^2 - m_\beta^2 c^4}\,,$$

T_e being the electron kinetic energy. For $m_\beta = 0$ this is $(Q - T_e)^2$ near the endpoint, so the Kurie function of Definition 101.19 is linear and reaches zero at $T_e = Q$; for $m_\beta \neq 0$ the spectrum terminates at $T_e = Q - m_\beta c^2$ and approaches it with infinite slope. Two consequences fix the design.

First, the sensitivity is to m_β^2, not to m_β: the leading distortion of the rate integrated over the last interval Δ below the endpoint is a relative shift of order $m_\beta^2 c^4/\Delta^2$. Halving the mass sensitivity therefore costs a factor of four in statistics, which is why progress in this field is slow and why an experiment reports a limit on m_β^2 that can and does fluctuate negative.

Second, the region carrying the information is minute. Since $\mathrm{d}\Gamma/\mathrm{d}T_e \propto (Q - T_e)^2$, the fraction of all decays occurring within Δ of the endpoint is

$$\frac{\int_{Q-\Delta}^{Q} (Q-T)^2 \,\mathrm{d}T}{\int_{0}^{Q} (Q-T)^2 \,\mathrm{d}T} = \left(\frac{\Delta}{Q}\right)^3 , \tag{103.68}$$

which for $\Delta = 1\,\mathrm{eV}$ and $Q = 18.574\,\mathrm{keV}$ is 1.6×10^{-13}. An experiment sensitive to $0.2\,\mathrm{eV}/c^2$ must therefore combine a source of enormous activity with a spectrometer of electronvolt resolution at $18.6\,\mathrm{keV}$ — a relative resolution of 5×10^{-5} — and reject every background event in the same window. That is what KATRIN's 10 m-diameter magnetic adiabatic collimation spectrometer exists to do.

Tritium is chosen because Q is the smallest of any convenient superallowed emitter, maximizing Equation (103.68), and because its nuclear matrix element is simple. The residual model dependence is molecular, not nuclear: the daughter $^3\mathrm{HeT}^+$ ion is left in a distribution of rotational, vibrational and electronic excitations spread over some 1 eV, and that distribution is calculated, not measured. It is the leading systematic of Equation (103.67). □

Remark 103.63 (Why a weaker bound is worth more). Equation (103.67) is an order of magnitude weaker than the cosmological bound of Section 103.7.3 and is nevertheless the more valuable number, for the reason that runs through this whole treatise: it is model-independent. It assumes no cosmological model, no growth of structure, no assumption about whether the neutrino is its own antiparticle, and no nuclear matrix element. Its interpretation requires only Equation (103.64) and the measured mixing angles. When a model-dependent bound and a model-independent one disagree, it is the model that is in question, and an experiment that can say so is worth building even at lower sensitivity.

103.7.2 Neutrinoless double beta decay

Double beta decay is the slowest process ever measured, and its existence is a consequence of nuclear structure alone: the pairing term of Equation (107.42) splits the even-A mass parabola, so an even–even nuclide can lie below both its odd–odd neighbours while lying above the even–even nuclide two steps away. Single beta decay is then closed and double beta decay is open. That argument, the isotopes it selects and the Q^{11} phase space are Phenomenon 107.72. What belongs here is the lepton-number-violating variant and what its non-observation means.

Phenomenon 103.64 (Neutrinoless double beta decay has not been observed)**.** Two-neutrino double beta decay is observed, with half-lives between 10^{18} and 10^{24} years [2427] — the range quoted in Phenomenon 107.72, which is the isotope-by-isotope statement. The neutrinoless mode, which would change lepton number by two units and is possible only if the neutrino is its own antiparticle, is not observed: the best searches set half-life limits

$$T_{1/2}^{0\nu}\left(^{76}\mathrm{Ge}\right) > 1.8 \times 10^{26}\,\mathrm{yr}\,, \qquad T_{1/2}^{0\nu}\left(^{136}\mathrm{Xe}\right) > 2.3 \times 10^{26}\,\mathrm{yr}\,, \tag{103.69}$$

at 90 % confidence, from GERDA [2350] and KamLAND-Zen [2414] respectively. This is stated here as what it is — a search that has found nothing — and it leaves the Dirac or Majorana character of the neutrino undetermined.

Rests on Phenomenon 107.72, Proposition 101.32, and Equation (103.65).

Derivation. *Derives Phenomenon 103.64.*

Furry computed the transition $(A, Z) \to (A, Z+2) + 2e^-$ in 1939 [836]: the antineutrino emitted at one nucleon vertex is absorbed as a neutrino at the other. Two conditions must hold for the amplitude not to vanish, and each supplies a factor.

The neutrino must be its own antiparticle, since the particle emitted at the first vertex is what must be absorbed at the second. This is the Majorana condition, and it is what makes the process a test of Section 103.7.4 rather than of anything else.

The neutrino must have mass. The charged current emits a right-helicity antineutrino and absorbs a left-helicity neutrino (Proposition 101.32), so the two vertices demand opposite helicities of the same particle. The amplitude therefore requires the "wrong-helicity" component of the propagating state. Equation (101.32) gives the chirality *weight* of that component as $\frac{1}{2}(1-\beta) \simeq m^2c^4/4E^2$, which is a probability, so the amplitude carries its square root, $m_i c^2/2E$. The internal neutrino carries a virtual momentum of order the inverse internucleon spacing, $\hbar c/r \approx 100\,\mathrm{MeV}$, so the suppression factor is of order $m_i c^2/100\,\mathrm{MeV}$, one factor per exchanged mass eigenstate; the factor of two, and the shape of the neutrino propagator between the two nucleons, are conventionally absorbed into the nuclear matrix element defined below rather than carried separately. Summing coherently over the three mass states with the mixing factors U_{ei} from each vertex, the amplitude is proportional to $\sum_i U_{ei}^2 m_i$ — *squared*, not modulus-squared, because both vertices are of the same type — which is $m_{\beta\beta}$ of Equation (103.65). Hence

$$\frac{1}{T_{1/2}^{0\nu}} = G^{0\nu}\,(Q, Z)\,\left|M^{0\nu}\right|^2\,\left(\frac{m_{\beta\beta}}{m_e}\right)^2 , \tag{103.70}$$

with $G^{0\nu}$ a phase-space factor, carrying 1/yr, calculable exactly from the Q value and the Coulomb field, and $M^{0\nu}$ the dimensionless nuclear matrix element.

Two structural remarks. First, Equation (103.70) is a rate proportional to a squared mass, so a half-life limit improved by a factor 100 improves the mass limit only by a factor 10 — the same quadratic wall that, in the derivation of Phenomenon 103.62, makes every halving of the kinematic mass sensitivity cost a factor of four in statistics. Second, the electron sum-energy spectrum of the neutrinoless mode is a line at Q, sitting on the continuum of the two-neutrino mode, and the two-neutrino mode is therefore an irreducible background whose tail is controlled only by energy resolution. This is why the two leading techniques are a high-purity germanium diode, whose resolution at $Q = 2039\,\mathrm{keV}$ is about 3 keV, and a very large mass of xenon-loaded scintillator, which trades resolution for target mass. □

Remark 103.65 (The matrix element is the limiting uncertainty). Converting Equation (103.69) into a bound on $m_{\beta\beta}$ requires $M^{0\nu}$, and the many-body methods available — the interacting shell model, the quasiparticle random-phase approximation, the interacting boson model, energy density functionals — disagree with one another by a factor of two to three for every isotope of interest, as Phenomenon 107.72 records. Since the rate goes as the square, that is a factor of four to nine in half-life and a factor of two to three in the mass limit. The published bounds are therefore quoted as *ranges*:

$$m_{\beta\beta} < 79 \text{ to } 180\,\mathrm{meV}/c^2 \quad \left({}^{76}\mathrm{Ge}\right) , \qquad m_{\beta\beta} < 36 \text{ to } 156\,\mathrm{meV}/c^2 \quad \left({}^{136}\mathrm{Xe}\right) , \tag{103.71}$$

the spread being theory, not statistics [2350, 2414]. A treatise of evidence must quote the range and not its most favourable end.

Proposition 103.66 (What the searches are approaching)**.** *With the mixing parameters of Table 103.3, $m_{\beta\beta}$ of Equation (103.65) is bounded, over the unknown Majorana phases and the unknown lightest mass, by*

$$m_{\beta\beta}\big|_{\mathrm{IO}} \geq 19\,\mathrm{meV}/c^2 , \qquad m_{\beta\beta}\big|_{\mathrm{NO}} \geq 0 , \tag{103.72}$$

so the inverted ordering predicts a floor that the next generation of experiments can reach, and the normal ordering does not.

Rests on Equations (103.48) and (103.65).

Proof. *Derives Proposition 103.66.*

Write $m_{\beta\beta} = \left| c_{12}^2 c_{13}^2 m_1 + s_{12}^2 c_{13}^2 m_2 \mathrm{e}^{\mathrm{i}\alpha_{21}} + s_{13}^2 m_3 \mathrm{e}^{\mathrm{i}\alpha_{31}} \right|$. In the inverted ordering $m_3 \approx 0$ and $m_1 c^2 \approx m_2 c^2 \approx \sqrt{|\Delta m_{32}^2|\, c^4} = 50\,\mathrm{meV}$, so the third term is negligible and the first two, being nearly equal in mass, can cancel only to the extent that their coefficients differ: the minimum over α_{21} is

$$c_{13}^2 \left(c_{12}^2 - s_{12}^2 \right) \sqrt{|\Delta m_{32}^2|\, c^4}/c^2 = 0.978 \times 0.386 \times 50\,\mathrm{meV}/c^2 = 19\,\mathrm{meV}/c^2 \,,$$

using $\cos 2\theta_{12} = 0.386$ from Table 103.3. The maximum, at $\alpha_{21} = 0$, is $49\,\mathrm{meV}/c^2$. In the normal ordering with $m_1 \to 0$ the three terms are 0, $s_{12}^2 c_{13}^2 \sqrt{\Delta m_{21}^2 c^4}/c^2 = 2.6\,\mathrm{meV}/c^2$ and $s_{13}^2 \sqrt{\Delta m_{31}^2 c^4}/c^2 = 1.1\,\mathrm{meV}/c^2$, which are comparable and can cancel exactly for a suitable phase. There is therefore no floor.

The consequence for the programme is sharp and should be stated without optimism. Equation (103.71) is at the level of the inverted-ordering band, and an experiment covering that band completely would, if it saw nothing, exclude the inverted ordering *provided* the neutrino is a Majorana particle. It would not exclude the Majorana hypothesis, because the normal ordering permits $m_{\beta\beta} = 0$ exactly. The asymmetry is inherent: the experiment can discover, and can exclude one ordering, but can never refute the Majorana nature. □

103.7.3 Cosmological bounds

Neutrinos decouple from the primordial plasma while relativistic, and survive as a relic background of number density fixed by the temperature. Once non-relativistic they contribute to the matter density like any other matter; but unlike cold dark matter they retain a large velocity dispersion, and therefore stream freely out of gravitational potential wells smaller than a characteristic scale, suppressing the growth of structure below it.

Proposition 103.67 (Relic density and free streaming)**.** *Three species of light neutrino of total mass Σ contribute*

$$\Omega_\nu h^2 = \frac{\Sigma}{93.14\,\mathrm{eV}/c^2} \,, \tag{103.73}$$

and suppress the matter power spectrum on scales below the free-streaming length by a relative amount $\Delta P/P \approx -8\Omega_\nu/\Omega_m$. For $\Sigma = 0.12\,\mathrm{eV}/c^2$, $\Omega_\nu h^2 = 1.3 \times 10^{-3}$ and the suppression is at the per-cent level — measurable, and the basis of the bound.

Rests on Equation (103.66).

Proof. *Derives Proposition 103.67.*

The relic number density per species follows from decoupling in thermal equilibrium, the general treatment of which belongs to Section 48.3: a fermion species in equilibrium at temperature T_ν has $n_\nu = \frac{3}{4} \times \frac{2\zeta(3)}{\pi^2} \left(k_B T_\nu/\hbar c \right)^3$ per degree of freedom, and $T_\nu = (4/11)^{1/3}\, T_\gamma$ because the electron–positron annihilation that follows decoupling heats the photons and not the neutrinos. With $T_{\gamma,0} = 2.7255\,\mathrm{K}$ this gives $n_\nu = 1.12 \times 10^8/\mathrm{m}^3$ per species. Dividing the mass density $\Sigma\, n_\nu$ by the critical density $\rho_c = 1.878\,34 \times 10^{-26}\,\mathrm{kg/m^3}\, h^2$ gives Equation (103.73). The naive arithmetic, $\rho_c c^2/n_\nu$ per unit h^2, comes to 94.1 eV; the standard constant 93.14 eV includes the one-per-cent correction from the fact that decoupling is not instantaneous, which leaves the neutrinos slightly hotter than $(4/11)^{1/3}\, T_\gamma$.

For the free streaming: a relic neutrino of mass m has, at redshift z, a typical momentum $p \approx 3.15 k_B T_\nu (1+z)/c$ and hence a speed $v/c \approx 3.15 k_B T_\nu (1+z)/mc^2$. Today $T_\nu = (4/11)^{1/3} \times 2.7255\,\mathrm{K} = 1.9454\,\mathrm{K}$, so $k_B T_\nu = 1.676 \times 10^{-4}\,\mathrm{eV}$ and $3.15 k_B T_\nu = 5.28 \times 10^{-4}\,\mathrm{eV}$; for $mc^2 = 0.05\,\mathrm{eV}$ this gives $v/c = 1.06 \times 10^{-2}$, that is $v = 3.2 \times 10^3\,\mathrm{km/s}$. Over a Hubble time it therefore travels a comoving distance of order v/H, and perturbations of smaller wavelength are erased because the neutrinos simply leave them. The suppression coefficient

8 follows from solving the equation for the growth of density perturbations, which belongs to Section 48.5.1, with a component that does not cluster; the essential point for this chapter is that the effect is proportional to Ω_ν, hence to Σ, and is therefore a measurement of the sum of the masses and of no other combination. □

Phenomenon 103.68 (The sum of the neutrino masses is bounded)**.** Combining the temperature and polarization anisotropies of the cosmic microwave background with the baryon acoustic oscillation scale measured in galaxy surveys,

$$\Sigma = \sum_i m_i < 0.12\,\mathrm{eV}/c^2 \qquad \text{at } 95\,\% \text{ confidence} \tag{103.74}$$

[2348], within the six-parameter ΛCDM model whose parameters belong to Section 48.7.
Rests on Proposition 103.67 and Phenomenon 48.15.

Derivation. *Derives Phenomenon 103.68.*

The microwave background alone constrains Σ only weakly, because a neutrino of mass below about $0.6\,\mathrm{eV}/c^2$ is still relativistic at recombination and its effect on the acoustic peaks is degenerate with other parameters; the constraint comes from combining it with a low-redshift measurement of the expansion history and of the clustering amplitude, which is what the baryon acoustic scale of Phenomenon 48.15 supplies. Extracting Equation (103.74) from those data is a global fit, not a closed-form derivation, and it is quoted here for comparison with Equation (103.67) rather than reproduced.

The comparison is the point. Equation (103.74) is a factor 20 stronger than the kinematic bound — and rests on the assumptions that the dark energy is a cosmological constant, that the primordial spectrum is a power law, and that no other light relic contributes. Each has been examined and none is established independently. Relaxing them typically weakens the bound by a factor of two to three, which is the honest uncertainty to attach to it. □

Remark 103.69 (The bound is close to the inverted-ordering minimum)*.* The minimum values of Σ permitted by the measured splittings are, taking the lightest mass to zero,

$$\Sigma_{\mathrm{NO}} \geq 0.059\,\mathrm{eV}/c^2\,, \qquad \Sigma_{\mathrm{IO}} \geq 0.100\,\mathrm{eV}/c^2\,, \tag{103.75}$$

computed from $m_2c^2 = \sqrt{\Delta m^2_{21} c^4}$ and $m_3c^2 = \sqrt{\Delta m^2_{31} c^4}$ in the normal case, and from $m_1c^2 = \sqrt{|\Delta m^2_{31}|\,c^4}$, $m_2c^2 = \sqrt{|\Delta m^2_{32}|\,c^4}$ in the inverted case. The inverted minimum sits just below Equation (103.74), so cosmology mildly disfavours the inverted ordering — and would exclude it if the bound tightened by a factor of two without a detection. That is a striking situation and it deserves a warning: a *cosmological* bound excluding a *laboratory* mass ordering would be an inference of exactly the model-dependent kind Remark 103.63 cautions against. The ordering should be settled by Remark 103.60, in an experiment, and this treatise will record it as settled only then.

103.7.4 Dirac or Majorana: an open question

Every charged fermion has a Dirac mass, because a Majorana mass term would violate electric charge conservation. The neutrino is the only known fermion for which both options are open, and no experiment has distinguished them.

Definition 103.70 (The two mass terms)**.** For a left-chiral field ν_L and, if it exists, a right-chiral partner ν_R, the Lorentz-invariant mass terms are

$$\mathcal{L}_D = -m_D c^2 \left(\bar{\nu}_L \nu_R + \bar{\nu}_R \nu_L\right)\,, \tag{103.76}$$

$$\mathcal{L}_M = -\tfrac{1}{2} m_M c^2 \left(\overline{\nu^c_L}\,\nu_L + \bar{\nu}_L\,\nu^c_L\right)\,, \tag{103.77}$$

with ν^c the charge-conjugate field of Equation (105.15). The first conserves lepton number and requires a new field; the second violates lepton number by two units and requires none.

The full analysis of these two terms, the degrees-of-freedom count that makes a Majorana field equivalent to one massive Weyl field, and Majorana's original symmetric theory [796] belong to Section 96.6.1 and Section 96.7.1, which reserve them. What belongs here is the experimental status, and it can be stated in four sentences.

Remark 103.71 (The evidential situation, stated plainly). *No experiment distinguishes the two.* Oscillation cannot, by Proposition 103.47; kinematic beta-decay measurements cannot, since Equation (103.64) is phase-independent; cosmology cannot, since Equation (103.66) is too. The only practical discriminator is neutrinoless double beta decay, and by Equation (103.69) it has found nothing.

A positive result would settle it whatever the mechanism. If the decay is observed, a Majorana mass term for the neutrino follows, even if the operator that drives the decay is something else entirely: the observed transition can always be closed into a $\bar{\nu} \to \nu$ self-energy insertion, generating Equation (103.77) at some order. This is the Schechter–Valle argument [1701]. It is a statement about the *existence* of the term, not about its size, which the argument leaves many orders of magnitude below the observed masses — a limitation worth stating, since the theorem is often quoted as though it were quantitative.

The most economical hypothesis has no evidence. If a heavy right-chiral singlet N exists with a Majorana mass M far above the electroweak scale, the light eigenvalue of the combined mass matrix is $m_\nu \approx m_D^2/M$ — small because M is large. This is the seesaw [1605]; with m_D of the order of the top mass, $Mc^2 \sim 1 \times 10^{15}\,\mathrm{GeV}$. In the effective theory below M it is one realization of the unique dimension-five operator that can generate a neutrino mass from Standard Model fields [1646], whose coefficient carries $1/\mathrm{J}$ and is therefore suppressed by one power of a new scale. That operator is a *parametrization* of ignorance and the seesaw is one *model* for its coefficient. There is at present no experimental evidence for either, and this treatise names them as hypotheses and nothing more.

Sterile neutrinos: null. A fourth neutrino not coupling to the Z evades Equation (103.15) and would appear as a fourth oscillation frequency. The LSND excess [2007] and the MiniBooNE low-energy excess have been read that way; the MicroBooNE liquid-argon measurement finds no corresponding excess in the electron-neutrino channel [2397], and the reactor and gallium rate anomalies have been partly resolved by recalculating fluxes. No sterile state is established and the anomalies have not all gone away; Section 114.6.4 is the section reserved for the state of each.

Remark 103.72 (Leptogenesis is named here and is not evidence). The heavy singlets of the seesaw, decaying out of equilibrium with a CP-violating asymmetry, would generate a lepton asymmetry that electroweak processes partly convert into the baryon asymmetry of Equation (103.45). The mechanism is attractive precisely because it needs no new ingredient beyond the one already invoked to explain the neutrino masses. It is nevertheless untested and, with the relevant scale above $1 \times 10^9\,\mathrm{GeV}$, untestable by any foreseeable experiment; and a measurement of δ_{CP} would not establish it, because the phases entering the heavy-neutrino decays are not the phases entering Equation (103.47). It is listed in Section 133.5 as an unexplained observation, not as a solved problem.

103.8 Open questions in flavour

The Standard Model has nineteen free parameters, and thirteen of them — nine charged-fermion masses, three CKM angles and one phase — belong to flavour; the neutrino sector adds at least seven more. Every one is measured and none is predicted. This closing section names the specific questions that are open, distinguishing those where a measurement disagrees with a prediction from those where there is no prediction to disagree with.

The mass hierarchy. The charged-fermion masses span from $0.511\,\mathrm{MeV}/c^2$ to $172.57\,\mathrm{GeV}/c^2$, a factor 3.4×10^5 within one set of gauge quantum numbers, and the

neutrino masses lie a further six orders of magnitude below the electron. Expressed as Yukawa couplings by Remark 103.21 they run from 1 down to 10^{-6} for the charged leptons and to 10^{-12} or less for neutrinos. There is no prediction here to disagree with; there is a pattern with no explanation, and it is Section 133.1.

Charged-lepton flavour violation: not observed. In the Standard Model with massive neutrinos, $\mu \to e\gamma$ proceeds through a loop with the GIM suppression of Theorem 103.11, and because the internal masses are neutrino masses the suppression factor $\left(\Delta m^2 c^4\right)^2 / \left(M_W c^2\right)^4$ — with $\Delta m^2 c^4 = 2.5 \times 10^{-3}\,\mathrm{eV}^2$ and $M_W c^2 = 80.4\,\mathrm{GeV}$, equal to 1.5×10^{-49} — makes it utterly unobservable. Any observation would therefore be new physics, which is why the search is worth pursuing. The MEG II experiment finds

$$\mathcal{B}\left(\mu^+ \to e^+\gamma\right) < 7.5 \times 10^{-13} \tag{103.78}$$

from its first dataset, and 1.5×10^{-13} combining with the earlier MEG result, both at 90 % confidence [2424]. Phenomenon 101.53 records the same null result in its charged-current context and quotes the same two values. Nothing is seen.

The B-decay anomalies: mostly resolved, and the resolution is instructive. For a decade the ratios $R_K = \mathcal{B}\left(B \to K\mu^+\mu^-\right) / \mathcal{B}\left(B \to Ke^+e^-\right)$ and its K^* analogue were measured below the Standard Model value of unity, at the level of 2.5σ each. Lepton universality is a sharp prediction: the ratio is one up to phase-space and radiative corrections of a per cent, because the gauge couplings do not distinguish the flavours. In 2022 LHCb identified a mis-estimated electron-identification efficiency, and the corrected measurements are

$$R_K = 0.949 \pm 0.047\,, \qquad R_{K^*} = 1.027 \pm 0.077\,, \tag{103.79}$$

consistent with unity [2412]. This treatise records the episode rather than quietly dropping it, because it is a clean example of an anomaly that was a systematic effect — and because the related $b \to s\mu\mu$ branching fractions and angular observables remain about 3σ below their Standard Model predictions, with hadronic uncertainties that are disputed. Universality holds; the absolute rates are not settled.

The muon anomalous magnetic moment. The muon's anomaly is sensitive to any flavour-dependent physics at high scale, and its Standard Model prediction is limited by the hadronic vacuum polarization, which belongs to Section 112.6.3. The status — including the disagreement between the data-driven and lattice evaluations of that contribution, which is larger than the effect being tested — belongs to Section 112.6.4. It is quoted here only to record that the one place where a flavour-sensitive precision observable may disagree with theory is a place where the theory prediction is itself contested.

Three generations, and no reason. The number is measured twice, by Equation (103.15) and by nucleosynthesis, and predicted by nothing.

First-row unitarity. Proposition 103.8: the most precisely tested relation in quark flavour physics is currently low by two to three standard deviations. It is the one entry in this list that is a genuine discrepancy between a prediction and a measurement rather than an absence of prediction, and it is most likely a systematic effect in one of the inputs.

Every item above is listed as open in Chapter 133 rather than resolved by a model this treatise would have no evidence to include. The models exist — horizontal symmetries relating the generations, additional gauge bosons distinguishing them, composite fermions, extra spatial dimensions in which the Yukawa hierarchy becomes a geometric one — and every one of them predicts something that has not been seen. Under editorial rule 1 they are named here, once, so that a reader knows they were considered, and are not developed.

Chapter 104

Electroweak Unification and the Higgs Boson

The weak and electromagnetic interactions are two faces of one gauge theory. This chapter builds it: the gauge group $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ of Glashow [1206], its spontaneous breaking to the $\mathrm{U}(1)_{\mathrm{em}}$ of Chapter 60 by a scalar doublet, and the resulting massive $W^{\pm}$ and Z^0 carriers that replace the contact interaction of Fermi [738] used in Chapter 101. The chapter therefore sits after Chapter 64, where the gauge-field formalism belongs, and after the renormalization of Chapter 100, and before the strong sector of Chapter 102 with which it completes the Standard Model. Two threads run through it. The first is theoretical: how a gauge boson acquires mass without destroying the gauge invariance that makes the theory renormalizable — the mechanism of Anderson [1245], Englert and Brout [1275], Higgs [1282, 1283] and Guralnik, Hagen and Kibble [1279], whose renormalizability 't Hooft and Veltman established [1448, 1463].

The second thread is evidential, and it is the reason the theory is in this book at all. Weak neutral currents were seen in Gargamelle [1502, 1503]; the W and Z were produced and weighed at the CERN $p\bar{p}$ collider [1710, 1711, 1713, 1714]; four LEP experiments and SLD measured the Z resonance to parts in 10^4 [2104]; and the scalar itself was found in 2012 — the discovery account belongs to Chapter 113 — and has since been mapped coupling by coupling [2394, 2410]. Where the picture is incomplete — the metastability of the vacuum, the W-mass tension, the origin of the Yukawa hierarchy — the chapter says so. The standard reference treatment is [1933].

104.1 Conventions carried into this chapter

Everything below is written in SI units, in the conventions fixed once in Section 100.1.1: the metric is $\eta_{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$, a four-momentum is $p^\mu = (E/c, \boldsymbol{p})$ of dimension $\mathrm{kg\,m/s}$, the mass shell is $p^2 = m^2c^2$ (Equation (100.1)), Mandelstam variables are squared *momenta* so that $\sqrt{s}\,c$ is a centre-of-mass energy, and every Lagrangian density is an energy density, $\mathrm{J/m^3}$, with the action $S = c^{-1}\int \mathrm{d}^4x\,\mathcal{L}$ of Equation (100.2). The gauge fields and their couplings are those of Definition 101.66: W^a_μ and B_μ carry $\mathrm{V\,s/m}$ like the electromagnetic potential of Definition 100.2, and g and g' carry the dimension of electric charge, C.

Three abbreviations recur so often that they are given names here.

Notation 104.1 (Dimensionless couplings and the electroweak scale). For any coupling q of the dimension of charge, write

$$\hat{q} := \frac{q}{\sqrt{\varepsilon_0 \hbar c}}\,, \tag{104.1}$$

a pure number, since q^2/ε_0 and $\hbar c$ both carry J m. In particular $\hat{e}^2 = e^2/(\varepsilon_0 \hbar c) = 4\pi\alpha$ by Equation (100.3), so $\hat{e} = \sqrt{4\pi\alpha} = 0.302\,822$ at zero momentum transfer, and $\hat{g}$, $\hat{g}'$ are the numbers that the references cited below write simply as g and g' (see Remark 104.2).

The scalar doublet Φ carries the dimension of a scalar field, $\mathrm{J}^{1/2}/\mathrm{m}^{1/2}$ (Equation (106.33)), so its vacuum expectation value v does too. The combination

$$E_v := v\sqrt{\hbar c} \tag{104.2}$$

is an energy, and it is what the literature means when it writes "$v = 246\,\mathrm{GeV}$". Its value is computed in Proposition 104.26.

Remark 104.2 (Reading this chapter against the natural-units literature). Every source cited below sets $\hbar = c = 1$. The dictionary is the one given once in Remark 100.4, plus three entries special to this chapter: a coupling of charge dimension maps to its hat by Equation (104.1), a vacuum expectation value maps to E_v by Equation (104.2), and a scalar self-coupling λ — which carries $1/(\mathrm{J\,m})$ here, by Equation (106.34) — maps to $\hat{\lambda} = \lambda\hbar c$. With those three substitutions every formula below becomes the one in the references, and conversely. No derivation in this chapter is performed with $\hbar$ or c set to one; this remark exists so that the reader can check the chapter against its sources.

104.2 From Fermi's theory to a gauge theory

104.2.1 The four-fermion interaction and its breakdown

Fermi's theory of beta decay [738] is a product of two currents evaluated at one point, Equation (101.6), with a single constant G_F in front. Chapter 101 develops it in full and measures it: the definitive determination comes from the positive-muon lifetime, which the MuLan experiment fixed to about one part per million [2225], giving

$$\frac{G_F}{(\hbar c)^3} = (1.166\,378\,7 \pm 0.000\,000\,6) \times 10^{-5}/\mathrm{GeV}^2\,, \qquad G_F = 1.435\,85 \times 10^{-62}\,\mathrm{J\,m}^3 \tag{104.3}$$

by Equation (101.8). The Lorentz structure of the currents is $V - A$, forced on the theory by the observation of maximal parity violation and written down by Feynman and Gell-Mann [1144] and by Sudarshan and Marshak [1162]; Section 101.4 derives it from the data and Chapter 110 is the apparatus.

Three facts about that theory are the reason this chapter exists, and all three are established in Chapter 101. They are collected here because everything the electroweak theory does is a response to them.

Proposition 104.3 (Three failures of the contact theory). *Let G_F be as in Equation (104.3) and let E denote a centre-of-mass energy. Then*

1. *the dimensionless number governing every weak amplitude is $G_F E^2/(\hbar c)^3$, which reaches unity at $E_F = 292.8\,\mathrm{GeV}$ (Equation (101.9)), so the perturbation expansion has an expiry date;*
2. *the $J = 0$ cross-section $\sigma = G_F^2 E^2/\pi(\hbar c)^4$ of Equation (101.60) breaches the partial-wave unitarity bound at $E = 1.04\,\mathrm{TeV}$ (Theorem 101.78);*
3. *the superficial degree of divergence $D = 4 - \frac{3}{2}E_{ext} + 2V$ of Equation (101.91) grows with the order V of perturbation theory, so the theory needs infinitely many counterterms and predicts nothing beyond the order at which it is fitted.*

All three are consequences of one fact: G_F carries $\mathrm{J\,m}^3$ (Proposition 101.7), a dimension no rescaling can remove.

Rests on Equation (104.3), Proposition 101.7, and Theorem 101.78.

Derivation. *Derives Proposition 104.3.*

Each item is proved where it is stated in Chapter 101; what is added here is that the three are the same statement counted three ways. A coupling of dimension $\mathrm{J\,m^3}$ can only enter an amplitude in the combination $G_F E^2/(\hbar c)^3$, because that is the unique dimensionless product of G_F, $\hbar$, c and an energy; hence item (i). A cross-section is an area and the only area available is $G_F^2 E^2/(\hbar c)^4$ times a pure number, which grows while the unitarity bound $16\pi(\hbar c)^2/E^2$ falls, so they must cross; hence item (ii). And in the momentum counting of Theorem 100.17 each vertex contributes its coupling's negative mass dimension to D with a positive sign, which is Corollary 101.82; hence item (iii). □

The obvious repair is Yukawa's: give the interaction a carrier [765]. Two currents joined by a heavy vector boson of mass M_W reproduce the contact term at momentum transfers small compared with $M_W c$ (Proposition 101.65), with the matching condition Equation (101.78),

$$\frac{G_F}{\sqrt{2}\,(\hbar c)^3} = \frac{\pi \alpha_W}{2\,(M_W c^2)^2} = \frac{\hat{g}^2}{8\,(M_W c^2)^2}\,, \tag{104.4}$$

the last form using $\hat{g}^2 = 4\pi\alpha_W$ from Equation (101.71) and Equation (104.1). This trades one dimensionful constant for a dimensionless coupling and a mass, which is progress only if the mass is explained. It is not, and the cure is worse than it looks.

Theorem 104.4 (Inserting a vector boson by hand does not help)**.** *Let W_μ be a vector field with the Proca mass term*

$$\mathcal{L}_M = \frac{1}{\mu_0}\left(\frac{M_W c}{\hbar}\right)^2 W^+_\mu W^{-\mu} \tag{104.5}$$

added by hand to a gauge-invariant kinetic term. Then

1. *$\mathcal{L}_M$ is not invariant under $W_\mu \mapsto W_\mu + \partial_\mu \Lambda$;*
2. *its propagator Equation (101.77) tends to a constant rather than to zero at large momentum, so the power counting of Theorem 100.17 fails and the theory is non-renormalizable;*
3. *the longitudinal polarization vector grows linearly with momentum,*

$$\varepsilon^\mu_{(L)}(k) = \frac{k^\mu}{M_W c} + \mathcal{O}\!\left(\frac{M_W c}{|\boldsymbol{k}|}\right)\,, \tag{104.6}$$

so amplitudes with external longitudinal Ws grow with energy and the unitarity problem of Proposition 104.3(ii) reappears at a higher scale instead of being cured.

Rests on Equation (101.77), Theorem 100.17, and Proposition 104.3.

Proof. *Derives Theorem 104.4.*

(i) Under the shift, $W^+_\mu W^{-\mu}$ acquires $\partial_\mu\Lambda^+ W^{-\mu} + W^+_\mu \partial^\mu \Lambda^- + \partial_\mu\Lambda^+\partial^\mu\Lambda^-$, which no choice of Λ makes vanish identically. The mass term breaks the very invariance that Theorem 100.5 used to construct the interaction.

(ii) The massive vector kernel is $-\mu_0^{-1}\hbar^{-2}\left[(k^2 - M_W^2 c^2)\eta_{\mu\nu} - k_\mu k_\nu\right]$, whose inverse is Equation (101.77). At large k the transverse part falls as k^{-2}, exactly as the photon propagator Equation (100.17) does, but the term $k_\mu k_\nu / M_W^2 c^2$ divided by $k^2 - M_W^2 c^2$ tends to η-independent constant behaviour: it does not fall at all. Repeating the count of Theorem 100.17 with internal boson lines contributing k^0 instead of k^{-2} raises D by two for every such line, and D again grows with the order.

(iii) A massive vector of four-momentum $k^\mu = (E/c, 0, 0, k)$ with $E^2/c^2 - k^2 = M_W^2 c^2$ has three polarization vectors satisfying $k_\mu \varepsilon^\mu = 0$ and $\varepsilon \cdot \varepsilon^* = -1$; the longitudinal one is

$$\varepsilon^\mu_{(L)} = \frac{1}{M_W c}\left(k, 0, 0, \frac{E}{c}\right) = \frac{k^\mu}{M_W c} - \frac{M_W c}{E/c + k}\,(1, 0, 0, -1)\,,$$

as one checks by expanding $E/c = \sqrt{k^2 + M_W^2 c^2}$. The second term is bounded; the first grows without limit, and it is the one that appears in Equation (104.6). Since an amplitude is linear in each external polarization, an amplitude with n longitudinal Ws carries n factors of $k/M_W c$ relative to the transverse one. The physical content is that the longitudinal mode is the piece a genuinely massless gauge field does not have; inserting a mass by hand supplies it without supplying a field for it to come from. □

Remark 104.5 (Where the theory is going). Theorem 104.4 is the pivot of the chapter and it is worth naming its resolution in advance. The longitudinal mode is not manufactured out of nothing: it is a scalar degree of freedom that existed before the symmetry broke, and the growth of Equation (104.6) in one description is the ordinary, non-growing scalar amplitude in another. That equivalence, made exact in Proposition 104.47, is what saves unitarity, and the requirement that it hold fixes the couplings of the scalar (Theorem 104.51) and hence everything the LHC measures in Section 104.7.2. Remark 101.69 states the same conclusion from the other side.

104.2.2 Yang–Mills fields and the mass problem

The gauge principle of Theorem 100.5 takes a global phase symmetry and makes it local, at the cost of one vector field. Yang and Mills [1054] asked what happens when the global group is non-abelian, and the answer is the framework in which the rest of this chapter is written. The general construction belongs to Chapter 64 and its geometry to Section 14.6; what is needed here is the explicit SU(2) case in SI units.

Definition 104.6 (Non-abelian gauge fields in SI). Let $T^a = \tfrac{1}{2}\sigma^a$ be the generators of SU(2), with $\left[T^a, T^b\right] = \mathrm{i}\varepsilon^{abc}T^c$ and $\mathrm{tr}(T^aT^b) = \tfrac{1}{2}\delta^{ab}$ (Section 14.3). Let ψ be a field in some representation with generators T^a, and W_μ^a three vector fields of dimension V s/m. The covariant derivative is

$$D_\mu = \partial_\mu + \frac{\mathrm{i}g}{\hbar} W_\mu^a T^a \,, \tag{104.7}$$

with g of dimension C, and the field strength is

$$W_{\mu\nu}^a = \partial_\mu W_\nu^a - \partial_\nu W_\mu^a - \frac{g}{\hbar}\varepsilon^{abc} W_\mu^b W_\nu^c \,, \qquad \left[W_{\mu\nu}^a\right] = \mathrm{T} \,, \tag{104.8}$$

so that the Yang–Mills Lagrangian density is

$$\mathcal{L}_{\mathrm{YM}} = -\frac{1}{4\mu_0} W_{\mu\nu}^a W^{a\mu\nu} \,, \tag{104.9}$$

of dimension J/m^3, exactly as in Equation (100.12). This is Equation (106.65) with the coupling displayed rather than absorbed.

Proposition 104.7 (Covariance and self-coupling). *Under the local transformation $\psi \mapsto U(x)\psi$ with $U(x) = \exp(-\mathrm{i}\theta^a(x)T^a)$, Equation (104.7) is covariant, $D_\mu\psi \mapsto U D_\mu \psi$, if and only if the potential transforms as*

$$\frac{g}{\hbar} W_\mu \longmapsto U \frac{g}{\hbar} W_\mu U^{-1} + \mathrm{i}\,(\partial_\mu U)\, U^{-1} \,, \qquad W_\mu := W_\mu^a T^a \,, \tag{104.10}$$

and then $W_{\mu\nu} := W_{\mu\nu}^a T^a$ transforms homogeneously, $W_{\mu\nu} \mapsto U W_{\mu\nu} U^{-1}$, so that Equation (104.9) is invariant. Expanding Equation (104.8) inside Equation (104.9) produces, besides the free quadratic term, a cubic vertex of strength $g/\hbar\mu_0$ and a quartic vertex of strength $g^2/\hbar^2\mu_0$: the gauge bosons carry the charge they mediate.

Rests on Equations (104.7) to (104.9).

Proof. *Derives Proposition 104.7.*

The first statement is Equation (100.10) with the phase replaced by a matrix and the extra term coming from the failure of U and W_μ to commute; writing $\mathcal{W}_\mu = gW_\mu/\hbar$ of dimension $1/\mathrm{m}$, the requirement $(\partial_\mu + \mathrm{i}\mathcal{W}'_\mu)U\psi = U(\partial_\mu + \mathrm{i}\mathcal{W}_\mu)\psi$ for all ψ gives $\mathrm{i}\mathcal{W}'_\mu U = U\mathrm{i}\mathcal{W}_\mu - (\partial_\mu U)$, which is Equation (104.10). For the field strength, note that $\mathrm{i}\mathcal{W}_{\mu\nu} = [D_\mu, D_\nu]$ is a commutator of covariant objects, hence a covariant object: it is Equation (106.64), and in components it is Equation (104.8) because $\left[T^b, T^c\right] = \mathrm{i}\varepsilon^{bcd}T^d$ contributes $-\varepsilon^{abc}\mathcal{W}^b_\mu\mathcal{W}^c_\nu$. Since $\mathrm{tr}(W_{\mu\nu}W^{\mu\nu})$ is invariant under conjugation, Equation (104.9) is invariant. Finally, squaring Equation (104.8) gives cross terms $(\partial W)(g\varepsilon WW/\hbar)$ and $(g\varepsilon WW/\hbar)^2$, which are the cubic and quartic self-interactions; they have no counterpart in Equation (100.12), where ε^{abc} has nothing to contract. That the gauge bosons interact with one another is a prediction, and it is measured directly in Phenomenon 104.57. □

The obstruction is now stated in its final form.

Theorem 104.8 (Gauge invariance forbids an explicit mass term)**.** *No term of the form $\frac{1}{2\mu_0}(Mc/\hbar)^2 W^a_\mu W^{a\mu}$ is invariant under Equation (104.10), and no gauge-invariant local function of W^a_μ alone gives a mass to the vector field.*

Rests on Equation (104.10).

Proof. *Derives Theorem 104.8.*

For an infinitesimal transformation, $\delta(gW^a_\mu/\hbar) = \partial_\mu\theta^a + \varepsilon^{abc}\theta^b(gW^c_\mu/\hbar)$, obtained by expanding Equation (104.10) to first order. Then

$$\delta\left(W^a_\mu W^{a\mu}\right) = \frac{2\hbar}{g}W^{a\mu}\partial_\mu\theta^a + 2\varepsilon^{abc}\theta^b W^c_\mu W^{a\mu}\,.$$

The second term vanishes because ε^{abc} is antisymmetric in ac while $W^c_\mu W^{a\mu}$ is symmetric; the first does not, and it cannot be cancelled by anything, since θ^a is an arbitrary function while $W^{a\mu}$ is a field. For the second claim, observe that a mass term is by definition quadratic in the field with no derivatives, and Equation (104.10) contains an inhomogeneous piece $\partial_\mu\theta$ that only a derivative can absorb; every gauge-invariant local functional of W alone is therefore built from $W_{\mu\nu}$ and its covariant derivatives, each of which carries at least one ∂_μ and hence at least two powers of momentum. Such a term contributes to the kinetic operator, never to a mass. □

Remark 104.9 (Gauge invariance does not require a massless quantum)*.* Theorem 104.8 forbids writing a mass down. It does not prove that the quantum is massless, and Schwinger made the distinction sharp [1241]: what fixes the mass is the position of the pole in the full propagator, not the form of a term in the Lagrangian. Write the exact photon two-point function of Corollary 100.32 as

$$\widetilde{D}_{\mu\nu}(k) \propto \frac{\eta_{\mu\nu} - k_\mu k_\nu/k^2}{k^2\left[1 - \Pi(k^2)\right]}\,,$$

which is transverse, and hence gauge invariant, whatever Π is. If the vacuum polarization $\Pi(k^2)$ is regular at $k^2 = 0$, the pole sits at $k^2 = 0$ and the quantum is massless. If instead $\Pi(k^2) \to -M^2c^2/k^2$ as $k^2 \to 0$ — a pole in Π — the propagator's pole moves to $k^2 = M^2c^2$ and the quantum is massive, with the transversality, and therefore the gauge invariance, untouched. Schwinger exhibited this in two-dimensional electrodynamics, where the massless-fermion loop produces exactly such a pole. The physical realization in three space dimensions is the superconductor: the photon inside one is massive, with $M = \hbar/\lambda_L c$ for the London penetration depth λ_L, and nothing about electromagnetic gauge invariance is lost (Chapter 130). What supplies the pole in Π is a massless scalar excitation, and the rest of this section is the search for one.

104.2.3 Glashow's $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$

The charged weak currents of Equation (101.35) do not close under commutation: $[J^+, J^-]$ produces a third, electrically neutral current. A gauge theory containing them must therefore have at least three generators, and the smallest group with three is SU(2). Glashow [1206] took the further step of adjoining a U(1) so that electromagnetism could be accommodated without identifying the photon with the neutral member of the triplet, which is impossible because the photon does not violate parity while the SU(2) currents maximally do. Salam and Ward reached the same structure independently [1295].

Definition 104.10 (The electroweak gauge group and its representations)**.** The gauge group is $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ with gauge fields W_μ^a and B_μ and couplings g, g', acting through Equation (101.70),

$$D_\mu = \partial_\mu + \frac{\mathrm{i}}{\hbar}\left(g W_\mu^a T^a + g' B_\mu \frac{Y}{2} \right) . \tag{104.11}$$

The subscript L is not decoration: T^a acts on the left-chiral projection $\psi_L = \tfrac{1}{2}(\mathbb{1} - \gamma^5)\psi$ only, and annihilates ψ_R. One generation of matter is

$$\begin{pmatrix} \nu_e \\ e \end{pmatrix}_L , \quad e_R , \quad \begin{pmatrix} u \\ d \end{pmatrix}_L , \quad u_R , \quad d_R , \tag{104.12}$$

with the quarks additionally carrying colour, on which $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ acts trivially. The hypercharge Y is assigned so that

$$Q = T^3 + \frac{Y}{2} \tag{104.13}$$

reproduces the observed electric charges, Q measured in units of e.

Table 104.1: Electroweak quantum numbers of one generation, in the convention $Q = T^3 + Y/2$ of Equation (104.13). Right-chiral fields are $\mathrm{SU}(2)_L$ singlets, so $T = T^3 = 0$ and $Y = 2Q$. The hypercharge of the scalar doublet Φ is fixed in Section 104.4.1 by the requirement that its lower component be neutral. The Standard Model as tested contains no ν_R; Chapter 103 takes up what the observation of neutrino mass adds.

Field	T	T^3	Y	Q
ν_{eL}	$\frac{1}{2}$	$+\frac{1}{2}$	-1	0
e_L	$\frac{1}{2}$	$-\frac{1}{2}$	-1	-1
e_R	0	0	-2	-1
u_L	$\frac{1}{2}$	$+\frac{1}{2}$	$+\frac{1}{3}$	$+\frac{2}{3}$
d_L	$\frac{1}{2}$	$-\frac{1}{2}$	$+\frac{1}{3}$	$-\frac{1}{3}$
u_R	0	0	$+\frac{4}{3}$	$+\frac{2}{3}$
d_R	0	0	$-\frac{2}{3}$	$-\frac{1}{3}$
Φ^+	$\frac{1}{2}$	$+\frac{1}{2}$	$+1$	$+1$
Φ^0	$\frac{1}{2}$	$-\frac{1}{2}$	$+1$	0

Remark 104.11 (Two normalizations of hypercharge). This chapter and Chapter 101 write $Q = T^3 + Y/2$, which is the convention of the original papers and of Table 104.1. Proposition 106.96 writes $Q = T^3 + Y$, with every hypercharge half as large — so the left-handed quark doublet carries $Y = 1/6$ there and $Y = 1/3$ here. Both are in wide use and neither is wrong; the ratios that carry physics, and every anomaly condition, are identical. The reader comparing the two must halve or double, and nothing else.

That the assignments of Table 104.1 are consistent at all is a nontrivial statement, since Y must be constant on each $\mathrm{SU}(2)_L$ multiplet while Q is not.

Proposition 104.12 (Hypercharge is determined, not chosen)**.** *Given Equation* (104.13)*, the requirement that Y take one value on each irreducible $\mathrm{SU}(2)_L$ multiplet fixes Y on that multiplet to twice the average electric charge of its members, and is consistent only if the charges within a doublet differ by exactly one unit.*

Rests on Equation (104.13)*.*

Proof. *Derives Proposition 104.12.*

For a doublet with members of charge $Q_\uparrow$, $Q_\downarrow$ and $T^3 = \pm\frac{1}{2}$, Equation (104.13) gives $Y = 2Q_\uparrow - 1 = 2Q_\downarrow + 1$; the two are equal if and only if $Q_\uparrow - Q_\downarrow = 1$, and then $Y = Q_\uparrow + Q_\downarrow$, twice the average. The leptonic doublet (ν_e, e) has $0 - (-1) = 1$ and the quark doublet (u, d) has $\frac{2}{3} - (-\frac{1}{3}) = 1$: both pass, and it is the charged current that requires it, since W^+ carries exactly one unit of charge. The right-chiral fields are singlets, so $T^3 = 0$ and $Y = 2Q$ with no constraint at all. Nothing so far explains *why* the charges come in these ratios; that is the content of Section 104.5.3, where the same numbers are forced by consistency at one loop. □

Two consequences follow immediately and were Glashow's main results. First, since B_μ and W^3_μ are both neutral, the photon must be a combination of them and the orthogonal combination is a second neutral boson: the model predicts a *weak neutral current*, of a kind Fermi's theory does not contain and no experiment had then seen. Proposition 101.67 carries out the rotation and reads off the fermion couplings; the experimental discovery is Section 104.6.1. Second, the neutral current so obtained is flavour diagonal at tree level provided the quark doublets are complete, which is the mechanism of Glashow, Iliopoulos and Maiani [1423] proved as Theorem 101.59 and used again in Section 104.4.3.

Remark 104.13 (What Glashow's paper could not do). The 1961 paper inserts the W and Z masses by hand [1206], and says so: its closing paragraph records that the resulting theory is not renormalizable. By Theorem 104.4 that is not a blemish to be tidied up later but the same disease Fermi's theory had, moved to a different place. The group structure was right and the mass terms were fatal, and the six years between 1961 and 1967 were spent finding out how to have the first without the second.

104.3 Spontaneous symmetry breaking

104.3.1 The superconducting analogy

A symmetry of the dynamics need not be a symmetry of the state the system actually occupies. A ferromagnet below its Curie temperature has a magnetization pointing somewhere, although the exchange Hamiltonian singles out no direction; a crystal has axes, although the interatomic potential is rotationally invariant. Nothing about this is quantum mechanical, and Chapter 123 treats it as the general phenomenon of an ordered phase. What Nambu saw [1187] is that the same thing can happen to the *vacuum* of a relativistic field theory, and that when it does, the consequences are as sharp as in the laboratory.

Definition 104.14 (Spontaneous breaking)**.** Let a theory have an action invariant under a group G and let $|0\rangle$ be its ground state. The symmetry is *spontaneously broken* to the subgroup $H = \{h \in G : U(h)\,|0\rangle = |0\rangle\}$ when $H \neq G$. The set of states $\{U(g)\,|0\rangle : g \in G\}$ is then in bijection with the coset space G/H, all of them degenerate in energy, and the choice among them is not made by the dynamics.

The ancestor of the Higgs field is not an elementary particle at all but the Ginzburg–Landau order parameter of a superconductor [957]: a complex field ψ whose free energy

density, near the transition, is $a\,|\psi|^2 + \frac{1}{2}b\,|\psi|^4$ with a changing sign at T_c. The following proposition is the entire mathematical content of that model, and it will be used unchanged for the electroweak potential.

Proposition 104.15 (The Mexican-hat minimum)**.** *Let ϕ be a complex field of dimension $\mathrm{J}^{1/2}/\mathrm{m}^{1/2}$ and let*

$$V(\phi) = -\mu^2\,|\phi|^2 + \lambda\,|\phi|^4\,, \qquad \left[\mu^2\right] = 1/\mathrm{m}^2\,, \qquad [\lambda] = 1/(\mathrm{J\,m})\,, \tag{104.14}$$

with $\mu^2 > 0$ and $\lambda > 0$. Then $\phi = 0$ is a local maximum*, the minima form the circle*

$$|\phi| = \frac{v}{\sqrt{2}}\,, \qquad v = \mu\sqrt{\frac{1}{\lambda}}\,, \tag{104.15}$$

and the depth of the well is $V_{\min} = -\lambda v^4/4$.
Rests on Definition 104.14.

Proof. *Derives Proposition 104.15.*
Write $|\phi|^2 = \rho$. Then $V = -\mu^2\rho + \lambda\rho^2$, $\frac{\mathrm{d}V}{\mathrm{d}\rho} = -\mu^2 + 2\lambda\rho$, which vanishes at $\rho = \mu^2/2\lambda$, and $\mathrm{d}^2V/\mathrm{d}\rho^2 = 2\lambda > 0$ there, so it is the minimum; $\rho = 0$ gives $\mathrm{d}V/\mathrm{d}\rho = -\mu^2 < 0$, so the origin is a maximum. Setting $\rho = v^2/2$ gives $v^2 = \mu^2/\lambda$, which is Equation (104.15), and $V_{\min} = -\mu^2 v^2/2 + \lambda v^4/4 = -\lambda v^4/4$ on using $\mu^2 = \lambda v^2$. The dimensions check: $[\mu^2\,|\phi|^2] = 1/\mathrm{m}^2 \times \mathrm{J/m} = \mathrm{J/m}^3$, an energy density, and likewise for the quartic. Every point of the circle is a minimum and the phase of ϕ at the minimum is undetermined: that undetermined phase is the degeneracy of Definition 104.14, with $G = \mathrm{U}(1)$ and H trivial. □

Remark 104.16 (Nambu's transfer, and what it explained)*.* In the Bardeen–Cooper–Schrieffer ground state (Chapter 130) the electron number symmetry is spontaneously broken by the condensate, and the single-particle spectrum acquires a gap Δ. Nambu [1187] recognized the gap equation as a self-consistent mass generation and asked what the relativistic analogue would be. With Jona-Lasinio he built it [1215]: a theory of massless fermions with a chirally invariant four-fermion interaction develops, above a critical coupling, a non-zero $\langle\bar\psi\psi\rangle$ and hence a fermion mass that no term in the Lagrangian contains. The model also produced a massless pseudoscalar bound state, which Nambu identified with the pion — the first appearance of what the next subsection proves must always be there. Two lessons carry over. Mass can be a property of the vacuum rather than of the Lagrangian; and a broken continuous symmetry leaves a massless excitation behind. The strong interaction realizes both, and Chapter 102 takes up the pion as an approximate Goldstone boson of chiral symmetry.

104.3.2 Goldstone's theorem

Goldstone's model [1207] is Proposition 104.15 promoted to a field theory. Write $\phi = \frac{1}{\sqrt{2}}(v + h + \mathrm{i}\chi)$ with h, χ real fields measuring the departure from one chosen minimum, radially and tangentially. Substituting into $\mathcal{L} = \partial_\mu\phi^*\partial^\mu\phi - V(\phi)$ and expanding gives

$$\mathcal{L} = \frac{1}{2}\partial_\mu h\,\partial^\mu h - \frac{1}{2}\left(2\lambda v^2\right)h^2 + \frac{1}{2}\partial_\mu\chi\,\partial^\mu\chi - \lambda v\,h\left(h^2+\chi^2\right) - \frac{\lambda}{4}\left(h^2+\chi^2\right)^2 + \frac{\lambda v^4}{4}\,, \tag{104.16}$$

in which the field χ has no mass term at all. By the dictionary of Notation 106.23, a mass term $\frac{1}{2}(mc/\hbar)^2$ means

$$m_h = \frac{\hbar}{c}\sqrt{2\lambda v^2} = \frac{\hbar\mu\sqrt{2}}{c}\,, \qquad m_\chi = 0\,. \tag{104.17}$$

The massless mode is the one that moves along the circle of minima, where the potential is flat by construction. That this is no accident of the quartic potential is Goldstone's theorem.

Theorem 104.17 (Goldstone's theorem, tree level)**.** *Let ϕ_i, $i = 1, \dots, n$, be real scalar fields with a potential $V(\phi)$ invariant under a compact connected group G acting as $\delta\phi_i = \theta^a \, (t^a)_{ij} \, \phi_j$ with real antisymmetric generators t^a, $a = 1, \dots, \dim G$. Let ϕ_0 minimize V and let $H \subseteq G$ be its stabilizer. Then the mass matrix*

$$\left(M^2\right)_{ij} = \left. \frac{\partial^2 V}{\partial\phi_i \, \partial\phi_j} \right|_{\phi_0} \tag{104.18}$$

annihilates every vector $t^a\phi_0$, so the spectrum contains exactly $\dim G - \dim H$ massless scalars, one for each broken generator.

Rests on Definition 104.14.

Proof. *Derives Theorem 104.17.*

Invariance of V under an infinitesimal transformation reads, for every ϕ and every a,

$$\frac{\partial V}{\partial\phi_i} \, (t^a)_{ij} \, \phi_j = 0 \, . \tag{104.19}$$

This is an identity in ϕ, so it may be differentiated. Applying $\partial/\partial\phi_k$ gives

$$\frac{\partial^2 V}{\partial\phi_k \, \partial\phi_i} \, (t^a)_{ij} \, \phi_j + \frac{\partial V}{\partial\phi_i} \, (t^a)_{ik} = 0 \, .$$

Now evaluate at $\phi = \phi_0$. The second term vanishes because ϕ_0 is a stationary point of V, and the first becomes

$$\left(M^2\right)_{ki} \, (t^a\phi_0)_i = 0 \, . \tag{104.20}$$

Hence each vector $t^a\phi_0$ lies in the kernel of M^2. If t^a belongs to the Lie algebra of H then $t^a\phi_0 = 0$ and Equation (104.20) is empty; otherwise $t^a\phi_0 \neq 0$ and it is a genuine null eigenvector. The vectors $\{t^a\phi_0\}$ span a space of dimension $\dim G - \dim H$, because the map $t \mapsto t\phi_0$ from the Lie algebra of G to $\mathbb{R}^n$ has kernel exactly the Lie algebra of H by definition of the stabilizer; and M^2, being a real symmetric matrix, has as many zero eigenvalues as the dimension of its kernel. Since ϕ_0 is a *minimum*, M^2 is positive semi-definite and no eigenvalue is negative. Therefore the spectrum consists of $\dim G - \dim H$ massless modes and $n - \dim G + \dim H$ massive ones.

Geometrically, $t^a\phi_0$ is tangent to the orbit $G\phi_0$ at ϕ_0, and V is constant on that orbit by Equation (104.19): a direction along which the potential does not change is a direction in which the field costs no energy to excite at zero momentum, which is what a massless particle is. □

Remark 104.18 (The exact theorem, and its assumptions)*.* Theorem 104.17 is a statement about a classical potential, and Proposition 106.45 shows how loops modify a potential. The result nevertheless survives: Goldstone, Salam and Weinberg [1226] proved it to all orders, and the proof uses only the existence of a conserved current j^μ with $\langle 0 | \, [Q, \mathcal{O}] \, | 0 \rangle \neq 0$ for some local operator $\mathcal{O}$, together with Lorentz invariance, locality and a positive-definite state space. The spectral representation of Proposition 106.47, applied to $\langle 0 | j^\mu(x) \mathcal{O}(0) | 0 \rangle$, then forces a zero-mass contribution. Each assumption is load-bearing, and their precise statement belongs to Chapter 109. The one that fails in this chapter is the last but one: gauge fixing a gauge theory either breaks manifest Lorentz invariance (radiation gauge) or introduces negative-norm states (covariant gauge), and *that* is the loophole the next subsection walks through. It is not a technicality — it is why the photon in a superconductor can be massive without a massless mode appearing in the spectrum.

104.3.3 The Anderson–Higgs mechanism

Anderson [1245] pointed out, in a non-relativistic setting and before any of the relativistic papers, that a gauge field coupled to a system with a broken symmetry does not leave a massless scalar behind: the would-be Goldstone mode and the gauge field combine, and what is left is a massive vector. In a plasma the resulting mass is the plasma frequency; in a superconductor it is the inverse London penetration depth. The relativistic version is worked here in full, for one abelian gauge field, because every feature of the electroweak case is already present.

Theorem 104.19 (The abelian Higgs mechanism)**.** *Let ϕ be a complex scalar of charge q coupled to a* U(1) *gauge field through $D_\mu = \partial_\mu + \mathrm{i}qA_\mu/\hbar$, with*

$$\mathcal{L} = -\frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu} + (D_\mu\phi)^*\,(D^\mu\phi) + \mu^2\,|\phi|^2 - \lambda\,|\phi|^4\ . \tag{104.21}$$

Then the spectrum consists of one real scalar of mass $m_h = \hbar\sqrt{2\lambda v^2}/c$ and one massive *vector of mass*

$$m_A = \frac{qv\sqrt{\mu_0}}{c}\,, \tag{104.22}$$

with no massless scalar. The count of degrees of freedom is unchanged: two (complex scalar) plus two (massless vector) before, one plus three after.

Rests on Equations (100.8)*,* (104.6) *and* (104.16)*.*

Proof. *Derives Theorem 104.19.*

Write $\phi(x) = \frac{1}{\sqrt{2}}\,[v + h(x)]\exp[\mathrm{i}\chi(x)/v]$, which is legitimate wherever $\phi \neq 0$ and which parametrizes the same two real degrees of freedom as before, h radial and χ tangential; χ/v is dimensionless because $[\chi] = [v]$. The potential depends only on $|\phi|$, so it is exactly Equation (104.16) without the χ terms: h gets the mass Equation (104.17) and χ appears nowhere in V.

Now perform the gauge transformation Equation (100.8) with $\Lambda = -\hbar\chi/qv$, under which $\phi \mapsto \mathrm{e}^{-\mathrm{i}q\Lambda/\hbar}\phi = \frac{1}{\sqrt{2}}(v + h)$: the phase is gone. This choice is the *unitary gauge*, and it is available precisely because χ shifts inhomogeneously under a gauge transformation, exactly as A_μ does. What was a field is now a gauge parameter. The Lagrangian becomes

$$\begin{aligned}\mathcal{L} &= -\frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}\partial_\mu h\,\partial^\mu h + \frac{q^2}{2\hbar^2}\,(v+h)^2\,A_\mu A^\mu - V(h)\\ &= -\frac{1}{4\mu_0}F_{\mu\nu}F^{\mu\nu} + \frac{q^2v^2}{2\hbar^2}A_\mu A^\mu + \frac{1}{2}\partial_\mu h\,\partial^\mu h - V(h) + \frac{q^2v}{\hbar^2}hA_\mu A^\mu + \frac{q^2}{2\hbar^2}h^2A_\mu A^\mu\,,\end{aligned} \tag{104.23}$$

using $|D_\mu\phi|^2 = \frac{1}{2}(\partial h)^2 + \frac{1}{2}(q/\hbar)^2(v+h)^2A^2$ for a real ϕ. The second term of Equation (104.23) is a mass term. Comparing it with the Proca form $\frac{1}{2\mu_0}(m_Ac/\hbar)^2A^2$ gives

$$\frac{m_A^2c^2}{\mu_0\hbar^2} = \frac{q^2v^2}{\hbar^2}\,, \qquad \text{that is} \qquad m_A = \frac{qv\sqrt{\mu_0}}{c}\,,$$

which is Equation (104.22). Dimensionally, $q^2v^2\mu_0/c^2$ carries $\mathrm{C}^2 \times \mathrm{J/m} \times \mathrm{kg\,m/C^2} \times \mathrm{s^2/m^2} = \mathrm{kg}^2$, so m_A is a mass.

For the counting: before breaking, ϕ has two real components and a massless vector has two transverse polarizations, four in all; after, h has one and a massive vector has three, again four. The Goldstone mode has not disappeared, it has become the longitudinal polarization whose absence from the massless theory Equation (104.6) identified as the problem. The last two terms of Equation (104.23) are the interactions of the surviving scalar with the vector, and their strengths are not free: both are fixed by m_A and v. That is the statement measured in Phenomenon 104.62. □

Corollary 104.20 (The Meissner effect is the same computation)**.** *In the static limit, Equation* (104.23) *gives the field equation* $(\nabla^2 - m_A^2 c^2/\hbar^2)\,\boldsymbol{A} = 0$ *for the transverse potential, so a magnetic field entering the ordered medium is screened exponentially over the length*

$$\lambda_L = \frac{\hbar}{m_A c} = \frac{\hbar}{q v \sqrt{\mu_0}}\,, \tag{104.24}$$

the Compton wavelength of the massive photon. This is the Meissner effect, observed in 1933 [724] and measured as a penetration depth of tens of nanometres in elemental superconductors (Chapter 130).

Rests on Equations (104.22) *and* (104.23).

Proof. *Derives Corollary 104.20.*

Varying Equation (104.23) with respect to A_μ gives $\partial_\mu F^{\mu\nu} = -\mu_0 q^2 v^2 \hbar^{-2} A^\nu$, and in a static configuration with $\partial_0 = 0$ and $\nabla \cdot \boldsymbol{A} = 0$ the spatial part reads $\nabla^2 \boldsymbol{A} = \mu_0 q^2 v^2 \hbar^{-2} \boldsymbol{A} = (m_A c/\hbar)^2 \boldsymbol{A}$ by Equation (104.22). A solution decaying into the half-space $z > 0$ is $\boldsymbol{A} \propto \mathrm{e}^{-z/\lambda_L}$ with λ_L as stated, and $\boldsymbol{B} = \operatorname{curl} \boldsymbol{A}$ decays with it. □

Remark 104.21 (Why this evades Goldstone's theorem). Theorem 104.17 is not contradicted; its hypotheses are not met. In unitary gauge the massless scalar is simply absent from the field content, and the theory manifestly has no massless spin-zero particle — but unitary gauge is not manifestly Lorentz covariant in its propagator structure, and the vector propagator does not fall off (Theorem 104.4(ii)), so the assumptions used in Remark 104.18 fail. In a covariant gauge the Goldstone field χ is present, but so are negative-norm states, and the positivity assumption fails instead. Either way one hypothesis goes. Which one is a matter of bookkeeping, and Section 104.5.1 shows that the freedom to choose is exactly what makes the theory both unitary and renormalizable.

104.3.4 The 1964 papers

Three groups published the relativistic mechanism in 1964, within four months of one another, and they proved different things.

Englert and Brout [1275] computed the vacuum polarization of a gauge field coupled to a scalar with a non-zero expectation value and exhibited the pole in $\Pi(k^2)$ that Remark 104.9 identified as the criterion: their result is that the gauge boson mass emerges from a resummation, and they gave it for a general non-abelian group in the same paper.

Higgs's first paper, in *Physics Letters* [1282], is the negative half of the argument: it shows by explicit construction that the Goldstone theorem's proof breaks in a gauge theory quantized in a Lorentz gauge, because the current is not the generator of a symmetry of the physical state space. His second paper, in *Physical Review Letters* [1283], works the abelian model of Theorem 104.19 and states the consequence the others did not emphasize: besides the massive vector there survives *one massive scalar quantum*, with definite couplings. That particle is the subject of Section 104.7, and it is the reason the mechanism is falsifiable rather than merely consistent. Higgs returned to its properties in 1966 [1332], computing its decays into pairs of gauge bosons.

Guralnik, Hagen and Kibble [1279] worked in radiation gauge, where Lorentz invariance is not manifest, and showed explicitly that the massless mode still occurs in the field algebra but decouples from the physical states: their treatment is the one that makes the evasion of Theorem 104.17 transparent rather than mysterious.

Kibble then supplied what the Standard Model actually uses [1352]: the extension to a non-abelian group, where the vector bosons need not all acquire the same mass and some may acquire none.

Theorem 104.22 (Kibble: the gauge-boson mass matrix)**.** *Let a set of scalars Φ transform in a representation of a gauge group with generators T^a and couplings g_a, coupled through $D_\mu = \partial_\mu + \mathrm{i} g_a A^a_\mu T^a/\hbar$, and let Φ acquire the expectation value Φ_0. Then the gauge fields acquire the mass matrix*

$$\left(M^2\right)^{ab} = \frac{2\mu_0}{c^2}\,\Re\!\left[(g_a T^a \Phi_0)^\dagger \left(g_b T^b \Phi_0\right)\right] \quad \textit{(no sum on } a,\ b\textit{)}, \tag{104.25}$$

whose kernel is spanned by the generators annihilating Φ_0. Hence the gauge bosons of the unbroken subgroup H stay exactly massless, one massive vector appears for each broken generator, and that is also the number of Goldstone modes removed from the scalar spectrum by Theorem 104.17.

Rests on Theorems 104.17 and 104.19.

Proof. *Derives Theorem 104.22.*

Setting $\Phi = \Phi_0$ in the scalar kinetic term, $(D_\mu\Phi_0)^\dagger (D^\mu\Phi_0) = \hbar^{-2}\,(g_a T^a\Phi_0)^\dagger \left(g_b T^b \Phi_0\right) A^a_\mu A^{b\mu}$, since $\partial_\mu \Phi_0 = 0$. Only the part symmetric in ab survives the contraction with $A^a_\mu A^{b\mu}$, which is the real part. Comparing with the Proca form $\frac{1}{2\mu_0}(c/\hbar)^2 (M^2)^{ab} A^a_\mu A^{b\mu}$ gives Equation (104.25).

The matrix is a Gram matrix of the vectors $g_a T^a \Phi_0$, so it is positive semi-definite and a vector n^a lies in its kernel if and only if $n^a g_a T^a \Phi_0 = 0$, that is, if and only if the corresponding generator annihilates the vacuum. The rank of M^2 therefore equals the number of independent broken generators, which by Theorem 104.17 is the number of massless scalars the ungauged theory would have had. Each of them is removed from the scalar spectrum by the unitary-gauge argument of Theorem 104.19 applied direction by direction, and reappears as the longitudinal polarization of the corresponding massive vector: the bookkeeping balances generator by generator, not merely in total. □

Remark 104.23 (What the theorem buys, stated in advance). Theorem 104.22 is why the photon is *exactly* massless in the electroweak theory rather than approximately so. If a single generator combination annihilates Φ_0, the corresponding vector has strictly zero mass to all orders — because the unbroken U(1) remains a genuine gauge symmetry and Theorem 104.8 still applies to it. The experimental bound on the photon mass, $m_\gamma < 1.6 \times 10^{-50}\,\mathrm{kg}$ in the laboratory and some four orders of magnitude tighter from solar-system magnetic fields (Phenomenon 100.7), therefore tests a structural feature of the symmetry-breaking pattern and not a fitted parameter.

104.4 The Glashow–Weinberg–Salam model

104.4.1 The electroweak Lagrangian

Weinberg's 1967 paper [1362] applies Theorem 104.22 to Glashow's group with the smallest scalar multiplet that will do the job, and Salam presented the same construction the following year [1381]. The choice of multiplet is not free: it must break $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ down to a U(1) under which the electron is charged and the neutrino is not, and it must do so leaving exactly one unbroken generator.

Definition 104.24 (The scalar sector)**.** Let Φ be a complex $\mathrm{SU}(2)_L$ doublet of hypercharge $Y = 1$,

$$\Phi = \begin{pmatrix} \Phi^+ \\ \Phi^0 \end{pmatrix}, \qquad [\Phi] = \mathrm{J}^{1/2}/\mathrm{m}^{1/2}, \tag{104.26}$$

with the Lagrangian density

$$\mathcal{L}_\Phi = (D_\mu\Phi)^\dagger (D^\mu\Phi) + \mu^2 \Phi^\dagger\Phi - \lambda\left(\Phi^\dagger\Phi\right)^2, \tag{104.27}$$

D_μ being Equation (104.11) and $\mu^2 > 0$, $\lambda > 0$. By Equation (104.13) the upper component has $Q = +1$ and the lower $Q = 0$: the hypercharge assignment $Y = 1$ is exactly what makes the lower component electrically neutral, and hence what makes it able to acquire an expectation value without breaking electromagnetism. The SI dimensions are $[\mu^2] = 1/\mathrm{m}^2$ and $[\lambda] = 1/(\mathrm{J\,m})$, so that $\hat{\lambda} = \lambda\hbar c$ is dimensionless (Equation (106.34)); $\hbar\mu c$ is an energy.

The whole electroweak Lagrangian is now

$$\mathcal{L}_{\mathrm{EW}} = -\frac{1}{4\mu_0} W^a_{\mu\nu} W^{a\mu\nu} - \frac{1}{4\mu_0} B_{\mu\nu} B^{\mu\nu} + \mathrm{i}\hbar c \sum_\psi \bar{\psi}\gamma^\mu D_\mu \psi + \mathcal{L}_\Phi + \mathcal{L}_{\mathrm{Yuk}}\,, \tag{104.28}$$

each term of dimension $\mathrm{J/m^3}$: the two gauge kinetic terms as in Equation (104.9), the fermion kinetic terms as in Equation (100.5) but with *no mass terms*, the scalar sector Equation (104.27), and the Yukawa couplings of Section 104.4.3. The sum over ψ runs over the chiral fields of Table 104.1, with D_μ carrying that field's own T^a and Y. There is not one free mass in it.

Theorem 104.25 (The breaking pattern)**.** *The potential in Equation (104.27) is minimized on the three-sphere $\Phi^\dagger\Phi = v^2/2$ with $v = \mu/\sqrt{\lambda}$. An $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ rotation brings any point of it to*

$$\Phi_0 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v \end{pmatrix}, \tag{104.29}$$

whose stabilizer is generated by $Q = T^3 + Y/2$ alone. Hence

$$\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y \longrightarrow \mathrm{U}(1)_{em}\,, \tag{104.30}$$

three of the four generators are broken, three of the four real scalar fields become the longitudinal polarizations of $W^\pm$ and Z^0, one real scalar survives as a particle, and the photon is exactly massless.

Rests on Equation (104.27) and Theorems 104.17 and 104.22.

Proof. *Derives Theorem 104.25.*

The potential depends on Φ only through $\rho = \Phi^\dagger\Phi$, so Proposition 104.15 applies verbatim with $|\phi|^2$ replaced by ρ: the minimum is at $\rho = \mu^2/2\lambda = v^2/2$. The set of Φ with $\Phi^\dagger\Phi = v^2/2$ is a sphere S^3 in the four real dimensions of the doublet, and SU(2) acts transitively on S^3 (it *is* S^3 as a manifold), so every minimum is gauge-equivalent to Equation (104.29).

For the stabilizer, compute the action of each generator on Φ_0. With $T^a = \frac{1}{2}\sigma^a$ and $Y = 1$,

$$\begin{aligned} T^1\Phi_0 &= \frac{v}{2\sqrt{2}} \begin{pmatrix} 1 \\ 0 \end{pmatrix}, & T^2\Phi_0 &= \frac{-\mathrm{i}v}{2\sqrt{2}} \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \\ T^3\Phi_0 &= \frac{-v}{2\sqrt{2}} \begin{pmatrix} 0 \\ 1 \end{pmatrix}, & \frac{Y}{2}\Phi_0 &= \frac{v}{2\sqrt{2}} \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \end{aligned} \tag{104.31}$$

none of which vanishes: each of the four generators moves the vacuum. But the combination $Q = T^3 + Y/2$ does annihilate it, by the last two lines of Equation (104.31), and it is the only combination that does, since the first two lines are linearly independent of one another and of the third. The unbroken subgroup is therefore one-dimensional and generated by Q, which is Equation (104.30); that Q is the electric charge is Equation (104.13), so what survives is electromagnetism and not some other U(1).

By Theorem 104.17 the ungauged model would have $\dim G - \dim H = 4 - 1 = 3$ massless scalars, leaving $4 - 3 = 1$ massive one. By Theorem 104.22 the gauge-boson mass matrix has rank 3 and a one-dimensional kernel spanned by the generator Q, so exactly one vector — the photon — stays massless, exactly to all orders by Remark 104.23, and three become massive by absorbing the three Goldstone modes. □

Proposition 104.26 (The vacuum expectation value in SI)**.** *Matching the low-energy limit of W exchange to the Fermi constant, Equation (104.4), fixes*

$$v^2 = \frac{(\hbar c)^2}{\sqrt{2}G_F}\,, \qquad E_v = v\sqrt{\hbar c} = \left(\frac{(\hbar c)^3}{\sqrt{2}G_F}\right)^{1/2} = 246.22\,\mathrm{GeV}\,, \tag{104.32}$$

that is $E_v = 3.9449 \times 10^{-8}\,\mathrm{J}$, $v = 2.2186 \times 10^{5}\,\mathrm{J}^{1/2}/\mathrm{m}^{1/2}$, and an associated length

$$\frac{\hbar c}{E_v} = 8.0143 \times 10^{-19}\,\mathrm{m} = 0.801\,43\,\mathrm{am}\,. \tag{104.33}$$

Rests on Equations (104.3) and (104.4).

Derivation. *Derives Proposition 104.26.*

The W mass is computed in Theorem 104.28 below as $M_W c^2 = \frac{1}{2}\hat{g}E_v$; substituting it into the matching condition Equation (104.4),

$$\frac{G_F}{\sqrt{2}\,(\hbar c)^3} = \frac{\hat{g}^2}{8\,(M_W c^2)^2} = \frac{\hat{g}^2}{8\cdot\frac{1}{4}\hat{g}^2E_v^2} = \frac{1}{2E_v^2}\,,$$

so $E_v^2 = (\hbar c)^3/\sqrt{2}G_F$, which is Equation (104.32); the coupling $\hat{g}$ has cancelled, which is why v is known far more precisely than either boson mass. Numerically, with $\sqrt{2} \times 1.166\,378\,7 \times 10^{-5} = 1.649\,508\,6 \times 10^{-5}$ from Equation (104.3), the reciprocal is $60\,624.1\,\mathrm{GeV}^2$ and its square root is $246.220\,\mathrm{GeV}$. Converting, $246.220\,\mathrm{GeV} \times 1.602\,176\,634 \times 10^{-10}\,\mathrm{J/GeV} = 3.944\,87 \times 10^{-8}\,\mathrm{J}$; dividing by $\sqrt{\hbar c} = 1.778\,068\,3 \times 10^{-13}\,\mathrm{J}^{1/2}\,\mathrm{m}^{1/2}$ gives v; and dividing $\hbar c = 3.161\,527 \times 10^{-26}\,\mathrm{J\,m}$ by E_v gives Equation (104.33). □

Remark 104.27 (What 246 GeV is, and what it is not)*.* E_v is not a mass and not the energy of anything. It is the value of a field, converted to an energy by the two constants available; the physical content of Equation (104.33) is that the electroweak condensate has a structure length of 0.8 am, about a thousandth of a proton radius ($8.4075 \times 10^{-16}\,\mathrm{m}$, [2431]). Every mass in the electroweak sector is E_v times a dimensionless coupling, so what the Standard Model explains is mass *ratios*; the overall scale is one input number, and why it is 10^{-17} of any gravitational scale is Section 104.8.2.

Theorem 104.28 (The gauge boson masses)**.** *With the vacuum Equation (104.29), the quadratic terms in the gauge fields obtained from $(D_\mu\Phi_0)^\dagger\,(D^\mu\Phi_0)$ are*

$$\frac{g^2v^2}{4\hbar^2}W_\mu^+W^{-\mu} + \frac{v^2}{8\hbar^2}\left(gW_\mu^3 - g'B_\mu\right)^2\,, \qquad W_\mu^\pm = \frac{W_\mu^1 \mp \mathrm{i}W_\mu^2}{\sqrt{2}}\,, \tag{104.34}$$

and therefore, defining

$$Z_\mu = \frac{gW_\mu^3 - g'B_\mu}{\sqrt{g^2+g'^2}}\,, \qquad A_\mu = \frac{g'W_\mu^3 + gB_\mu}{\sqrt{g^2+g'^2}}\,, \tag{104.35}$$

the masses

$$M_W c^2 = \frac{1}{2}\hat{g}E_v\,, \qquad M_Z c^2 = \frac{1}{2}\sqrt{\hat{g}^2+\hat{g}'^2}\,E_v\,, \qquad M_\gamma = 0\,, \tag{104.36}$$

with $\hat{g}$, $\hat{g}'$ and E_v as in Notation 104.1.

Rests on Equation (104.29), Notation 104.1, and Theorem 104.22.

Proof. *Derives Theorem 104.28.*

Since $\partial_\mu\Phi_0 = 0$, $D_\mu\Phi_0 = \frac{\mathrm{i}}{\hbar}\left(gW_\mu^aT^a + \frac{1}{2}g'B_\mu\right)\Phi_0$, using $Y = 1$. Then

$$(D_\mu\Phi_0)^\dagger\,(D^\mu\Phi_0) = \frac{1}{\hbar^2}\Phi_0^\dagger\left(gW_\mu^aT^a + \tfrac{1}{2}g'B_\mu\right)\left(gW^{b\mu}T^b + \tfrac{1}{2}g'B^\mu\right)\Phi_0\,.$$

Insert $T^a = \frac{1}{2}\sigma^a$ and $\Phi_0 = \frac{v}{\sqrt{2}}(0,1)^{\mathsf{T}}$. The matrix in the middle is

$$\frac{1}{2}\begin{pmatrix} gW^3 + g'B & g\,(W^1 - \mathrm{i}W^2) \\ g\,(W^1 + \mathrm{i}W^2) & -gW^3 + g'B \end{pmatrix} = \frac{1}{2}\begin{pmatrix} gW^3 + g'B & \sqrt{2}gW^+ \\ \sqrt{2}gW^- & -gW^3 + g'B \end{pmatrix},$$

so acting on Φ_0 it returns $\frac{v}{2\sqrt{2}}\left(\sqrt{2}gW_\mu^+, -gW_\mu^3 + g'B_\mu\right)^{\mathsf{T}}$, whose squared norm is

$$\frac{v^2}{8}\left[2g^2 W_\mu^+ W^{-\mu} + \left(gW_\mu^3 - g'B_\mu\right)^2\right],$$

which divided by $\hbar^2$ is Equation (104.34). Note that B_μ and W_μ^3 enter only through the single combination $gW^3 - g'B$: the orthogonal combination A_μ of Equation (104.35) is absent, so it has no mass, which is the algebraic form of Theorem 104.22 here.

Reading off the masses requires the Proca normalizations. A complex vector has mass term $\mu_0^{-1}\,(M_W c/\hbar)^2\, W_\mu^+ W^{-\mu}$ and a real one $\frac{1}{2\mu_0}\,(M_Z c/\hbar)^2\, Z_\mu Z^\mu$, so

$$M_W^2 = \frac{\mu_0 g^2 v^2}{4c^2}, \qquad M_Z^2 = \frac{\mu_0\,(g^2 + g'^2)\,v^2}{4c^2}.$$

Now convert to the hatted couplings. With $g = \hat{g}\sqrt{\varepsilon_0 \hbar c}$ from Equation (104.1) and $v = E_v/\sqrt{\hbar c}$ from Equation (104.2),

$$M_W c^2 = \frac{c\sqrt{\mu_0}\,g v}{2} = \frac{c\sqrt{\mu_0\varepsilon_0}\,\hat{g}\sqrt{\hbar c}\,E_v}{2\sqrt{\hbar c}} = \frac{\hat{g}E_v}{2},$$

because $c\sqrt{\mu_0\varepsilon_0} = 1$ exactly. The same substitution in M_Z gives the second of Equation (104.36). Dimensionally $\mu_0 g^2 v^2/c^2$ carries $\mathrm{kg\,m/C^2 \times C^2 \times J/m \times s^2/m^2 = kg^2}$, as a squared mass must. □

Corollary 104.29 (The physical scalar and its self-coupling)**.** *Writing* $\Phi = \frac{1}{\sqrt{2}}\,(0, v + h)^{\mathsf{T}}$ *in unitary gauge, the surviving real scalar* h *has*

$$m_h c^2 = \hbar c\, v\sqrt{2\lambda} = \sqrt{2\hat{\lambda}}\,E_v, \qquad \hbar\mu c = \frac{m_h c^2}{\sqrt{2}}, \tag{104.37}$$

and the measured $m_h c^2 = (125.20 \pm 0.11)\,\mathrm{GeV}$ *[2427] gives*

$$\hat{\lambda} = \frac{1}{2}\left(\frac{m_h c^2}{E_v}\right)^2 = 0.1293, \qquad \hbar\mu c = 88.53\,\mathrm{GeV}. \tag{104.38}$$

Rests on Equations (104.14) *and* (104.16) *and Notation 106.23.*

Proof. *Derives Corollary 104.29.*

The potential restricted to the radial direction is Equation (104.14) with $|\phi|^2 = (v + h)^2/2$, so Equation (104.16) applies unchanged: the h mass term is $\frac{1}{2}(2\lambda v^2)h^2$, which by Notation 106.23 means $(m_h c/\hbar)^2 = 2\lambda v^2$. Multiplying by $(\hbar c)^2$, $(m_h c^2)^2 = 2(\hbar c)^2\lambda v^2 = 2(\lambda\hbar c)(v^2\hbar c) = 2\hat{\lambda}E_v^2$, which is Equation (104.37); and $\mu^2 = \lambda v^2$ gives $\hbar\mu c = m_h c^2/\sqrt{2}$. Numerically $m_h c^2/E_v = 125.20/246.22 = 0.508\,48$, whose square halved is $0.129\,28$, and $125.20/\sqrt{2} = 88.53$. □

Remark 104.30 (The energy stored in the vacuum). Proposition 104.15 gives the depth of the well as $V_{\min} = -\lambda v^4/4 = -\hat{\lambda}E_v^4/4(\hbar c)^3$, which with Equation (104.38) is $-2.5 \times 10^{45}\,\mathrm{J/m^3}$. Gravity responds to absolute energy density, and the observed dark-energy density is of order $1 \times 10^{-9}\,\mathrm{J/m^3}$ [2348]: the electroweak condensate alone exceeds it by some 54 orders of magnitude. Nothing in this chapter, or anywhere in the Standard Model, cancels that. It is recorded here because it is a consequence of the mechanism just derived and not of anything speculative, and it is taken up as an open problem in Chapter 133.

104.4.2 Mixing and the weak mixing angle

The rotation Equation (104.35) is a rotation by an angle, and Proposition 101.67 has already carried out the consequences for the fermion couplings. Collecting what Theorem 104.28 adds:

Proposition 104.31 (The tree-level electroweak relations)**.** *Define* θ_W *by*

$$\cos\theta_W = \frac{\hat{g}}{\sqrt{\hat{g}^2+\hat{g}'^2}}\,, \qquad \sin\theta_W = \frac{\hat{g}'}{\sqrt{\hat{g}^2+\hat{g}'^2}}\,. \tag{104.39}$$

Then

$$M_W c^2 = \frac{1}{2}\hat{g}E_v\,, \qquad \frac{M_W}{M_Z} = \cos\theta_W\,, \qquad \hat{e} = \hat{g}\sin\theta_W = \hat{g}'\cos\theta_W\,, \tag{104.40}$$

and, eliminating $\hat{g}$ *in favour of* $\hat{e}$ *and* E_v *and using Equation* (104.32)*,*

$$\left(M_W c^2\right)^2 \sin^2\theta_W = \frac{\pi\alpha\,(\hbar c)^3}{\sqrt{2}G_F} = 1389.8\,\mathrm{GeV}^2\,. \tag{104.41}$$

Four measurable quantities — α, G_F, M_W, M_Z — are thus expressed through three parameters $\hat{g}$, $\hat{g}'$, v, so one relation among them is a prediction.

Rests on Equations (104.32) *and* (104.36) *and Proposition 101.67.*

Proof. *Derives Proposition 104.31.*

The first two of Equation (104.40) are Equation (104.36) with Equation (104.39). The third is Equation (101.73), whose derivation is Proposition 101.67: substituting Equation (104.35) into Equation (104.11), the coefficient of A_μ is $\hat{g}\sin\theta_W T^3 + \hat{g}'\cos\theta_W Y/2$, which is proportional to $Q = T^3 + Y/2$ if and only if the two coefficients coincide, and then their common value is $\hat{e}$. For Equation (104.41), square the first relation and use $\hat{g}\sin\theta_W = \hat{e}$: $(M_W c^2)^2\sin^2\theta_W = \frac{1}{4}\hat{e}^2E_v^2 = \pi\alpha E_v^2$, since $\hat{e}^2 = 4\pi\alpha$; and $E_v^2 = (\hbar c)^3/\sqrt{2}G_F$ by Equation (104.32). Numerically, $\pi \times 7.297\,352\,564\,3 \times 10^{-3} \times 60\,624.1\,\mathrm{GeV}^2 = 1389.8\,\mathrm{GeV}^2$. □

Two numbers can now be extracted from the measured masses.

Proposition 104.32 (The couplings, from the masses)**.** *With* $M_W c^2 = (80.369 \pm 0.013)\,\mathrm{GeV}$ *and* $M_Z c^2 = (91.1880 \pm 0.0020)\,\mathrm{GeV}$ *[2427] and* E_v *from Equation* (104.32)*,*

$$\hat{g} = 0.6528\,, \qquad \hat{g}' = 0.3500\,, \qquad \sin^2\theta_W\big|_{\text{on-shell}} = 1 - \frac{M_W^2}{M_Z^2} = 0.2232\,. \tag{104.42}$$

The value of $\hat{e}$ *implied by Equation* (104.40) *is then* 0.3084*, corresponding to* $\alpha = \hat{e}^2/4\pi = 1/132.1$ *— which is neither* $\alpha(0) = 1/137.036$ *[2431] nor* $\alpha(M_Z c^2) = 1/128.94$ *(Phenomenon 100.62), but lies between them.*

Rests on Equations (104.32) *and* (104.40)*.*

Derivation. *Derives Proposition 104.32.*

$\hat{g} = 2M_W c^2/E_v = 2(80.369)/246.220 = 0.652\,82$, and $\sqrt{\hat{g}^2+\hat{g}'^2} = 2M_Z c^2/E_v = 2(91.1880)/246.220 = 0.740\,70$, whence $\hat{g}'^2 = 0.548\,643 - 0.426\,179 = 0.122\,464$ and $\hat{g}' = 0.349\,95$. Then $\sin^2\theta_W = \hat{g}'^2/(\hat{g}^2+\hat{g}'^2) = 0.122\,464/0.548\,643 = 0.223\,21$, which is also $1 - (80.369/91.1880)^2$ as Equation (104.40) requires. Finally $\hat{e} = \hat{g}\sin\theta_W = 0.652\,82 \times 0.472\,45 = 0.308\,43$ and $\hat{e}^2/4\pi = 0.095\,129/12.566\,37 = 0.007\,569\,9 = 1/132.10$. □

Remark 104.33 (Why the tree relations do not close, and by how much). Proposition 104.32 is the chapter's first honest failure and it is instructive. Four measured quantities were fitted with three parameters, and the leftover is a 3.7 per cent discrepancy in $\hat{e}^2$ — far outside every experimental error. Nothing is wrong: the relations are tree-level, and a one-loop

electroweak theory is not a tree-level one. The discrepancy is conventionally packaged as a single correction Δr defined by replacing Equation (104.41) with

$$\left(M_W c^2\right)^2 \left(1 - \frac{M_W^2}{M_Z^2}\right) = \frac{\pi \alpha \, (\hbar c)^3}{\sqrt{2} G_F \, (1 - \Delta r)} \, , \tag{104.43}$$

and its value follows from the measured masses. Solving Equation (104.43) for M_W with $\Delta r = 0$ and $\alpha = \alpha(0)$ gives

$$\left(M_W c^2\right)^2 = \frac{\left(M_Z c^2\right)^2}{2} \left[1 + \sqrt{1 - \frac{4 \times 1389.8 \, \mathrm{GeV}^2}{\left(M_Z c^2\right)^2}}\right] ,$$

that is $M_W c^2 = 80.94 \, \mathrm{GeV}$, against the measured $80.369 \, \mathrm{GeV}$; matching them requires $\Delta r = 0.036$. Two effects account for most of it, and they act in opposite directions. The running of the electromagnetic coupling from zero momentum transfer to $M_Z c^2$ (Phenomenon 100.62), with $\alpha^{-1}(M_Z c^2) = 128.94$, contributes $\Delta\alpha = 1 - \alpha(0)/\alpha(M_Z c^2) \approx 0.059$, and the top quark contributes $-\left(\cos^2\theta_W / \sin^2\theta_W\right) \Delta\rho \approx -3.48 \times 0.0093 = -0.032$ through Equation (104.52) below; the sum, 0.027, lands within about 0.009 of the required 0.036, the remainder coming from the scalar-mass logarithm, the remaining bosonic self-energies and higher orders. That these two one-loop terms capture the bulk of a 3.7 per cent effect — and that the rest is calculable — is the reason the electroweak fit of Section 104.6.4 can measure the top and scalar masses without producing either particle.

Remark 104.34 (There is no such thing as *the* weak mixing angle). Proposition 104.32 defines $\sin^2\theta_W$ by the mass ratio. Other definitions are in use and they do not agree, because beyond tree level the angle is a renormalized quantity and a renormalized quantity needs a scheme (Definition 100.54). Three are standard:

- the *on-shell* angle, $s_W^2 := 1 - M_W^2/M_Z^2 = 0.2232$, defined to all orders by the physical masses;
- the $\overline{\mathrm{MS}}$ angle at the Z scale, $\hat{s}_Z^2 = 0.231\,29 \pm 0.000\,04$, defined by the ratio of running couplings in the scheme of Equation (100.75);
- the *effective leptonic* angle $\sin^2\theta_{\mathrm{eff}}^{\ell} = 0.231\,55 \pm 0.000\,04$, defined so that the measured Z-pole asymmetries take their tree-level form,

the last two as quoted in the electroweak review of [2427]. The differences, about one per cent, are hundreds of times the experimental errors, so a number quoted without its scheme is not a measurement of anything. This is why the honest statement of the unification test is Phenomenon 104.55: not that some number equals 0.23, but that one running, scheme-defined angle fits every process at every momentum transfer.

The first determination of the angle away from the Z was Prescott's measurement of the parity-violating asymmetry in the scattering of longitudinally polarized electrons from deuterium at SLAC [1625], which gave $\sin^2\theta_W = 0.20 \pm 0.03$, sharpened to 0.224 ± 0.020 by the follow-up scan over beam energies [1643]; the measurement belongs to Chapter 110. Its significance was not the number but that the number agreed with the one Gargamelle had extracted from neutrino scattering in an entirely different process.

Phenomenon 104.35 (The boson masses and the mixing angle are not independent)**.** The measured masses of the two weak bosons,

$$m_W c^2 = (80.369 \pm 0.013) \, \mathrm{GeV} \, , \qquad m_Z c^2 = (91.1880 \pm 0.0020) \, \mathrm{GeV} \tag{104.44}$$

[2427] determine a mixing angle through $\cos\theta_W = m_W/m_Z$, and that angle agrees with the one determined independently from the neutral-current couplings of Phenomenon 104.55. Equivalently the parameter

$$\rho := \frac{m_W^2}{m_Z^2 \cos^2\theta_W} \tag{104.45}$$

is measured to be unity to within the small radiative corrections [2104, 2427]. Three quantities measured in unrelated ways — two masses and a coupling ratio — satisfy one relation that nothing obliged them to satisfy. The statement has content only when the same renormalization scheme defines the angle on both sides: taken as a *definition* of θ_W from the masses, $\rho = 1$ says nothing, and what is tested is the agreement of that angle with the one the couplings give.

Rests on Equations (104.36) *and* (104.39).

Derivation. *Derives Phenomenon 104.35.*

The masses are Equation (104.36), so $m_W^2/m_Z^2 = \hat{g}^2/(\hat{g}^2 + \hat{g}'^2) = \cos^2\theta_W$ by Equation (104.39), and Equation (104.45) gives $\rho = 1$ identically. Two features of that one-line computation carry the physics.

First, E_v has cancelled. The relation is therefore a statement about the *representation* the breaking field occupies and not about how strongly the symmetry is broken; it survives any number of doublets and, as Theorem 104.41 shows, fails for almost any other multiplet.

Second, the angle in Equation (104.45) is defined by Equation (104.39) from the couplings, while the ratio on the left is measured from masses. What is tested is that these two determinations agree, and the test is quantitative only when a scheme is fixed, per Remark 104.34. In the on-shell scheme $\rho = 1$ is an identity and the content moves into the agreement of the mass-derived angle with the asymmetry-derived one; in $\overline{\text{MS}}$ the content stays in ρ itself, whose measured deviation from unity is the few-per-mille effect predicted by Equation (104.52). The measured ρ is in either case evidence that the electroweak symmetry is broken by doublets, which is a fact about the vacuum, not a convention. □

104.4.3 Fermion masses and the Yukawa couplings

Equation (104.28) contains no fermion mass term, and that was not an omission.

Proposition 104.36 (Chiral gauge charges forbid a bare Dirac mass)**.** *For any fermion of Table 104.1, the Dirac mass term* $-mc^2\bar{\psi}\psi = -mc^2\left(\bar{\psi}_L\psi_R + \bar{\psi}_R\psi_L\right)$ *is not invariant under* $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$.

Rests on Definition 104.10 and Table 104.1.

Proof. *Derives Proposition 104.36.*

Insert $\psi = \psi_L + \psi_R$ with $\psi_{L,R} = \frac{1}{2}(\mathbb{1} \mp \gamma^5)\psi$ and use $\bar{\psi}_L\psi_L = \bar{\psi}_R\psi_R = 0$, which follows from $\gamma^5\gamma^0 = -\gamma^0\gamma^5$: the mass term connects the two chiralities and nothing else. But ψ_L is a component of an $\mathrm{SU}(2)_L$ doublet while ψ_R is a singlet, so $\bar{\psi}_L\psi_R$ transforms as a doublet, not a singlet, and cannot be a term in an invariant Lagrangian. Even setting the $\mathrm{SU}(2)_L$ aside, the hypercharges do not match: for the electron $Y_L = -1$ and $Y_R = -2$, so $\bar{\psi}_L\psi_R$ carries $Y = -2 - (-1) = -1 \neq 0$ and is not $\mathrm{U}(1)_Y$ invariant either. The statement is not that the electron is massless; it is that its mass cannot be a parameter of the symmetric Lagrangian, and must come from the vacuum. □

Definition 104.37 (Yukawa couplings)**.** Let Q_L, L_L be the left-chiral doublets and u_R, d_R, e_R the singlets, each carrying a generation index $i = 1, 2, 3$. The most general gauge-invariant, renormalizable coupling to Φ is

$$\mathcal{L}_{\text{Yuk}} = -\left[y^d_{ij}\bar{Q}_{Li}\Phi\, d_{Rj} + y^u_{ij}\bar{Q}_{Li}\tilde{\Phi}\, u_{Rj} + y^e_{ij}\bar{L}_{Li}\Phi\, e_{Rj}\right] + \text{h.c.}\,, \tag{104.46}$$

where

$$\tilde{\Phi} := \mathrm{i}\sigma^2\Phi^* = \begin{pmatrix} \Phi^{0*} \\ -\Phi^- \end{pmatrix} \tag{104.47}$$

is the conjugate doublet, which transforms as a doublet with $Y = -1$. The couplings y_{ij} are arbitrary complex matrices of dimension $\mathrm{J}^{1/2}\,\mathrm{m}^{1/2}$, so that $\hat{y} := y/\sqrt{\hbar c}$ is dimensionless.

Derivation of the dimension and of Equation (104.47). *Derives Equation* (104.47).

A fermion bilinear $\bar{\psi}\psi$ carries $1/\mathrm{m}^3$ by Definition 100.2 and Φ carries $\mathrm{J}^{1/2}/\mathrm{m}^{1/2}$, so for Equation (104.46) to be an energy density, $[y] = \mathrm{J}/\mathrm{m}^3 \times \mathrm{m}^3 \times \mathrm{m}^{1/2}/\mathrm{J}^{1/2} = \mathrm{J}^{1/2}\,\mathrm{m}^{1/2}$, and dividing by $\sqrt{\hbar c} = \mathrm{J}^{1/2}\,\mathrm{m}^{1/2}$ leaves a pure number. As for $\tilde{\Phi}$: under $\Phi \mapsto U\Phi$ with $U \in \mathrm{SU}(2)$, $\Phi^* \mapsto U^*\Phi^*$, and the identity $\sigma^2 U^* \sigma^2 = U$, valid for every SU(2) matrix because the doublet representation is *pseudoreal* — unitarily equivalent to its own complex conjugate — gives $\mathrm{i}\sigma^2\Phi^* \mapsto U\,(\mathrm{i}\sigma^2\Phi^*)$. Complex conjugation flips the sign of Y, so $\tilde{\Phi}$ has $Y = -1$, and $\bar{Q}_L\tilde{\Phi}u_R$ carries $Y = -\frac{1}{3} - 1 + \frac{4}{3} = 0$ as required, while $\bar{Q}_L\Phi d_R$ carries $Y = -\frac{1}{3} + 1 - \frac{2}{3} = 0$. Without $\tilde{\Phi}$ the up-type quarks could not be given mass by this doublet at all. □

Theorem 104.38 (Masses, mixing, and where the CKM matrix comes from)**.** *Substituting Equation* (104.29) *into Equation* (104.46) *produces mass matrices* $m^f_{ij}c^2 = \hat{y}^f_{ij}E_v/\sqrt{2}$. *Each is a general complex matrix and is brought to non-negative diagonal form by a* biunitary *transformation,*

$$U_f^\dagger m^f V_f = \mathrm{diag}\,(m_{f1}, m_{f2}, m_{f3})\ , \tag{104.48}$$

with U_f *acting on left-chiral and* V_f *on right-chiral fields. In the mass basis so defined,*

1. *the charged current acquires the matrix* $V_{\mathrm{CKM}} = U_u^\dagger U_d$, *which is unitary but not in general diagonal;*
2. *the neutral currents — both the photon's and the* Z*'s — remain exactly diagonal in flavour;*
3. *the couplings of* h *to fermions remain diagonal, and proportional to the masses.*

Rests on Equations (104.29) *and* (104.46) *and Theorem 101.59.*

Proof. *Derives Theorem 104.38.*

With $\Phi \to \Phi_0$ the term $y^d_{ij}\bar{Q}_{Li}\Phi d_{Rj}$ becomes $\left(y^d_{ij}v/\sqrt{2}\right)\bar{d}_{Li}d_{Rj}$, which compared with $-mc^2\bar{\psi}_L\psi_R$ identifies $m^d_{ij}c^2 = \hat{y}^d_{ij}\sqrt{\hbar c}\,v/\sqrt{2} = \hat{y}^d_{ij}E_v/\sqrt{2}$; likewise for u and e, the conjugate doublet supplying $\Phi^{0*} \to v/\sqrt{2}$ for the up type.

For Equation (104.48): given any complex m, the matrix $mm^\dagger$ is Hermitian positive semi-definite, hence $mm^\dagger = U\Sigma^2U^\dagger$ with U unitary and $\Sigma \geq 0$ diagonal, by the spectral theorem for normal operators. Define $V := m^\dagger U\Sigma^{-1}$ where Σ is invertible; then $V^\dagger V = \Sigma^{-1}U^\dagger mm^\dagger U\Sigma^{-1} = \Sigma^{-1}\Sigma^2\Sigma^{-1} = \mathbb{1}$, so V is unitary, and $U^\dagger mV = U^\dagger mm^\dagger U\Sigma^{-1} = \Sigma$. (If Σ has zero entries, restrict to its support and extend V arbitrarily unitarily on the complement.) This is the singular-value decomposition, and the two unitaries are independent precisely because the left- and right-chiral fields are independent — which is possible only because the theory is chiral.

(i) The charged current is $\bar{u}_{Li}\gamma^\mu d_{Li}$ in the gauge basis. Substituting $u_L = U_u u'_L$ and $d_L = U_d d'_L$ with primes denoting mass eigenstates gives $\bar{u}'_L U_u^\dagger\gamma^\mu U_d d'_L = \bar{u}'_L\gamma^\mu\left(U_u^\dagger U_d\right)d'_L$, which is Equation (101.67) with $V_{\mathrm{CKM}} = U_u^\dagger U_d$, manifestly unitary as the product of two unitaries — which is Theorem 101.62 and is what Chapter 5 licenses.

(ii) A neutral current is $\bar{f}_{Li}\gamma^\mu$ (coefficient) f_{Li} with a coefficient depending only on T^3 and Q (Equation (101.75)), hence *the same for every generation*; it is therefore proportional to the identity matrix in generation space, and $U_f^\dagger\mathbb{1}U_f = \mathbb{1}$. Nothing survives the rotation. This is the Glashow–Iliopoulos–Maiani mechanism [1423] in its general form, proved as

Theorem 101.59; note that the argument needs the coefficient to depend only on the gauge quantum numbers, which fails as soon as two fields with the *same* T^3 and Q but different masses can mix — the reason a second scalar doublet, or an extra quark that is not part of a complete doublet, generically produces flavour-changing neutral currents and is excluded by the kaon and B-meson data of Chapter 111.

(iii) The Yukawa term with $\Phi = \frac{1}{\sqrt{2}}(0, v+h)^{\mathsf{T}}$ is the mass term multiplied by $(1 + h/v)$, so the coupling matrix of h is m^f/v — the *same* matrix, diagonalized by the same U_f, V_f. Hence h has no flavour-changing couplings and its coupling to each fermion is $m_f c^2/E_v$ per unit field, which is the statement measured in Phenomenon 104.62. □

Table 104.2: Dimensionless Yukawa couplings $\hat{y}_f = \sqrt{2}\, m_f c^2/E_v$ implied by the measured fermion masses of [2427] and $E_v = 246.22\,\text{GeV}$. The quark masses are scheme-dependent quantities — u, d, s quoted in $\overline{\text{MS}}$ at 2 GeV, c and b at their own scale, the top from direct reconstruction — so these numbers are indicative to a few per cent, not metrological; the point is the range they span. No principle in the Standard Model relates them: they are nine of its free parameters.

Fermion	$m_f c^2$ [GeV]	$\hat{y}_f$
t	172.57	0.991
b	4.183	0.0240
τ	1.776 93	0.0102
c	1.273	0.007 31
μ	0.105 658 4	6.07×10^{-4}
s	0.0935	5.37×10^{-4}
d	0.004 70	2.70×10^{-5}
u	0.002 16	1.24×10^{-5}
e	$5.109\,990 \times 10^{-4}$	2.93×10^{-6}

Remark 104.39 (The one coupling of order unity). Table 104.2 spans a factor of 3.4×10^5 from top to electron. Exactly one entry is of order one, and it is the top's: $\hat{y}_t = 0.991$, within one per cent of unity. Whether that is a coincidence is not known. What is known is that it makes the top quark the dominant virtual particle in every electroweak loop, which is why $\Delta\rho$ in Equation (104.52) goes as m_t^2, why the vacuum stability analysis of Section 104.8.1 turns on the top mass at the 1 GeV level, and why the electroweak fit could locate the top before it was produced. The spread itself is an input, not a prediction: Table 104.2 lists numbers the theory takes from experiment, and Chapter 133 records that no evidence-based explanation of the pattern exists. Neutrino masses are not in the table at all, because Equation (104.46) cannot generate them without a right-chiral neutrino; that the masses are nonetheless non-zero (Chapters 103 and 114) is the one laboratory fact this Lagrangian does not accommodate.

104.4.4 Custodial symmetry and the ρ parameter

$\rho = 1$ came out of Phenomenon 104.35 as an accident of the doublet. It is not an accident: it follows from a global symmetry of the scalar sector that the gauge couplings do not respect, which is why the corrections to it are small and calculable.

Theorem 104.40 (Custodial symmetry)**.** *Assemble the doublet and its conjugate into the* 2×2 *matrix*

$$\mathcal{M} := \begin{pmatrix} \tilde{\Phi} & \Phi \end{pmatrix} = \begin{pmatrix} \Phi^{0*} & \Phi^{+} \\ -\Phi^{-} & \Phi^{0} \end{pmatrix}. \tag{104.49}$$

Then $\Phi^\dagger\Phi = \frac{1}{2}\operatorname{tr}\left(\mathcal{M}^\dagger\mathcal{M}\right)$*, so the scalar potential in Equation* (104.27) *is invariant under the* global *group*

$$\mathcal{M} \longmapsto L\,\mathcal{M}\,R^\dagger\,, \qquad (L,R)\in \mathrm{SU}(2)_L\times\mathrm{SU}(2)_R\,, \tag{104.50}$$

larger than the gauged $\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$*. The vacuum* $\mathcal{M}_0 = \left(v/\sqrt{2}\right)\mathbb{1}$ *is invariant under the diagonal subgroup* $L=R$*, the* custodial $\mathrm{SU}(2)_V$*, under which* (W^1,W^2,W^3) *transforms as a triplet. Hence in the limit* $g'\to 0$ *the three fields have equal masses and* $\rho = 1$ *exactly.*

Rests on Equations (104.27)*,* (104.35) *and* (104.45)*.*

Proof. *Derives Theorem 104.40.*

That $\Phi^\dagger\Phi = \frac{1}{2}\operatorname{tr}(\mathcal{M}^\dagger\mathcal{M})$ is a computation: $\operatorname{tr}(\mathcal{M}^\dagger\mathcal{M}) = 2\left(|\Phi^0|^2+|\Phi^+|^2\right)$, since the two columns of $\mathcal{M}$ have the same norm. A trace of the form $\operatorname{tr}(\mathcal{M}^\dagger\mathcal{M})$ is invariant under Equation (104.50) for any unitary L, R, and the potential depends on $\mathcal{M}$ only through it. The kinetic term is

$$(D_\mu\Phi)^\dagger\,(D^\mu\Phi) = \frac{1}{2}\operatorname{tr}\left[(D_\mu\mathcal{M})^\dagger\,D^\mu\mathcal{M}\right]\,, \qquad D_\mu\mathcal{M} = \partial_\mu\mathcal{M} + \frac{\mathrm{i}g}{\hbar}W_\mu^a T^a\mathcal{M} - \frac{\mathrm{i}g'}{\hbar}B_\mu\mathcal{M}T^3\,,$$

the relative sign in the last term coming from the opposite hypercharge of $\tilde\Phi$. The $\mathrm{SU}(2)_L$ term is invariant under $\mathrm{SU}(2)_R$, since R acts on the right; the $\mathrm{U}(1)_Y$ term is not, because only T^3 of $\mathrm{SU}(2)_R$ is gauged. So $\mathrm{SU}(2)_R$ is a symmetry of the whole Lagrangian when $g'=0$ and of the scalar potential always.

At the vacuum, $\Phi^+=0$ and $\Phi^0 = v/\sqrt{2}$, so $\mathcal{M}_0 = \left(v/\sqrt{2}\right)\mathbb{1}$ and $L\mathcal{M}_0R^\dagger = \mathcal{M}_0$ if and only if $LR^\dagger = \mathbb{1}$, that is $L=R$: the unbroken global group is the diagonal $\mathrm{SU}(2)_V$. Under it the gauge fields W_μ^a, which carry an adjoint index of $\mathrm{SU}(2)_L$, transform as an $\mathrm{SU}(2)_V$ triplet, and a mass matrix invariant under a group that acts irreducibly on a triplet must be proportional to the identity by Schur's lemma (Chapter 5). Hence $M_{W^1} = M_{W^2} = M_{W^3}$ when $g'=0$. Reinstating g' mixes W^3 with B but changes no mass in the W sector, so $M_W = M_{W^3} = M_Z\cos\theta_W$ by Equation (104.35), and Equation (104.45) gives $\rho = 1$. □

Theorem 104.41 (Ross–Veltman: ρ counts the representation)**.** *Let the symmetry be broken by several complex scalar multiplets labelled* i*, the* i*-th having weak isospin* T_i *and acquiring an expectation value* $v_i/\sqrt{2}$ *in the component of third component* T_i^3*, that component being electrically neutral. Then at tree level*

$$\rho = \frac{\sum_i\left[T_i\,(T_i+1) - \left(T_i^3\right)^2\right]v_i^2}{2\sum_i\left(T_i^3\right)^2 v_i^2}\,. \tag{104.51}$$

For doublets ($T=\frac{1}{2}$*,* $T^3=-\frac{1}{2}$) *this is* 1 *for any number of them; for a complex triplet with* $T^3=\pm1$ *it is* $\frac{1}{2}$*; for a triplet breaking through its* $T^3=0$ *component the denominator vanishes. The measurement* $\rho=1$ *is thus evidence about the multiplet structure of the breaking sector [1561, 1659].*

Rests on Theorem 104.28 and Equation (104.45)*.*

Proof. *Derives Theorem 104.41.*

Repeat the computation of Theorem 104.28 for a general multiplet. Writing $T^\pm = T^1\pm\mathrm{i}T^2$ and $W_\mu^\pm = (W_\mu^1 \mp \mathrm{i}W_\mu^2)/\sqrt{2}$, one has $T^1W_\mu^1 + T^2W_\mu^2 = \frac{1}{\sqrt{2}}\left(T^+W_\mu^+ + T^-W_\mu^-\right)$, so the part of $\hbar^{-2}\left|gW_\mu^aT^a\Phi_0\right|^2$ containing $W_\mu^+W^{-\mu}$ is

$$\frac{g^2}{2\hbar^2}\Phi_0^\dagger\left\{T^+,T^-\right\}\Phi_0\,W_\mu^+W^{-\mu} = \frac{g^2}{\hbar^2}\Phi_0^\dagger\left[T\,(T+1) - \left(T^3\right)^2\right]\Phi_0\,W_\mu^+W^{-\mu}\,,$$

using $\{T^+,T^-\}=2\left[(T^1)^2+(T^2)^2\right]=2\left[\boldsymbol{T}^2-(T^3)^2\right]$ and the eigenvalue $T(T+1)$ of the Casimir (Chapter 14). With $\Phi_0^\dagger\Phi_0=v_i^2/2$ in the i-th multiplet, summing over multiplets and matching to the Proca form gives

$$M_W^2=\frac{\mu_0 g^2}{2c^2}\sum_i\left[T_i\left(T_i+1\right)-\left(T_i^3\right)^2\right]v_i^2\,.$$

For the neutral sector, the coefficient of the vacuum in the neutral covariant derivative is $gT^3W_\mu^3+g'\left(Y/2\right)B_\mu$ with $Y/2=Q-T^3$, and $Q\Phi_0=0$ because the component acquiring the expectation value is neutral; hence the coefficient is $\left(gW_\mu^3-g'B_\mu\right)T^3$, and

$$M_Z^2=\frac{\mu_0\left(g^2+g'^2\right)}{c^2}\sum_i\left(T_i^3\right)^2v_i^2\,.$$

Dividing, with $\cos^2\theta_W=g^2/\left(g^2+g'^2\right)$, every coupling cancels and Equation (104.51) remains. Substituting $T=\frac12$, $T^3=-\frac12$ gives numerator $\left(\frac34-\frac14\right)v^2$ and denominator $2\cdot\frac14v^2$, equal; substituting $T=1$, $T^3=-1$ gives $(2-1)\,v^2$ over $2v^2$, that is $\frac12$; and $T=1$, $T^3=0$ gives $2v^2$ over 0. □

Custodial symmetry is broken by two things in the real theory, and each produces a calculable shift.

Proposition 104.42 (The sources of custodial violation)**.** *$\mathrm{SU}(2)_V$ is violated (i) by the hypercharge coupling g', which gauges only T^3 of $\mathrm{SU}(2)_R$, and (ii) by the Yukawa matrices, which are $\mathrm{SU}(2)_R$ symmetric only if $y^u=y^d$ within each doublet. Since $\hat y_t=0.991$ and $\hat y_b=0.0240$ by Table 104.2, the third generation violates it maximally, and it dominates.*

Rests on Theorem 104.40 and Equation (104.46).

Proof. *Derives Proposition 104.42.*

(i) is proved inside Theorem 104.40: the B_μ term carries $\mathcal{M}T^3$ on the right and is invariant only under the U(1) subgroup of $\mathrm{SU}(2)_R$ generated by T^3. (ii) follows by writing Equation (104.46) in the $\mathcal{M}$ notation: $\bar Q_L\mathcal{M}\,\mathrm{diag}(y^u,y^d)\,Q_R$ with $Q_R=(u_R,d_R)^{\mathsf T}$ is invariant under $\mathcal{M}\mapsto\mathcal{M}R^\dagger$, $Q_R\mapsto RQ_R$ if and only if $\mathrm{diag}(y^u,y^d)$ commutes with every $R\in\mathrm{SU}(2)$, that is if and only if $y^u=y^d$. □

Proposition 104.43 (The top contribution to ρ)**.** *At one loop the leading custodial violation from the third generation is*

$$\Delta\rho:=\rho-1=\frac{3G_F\left(m_tc^2\right)^2}{8\sqrt2\pi^2\left(\hbar c\right)^3}+\cdots=9.3\times10^{-3}\,,\tag{104.52}$$

for $m_tc^2=(172.57\pm0.29)\,\mathrm{GeV}$ [2427], the omitted terms being the bottom mass (negligible) and the logarithmic scalar contribution. The dependence is quadratic *in the top mass, and only logarithmic in m_h — the screening theorem of Veltman [1612].*

Rests on Proposition 104.42 and Equation (104.32).

Derivation of the parametric form. *Derives Proposition 104.43.*

$\Delta\rho$ measures the difference between the W and Z self-energies at zero momentum, $\Delta\rho=\Pi_{WW}(0)/M_W^2c^2-\Pi_{ZZ}(0)/M_Z^2c^2$, each computed from a quark loop. By Proposition 104.42 the difference vanishes when $m_t=m_b$, so it is proportional to the isospin splitting. Each self-energy carries two Yukawa or gauge vertices and one loop factor $1/16\pi^2$ (Equation (100.82) shows the same factor in QED), and the only dimensionful quantities available are the quark masses and E_v; since $\Delta\rho$ is dimensionless and the vertices are the Yukawa couplings $\hat y\propto m_fc^2/E_v$, the leading term must be $N_c\left(m_tc^2\right)^2/16\pi^2E_v^2$ times a pure number, with

$N_c = 3$ for colour. Writing $E_v^2 = (\hbar c)^3/\sqrt{2}G_F$ turns this into Equation (104.52) up to the pure number, which the explicit loop integration of [1612] fixes to exactly 1: Equation (104.52) *is* $N_c\,(m_t c^2)^2/16\pi^2 E_v^2$. Numerically, $3 \times 1.166\,378\,7 \times 10^{-5} \times (172.57)^2 = 1.0421$ and $8\sqrt{2}\pi^2 = 111.66$, giving 9.33×10^{-3}. That the answer grows with m_t^2 rather than $\ln m_t$ is what made the top mass predictable from LEP data before the Tevatron produced it [1891, 1892]. □

Derivation pending #157

The one-loop coefficient in the top contribution to the rho parameter: the W and Z vacuum-polarization integrals with a t–b doublet in the loop, regulated dimensionally, whose difference at zero momentum transfer gives the factor $3/8\sqrt{2}\pi^2$ quoted from Veltman's paper above; and the accompanying logarithmic dependence on the scalar mass, which is what the screening theorem asserts. Belongs in Appendix A.

Definition 104.44 (The oblique parameters)**.** Corrections that enter only through the gauge-boson self-energies — which is where any heavy new state that does not couple directly to light fermions must show up — are parametrized by three numbers S, T, U [1835], normalized to vanish for the Standard Model at a reference point. T is custodial violation, $\alpha T = \Delta\rho$; S measures the difference between the self-energies at $q^2 = M_Z^2 c^2$ and at $q^2 = 0$; U is rarely significant and is usually fixed to zero. Their measured values are consistent with zero at the level of a few hundredths [2427], which is a quantitative statement that no heavy particle with electroweak quantum numbers has yet made itself felt indirectly.

104.5 Renormalizability

104.5.1 't Hooft's proofs

Between 1967 and 1971 the Weinberg–Salam model was cited about as often as a paper is cited when nobody believes it matters. What changed was not a measurement: 't Hooft proved that the theory makes finite predictions at every order. He did it in two papers, and the citation keys used in this book do *not* follow the order of publication — [1449] is the earlier, on *massless* Yang–Mills fields, and [1448] is the later, on the spontaneously broken case; both entries in the bibliography record the fact.

The massless paper establishes that a pure Yang–Mills theory, gauge fixed by the Faddeev–Popov procedure of Theorem 106.52 with its ghosts, has divergences that are absorbed into a redefinition of the finitely many parameters already present. The broken paper is the one this chapter needs, and its instrument is a family of gauges interpolating between two descriptions each of which makes one property manifest and the other obscure.

Theorem 104.45 (The R_ξ gauges)**.** *Take the abelian Higgs model of Theorem 104.19 and, instead of the unitary gauge, write $\phi = \frac{1}{\sqrt{2}}(v + h + \mathrm{i}\chi)$ with h and χ both retained. Then*

1. *the quadratic Lagrangian contains the mixing term $(qv/\hbar)\,A^\mu \partial_\mu \chi$, which prevents the propagators from being read off;*

2. *adding the gauge-fixing term*

$$\mathcal{L}_{\mathrm{gf}} = -\frac{1}{2\mu_0 \xi}\left(\partial^\mu A_\mu - \xi\mu_0 \frac{qv}{\hbar}\chi\right)^2 \tag{104.53}$$

cancels the mixing exactly and gives χ the mass $\sqrt{\xi}\,m_A$;

3. the gauge propagator becomes

$$\widetilde{D}_{\mu\nu}(k) = \frac{-\mathrm{i}\mu_0\hbar^3 c}{k^2 - m_A^2c^2 + \mathrm{i}\epsilon}\left[\eta_{\mu\nu} - (1-\xi)\,\frac{k_\mu k_\nu}{k^2 - \xi m_A^2 c^2}\right], \tag{104.54}$$

which falls as k^{-2} for every finite ξ;

4. the Faddeev–Popov ghost acquires the same mass $\sqrt{\xi}\,m_A$ and does not decouple.

The limit $\xi \to \infty$ returns the unitary gauge and Equation (101.77); $\xi = 1$ is the 't Hooft–Feynman gauge, in which the propagator is simply $-\mathrm{i}\mu_0\hbar^3 c\,\eta_{\mu\nu}/(k^2 - m_A^2c^2)$.

Rests on Theorem 104.19 and Equations (101.77) and (104.22).

Proof. *Derives Theorem 104.45.*

(i) Expanding $|D_\mu\phi|^2$ with $D_\mu = \partial_\mu + \mathrm{i}qA_\mu/\hbar$ and $\phi = \frac{1}{\sqrt{2}}(v + h + \mathrm{i}\chi)$,

$$|D_\mu\phi|^2 = \frac{1}{2}(\partial h)^2 + \frac{1}{2}(\partial\chi)^2 + \frac{q^2}{2\hbar^2}\left[(v+h)^2 + \chi^2\right]A_\mu A^\mu + \frac{q}{\hbar}A^\mu\left[(v+h)\,\partial_\mu\chi - \chi\,\partial_\mu h\right],$$

whose last bracket contains, at quadratic order, exactly $(qv/\hbar)A^\mu\partial_\mu\chi$. A term linear in A and linear in χ makes the quadratic form non-diagonal in field space.

(ii) Expand Equation (104.53):

$$\mathcal{L}_{\mathrm{gf}} = -\frac{1}{2\mu_0\xi}(\partial^\mu A_\mu)^2 + \frac{qv}{\hbar}(\partial^\mu A_\mu)\,\chi - \frac{\xi\mu_0 q^2 v^2}{2\hbar^2}\chi^2 .$$

The middle term integrates by parts to $-(qv/\hbar)A^\mu\partial_\mu\chi$ up to a total derivative, cancelling (i). The last term is a mass term for χ; comparing with $-\frac{1}{2}(m_\chi c/\hbar)^2\chi^2$ and using $\mu_0 q^2 v^2/\hbar^2 = (m_A c/\hbar)^2$ from Equation (104.22) gives $m_\chi = \sqrt{\xi}\,m_A$. The would-be Goldstone boson thus has a gauge-dependent mass, which is the sharpest possible statement that it is not a particle.

(iii) With the mixing gone, the gauge kernel in momentum space (Fourier convention Equation (100.14)) is

$$\widetilde{M}_{\mu\nu} = -\frac{1}{\mu_0\hbar^2}\left[\left(k^2 - m_A^2c^2\right)\eta_{\mu\nu} - \left(1 - \xi^{-1}\right)k_\mu k_\nu\right],$$

which on the transverse projector $P^{\mathrm{T}}_{\mu\nu} = \eta_{\mu\nu} - k_\mu k_\nu/k^2$ is $-(k^2 - m_A^2c^2)/\mu_0\hbar^2$ and on the longitudinal projector P^{L} is $-(k^2 - \xi m_A^2c^2)/\mu_0\hbar^2\xi$. Inverting on each eigenspace and multiplying by $\mathrm{i}\hbar c$, exactly as in Proposition 100.8, gives

$$\widetilde{D}_{\mu\nu} = -\mathrm{i}\mu_0\hbar^3 c\left[\frac{P^{\mathrm{T}}_{\mu\nu}}{k^2 - m_A^2c^2} + \frac{\xi P^{\mathrm{L}}_{\mu\nu}}{k^2 - \xi m_A^2c^2}\right],$$

and combining the two fractions over the common denominator gives Equation (104.54), since $-(k^2 - \xi m_A^2c^2) + \xi(k^2 - m_A^2c^2) = k^2(\xi - 1)$. As $\xi \to \infty$ the bracket tends to $\eta_{\mu\nu} - k_\mu k_\nu/m_A^2c^2$, which is Equation (101.77): the unitary gauge is the infinite-ξ member of the family, and χ becomes infinitely heavy and drops out, which is why it was absent there.

(iv) The Faddeev–Popov determinant is that of $\delta G/\delta\Lambda$ for G the bracket in Equation (104.53). Under a gauge transformation of parameter Λ, $\delta A_\mu = \partial_\mu\Lambda$ and, from $\phi \mapsto \mathrm{e}^{-\mathrm{i}q\Lambda/\hbar}\phi$ to first order, $\delta\chi = -q\Lambda(v+h)/\hbar$. Hence

$$\frac{\delta G}{\delta\Lambda} = \Box + \xi\left(\frac{m_A c}{\hbar}\right)^2\left(1 + \frac{h}{v}\right),$$

so the ghost has mass $\sqrt{\xi}\,m_A$ and a coupling to h. In the abelian *unbroken* theory this operator is field-independent and the ghosts may be discarded (Corollary 106.53); here they may not. □

Remark 104.46 (What the two limits buy, and why both are needed). Theorem 104.45 is the technical heart of the renormalizability proof. At $\xi \to \infty$ the field content is manifestly physical — one massive vector with three polarizations, one scalar, no ghosts, no Goldstone — so unitarity is evident and power counting fails (Theorem 104.4(ii)). At finite ξ every propagator falls as k^{-2}, so power counting works exactly as in Theorem 100.17 and the theory is renormalizable by inspection, but the spectrum now contains a Goldstone of mass $\sqrt{\xi} m_A$ and a ghost of the same mass, neither of which is a particle. Since ξ is an arbitrary parameter, no observable can depend on it, and Theorem 106.61 proves that none does — so the two descriptions compute the same numbers, and the theory is unitary *and* renormalizable although no single gauge makes both obvious. The masses coinciding is not a coincidence: the Goldstone and the ghost are two members of a BRST quartet (Proposition 106.60) and cancel each other in every physical cut.

Proposition 104.47 (The Goldstone-boson equivalence theorem)**.** *Let $\mathcal{M}^{\mu_1 \cdots \mu_n}$ be an amplitude with n external gauge bosons of mass M and momenta k_i, and let $\mathcal{M}_\chi$ be the corresponding amplitude with each gauge boson replaced by its would-be Goldstone boson. Then at energies $E \gg Mc^2$,*

$$\mathcal{M}\left(W_L^{(1)} \dots W_L^{(n)}\right) = (\mathrm{i})^n \, \mathcal{M}_\chi + \mathcal{O}\left(\frac{Mc^2}{E}\right) . \tag{104.55}$$

Rests on Theorem 104.45 and Equations (104.6) and (106.76).

Derivation. *Derives Proposition 104.47.*

The Slavnov–Taylor identity Equation (106.76), applied to the broken theory in an R_ξ gauge, says that the BRST variation of any correlator vanishes. Applied to a Green function with one gauge leg and the ghost of that leg, it gives the relation between the longitudinal part of the gauge amplitude and the Goldstone amplitude,

$$k_\mu \mathcal{M}^\mu(k) = \mathrm{i} M c \, \mathcal{M}_\chi(k) ,$$

which is the broken-theory counterpart of the transversality $k_\mu \mathcal{M}^\mu = 0$ of Equation (100.18) — the right-hand side is zero only when $M = 0$. Now use Equation (104.6): the longitudinal polarization is $\varepsilon_L^\mu = k^\mu / Mc + v^\mu$ with v^μ of order $Mc/|\boldsymbol{k}|$ and bounded. Contracting,

$$\mathcal{M}(W_L) = \varepsilon_{L\mu} \mathcal{M}^\mu = \frac{k_\mu \mathcal{M}^\mu}{Mc} + v_\mu \mathcal{M}^\mu = \mathrm{i} \mathcal{M}_\chi + \mathcal{O}\left(\frac{Mc^2}{E}\right) ,$$

and iterating over the n legs gives Equation (104.55). (The identity holds with $\mathcal{M}_\chi$ computed in the same R_ξ gauge, and the corrections are uniform in the scattering angle away from the forward region.) □

Remark 104.48 (What the equivalence theorem resolves). An amplitude with longitudinal gauge bosons appeared, in the unitary-gauge computation, to grow like $(E/Mc^2)^n$ because each polarization vector grows. Proposition 104.47 says that the whole amplitude equals a *scalar* amplitude with no growing polarization vectors at all. The individual diagrams therefore must cancel among themselves down to the size of the scalar amplitude, and that cancellation is not optional — it is forced by the Slavnov– Taylor identity, which is forced by the gauge symmetry. It will be used twice: in Theorem 104.51 to bound the scalar mass, and in Phenomenon 104.57 to read the non-abelian group structure off a measured cross-section.

The identities that organize the cancellations to all orders are the non-abelian generalization of the Ward–Takahashi identity of Theorem 100.48, found by Slavnov [1484] and Taylor [1458], and their modern algebraic form is the BRST master equation Equation (106.76) of Section 106.4.2.

Remark 104.49 (A theorem, not a datum, made the model orthodox). No new measurement stood between the general indifference to [1362] in 1968 and its status as the consensus theory in 1972. What changed was 't Hooft's proof [1448, 1463]. This is worth recording plainly in a book organized around evidence: the criterion applied here was internal consistency, and it was applied *before* the decisive experiments — neutral currents in 1973, the bosons in 1983 — which the theory then survived. Consistency is not evidence, and the chapter's evidential claims all rest on Section 104.6; but a theory that cannot be computed cannot be tested, and renormalizability is what made the tests possible.

104.5.2 Dimensional regularization and gauge cancellations

The regulator used throughout is the one 't Hooft and Veltman introduced for this problem [1463] and which Definition 100.30 states: continue the loop integral to $d = 4-2\varepsilon$ dimensions. Its virtue over a momentum cutoff is precisely that it preserves gauge invariance — a cutoff $|\ell| < \Lambda$ is not invariant under a gauge transformation that shifts the loop momentum, and the resulting non-invariant counterterms would include exactly the photon mass term that Theorem 104.8 forbids. The systematic treatment of the scheme dependence belongs to Chapter 108.

Remark 104.50 (One honest blemish: γ^5 in d dimensions). Dimensional regularization has a defect specific to a chiral theory. γ^5 is defined by $\gamma^5 = \mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$, a four-dimensional construction, and there is no continuation to $d \neq 4$ that is simultaneously anticommuting with all γ^μ and consistent with the cyclicity of the trace. The standard resolution splits the Dirac algebra into four-dimensional and $(d-4)$-dimensional parts, at the cost of extra non-invariant counterterms that must be fixed by imposing the Slavnov–Taylor identities by hand. This is not a hidden inconsistency — the identities can be restored order by order — but it is real work, and it is the reason the anomaly of Section 104.5.3 shows up in this scheme as an unavoidable obstruction rather than as an artefact one could regulate away.

The most consequential gauge cancellation in the theory is the one that made the scalar mandatory before it was found.

Theorem 104.51 (Longitudinal W scattering bounds the scalar mass)**.** *Consider $W_L^+W_L^- \to W_L^+W_L^-$ at $\sqrt{s}\,c \gg M_W c^2$. Without the scalar, the $J=0$ partial wave grows as s and violates unitarity. With the scalar of mass m_h included, the growth cancels and the surviving constant amplitude is*

$$a_0 = -\frac{G_F\,(m_h c^2)^2}{4\sqrt{2}\pi\,(\hbar c)^3}\,, \tag{104.56}$$

so that the requirement $|\Re a_0| \le \tfrac{1}{2}$ gives

$$m_h c^2 \le \left(\frac{2\sqrt{2}\pi\,(\hbar c)^3}{G_F}\right)^{1/2} = 873\,\mathrm{GeV}\,, \tag{104.57}$$

improved to 713 GeV *when the coupled channels W_LW_L, Z_LZ_L, hh, hZ_L are diagonalized [1601] (the result was announced in a companion letter the same year). The measured $m_h c^2 = (125.20 \pm 0.11)\,\mathrm{GeV}$ satisfies it with room to spare.*

Rests on Proposition 104.47 and Equations (101.89) and (104.37).

Proof. *Derives Theorem 104.51.*

By Proposition 104.47 the high-energy amplitude equals that for the eaten Goldstone bosons, $\chi^+\chi^- \to \chi^+\chi^-$, computed from the scalar sector alone: the gauge couplings drop out of the leading behaviour entirely. Write the doublet as

$$\Phi = \begin{pmatrix} \chi^+ \\ \frac{1}{\sqrt{2}}\,(v + h + \mathrm{i}\chi^0) \end{pmatrix}\,, \qquad \Phi^\dagger\Phi = \left|\chi^+\right|^2 + \tfrac{1}{2}\left[(v+h)^2 + \left(\chi^0\right)^2\right]\,,$$

and expand $-\lambda(\Phi^\dagger\Phi)^2$. Two vertices matter: the contact term $-\lambda\left|\chi^+\right|^4$ and the coupling $-2\lambda v\, h\left|\chi^+\right|^2$, in which $2\lambda v = \left(m_h c/\hbar\right)^2/v$ by Equation (104.37). Summing the contact term with h exchange in the s and t channels, and using the Mandelstam conventions of Notation 100.1 in which s and t are squared momenta,

$$\mathcal{M} = -\hbar^2\frac{\left(m_h c^2\right)^2}{E_v^2}\left[\frac{s}{s-m_h^2c^2}+\frac{t}{t-m_h^2c^2}\right],$$

the factor $\hbar^2$ being the dimension an amplitude carries in the normalization of Proposition 100.24, and $(m_hc^2)^2/E_v^2 = 2\hat{\lambda}$ by Equation (104.37). The two propagator poles have absorbed the contact term: each channel contributes the vertex $2\lambda v$ twice with a propagator between them, and the leftover constant is exactly the quartic. For $s \gg m_h^2c^2$, and away from the forward region where $|t|$ is also large, both brackets tend to 1 and the amplitude tends to the *constant* $-2\hbar^2(m_hc^2)^2/E_v^2$. That it is constant rather than growing is the cancellation: had the h been absent, only the contact term would survive and the bracket would be $-s/m_h^2c^2$ in disguise — growth without limit.

The $J=0$ projection is $a_0 = \frac{1}{32\pi\hbar^2}\int_{-1}^{1}\mathcal{M}\,\mathrm{d}(\cos\theta)$, the normalization being the one in which $\sigma_J = 16\pi\hbar^2(2J+1)\left|a_J\right|^2/s$ reproduces Equation (101.89). For a constant amplitude the integral is $2\mathcal{M}$, so $a_0 = \mathcal{M}/16\pi\hbar^2$, that is

$$a_0 = -\frac{\left(m_h c^2\right)^2}{8\pi E_v^2},$$

manifestly dimensionless; and $E_v^2 = (\hbar c)^3/\sqrt{2}G_F$ turns it into Equation (104.56). Imposing $|a_0| \le \frac{1}{2}$,

$$\left(m_h c^2\right)^2 \le \frac{2\sqrt{2}\pi\left(\hbar c\right)^3}{G_F} = 2\sqrt{2}\pi \times 85\,735\,\mathrm{GeV}^2 = 7.618\times10^5\,\mathrm{GeV}^2,$$

whose square root is 873 GeV. The coupled-channel analysis replaces the coefficient 1 by 3/2 in the largest eigenvalue, giving $m_hc^2 \le \left(4\sqrt{2}\pi(\hbar c)^3/3G_F\right)^{1/2} = 713\,\mathrm{GeV}$. □

Remark 104.52 (What a failure of the bound would have meant). Theorem 104.51 is a prediction of a very unusual kind: it does not say what exists, it says that *something* must, below about a TeV, or the theory is inconsistent there. Either a scalar with the couplings the mechanism requires, or a strongly interacting sector in which W_LW_L scattering saturates the bound and the perturbative description fails. The two alternatives are distinguishable, and the LHC was built with enough energy to settle it. It found the first (Chapter 113), and the couplings match (Phenomenon 104.62). Had it found the second, this chapter would look very different; had it found neither, the Standard Model would have been falsified as a description of energies above a TeV. That is the sense in which Equation (104.57) was a genuine risk.

104.5.3 Anomaly cancellation

A symmetry of the classical action need not survive quantization. The axial current of a massless Dirac field is conserved classically and not quantum mechanically, by the triangle anomaly of Adler [1388] and of Bell and Jackiw [1391], derived in Theorem 106.87 and measured in the π^0 lifetime (Section 106.7.2). In a *global* symmetry that is a prediction. In a *gauge* symmetry it is fatal, because the Slavnov–Taylor identities on which Theorem 104.45 and Remark 104.46 depend then fail: the unphysical polarizations stop decoupling, the S-matrix stops being unitary and the divergences stop organizing themselves. That is Theorem 106.94.

The electroweak theory is chiral by construction — T^a acts on ψ_L and not on ψ_R — so it is exactly the case in which the anomaly can occur. The condition for it not to is Theorem 106.95: the symmetrized trace $\mathsf{A}^{abc} = \mathrm{tr}(\{T^a, T^b\} T^c)_L - \mathrm{tr}(\{T^a, T^b\} T^c)_R$ must vanish for every triple of gauge generators. Bouchiat, Iliopoulos and Meyer [1467] checked it for this theory and found that it holds — but only for a complete generation, and only with three colours.

Proposition 104.53 (One generation is anomaly free)**.** *With the hypercharges of Table 104.1, in the convention $Q = T^3 + Y/2$, the four independent conditions are satisfied:*

$$[\mathrm{SU}(2)_L]^2\,\mathrm{U}(1)_Y: \quad N_c \cdot \tfrac{1}{3} + 1 \cdot (-1) = \frac{N_c - 3}{3} = 0\,, \tag{104.58}$$

$$[\mathrm{SU}(3)_c]^2\,\mathrm{U}(1)_Y: \quad 2 \cdot \tfrac{1}{3} - \tfrac{4}{3} - \left(-\tfrac{2}{3}\right) = 0\,, \tag{104.59}$$

$$[\mathrm{U}(1)_Y]^3: \quad \left[6\left(\tfrac{1}{3}\right)^3 + 2\,(-1)^3\right] - \left[3\left(\tfrac{4}{3}\right)^3 + 3\left(-\tfrac{2}{3}\right)^3 + (-2)^3\right] = 0\,, \tag{104.60}$$

$$\textit{gravitational}\ \mathrm{U}(1)_Y: \quad \left[6 \cdot \tfrac{1}{3} + 2\,(-1)\right] - \left[3 \cdot \tfrac{4}{3} + 3\left(-\tfrac{2}{3}\right) - 2\right] = 0\,, \tag{104.61}$$

where the multiplicities count colour and SU(2) *components and the first bracket in each of the last two is the left-chiral contribution, the second the right-chiral one.*

Rests on Table 104.1 and Theorem 106.95.

Proof. *Derives Proposition 104.53.*

$[\mathrm{SU}(2)]^3$ vanishes identically because the symmetrized trace of three SU(2) generators is zero in every representation, SU(2) having only real and pseudoreal representations; and $[\mathrm{SU}(3)]^3$ vanishes because the quarks appear in triplet and antitriplet with respect to colour once the two chiralities are combined. What remains is the four displayed conditions.

For Equation (104.58): only $\mathrm{SU}(2)_L$ doublets contribute, each with $\mathrm{tr}(\{T^a, T^b\}) = \delta^{ab}$, so the condition is $\sum_{\text{doublets}} Y = 0$ with colour multiplicity; the quark doublet contributes $N_c \times \frac{1}{3}$ and the lepton doublet -1. This is where the number of colours enters: the condition fixes $N_c = 3$.

For Equation (104.59): only coloured fields contribute, with $\mathrm{tr}(\{T^a, T^b\}) = \delta^{ab}$ for the fundamental, so the condition is $\sum_L Y - \sum_R Y = 0$ over the quark SU(2) components: the left doublet supplies $2 \times \frac{1}{3}$ and the right singlets $\frac{4}{3}$ and $-\frac{2}{3}$.

For Equation (104.60): the trace is $\sum Y^3$ with all multiplicities. Left: 6 quark states (three colours, two isospin) of $Y = \frac{1}{3}$, giving $6/27$, plus 2 lepton states of $Y = -1$, giving -2; total $-\frac{16}{9}$. Right: $3(\frac{4}{3})^3 = \frac{64}{9}$, $3(-\frac{2}{3})^3 = -\frac{8}{9}$, and $(-2)^3 = -8$; total $\frac{56}{9} - 8 = -\frac{16}{9}$. Equal.

For Equation (104.61), the triangle with two insertions of the energy–momentum tensor requires $\sum Y = 0$ separately for each chirality summed with sign: left gives $2 - 2 = 0$, right gives $4 - 2 - 2 = 0$. This is a statement about the electroweak currents in a fixed classical background metric and not a claim about quantum gravity.

In every case the quarks alone fail and the leptons alone fail; only the complete generation cancels. Proposition 106.96 does the same arithmetic in the halved-hypercharge convention of Remark 104.11, with identical conclusions. □

Remark 104.54 (The condition read backwards predicted the top). Proposition 104.53 is usually presented as a consistency check. Read the other way it is a prediction. When the b quark was found in 1977 [1597], the third generation had a charged lepton, a neutrino and a charge $-\frac{1}{3}$ quark, and Equation (104.58) then reads $N_c Y_Q + Y_L \neq 0$ unless the b has an $\mathrm{SU}(2)_L$ partner of charge $+\frac{2}{3}$. The theory therefore required a top quark — not as an aesthetic preference but because without it the theory does not exist — and it was found eighteen years later [1891, 1892] with the mass the electroweak fit had by then indicated. The same argument forbids a fourth generation consisting of leptons alone, and Phenomenon 101.76 independently excludes a fourth light neutrino.

104.6 Experimental confirmation

104.6.1 Weak neutral currents

The neutral current is the model's first genuinely new prediction. Every weak process known in 1970 changed the charge of the fermions involved; Proposition 101.67 says a fourth current exists which changes neither charge nor flavour, with a strength fixed relative to the charged current by the single angle θ_W. A theory of this kind is falsifiable in the strongest sense: it predicted a class of events nobody had seen.

Gargamelle was a heavy-liquid bubble chamber of about $12\,\mathrm{m}^3$, filled with freon, exposed at CERN to a neutrino beam. The signature of a neutral-current event is what is *not* there: hadrons produced with no outgoing muon. Two publications in 1973 carried the discovery. The leptonic one [1503] rests on a single event, $\bar{\nu}_\mu e^- \to \bar{\nu}_\mu e^-$ — one electron recoiling with nothing else in the chamber — for which the expected background was a small fraction of an event; the hadronic one [1502] reports a sample of muonless hadronic events at a rate of about 0.2 of the charged-current rate. The credibility of the second rested on an argument about backgrounds rather than on the events themselves: neutrons produced by neutrino interactions in the surrounding material could enter the chamber and produce hadrons with no muon. The collaboration showed that such events would cluster near the chamber walls and fall off with depth, whereas the observed muonless events were distributed through the fiducial volume exactly as the charged-current events were. Phenomenon 101.72 states the result and Proposition 101.71 computes the cross-sections it is compared with.

Confirmation in a different process came from SLAC experiment E122 [1625]: longitudinally polarized electrons scattered from deuterium show an asymmetry between the two helicities, of order 10^{-4}, which arises only from the interference of the electromagnetic amplitude with a parity-violating neutral-current one. The measurement gave $\sin^2\theta_W = 0.20 \pm 0.03$ [1625], refined to 0.224 ± 0.020 by the 1979 scan over beam energies [1643], and, crucially, excluded the alternative models then in play — several of which reproduced the Gargamelle neutrino data with a parity-conserving neutral current and were killed by this single number. The apparatus belongs to Chapter 110.

Phenomenon 104.55 (One mixing angle describes every neutral-current measurement)**.** The weak neutral current is not the electromagnetic one. It couples to neutrinos, which carry no electric charge [1502, 1503], and it violates parity, as the asymmetry between the scattering of right- and left-handed polarized electrons from deuterium first showed [1625]. One parameter, the weak mixing angle, fixes its strength relative to electromagnetism in every process, and the value extracted from neutrino scattering, from polarized electron scattering, from atomic parity violation and from the asymmetries on the Z resonance is the same,

$$\sin^2\theta_W \approx 0.231 \tag{104.62}$$

in the conventions of [2427], over momentum transfers spanning several orders of magnitude. That one number should serve for all of them is the empirical content of unification.

Rests on Equations (104.35) *and* (104.40) *and Proposition 101.67.*

Derivation. *Derives Phenomenon 104.55.*

Three steps: the rotation that produces the current, the couplings it gives each fermion, and the reason a scheme must be attached to any number quoted.

The rotation. The neutral part of Equation (104.11) is $\hbar^{-1}\left(gT^3W_\mu^3 + g'\frac{Y}{2}B_\mu\right)$. Substituting Equation (104.35) and demanding that the massless combination A_μ couple to Q and to nothing else forces $\hat{e} = \hat{g}\sin\theta_W = \hat{g}'\cos\theta_W$, which is Equation (104.40); the orthogonal combination then couples to $T^3 - \sin^2\theta_W Q$ with strength $\hat{e}/\sin\theta_W\cos\theta_W$. This is Proposition 101.67, proved there in full.

The couplings. Projecting onto chiralities gives Equation (101.75): for each fermion

$$g_V = T^3 - 2Q\sin^2\theta_W\,, \qquad g_A = T^3\,,$$

with T^3 that of the *left-chiral* component. The whole predictive content follows: the neutrino has $Q = 0$, so $g_V = g_A = \frac{1}{2}$ and its neutral-current coupling is independent of θ_W — which is why the ratio of neutral- to charged-current neutrino cross-sections measures the angle cleanly. The electron has $g_A = -\frac{1}{2}$ and $g_V = -\frac{1}{2} + 2\sin^2\theta_W$, which is small and changes sign near $\sin^2\theta_W = \frac{1}{4}$: a parity-violating electron asymmetry is therefore a sensitive, and sign-carrying, probe. The Z-pole asymmetries measure the combination $\mathcal{A}_f = 2g_V g_A/(g_V^2 + g_A^2)$, which for the electron is a steep function of $\sin^2\theta_W$ for exactly the same reason. Four independent kinds of measurement thus depend on one number in four different functional ways, and that is what makes their agreement a test rather than a fit.

The scheme. Beyond tree level, θ_W is not a parameter of the Lagrangian but a renormalized quantity, and different definitions differ by finite amounts of order α/π — the three standard ones are listed in Remark 104.34 and differ by about one per cent, which is hundreds of times the experimental errors. Worse, in the $\overline{\text{MS}}$ scheme the angle *runs*: the same definition gives about 0.2313 at $\mu = M_Z c^2$ and about 0.2387 at $\mu \to 0$, the difference being real physics — vacuum polarization by charged particles, Section 100.7 — and not a change of convention. Table 104.3 lists the determinations across momentum transfer, and the content of Equation (104.62) is that one running curve passes through all of them. A number quoted without its scheme and its scale is not a measurement. □

Table 104.3: Determinations of the weak mixing angle across six orders of magnitude in momentum transfer, as quoted by the experiments. The low-Q entries are expressed in the $\overline{\text{MS}}$ scheme, in which the angle runs, so they are not expected to equal the Z-pole value: the prediction is the *difference*, about 0.007 between $Q = 0$ and $Q = M_Z c$, and it is what the table tests. Uncertainties are as published and are combined statistical and systematic.

Measurement	Momentum transfer	$\sin^2\theta_W$	Reference
Cesium atomic parity violation	≈ 0	≈ 0.24	[1946]
Polarized Møller scattering, SLAC E158	$Q^2 = 0.026\,\text{GeV}^2/c^2$	0.2397 ± 0.0013	[2069]
Polarized *ep* scattering, Qweak	$Q = 0.157\,\text{GeV}/c$	0.2383 ± 0.0011	[2301]
Polarized *ed* scattering, SLAC E122	$Q^2 \approx 1.5\,\text{GeV}^2/c^2$	$\approx 0.20 \pm 0.03$	[1625]
Z-pole asymmetries, LEP and SLD	$Q = M_Z c$	$0.231\,53 \pm 0.000\,16$	[2104]

104.6.2 Discovery of the W and Z bosons

By 1980 the masses were predicted. Putting $\sin^2\theta_W = 0.23$ from Table 104.3 into Equation (104.41),

$$M_W c^2 = \frac{37.28\,\text{GeV}}{\sin\theta_W} \approx 78\,\text{GeV}\,, \qquad M_Z c^2 = \frac{M_W c^2}{\cos\theta_W} \approx 89\,\text{GeV}\,, \tag{104.63}$$

at tree level, and about 80 GeV and 91 GeV once Δr of Remark 104.33 is included — numbers derived from a neutrino cross-section and a muon lifetime, with no collider involved.

Producing them required a beam of a few hundred GeV in the centre of mass, and CERN got one by converting the SPS into a proton–antiproton collider. The enabling invention was stochastic cooling [1760]: a pickup senses the deviation of a sample of the circulating beam from the mean orbit, and a kicker one straight section downstream applies a correcting impulse, reducing the phase-space volume of the antiproton beam by many orders of magnitude over hours. Without it there is no way to accumulate enough antiprotons.

The signature is a lepton of high transverse momentum with nothing balancing it. UA1 [1710] and UA2 [1714] reported in 1983 events with an isolated electron of $p_T \gtrsim 20\,\mathrm{GeV}/c$ and large missing transverse energy — the neutrino — from $W \to e\nu$. The mass is read from the transverse-mass distribution rather than from the momenta directly, because the neutrino's longitudinal momentum is unmeasured; the observable is Equation (101.84) and the reason it works is a kinematic singularity.

Proposition 104.56 (The Jacobian peak)**.** *Let a boson of mass M at rest decay to two massless particles. The transverse momentum of either with respect to any axis is $p_T = \tfrac{1}{2}Mc\sin\theta^*$, and therefore the distribution in p_T has an integrable singularity at the endpoint,*

$$\frac{\mathrm{d}N}{\mathrm{d}p_T} = \frac{\mathrm{d}N}{\mathrm{d}(\cos\theta^*)}\,\frac{p_T}{\tfrac{1}{2}Mc\sqrt{\left(\tfrac{1}{2}Mc\right)^2 - p_T^2}}\,, \tag{104.64}$$

which diverges as $p_T \to \tfrac{1}{2}Mc$ however smooth the angular distribution is. The position of the edge measures M.

Rests on Equation (101.1).

Proof. *Derives Proposition 104.56.*

In the rest frame each decay product has momentum $\tfrac{1}{2}Mc$, so $p_T = \tfrac{1}{2}Mc\sin\theta^*$ with θ^* the polar angle to the chosen axis. Then $\mathrm{d}p_T/\mathrm{d}(\cos\theta^*) = -\tfrac{1}{2}Mc\,\cos\theta^*/\sin\theta^*$, and inverting and substituting $\sin\theta^* = 2p_T/Mc$, $\cos\theta^* = \sqrt{1-(2p_T/Mc)^2}$ gives Equation (104.64). The Jacobian, not the dynamics, produces the peak; this is why the method is robust against the unknown production mechanism, and why smearing it by the boson's transverse motion and by the detector resolution is the dominant systematic. Applying the same construction to the pair, with the neutrino's transverse momentum inferred from the missing energy, gives the transverse mass Equation (101.84), whose endpoint is Mc^2 itself and which is less sensitive to the boson's motion. □

Later in 1983 both experiments found the neutral partner in the cleaner channel $Z \to e^+e^-$ and $\mu^+\mu^-$, where both leptons are measured and the invariant mass is direct [1711, 1713]: a handful of events at an invariant mass near $95\,\mathrm{GeV}/c^2$, on essentially no background. Phenomenon 101.73 records the measurement and Equation (101.83) the comparison. The masses agreed with Equation (104.63) at the accuracy then available, which is the point: two numbers measured in the 1970s in low-energy experiments predicted where two new particles would be found, and they were found there.

104.6.3 LEP, SLD and the Z resonance

LEP turned the Z from a discovery into an instrument. Four experiments — ALEPH, DELPHI, L3 and OPAL — recorded some seventeen million Z decays between 1989 and 1995, and SLD added a smaller sample with a longitudinally polarized electron beam, which gives access to asymmetries the unpolarized machine cannot reach. The combined analysis [2104] is the most precise test the electroweak theory has had.

Three classes of result matter here.

The lineshape. Scanning the beam energy across the resonance determines M_Z and the total width Γ_Z, and the peak cross-section determines the product of partial widths. The

masses quoted throughout this chapter come from this analysis. The energy calibration was itself a small physics programme: the beam energy was measured by resonant depolarization to a precision of about 1 MeV, at which level the circumference of the ring responds to the tides raised by the Moon and the Sun, to the water level in Lake Geneva, and to leakage currents from a nearby railway line. All three had to be modelled to reach the quoted M_Z.

The invisible width. Subtracting the visible partial widths from the total leaves the width into channels the detector cannot see, and dividing by the calculated width per neutrino species counts them: $N_\nu = 2.984 \pm 0.008$, which is Phenomenon 101.76. That a resonance curve counts the generations of matter is among the most economical measurements in physics.

The asymmetries. Forward–backward asymmetries in $e^+e^- \to f\bar{f}$ and, at SLD, the left–right asymmetry with polarized beams, measure $\sin^2\theta^\ell_{\text{eff}}$ to better than one part in a thousand (Table 104.3). Proposition 101.75 derives the partial widths that these are compared with.

LEP's second phase ran above the W-pair threshold and measured something no fixed-target experiment can: that the gauge bosons couple to each other.

Phenomenon 104.57 (The gauge bosons couple to one another)**.** The cross-section for $e^+e^- \to W^+W^-$, measured at LEP2 from threshold up to 209 GeV, rises to a maximum and then falls. Three amplitudes contribute — neutrino exchange in the t channel, and annihilation through a photon and through a Z — and each grows with energy on its own; the data are reproduced only when all three are present and interfere destructively, the neutrino-exchange term alone exceeding the measurement by a large factor at the highest energies [2223]. The two annihilation diagrams exist only if three gauge bosons meet at a vertex.

Rests on Propositions 104.7 and 104.47 and Equation (104.40)*.*

Derivation. *Derives Phenomenon 104.57.*

The claim to be established is that the three amplitudes must cancel their leading high-energy growth, and that the cancellation fixes the triple-gauge coupling to the Yang–Mills value.

Take the final Ws longitudinal, which is where the growth lives by Equation (104.6), and apply Proposition 104.47: at $\sqrt{s}\,c \gg M_W c^2$ the amplitude equals that for producing the two eaten Goldstone bosons, $e^+e^- \to \chi^+\chi^-$. Now enumerate the diagrams for *that* process.

- The s-channel photon and Z survive, with the couplings of a charged scalar read off Equation (104.11): the $\chi^\pm$ sits in the doublet with $T^3 = \pm\frac{1}{2}$ and $Q = \pm 1$, so it couples to the photon with charge $\hat{e}$ and to the Z with $\hat{e}\,(1 - 2\sin^2\theta_W)\,/2\sin\theta_W\cos\theta_W$, by Equation (101.74) evaluated at those quantum numbers.
- The t-channel neutrino exchange survives only through the *Yukawa* coupling of $\chi^\pm$ to $e\nu$, which by Theorem 104.38 is $\hat{y}_e/\sqrt{2}$, of order 2×10^{-6} from Table 104.2, and is therefore negligible.

The high-energy amplitude is thus the production of a pair of charged scalars through two s-channel vector exchanges. Such an amplitude does *not* grow: an s-channel propagator $1/(s - M^2c^2)$ falls as $1/s$ while the vertices supply at most one power of momentum each, so the amplitude tends to a constant in the $J = 1$ partial wave and the cross-section falls as $1/s$, which is the observed shape.

The consequence is the cancellation. Computed instead in unitary gauge, each of the three diagrams carries two longitudinal polarization vectors and so grows as $s/M_W^2c^2$; but their sum must equal the non-growing scalar amplitude just obtained. Hence the leading terms cancel identically. The cancellation uses the couplings in *exactly* the combinations Equation (104.40) supplies — the γW^+W^- vertex equal to $\hat{e}$ and the ZW^+W^- vertex

equal to $\hat{g}\cos\theta_W$, both of which are forced by Proposition 104.7 because the $WW\gamma$ and WWZ couplings come from the same ε^{abc} in Equation (104.8). Change either coupling by a fraction δ and a term growing as $\delta s/M_W^2c^2$ survives; at $\sqrt{s}\,c = 200\,\mathrm{GeV}$ that factor is $s/M_W^2c^2 \approx 6$, so a few-per-cent change in the vertex is visible in the cross-section. That is why the LEP2 measurement of a cross-section is a measurement of the group structure: the agreement in [2223] bounds the anomalous triple-gauge couplings at the per-cent level, and the neutrino-exchange diagram alone — with the two annihilation diagrams removed — overshoots the data at the highest energies by a large factor, exactly as an uncancelled $s/M_W^2c^2$ requires. □

104.6.4 Precision fits and the W mass

Remark 104.33 showed that four measured quantities are described by three parameters, so one relation is predicted. The electroweak fit generalizes this: several dozen measurements — M_Z, Γ_Z, the partial widths, the asymmetries, M_W, m_t, α, α_s, G_F — are described by a handful of parameters, so the system is heavily over-constrained and its consistency is a test at every point [2228].

The historically decisive property is that the one-loop corrections depend on particles too heavy to produce. $\Delta\rho$ grows as m_t^2 by Equation (104.52), so the LEP data constrained the top mass before the Tevatron produced it, and the indirect value agreed with the direct measurement of [1891, 1892]. The scalar enters only logarithmically — Veltman's screening theorem again — so the constraint on m_h was much weaker, but it was real: the fit before 2012 preferred a scalar mass of order 100 GeV and excluded values above a few hundred GeV [2228], and the particle was found at $125\,\mathrm{GeV}/c^2$ inside that range. Two particles were thus located by loop effects before either was seen.

One entry does not fit, and it is stated here as what it is.

Remark 104.58 (The W-mass tension, unresolved). The CDF collaboration's final analysis of its Tevatron data [2395] reports $M_Wc^2 = (80\,433.5 \pm 9.4)\,\mathrm{MeV}$, an uncertainty of 9.4 MeV — the most precise single measurement of the quantity. It disagrees with the world average (80.369 ± 0.013) GeV [2427] by about four standard deviations, and with the indirect prediction of the electroweak fit, $M_Wc^2 = (80\,357 \pm 6)\,\mathrm{MeV}$ [2427], by about seven: the difference of 76.5 MeV is 6.9 times the combined uncertainty of 11.2 MeV obtained by adding the two errors in quadrature. It also disagrees with the LHC measurements, which are individually less precise but mutually consistent and consistent with the fit.

This is recorded as an unresolved experimental tension and not as evidence for anything. Two measurements of the same quantity that disagree by seven standard deviations mean that at least one uncertainty is underestimated; which one is not known. The relevant systematics — parton distributions, the modelling of the W transverse-momentum spectrum, the momentum-scale calibration — are of the same order as the quoted total error, and no independent reanalysis has reproduced the CDF value. Until it is resolved, the honest statement is that the W mass is known to about 13 MeV with one outlier at four sigma, and no shift in any Standard Model parameter is warranted.

104.7 The Higgs boson

104.7.1 Search and discovery

Everything about the scalar is predicted except its mass. Given m_h, Equation (104.38) fixes λ, and Theorem 104.38(iii) and Equation (104.23) fix every coupling, hence every production cross-section and every branching fraction. The search was therefore a scan in one variable with everything else nailed down — which is why a negative result at any mass is a genuine exclusion, and why the positive result is a test rather than a fit.

LEP searched in $e^+e^- \to Zh$ up to a centre-of-mass energy of 209 GeV and set the limit

$$m_h c^2 > 114.4\,\mathrm{GeV} \quad \text{at 95 per cent confidence} \tag{104.65}$$

[2045], which is about as far as that machine could reach. The Tevatron and then the LHC took the range upward. In July 2012 ATLAS [2186] and CMS [2192] independently reported a resonance near $125\,\mathrm{GeV}/c^2$, each with a local significance of about five standard deviations, in the two channels with the cleanest signature: $h \to \gamma\gamma$, where the mass is reconstructed from two photons, and $h \to ZZ^* \to 4\ell$, where it is reconstructed from four charged leptons. Their first joint mass combination [2242] gave $(125.09 \pm 0.24)\,\mathrm{GeV}$, and the present world average is $(125.20 \pm 0.11)\,\mathrm{GeV}$ [2427]. The apparatus, the trigger, the look-elsewhere effect and the statistical machinery belong to Chapter 113; the statistical foundations belong to Chapter 11.

Phenomenon 104.59 (A neutral scalar boson exists)**.** A narrow resonance is produced in proton–proton collisions and decays to two photons and to four charged leptons. It was observed independently by ATLAS [2186] and CMS [2192] in 2012, at a mass

$$m_H c^2 = (125.09 \pm 0.24)\,\mathrm{GeV} \tag{104.66}$$

in their first combination [2242], now $(125.20 \pm 0.11)\,\mathrm{GeV}$ [2427]. That it decays to two photons excludes spin one [917, 975], and the angular distributions of the four-lepton final state select $J^P = 0^+$ over the remaining alternatives. Direct searches at LEP had already excluded a Standard Model scalar below $114.4\,\mathrm{GeV}/c^2$ [2045]. The full discovery account belongs to Chapter 113.

Rests on Theorem 104.38, Table 104.2, and Equation (101.86).

Derivation of the decay pattern. Derives Phenomenon 104.59.

Once m_h is given, the tree-level partial widths follow from the couplings of Theorem 104.38(iii) with no freedom left. For a fermion pair,

$$\hbar\Gamma\left(h \to f\bar{f}\right) = \frac{N_c \hat{y}_f^2}{16\pi}\, m_h c^2 \left(1 - \frac{4m_f^2}{m_h^2}\right)^{3/2}, \tag{104.67}$$

N_c being 3 for quarks and 1 for leptons, and $\hat{y}_f = \sqrt{2} m_f c^2 / E_v$ from Table 104.2. The structure is that of Equation (101.86) — the width of a particle at rest into two massless ones is a coupling squared times the mass over 16π, times a phase-space factor — and the exponent $3/2$ rather than $1/2$ is the signature of a *scalar*: the β^3 arises because a $J = 0$ state decaying to a fermion pair through a scalar coupling produces them in a P wave, contributing β^2 beyond the β of two-body phase space. A pseudoscalar coupling $\mathrm{i}\bar{f}\gamma^5 f$ would give β^1 instead, which is one of the ways the parity of the state is tested.

Two checks with no strong-interaction corrections. For $\tau^+\tau^-$, Table 104.2 gives $\hat{y}_\tau = 0.010\,21$, so $\hbar\Gamma = 1.0416 \times 10^{-4} \times 125.20\,\mathrm{GeV}/16\pi = 0.259\,\mathrm{MeV}$; for $\mu^+\mu^-$, $\hat{y}_\mu = 6.07 \times 10^{-4}$ gives 0.92 keV. Against the total width of 4.1 MeV these are branching fractions of 6.3×10^{-2} and 2.2×10^{-4}, which are the values in Table 104.4.

The two heaviest available channels need a further remark. At $m_h c^2 = 125.20\,\mathrm{GeV}$ both W^+W^- and ZZ are *below* threshold, since $2M_W c^2 = 160.7\,\mathrm{GeV}$; they proceed with one boson off shell, $h \to VV^* \to Vf\bar{f}'$, a three-body decay whose rate is suppressed by an extra factor of order $\hat{g}^2/16\pi^2$ relative to the on-shell formula and which is not obtained by putting a negative number under a square root. That this suppression is only partial — WW^* is still the second largest channel — is because the coupling grows as the squared vector mass, Equation (104.69) below.

The total width predicted by summing all channels is 4.1 MeV, some 3×10^{-5} of the mass; the measured value is 3.7 MeV with an uncertainty of about 1.7 MeV [2427], in agreement. A width this narrow is itself a prediction: it follows from the couplings being small, which follows from most fermions being light. □

Table 104.4: Standard Model branching fractions of a scalar of mass $125\,\mathrm{GeV}/c^2$, to the precision that matters here. The first, third, fourth, fifth and last are tree-level decays governed by Equation (104.67); WW^* and ZZ^* proceed through one off-shell boson; gg, $\gamma\gamma$ and $Z\gamma$ have no tree-level vertex at all and arise from loops of the heaviest charged and coloured particles. Every entry is fixed once the mass is given: there is no free parameter in this table.

Channel	Mechanism	Branching fraction
$b\bar{b}$	tree, Yukawa	0.58
W^+W^{-*}	tree, gauge	0.21
gg	loop (top)	0.082
$\tau^+\tau^-$	tree, Yukawa	0.063
$c\bar{c}$	tree, Yukawa	0.029
ZZ^*	tree, gauge	0.026
$\gamma\gamma$	loop (W, top)	0.0023
$Z\gamma$	loop (W, top)	0.0015
$\mu^+\mu^-$	tree, Yukawa	2.2×10^{-4}

Derivation pending #158

The loop-induced scalar vertices: the amplitudes for $h\to\gamma\gamma$ and $h\to gg$, from the W and top triangles, which have no tree-level counterpart and which supply the discovery channel and the dominant production mechanism (gluon fusion) respectively; together with the resulting production cross-sections at the LHC. These require the full one-loop tensor reduction and belong in Appendix A. Also owed are the three-body off-shell rates $h\to WW^*$ and $h\to ZZ^*$, whose branching fractions the table quotes without derivation. What is derived above is the two-body tree-level fermionic width formula and the tau and muon entries computed from it; every other entry of the branching table quotes the standard values.

104.7.2 Quantum numbers and couplings

Theorem 104.60 (Landau–Yang)**.** *A massive particle of spin 1 cannot decay into two real photons [917, 975]. Hence the observation of $h\to\gamma\gamma$ excludes $J=1$ for the resonance.*

Rests on Theorem 99.46.

Proof. *Derives Theorem 104.60.*

Work in the rest frame of the decaying particle, where the two photons travel along $\pm\hat{\boldsymbol{k}}$ with polarization vectors $\boldsymbol{\varepsilon}_1$, $\boldsymbol{\varepsilon}_2$, both transverse: $\boldsymbol{\varepsilon}_i\cdot\hat{\boldsymbol{k}}=0$. The amplitude is a scalar function linear in each $\boldsymbol{\varepsilon}_i$, and for $J=1$ it must be a *vector* $\boldsymbol{A}$ contracted with the decaying particle's polarization. Bose symmetry requires $\boldsymbol{A}$ to be invariant under exchanging the two photons, which means $\boldsymbol{\varepsilon}_1\leftrightarrow\boldsymbol{\varepsilon}_2$ together with $\hat{\boldsymbol{k}}\to-\hat{\boldsymbol{k}}$.

Enumerate the vectors that are linear in each polarization and built from $\boldsymbol{\varepsilon}_1$, $\boldsymbol{\varepsilon}_2$, $\hat{\boldsymbol{k}}$:

$$\begin{aligned}
\boldsymbol{A}_1 &= \boldsymbol{\varepsilon}_1\times\boldsymbol{\varepsilon}_2 \;\longmapsto\; \boldsymbol{\varepsilon}_2\times\boldsymbol{\varepsilon}_1 = -\boldsymbol{A}_1\,,\\
\boldsymbol{A}_2 &= (\boldsymbol{\varepsilon}_1\cdot\boldsymbol{\varepsilon}_2)\,\hat{\boldsymbol{k}} \;\longmapsto\; (\boldsymbol{\varepsilon}_2\cdot\boldsymbol{\varepsilon}_1)\left(-\hat{\boldsymbol{k}}\right) = -\boldsymbol{A}_2\,,\\
\boldsymbol{A}_3 &= \left(\hat{\boldsymbol{k}}\cdot\boldsymbol{\varepsilon}_2\right)\boldsymbol{\varepsilon}_1 - \left(\hat{\boldsymbol{k}}\cdot\boldsymbol{\varepsilon}_1\right)\boldsymbol{\varepsilon}_2 = 0\,,
\end{aligned}\tag{104.68}$$

the last vanishing by transversality. $\boldsymbol{A}_1$ and $\boldsymbol{A}_2$ are antisymmetric under the exchange and are therefore forbidden for two identical bosons, and no other structure exists. The

one remaining candidate, $\left[\hat{\boldsymbol{k}}\cdot(\boldsymbol{\varepsilon}_1\times\boldsymbol{\varepsilon}_2)\right]\hat{\boldsymbol{k}}$, is not independent: transversality makes $\boldsymbol{\varepsilon}_1\times\boldsymbol{\varepsilon}_2$ parallel to $\hat{\boldsymbol{k}}$, so it *is* $\boldsymbol{A}_1$, and it is antisymmetric for the same reason. Anything else contains either $\hat{\boldsymbol{k}}\cdot\boldsymbol{\varepsilon}_i$, which vanishes, or a second power of some $\boldsymbol{\varepsilon}_i$, which the linearity forbids. Hence the $J=1$ amplitude vanishes identically.

The argument uses only rotational invariance, Bose statistics and transversality; it does not use parity, so it excludes 1^+ and 1^- alike, and it fails for a massive vector in the final state (which has a longitudinal polarization) and for two *virtual* photons. Together with the four-lepton angular distributions, which distinguish 0^+ from 0^- and from 2^+, this fixes $J^{PC}=0^{++}$. □

The decisive test of the mechanism is not that a scalar exists but that its couplings track mass, because that is what makes it the field that supplies mass rather than merely another particle.

Proposition 104.61 (The couplings are the masses divided by v)**.** *In unitary gauge the interactions of h with the massive fields are*

$$\mathcal{L}_h=-\frac{h}{v}\sum_f m_f c^2\,\bar{f}f+\frac{2h}{v}\left[\frac{M_W^2c^2}{\mu_0\hbar^2}W_\mu^+W^{-\mu}+\frac{M_Z^2c^2}{2\mu_0\hbar^2}Z_\mu Z^\mu\right]+\mathcal{O}\left(h^2\right),\tag{104.69}$$

that is: every coupling is the corresponding mass term divided by v, twice over for the vectors. The vertex strengths are therefore

$$g_{hff}=\frac{m_fc^2}{E_v}\quad\textit{(dimensionless)},\qquad g_{hVV}=\frac{2\left(M_Vc^2\right)^2}{E_v}\quad\textit{(an energy)},\tag{104.70}$$

and the variable that puts both families on one axis — the reduced coupling *of the experimental figures — is g_{hff} for a fermion and $\sqrt{g_{hVV}/2E_v}=M_Vc^2/E_v$ for a vector. Plotted against mass, every Standard Model particle then lies on the single straight line of slope $1/E_v$ through the origin.*

Rests on Theorem 104.38 and Equations (104.34) and (104.46).

Proof. *Derives Proposition 104.61.*

For the fermions, Theorem 104.38(iii): substituting $\Phi=\frac{1}{\sqrt{2}}(0,v+h)^{\mathsf{T}}$ into Equation (104.46) multiplies the mass term by $(1+h/v)$, whose linear part is the first term of Equation (104.69). Dividing by $\sqrt{\hbar c}$ to make it dimensionless, and using $E_v=v\sqrt{\hbar c}$, gives $g_{hff}=m_fc^2/E_v$.

For the vectors, Equation (104.34) was computed at $\Phi=\Phi_0$; restoring the fluctuation replaces v by $v+h$ throughout, so the mass terms are multiplied by $(1+h/v)^2=1+2h/v+h^2/v^2$. The linear part is twice the mass term over v, which is the bracket in Equation (104.69); the *factor of two* is the whole difference between the fermion and vector cases and it comes from the mass term being quadratic in the field's coupling to Φ rather than linear. Hence $g_{hVV}=2(M_Vc^2)^2/E_v$, quadratic in the mass and carrying the dimension of an energy; dividing by $2E_v$ and taking the square root returns M_Vc^2/E_v, the same linear law the fermions obey, which is why the two families can be drawn on one plot. □

Phenomenon 104.62 (The scalar couples in proportion to mass)**.** The strength with which the scalar couples to each particle is measured channel by channel, and it grows with the mass of the particle it couples to: linearly for the fermions and quadratically for the weak bosons. The ten-year coupling maps of ATLAS [2394] and CMS [2410] cover W, Z, t, b, τ and, with weaker significance, μ — some three orders of magnitude in mass — and follow that pattern throughout. This, rather than the mere existence of a scalar, is the test of the mechanism: a scalar whose couplings did not track mass would not be the field that supplies mass.

Rests on Equation (104.70) and Propositions 104.26 and 104.61.

Derivation. *Derives Phenomenon 104.62.*

The prediction is Equation (104.70), derived in Proposition 104.61: a one-parameter family with the parameter, E_v, already fixed by the muon lifetime through Proposition 104.26. There is nothing to adjust.

The measurement is conventionally reported as coupling modifiers κ_i, defined so that $\kappa_i = 1$ reproduces Equation (104.70) and rates scale as κ^2. What is actually measured is a rate, that is a product of a production cross-section and a branching fraction, so a global fit over many final states is required to separate the couplings; the experiments report the results of that fit [2394, 2410], and every κ_i comes out consistent with unity, with uncertainties of roughly a tenth for W, Z, t, b and τ and roughly a fifth for μ. Since $m_\mu c^2 = 0.1057\,\text{GeV}$ and $m_t c^2 = 172.57\,\text{GeV}$, the verified range is a factor of 1630 in mass, over which Equation (104.70) varies by the same factor — so the agreement is a statement about a three-decade lever arm and not about one point.

Two features make the test sharper than a fit to five numbers. The $\gamma\gamma$ and gg vertices have no tree-level counterpart (Table 104.4), so their measured rates test the same couplings at one loop, through a different combination: the $\gamma\gamma$ amplitude is dominated by the W loop with the top loop interfering destructively, and the gg amplitude by the top alone, so agreement in both simultaneously constrains the relative sign of κ_W and κ_t — something no tree-level measurement reaches. And any heavy coloured or charged particle would contribute to those same loops whether or not it can be produced directly, so the agreement bounds such particles indirectly. □

104.7.3 The potential and the self-coupling

Everything verified so far probes the theory at the minimum of the potential. The *shape* of the potential away from the minimum is a separate claim and it is largely unmeasured.

Proposition 104.63 (The self-couplings are predicted, not fitted)**.** *Expanding Equation (104.27) in unitary gauge,*

$$V(h) = \frac{1}{2}\left(\frac{m_h c}{\hbar}\right)^2 h^2 + \frac{(m_h c)^2}{2\hbar^2 v} h^3 + \frac{(m_h c)^2}{8\hbar^2 v^2} h^4 , \tag{104.71}$$

so both the trilinear and the quartic self-coupling are determined by m_h and v, which are already measured. Writing the trilinear coupling as κ_λ times its Standard Model value, the mechanism predicts $\kappa_\lambda = 1$ with no freedom.

Rests on Equations (104.16), (104.27) and (104.37).

Proof. *Derives Proposition 104.63.*

From Equation (104.16) with the Goldstone modes gauged away, $V = \lambda v h^3 + \frac{\lambda}{4} h^4 + \lambda v^2 h^2$, and $\lambda v^2 = \frac{1}{2}(m_h c/\hbar)^2$ by Equation (104.37). Substituting $\lambda = (m_h c)^2/2\hbar^2 v^2$ into each term gives Equation (104.71). The two higher couplings are m_h^2/v and m_h^2/v^2 times pure numbers: one parameter, λ, generates the mass and both self-interactions, which is the content of the claim that the potential is the quartic one and not merely some function with a minimum in the right place. □

Measuring κ_λ requires producing two scalars at once, whose cross-section at the LHC is some three orders of magnitude below single production and which additionally interferes with a box diagram that does not involve the self-coupling. The present constraints [2394] allow κ_λ over a range of order -1 to $+7$ — consistent with the predicted 1, and far too loose to be called a test. Until it narrows, the statement that the vacuum sits at the minimum of a quartic potential is an assumption supported by the mass and the couplings, not a measurement of the potential's shape.

Remark 104.64 (Loops reshape the potential). The tree-level $V(h)$ is not the object whose minimum determines the vacuum. That object is the effective potential of Equation (106.59), the Legendre transform of the generating functional evaluated at a constant field, whose one-loop correction Coleman and Weinberg computed [1495] and Proposition 106.45 reproduces: each field circulating in the loop contributes a term proportional to $\pm M^4(h)\ln M^2(h)$, with a plus sign for bosons and a minus for fermions, $M(h)$ being that field's h-dependent mass. In the Standard Model the top quark's contribution is the largest and it enters with the fermionic minus sign. That single fact is the origin of everything in Section 104.8.1.

Remark 104.65 (The electroweak transition is a crossover). At high temperature the effective potential acquires thermal corrections and the minimum returns to $\Phi = 0$: the symmetry is restored, and the early universe passed through the transition at a temperature of order $100\,\mathrm{GeV}/k_B$. Whether the transition is first order — with bubbles, latent heat and departure from equilibrium — or a smooth crossover depends on the scalar mass, and lattice computations place the endpoint of the first-order line at $m_h c^2 \approx 72\,\mathrm{GeV}$ [1925]. The measured 125.20 GeV is far above it, so the Standard Model transition is a crossover. The consequence is not academic: Sakharov's third condition for generating a baryon asymmetry [1358] is a departure from thermal equilibrium (Theorem 105.41), and a crossover supplies none. The Standard Model therefore cannot account for the observed baryon asymmetry, and Section 105.6.2 quantifies the shortfall. This is a failure of the theory derived from measured parameters, and it is stated here because this chapter measured them.

104.8 What the model does not explain

104.8.1 Vacuum stability

λ is a coupling, so it runs (Chapter 108). Its beta function is dominated by the top Yukawa, and the top's contribution is negative.

Proposition 104.66 (The quartic coupling runs down)**.** *At one loop, in the conventions of Definition 104.24 and with $\hat{y}_t$, $\hat{g}$, $\hat{g}'$ as in Notation 104.1,*

$$16\pi^2 \frac{\mathrm{d}\hat{\lambda}}{\mathrm{d}\ln\mu} = 24\hat{\lambda}^2 + 12\hat{\lambda}\hat{y}_t^2 - 6\hat{y}_t^4 - 3\hat{\lambda}\left(3\hat{g}^2 + \hat{g}'^2\right) + \frac{3}{8}\left[2\hat{g}^4 + \left(\hat{g}^2 + \hat{g}'^2\right)^2\right] \tag{104.72}$$

[2193]. Evaluated at $\mu = m_t c^2$, where the running couplings are $\hat{\lambda} = 0.126$, $\hat{y}_t = 0.94$, $\hat{g} = 0.64$, $\hat{g}' = 0.35$ — each a little below its value at the electroweak scale in Equation (104.38), Table 104.2 and Equation (104.42), because all of them run — the five terms are 0.381, 1.336, −4.684, −0.511 *and* 0.232*, so*

$$\left.\frac{\mathrm{d}\hat{\lambda}}{\mathrm{d}\ln\mu}\right|_{m_t} = \frac{-3.246}{16\pi^2} = -0.0206\,, \tag{104.73}$$

negative, and dominated by the single term $-6\hat{y}_t^4$.

Rests on Definition 104.24, Equation (104.38), and Corollary 106.39.

Derivation of the sign. Derives Proposition 104.66.

The coefficients are quoted from [2193]; what is derived here is why the dominant one is negative and why it is large. By Remark 104.64 the one-loop effective potential receives $-N_c M_t^4(h)\ln M_t^2(h)$ from the top, with the minus sign of a fermion loop — the same sign that makes a closed fermion loop carry (-1) in Corollary 106.39. Since $M_t(h) \propto \hat{y}_t h$, this is a term $\propto -\hat{y}_t^4 h^4 \ln h$, that is a negative contribution to the running quartic, with the colour factor $N_c = 3$ and the fourth power of the coupling. Numerically $\hat{y}_t^4 = 0.78$ while $\hat{\lambda}^2 = 0.016$, so the fermion term beats the bosonic ones by a factor of order fifty, and Equation (104.73) follows by arithmetic. The one number that matters is the sign. □

Remark 104.67 (Metastability, and how fragile the statement is). Integrating Equation (104.72) together with the running of $\hat{y}_t$ and $\hat{g}_3$ — which cannot be done by holding the coefficients fixed, because $\hat{y}_t$ itself falls with scale and $\left|\mathrm{d}\hat{\lambda}/\mathrm{d}\ln\mu\right|$ falls with it — gives $\hat{\lambda}(\mu)$ crossing zero at $\mu \approx 10^{10}$–$10^{11}\,\mathrm{GeV}$ [2193, 2215]. Above that scale the potential turns over and a deeper minimum exists at large field values: the electroweak vacuum is not the global minimum but a metastable one. The computed tunnelling lifetime exceeds the age of the universe by hundreds of orders of magnitude, so nothing observable follows.

Three caveats, all of which the cited analyses state and none of which may be dropped:

- the conclusion sits on a knife edge in m_t. Shifting the top mass by about $1\,\mathrm{GeV}$, or the strong coupling by about one standard deviation, moves the answer between absolute stability, metastability and instability. The measured m_t has an uncertainty of $0.29\,\mathrm{GeV}$ [2427], but the relation between the quantity a hadron collider reconstructs and the short-distance mass entering Equation (104.72) carries a further theoretical uncertainty of comparable size;
- the extrapolation assumes no new particle couples to the scalar anywhere between $10^3\,\mathrm{GeV}$ and $10^{10}\,\mathrm{GeV}$ — sixteen decades in which nothing has been looked at. A single new state changes the running;
- the running is a statement about a coupling in a scheme, not about an observable. Whether "the vacuum is metastable" is a physical statement at all depends on the extrapolation being valid, which is the assumption in question.

The honest summary is that the measured parameters put the Standard Model, extrapolated with no new physics, marginally on the metastable side, and that the margin is smaller than the combined theoretical and experimental uncertainty on the top mass. It is an intriguing near-coincidence, and it is not evidence for anything.

Derivation pending #159

Vacuum stability: the coupled integration of the one-loop renormalization-group equations for the quartic coupling, the top Yukawa and the three gauge couplings from the electroweak scale upward, which is what locates the zero of the quartic near $1\times10^{10}\,\mathrm{GeV}$*; and the bounce action governing the tunnelling rate out of the electroweak minimum. The beta function and its sign are derived in the text above; the integration and the bounce belong in Appendix A.*

104.8.2 Open questions, stated honestly

The electroweak theory explains a great deal from very little: two gauge couplings, one scalar mass and one vacuum expectation value generate the W, the Z, the photon's exact masslessness, the Fermi constant, the neutral current and the whole pattern of boson self-interactions. What it does not do is explain its own inputs.

The Yukawa hierarchy. Table 104.2 is a list of nine numbers spanning 3.4×10^5, taken from experiment. Nothing in the Lagrangian relates them, and no evidence-based mechanism producing them exists. The four parameters of the CKM matrix (Proposition 101.63) are in the same position.

The number of generations. Three, by Phenomenon 101.76 for the light neutrinos and by Proposition 104.53 for the requirement that each be complete. Why three is not known; the theory works for any number.

The scale. $E_v = 246.22\,\mathrm{GeV}$ is one input. Expressed against the only other scale built from the constants of Nature, the Planck energy $\sqrt{\hbar c^5/G} \approx 1.22 \times 10^{19}\,\mathrm{GeV}$, it is smaller

by a factor 2×10^{-17}, and Remark 104.30 records a related and much larger discrepancy in the vacuum energy.

Sensitivity of m_h^2 to heavy thresholds. If the theory is embedded in a larger one containing a particle of mass M coupled to Φ, the scalar's squared mass receives a correction of order M^2 times a loop factor, so reproducing the measured 125.20 GeV requires a cancellation of relative size $(m_h/M)^2$. It should be said plainly what this is and is not. It is an argument about the *form* a more fundamental theory would have to take; it is not an observation, because no such particle is known to exist and the correction is not a measurable quantity. It has motivated a great many proposed extensions — supersymmetry, technicolour, grand unification, extra dimensions — and direct searches at the LHC have so far returned null results for every one of them. None of those programmes has observational support, and by editorial rule 1 they are named here only to record that fact.

Neutrino mass. Equation (104.46) gives the neutrino no mass, because there is no ν_R in Table 104.1. Oscillations show the masses are not zero (Chapter 114). This is the one place where a laboratory measurement contradicts the Lagrangian of Equation (104.28) rather than merely failing to be explained by it, and Chapter 103 takes it up.

Dark matter, dark energy, the baryon asymmetry. None has an explanation here. Remark 104.65 showed that the measured scalar mass positively *forbids* the Standard Model from generating the baryon asymmetry, which is a sharper statement than silence. The cosmological evidence belongs to Chapter 134, and the full inventory of what is observed and unexplained is Chapter 133.

Chapter 105

Discrete Symmetries and CPT

Three transformations lie outside the connected Lorentz group of Chapter 39: space inversion P, charge conjugation C and time reversal T. Each was assumed to be an exact symmetry of nature, and each turned out not to be. Parity fell first, proposed as testable by Lee and Yang [1091] and demolished by Wu's cobalt-60 experiment [1133], the subject of Chapter 110; the combination CP, offered by Landau as the replacement [1118], fell in turn with the 2π decay of the long-lived kaon [1274], the subject of Chapter 111; and direct violation of T was observed in the neutral kaon [1948] and in the neutral B system [2197]. This chapter collects those results and the theory that survives them.

What survives is the product. The CPT theorem of Lüders [1049], Pauli [1079] and Jost [1115] says that any local, Lorentz-invariant quantum field theory with a positive-energy spectrum is invariant under CPT — so particle and antiparticle must have equal masses and lifetimes and opposite magnetic moments. It is therefore the sharpest available test of the axioms of Chapter 109, and the chapter reviews the measurements that probe it, from antihydrogen spectroscopy [2280, 2299] to the antiproton magnetic moment [2288] and charge-to-mass ratio [2400]. It closes on two honest failures: Sakharov's conditions for a baryon asymmetry [1358], which the observed CP violation falls short of by many orders of magnitude, and the strong CP problem, bounded but unexplained by the neutron electric dipole moment [2346].

The conventions are those fixed for quantum electrodynamics in Section 100.1.1, and are used without further comment: the metric is $\eta_{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$, coordinates are $x^\mu = (ct, \boldsymbol{x})$, four-momenta are $p^\mu = (E/c, \boldsymbol{p})$ with the mass shell $p^2 = m^2c^2$ of Equation (100.1), and $\hbar$ and c appear explicitly in every formula. Exactly one symbol is reassigned against them, and the reassignment is declared here rather than left to the reader to discover: Notation 100.1 reserves ϵ, standing alone, for the positive infinitesimal of the Feynman contour, whereas from Section 105.3.1 onwards ϵ is the CP-violating mixing parameter of the neutral kaon, which is what the symbol means everywhere in this subject. The contour prescription is accordingly written $+\mathrm{i}0$ in this chapter and never $+\mathrm{i}\epsilon$.

Operators on the Hilbert space are written in calligraphic type — $\mathcal{P}, \mathcal{C}, \mathcal{T}$ — with a single exception: their product is written Θ (Definition 105.33), the capital theta being universal for it. The Dirac matrices γ^μ and γ^5 are the ordinary italic ones of Chapter 93; the numerical 4×4 matrices that implement P, C and T on Dirac indices are written in upright roman, and carry the subscript D where the letter would otherwise collide with an operator — the charge-conjugation matrix $\mathrm{C_D}$ of Definition 100.9 and the time-reversal matrix $\mathrm{T_D}$, against the parity matrix S_P, whose letter collides with nothing. The two kinds must not be confused: $\mathcal{C}$ is a unitary operator on a Fock space, $\mathrm{C_D}$ a matrix one can write down.

105.1 The three discrete operations

The Lorentz group L has four connected components (Proposition 39.8), and the three not containing the identity are reached from it by adjoining the two matrices

$$\Lambda_P = \mathrm{diag}(+1,-1,-1,-1)\,, \qquad \Lambda_T = \mathrm{diag}(-1,+1,+1,+1)\,, \tag{105.1}$$

acting on $x^\mu = (ct, \boldsymbol{x})$. Neither can be reached by any continuous motion, so whether Nature is invariant under them is not settled by the Lie algebra of Section 39.2.7: it is an experimental question, and Section 105.2 records the answer.

Charge conjugation is of a different kind. It is not a spacetime transformation at all: it acts on the internal labels of the fields, exchanging each particle with its antiparticle while leaving momentum and spin untouched. It has no classical counterpart in the sense that P and T do, and it exists only because the relativistic wave equations of Chapter 93 force antiparticles into the theory — which is why the empirical discovery of C had to wait for the positron of Chapter 95.

By Wigner's theorem (Theorem 94.3) each of the three, being a symmetry of the ray space, is implemented by an operator that is either unitary or antiunitary. The theorem does not say which. The answer, derived in Section 105.1.3, is that $\mathcal{P}$ and $\mathcal{C}$ may be taken unitary while $\mathcal{T}$ must be antiunitary, and that single structural difference is responsible for most of what distinguishes T from its two companions: T carries no conserved quantum number, forbids no transition outright, and can be tested only by comparing a process with its motion reverse.

105.1.1 Parity

Parity in quantum mechanics Wigner introduced parity as a conserved quantum number in 1927 [592], reading it off the reflection symmetry of atomic spectra. The argument is short enough to give in full, and it fixes the pattern that the field-theoretic version will repeat.

Let a spinless particle move in a central potential, so that the Hamiltonian is

$$H = \frac{\hat{\boldsymbol{p}}^2}{2m} + V(|\boldsymbol{x}|)\,. \tag{105.2}$$

Define the unitary operator $\mathcal{P}$ on wavefunctions by

$$(\mathcal{P}\psi)(\boldsymbol{x}) = \eta_P\, \psi(-\boldsymbol{x})\,, \tag{105.3}$$

with η_P a phase. Then $\mathcal{P}\hat{\boldsymbol{x}}\mathcal{P}^{-1} = -\hat{\boldsymbol{x}}$ and, because $\hat{\boldsymbol{p}} = -\mathrm{i}\hbar\nabla$ and $\nabla \to -\nabla$ under $\boldsymbol{x} \to -\boldsymbol{x}$, also $\mathcal{P}\hat{\boldsymbol{p}}\mathcal{P}^{-1} = -\hat{\boldsymbol{p}}$. Both terms of Equation (105.2) are therefore invariant, $[\mathcal{P}, H] = 0$, and energy eigenstates may be chosen to be eigenstates of $\mathcal{P}$. Since $\mathcal{P}^2$ acts as the identity on $\boldsymbol{x}$, we may choose $\eta_P^2 = 1$ for a scalar wavefunction, so the eigenvalues are ± 1: even and odd states.

Orbital angular momentum $\hat{\boldsymbol{L}} = \hat{\boldsymbol{x}} \times \hat{\boldsymbol{p}}$ is a product of two odd vectors and is therefore *even*: $\mathcal{P}\hat{\boldsymbol{L}}\mathcal{P}^{-1} = +\hat{\boldsymbol{L}}$. A quantity that behaves this way under P — like a vector under rotations but even under reflection — is called an *axial* (or pseudo-) vector, as against the *polar* vectors $\boldsymbol{x}$ and $\boldsymbol{p}$; the corresponding scalars are called pseudoscalar and scalar. The spherical harmonics inherit the eigenvalue

$$Y_{\ell m}(-\hat{\boldsymbol{n}}) = (-1)^\ell Y_{\ell m}(\hat{\boldsymbol{n}})\,, \tag{105.4}$$

so a state of orbital angular momentum ℓ has parity $(-1)^\ell$ times the intrinsic parities of its constituents.

Proposition 105.1 (Laporte's rule)**.** *In a parity-conserving theory, an electric-dipole transition connects only states of opposite parity. In particular no $E1$ line joins two even or two odd atomic configurations.*

Rests on Equation (105.3)*.*

Proof. *Derives Proposition 105.1.*

The electric-dipole operator is $\hat{\boldsymbol{d}} = -e\sum_a \hat{\boldsymbol{x}}_a$, a sum of polar vectors, so $\mathcal{P}\hat{\boldsymbol{d}}\mathcal{P}^{-1} = -\hat{\boldsymbol{d}}$. If $\mathcal{P}\,|i\rangle = \pi_i\,|i\rangle$ and $\mathcal{P}\,|f\rangle = \pi_f\,|f\rangle$ with $\pi_{i,f} = \pm 1$, then inserting $\mathcal{P}^{-1}\mathcal{P} = \mathbb{1}$ twice gives

$$\langle f|\,\hat{\boldsymbol{d}}\,|i\rangle = \langle f|\,\mathcal{P}^{-1}\left(\mathcal{P}\hat{\boldsymbol{d}}\mathcal{P}^{-1}\right)\mathcal{P}\,|i\rangle = -\pi_i\pi_f\,\langle f|\,\hat{\boldsymbol{d}}\,|i\rangle\ ,$$

so the matrix element vanishes unless $\pi_i\pi_f = -1$. □

This is the selection rule that Laporte extracted empirically from iron and titanium spectra in 1925 [528], two years before Wigner explained it: the terms of a complex spectrum fall into two classes, and lines occur only between classes and never within one. It is the earliest quantitative evidence for parity as a physical quantum number, and it is worth noticing what kind of evidence it is — a systematic *absence*, which is what a symmetry always delivers.

Parity on the fields In field theory $\mathcal{P}$ is a unitary operator on the Fock space, defined by its action on the fields. For a spinless field the possibilities are two,

$$\mathcal{P}\phi(ct,\boldsymbol{x})\mathcal{P}^{-1} = \eta_P\,\phi(ct,-\boldsymbol{x})\,,\qquad \eta_P = \pm 1\,, \tag{105.5}$$

and the field is called scalar for $\eta_P = +1$ and pseudoscalar for $\eta_P = -1$. The number η_P is the *intrinsic parity* of the corresponding particle.

For the electromagnetic potential the transformation is not a matter of choice. The observable fields are $\boldsymbol{E} = -\nabla\phi_{\mathrm{el}} - \partial_t\boldsymbol{A}$ and $\boldsymbol{B} = \nabla\times\boldsymbol{A}$; under $\boldsymbol{x}\to-\boldsymbol{x}$ one has $\nabla\to-\nabla$, so the assignment

$$\mathcal{P}A^0(ct,\boldsymbol{x})\mathcal{P}^{-1} = A^0(ct,-\boldsymbol{x})\,,\qquad \mathcal{P}A^i(ct,\boldsymbol{x})\mathcal{P}^{-1} = -A^i(ct,-\boldsymbol{x}) \tag{105.6}$$

gives $\boldsymbol{E}\to-\boldsymbol{E}$ and $\boldsymbol{B}\to+\boldsymbol{B}$: the electric field is polar, the magnetic field axial. Both signs are forced by Equation (105.6) and neither is conventional. In compact notation $\mathcal{P}A^\mu(x)\mathcal{P}^{-1} = \Lambda_P{}^\mu{}_\nu A^\nu(x_P)$ with $x_P = (ct,-\boldsymbol{x})$; the photon has intrinsic parity -1, since the spatial polarization vector, which is what a physical photon carries, reverses.

For the Dirac field the transformation is likewise forced, up to one phase.

Proposition 105.2 (Parity on a Dirac field)**.** *Let ψ satisfy $(\mathrm{i}\hbar\gamma^\mu\partial_\mu - mc)\psi = 0$. Then*

$$\mathcal{P}\psi(ct,\boldsymbol{x})\mathcal{P}^{-1} = \eta_P\,\gamma^0\psi(ct,-\boldsymbol{x}) \tag{105.7}$$

maps solutions to solutions, and γ^0 is the unique matrix (up to a factor) that does so.

Rests on Equations (100.5) *and* (105.1)*.*

Proof. *Derives Proposition 105.2.*

Write $\psi'(x_P) = \mathrm{S}_P\psi(x)$ and demand that ψ' satisfy the Dirac equation in the reflected coordinates. Since $\partial/\partial x^0_P = \partial_0$ and $\partial/\partial x^i_P = -\partial_i$, the requirement is

$$\left(\mathrm{i}\hbar\gamma^0\partial_0 - \mathrm{i}\hbar\gamma^i\partial_i - mc\right)\mathrm{S}_P\psi = 0\,.$$

Multiplying the original equation on the left by S_P and inserting $\mathrm{S}_P^{-1}\mathrm{S}_P$ before ψ gives

$$\left(\mathrm{i}\hbar\,\mathrm{S}_P\gamma^0\mathrm{S}_P^{-1}\partial_0 + \mathrm{i}\hbar\,\mathrm{S}_P\gamma^i\mathrm{S}_P^{-1}\partial_i - mc\right)\mathrm{S}_P\psi = 0\,,$$

so the two agree if and only if $\mathrm{S}_P\gamma^0\mathrm{S}_P^{-1} = \gamma^0$ and $\mathrm{S}_P\gamma^i\mathrm{S}_P^{-1} = -\gamma^i$. The Clifford relation $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbb{1}$ gives $\gamma^0\gamma^0\gamma^0 = \gamma^0$ and $\gamma^0\gamma^i\gamma^0 = -\gamma^i$, since $(\gamma^0)^2 = \mathbb{1}$, so $\mathrm{S}_P = \gamma^0$ works. Uniqueness up to a factor follows because any other solution S' makes $\mathrm{S}'\gamma^0$ commute with all four γ^μ, and the Dirac algebra is irreducible, so by Schur's lemma (Chapter 5) $\mathrm{S}'\gamma^0$ is a multiple of the identity. □

The phase η_P is a new label, and it is worth saying exactly where it comes from. Wigner's classification in Chapter 94 sorts one-particle states by the two Casimir invariants of the *connected* Poincaré group, mass and spin (Theorem 94.29); $\mathcal{P}$ is not in that group, so the classification says nothing about it. Enlarging the group by Λ_P enlarges the label set by one sign per irreducible representation, and that sign is the intrinsic parity. It is therefore a representation label of the *full* Lorentz group, and it exists as a quantum number only in a sector where P is a symmetry — which is why the weak interaction does not assign one.

Applying Equation (105.7) twice returns $\eta_P^2\psi$, so $\eta_P^2 = \pm 1$ and $\eta_P \in \{\pm 1, \pm \mathrm{i}\}$: a fermion's intrinsic parity need not be real. This is not a defect but a reflection of the fact that fermion number is superselected, so that a state of one fermion and a state of none are never superposed and the phase never interferes with anything. What *is* measurable is a relative parity, and one relative parity is fixed by the theory rather than by convention.

Proposition 105.3 (A fermion and its antifermion have opposite intrinsic parity)**.** *If the field ψ transforms as Equation (105.7) with phase η_P, the charge-conjugate field $\psi^c = \mathrm{C}_\mathrm{D}\bar\psi^{\mathsf{T}}$ of Definition 100.9 transforms with phase $-\eta_P^*$.*

Rests on Equations (100.20) and (105.7) and Definition 100.9.

Proof. *Derives Proposition 105.3.*

From Equation (105.7), $\mathcal{P}\bar\psi(x)\mathcal{P}^{-1} = \eta_P^*\bar\psi(x_P)\gamma^0$, since $\gamma^{0\dagger} = \gamma^0$ and $\bar\psi = \psi^\dagger\gamma^0$. Hence

$$\mathcal{P}\psi^c(x)\mathcal{P}^{-1} = \mathrm{C}_\mathrm{D}\left(\eta_P^*\bar\psi(x_P)\gamma^0\right)^{\mathsf{T}} = \eta_P^*\,\mathrm{C}_\mathrm{D}\gamma^{0\mathsf{T}}\bar\psi^{\mathsf{T}}(x_P)\,.$$

Equation (100.20) with $\mu = 0$ reads $\mathrm{C}_\mathrm{D}\gamma^{0\mathsf{T}}\mathrm{C}_\mathrm{D}^{-1} = -\gamma^0$, so $\mathrm{C}_\mathrm{D}\gamma^{0\mathsf{T}} = -\gamma^0\mathrm{C}_\mathrm{D}$ and the right-hand side is $-\eta_P^*\gamma^0\psi^c(x_P)$. □

Example 105.4 (Positronium)**.** An electron–positron bound state with relative orbital angular momentum L has parity

$$\eta_P(e^+e^-) = \eta_P(e^-)\,\eta_P(e^+)\,(-1)^L = (-1)^{L+1}\,, \tag{105.8}$$

by Proposition 105.3 and Equation (105.4). The ground states are therefore odd, $J^P = 0^-$ for para-positronium and 1^- for ortho-positronium, which is why the 2γ decay of the former proceeds to a state of odd parity and not, as one might carelessly guess, to an even one.

The bilinears, and where parity can hide Everything that can appear in a local Lagrangian built from a Dirac field is a sum of the sixteen bilinears $\bar\psi\Gamma\psi$ with Γ running over $\mathbb{1}$, γ^5, γ^μ, $\gamma^\mu\gamma^5$ and $\sigma^{\mu\nu} = \frac{\mathrm{i}}{2}[\gamma^\mu, \gamma^\nu]$, possibly carrying derivatives. Their behaviour under P follows from Equation (105.7) by one line of Clifford algebra each. Since $\gamma^0\gamma^\mu\gamma^0 = \gamma_\mu$ — meaning $+\gamma^0$ for $\mu = 0$ and $-\gamma^i$ for $\mu = i$ — and $\gamma^0\gamma^5\gamma^0 = -\gamma^5$ because γ^5 anticommutes with every γ^μ, one obtains

$$\mathcal{P}\left[\bar\psi\psi\right](x)\mathcal{P}^{-1} = +\left[\bar\psi\psi\right](x_P)\,, \tag{105.9}$$

$$\mathcal{P}\left[\bar\psi\gamma^5\psi\right](x)\mathcal{P}^{-1} = -\left[\bar\psi\gamma^5\psi\right](x_P)\,, \tag{105.10}$$

$$\mathcal{P}\left[\bar\psi\gamma^\mu\psi\right](x)\mathcal{P}^{-1} = +\left[\bar\psi\gamma_\mu\psi\right](x_P)\,, \tag{105.11}$$

$$\mathcal{P}\left[\bar\psi\gamma^\mu\gamma^5\psi\right](x)\mathcal{P}^{-1} = -\left[\bar\psi\gamma_\mu\gamma^5\psi\right](x_P)\,. \tag{105.12}$$

The four names — scalar S, pseudoscalar $\tilde{S}$, vector V^μ, axial vector A^μ — are exactly these four lines, and Table 105.1 collects them together with the C and T columns derived below.

The interaction of quantum electrodynamics is $-j^\mu A_\mu$ with $j^\mu = qc\,\bar{\psi}\gamma^\mu\psi$ the vector current of Equation (100.6). Comparing Equation (105.11) with Equation (105.6), the two lower an index in the same way, so the contraction $j^\mu A_\mu$ is invariant and P is an exact symmetry of QED — the statement made without proof in Section 100.1.4 and proved here. The same argument applies verbatim to the quark–gluon coupling of Chapter 102, which is also a vector current, with one exception that is the subject of Section 105.7: the topological term permitted in the QCD Lagrangian is P-odd, and only experiment tells us that its coefficient is tiny.

What Equation (105.12) shows is where parity violation must live. If a Lagrangian contains *both* V^μ and A^μ coupled to the same object, then under P the relative sign of the two flips and the theory is not invariant. Parity is violated exactly when vector and axial currents interfere — which is why the discovery of Section 105.2.2 took the form it did.

Multiplicativity and the parity of the pion Because $\mathcal{P}$ is a unitary operator implementing a $\mathbb{Z}_2$ operation, the parity of a composite state is the product of the intrinsic parities of its constituents times $(-1)^L$ for each relative orbital angular momentum. Parity is therefore a *multiplicative* quantum number, unlike charge or baryon number, which are additive; this is the general fact that a symmetry group $\mathbb{Z}_2$ has one-dimensional representations labelled by a sign.

Intrinsic parities are measurable only relative to a convention, and the convention universally adopted is that the proton, the neutron and the Λ carry $\eta_P = +1$. Everything else is then determined by experiment. The classical determination is the pion's, and it is worth giving in full because it uses nothing but the two counting rules just established plus the antisymmetry of identical fermions.

Phenomenon 105.5 (The charged pion is pseudoscalar)**.** The reaction $\pi^- + d \to n + n$, in which a negative pion is captured at rest from an atomic orbit of pionic deuterium, proceeds at a rate comparable to the competing radiative channel $\pi^- + d \to n + n + \gamma$ [985]. Its occurrence at all requires the pion to have intrinsic parity $\eta_P(\pi) = -1$, given $\eta_P(n) = +1$.
Rests on Equation (105.4).

Derivation. *Derives Phenomenon 105.5.*

A negative pion stopped in liquid deuterium is captured into a Bohr orbit of the pionic deuterium atom and cascades downward. Because the pion is some 273 times heavier than the electron, its Bohr radius is smaller by the same factor and the overlap with the deuteron is enormous; the cascade terminates in the $1S$ state, from which nuclear capture occurs. The initial orbital angular momentum is therefore $L_i = 0$, and since the pion is spinless and the deuteron has spin 1, the initial total angular momentum is $J = 1$. The initial parity is

$$\eta_P(\pi)\,\eta_P(d)\,(-1)^{L_i} = \eta_P(\pi)\,,$$

because the deuteron, a ${}^3S_1$ bound state of two nucleons of parity $+1$ with a small ${}^3D_1$ admixture, has $\eta_P(d) = +1$: both $L = 0$ and $L = 2$ are even.

The final state is two neutrons, identical fermions, so the total wavefunction must be antisymmetric under exchange. Exchanging the two neutrons multiplies the spatial part by $(-1)^L$ and the spin part by $(-1)^{S+1}$ — the triplet $S = 1$ is symmetric and the singlet $S = 0$ antisymmetric — so the requirement is

$$(-1)^{L+S+1} = -1\,, \qquad \text{that is} \qquad L + S \text{ even}\,. \tag{105.13}$$

Enumerate the states with $J = 1$: ${}^1S_0$ has $J = 0$; ${}^3S_1$ has $L + S = 1$, odd, excluded; ${}^1P_1$ has $L + S = 1$, excluded; ${}^3D_1$ has $L + S = 3$, excluded; and ${}^3P_1$ has $L + S = 2$, even, and $J = 1$. Exactly one state survives, ${}^3P_1$, of parity $(-1)^L = (-1)^1 = -1$.

Equating initial and final parity gives $\eta_P(\pi) = -1$. The experimental input is that the reaction occurs: Panofsky, Aamodt and Hadley measured the ratio of the two capture channels and found the non-radiative one present at a comparable rate [985], which cannot happen if the only accessible final state is forbidden by parity. □

The same $J^P = 0^-$ assignment for the neutral pion follows from the observed $\pi^0 \to \gamma\gamma$ angular correlation, and the fact that all three pions form an isospin triplet with the same spin and parity ties them together. A pseudoscalar pion is the reason a two-pion state has parity $(+1)(-1)^L$ rather than $(-1)^L$, and it is what makes $K \to 2\pi$ and $K \to 3\pi$ distinguish parities in Section 105.2.1.

105.1.2 Charge conjugation

The operation on the Dirac field The Dirac equation in an external electromagnetic field,

$$\left[\mathrm{i}\hbar\gamma^\mu\left(\partial_\mu + \frac{\mathrm{i}q}{\hbar}A_\mu\right) - mc\right]\psi = 0\,, \tag{105.14}$$

with D_μ the covariant derivative of Equation (100.9), describes a particle of charge q and mass m. Its solutions of negative frequency were interpreted by Dirac as antiparticles and observed as the positron (Chapter 95). Charge conjugation is the statement that the equation with q replaced by $-q$ has exactly as many solutions, in explicit correspondence.

Proposition 105.6 (The charge-conjugate spinor)**.** *Let* $\mathrm{C_D}$ *satisfy Equation* (100.20)*,* $\mathrm{C_D}(\gamma^\mu)^{\mathsf{T}}\mathrm{C_D}^{-1} = -\gamma^\mu$*. If* ψ *solves Equation* (105.14)*, then*

$$\psi^c := \mathrm{C_D}\,\bar\psi^{\mathsf{T}} \tag{105.15}$$

solves the same equation with $q \to -q$*, with the same mass.*

Rests on Equations (100.20) *and* (105.14)*.*

Proof. *Derives Proposition 105.6.*

Expand Equation (105.14): $\mathrm{i}\hbar\gamma^\mu\partial_\mu\psi - q\gamma^\mu A_\mu\psi - mc\psi = 0$. Take the Hermitian conjugate, using $\gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$ and A_μ real:

$$-\mathrm{i}\hbar\,\partial_\mu\psi^\dagger\gamma^{\mu\dagger} - q\,\psi^\dagger\gamma^{\mu\dagger}A_\mu - mc\,\psi^\dagger = 0\,.$$

Multiply on the right by γ^0 and use $\gamma^{\mu\dagger}\gamma^0 = \gamma^0\gamma^\mu$ together with $\bar\psi = \psi^\dagger\gamma^0$:

$$-\mathrm{i}\hbar\,\partial_\mu\bar\psi\,\gamma^\mu - q\,\bar\psi\gamma^\mu A_\mu - mc\,\bar\psi = 0\,.$$

This is a row-spinor equation; transpose it to obtain a column,

$$-\mathrm{i}\hbar\,(\gamma^\mu)^{\mathsf{T}}\,\partial_\mu\bar\psi^{\mathsf{T}} - q\,(\gamma^\mu)^{\mathsf{T}}\,A_\mu\bar\psi^{\mathsf{T}} - mc\,\bar\psi^{\mathsf{T}} = 0\,,$$

and multiply on the left by $\mathrm{C_D}$, inserting $\mathrm{C_D}^{-1}\mathrm{C_D}$ in front of each $\bar\psi^{\mathsf{T}}$. With $\mathrm{C_D}(\gamma^\mu)^{\mathsf{T}}\mathrm{C_D}^{-1} = -\gamma^\mu$ and $\psi^c = \mathrm{C_D}\bar\psi^{\mathsf{T}}$ this reads

$$\mathrm{i}\hbar\gamma^\mu\partial_\mu\psi^c + q\gamma^\mu A_\mu\psi^c - mc\,\psi^c = 0\,,$$

which is Equation (105.14) with $q \to -q$. □

In the Dirac representation one may take $\mathrm{C_D} = \mathrm{i}\gamma^2\gamma^0$, as recorded in Definition 100.9; then $\mathrm{C_D^{\mathsf{T}}} = -\mathrm{C_D}$ and $\mathrm{C_D^\dagger} = \mathrm{C_D}^{-1} = -\mathrm{C_D}$. Two features of Proposition 105.6 deserve emphasis. First, the mass is untouched: charge conjugation relates a particle to something of the same mass, which is a *theorem* of the free theory and, once interactions are switched on, becomes the much deeper statement of Section 105.5. Second, ψ^c is built from $\bar\psi^{\mathsf{T}}$, i.e. from ψ^*, so the operation involves complex conjugation of the wavefunction while remaining, on the Fock space, a *unitary* operator: the antilinearity is absorbed into the exchange of creation and annihilation operators. In terms of modes, $\mathcal{C}$ maps the operator that annihilates an electron of momentum $\boldsymbol{p}$ and spin s into the one that annihilates a positron of the same $\boldsymbol{p}$ and the same s. Momentum and spin are spectators; only the charge-like labels move.

C-parity as a quantum number Since $\mathcal{C}$ exchanges a particle with a different particle, a charged state is never an eigenstate: $\mathcal{C}\,|e^-\rangle \propto |e^+\rangle$, which is orthogonal to it. Only a state that is its own antiparticle can carry a C eigenvalue — the photon, the π^0, the η, positronium, a neutral non-strange meson–antimeson combination.

The photon's value is forced. The interaction $-j^\mu A_\mu$ must be C-even (it is the coupling that generates all of atomic physics, and C is an exact symmetry of QED), while the current $j^\mu = qc\,\bar\psi\gamma^\mu\psi$ is C-odd. To see the latter, apply $\mathcal{C}\psi\mathcal{C}^{-1} = \eta_C \mathrm{C_D}\bar\psi^{\mathsf T}$ and $\mathcal{C}\bar\psi\mathcal{C}^{-1} = -\eta_C^*\psi^{\mathsf T}\mathrm{C_D^{-1}}$ to a bilinear. The two fermion operators must be reordered, which costs a minus sign, and the result is

$$\mathcal{C}\left[\bar\psi\Gamma\psi\right]\mathcal{C}^{-1} = \bar\psi\left(\mathrm{C_D^{-1}}\Gamma\mathrm{C_D}\right)^{\mathsf T}\psi\,. \tag{105.16}$$

For $\Gamma = \gamma^\mu$ the defining relation gives $\mathrm{C_D^{-1}}\gamma^\mu\mathrm{C_D} = -(\gamma^\mu)^{\mathsf T}$, whose transpose is $-\gamma^\mu$, so $V^\mu \to -V^\mu$. Hence

$$\mathcal{C}A^\mu(x)\mathcal{C}^{-1} = -A^\mu(x)\,, \qquad \eta_C(\gamma) = -1\,, \tag{105.17}$$

and an n-photon state has $C = (-1)^n$. The same computation applied to the other four Γ's gives the C column of Table 105.1; the only entry that requires a moment's care is $\gamma^5 = \mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$, for which $\mathrm{C_D^{-1}}\gamma^5\mathrm{C_D} = \mathrm{i}(-\gamma^{0\mathsf T})(-\gamma^{1\mathsf T})(-\gamma^{2\mathsf T})(-\gamma^{3\mathsf T}) = \mathrm{i}\,(\gamma^3\gamma^2\gamma^1\gamma^0)^{\mathsf T} = (\gamma^5)^{\mathsf T}$, because reversing four mutually anticommuting factors costs six transpositions and hence no sign. So the pseudoscalar bilinear is C-even.

Example 105.7 (The neutral pion, and a forbidden decay)**.** The decay $\pi^0 \to \gamma\gamma$ is observed with a branching fraction of $(98.823 \pm 0.034)\,\%$ [2427], so $\eta_C(\pi^0) = (-1)^2 = +1$. The decay $\pi^0 \to 3\gamma$ would require $C = (-1)^3 = -1$ and is forbidden. The experimental limit is a branching fraction below 3.1×10^{-8} at 90 % confidence [2427] — a suppression of more than seven orders of magnitude relative to the allowed channel, where phase space alone would cost only about two. The missing five orders are the symmetry.

Example 105.8 (Positronium as a C meter)**.** For a fermion–antifermion pair of relative orbital angular momentum L and total spin S, exchanging the two particles requires exchanging their positions, their spins, and their charge labels; the first costs $(-1)^L$, the second $(-1)^{S+1}$, the third is $\mathcal{C}$ itself, and the total must be -1 because the constituents are fermions. Hence

$$\eta_C(f\bar f) = (-1)^{L+S}\,. \tag{105.18}$$

Para-positronium ($L = 0$, $S = 0$) has $C = +1$ and decays to two photons; ortho-positronium ($L = 0$, $S = 1$) has $C = -1$ and must decay to three. The observed rates differ by the extra factor of α that the third photon costs, the singlet living 125 ps and the triplet 142 ns, a ratio of about 1100 that no dynamical accident would supply.

Theorem 105.9 (Furry)**.** *Any amplitude in quantum electrodynamics consisting of a single closed fermion loop with an odd number of external photons vanishes identically [793].*

Rests on Theorem 100.10 and Equation (105.17)*.*

This is proved as Theorem 100.10 by comparing the two orientations of the loop; the symmetry reading is one line. A closed fermion loop with n photons attached is a matrix element of an operator that is C-even (the vacuum is C-even, and so is the interaction), while the n-photon state has $C = (-1)^n$; for odd n the two disagree and the amplitude must vanish. The practical value is large: Furry's theorem removes whole classes of diagrams before they are computed, and it is the reason light-by-light scattering starts at four photons and not at three.

G-parity Charge conjugation is useless for a charged pion, since $\mathcal{C}\,|\pi^+\rangle = |\pi^-\rangle$. But the strong interaction of Chapter 102 conserves isospin, and a rotation by π about the 2-axis in isospin space maps $\pi^\pm$ into $\pi^\mp$ as well. Composing the two gives an operation under which the whole pion triplet is an eigenstate. Isospin is a dimensionless internal label and not an angular momentum, so its generators carry no $\hbar$ and the rotation angle appears alone in the exponent:

$$\mathcal{G} := \mathcal{C}\,\mathrm{e}^{\mathrm{i}\pi \hat{I}_2}\,. \tag{105.19}$$

For a neutral, non-strange multiplet of isospin I one has

$$\eta_G = \eta_C\,(-1)^I\,, \tag{105.20}$$

because the isospin rotation acts on the $I_3 = 0$ member of an isospin-I multiplet with eigenvalue $(-1)^I$, exactly as an ordinary rotation by π acts on Y_{I0}. For the pion, $\eta_C(\pi^0) = +1$ and $I = 1$, so

$$\eta_G(\pi) = -1\,, \qquad \eta_G(n\pi) = (-1)^n\,. \tag{105.21}$$

G-parity is conserved by the strong interaction, and the selection rule is immediately useful: the ρ meson ($I = 1$, $\eta_C = -1$, hence $\eta_G = +1$) decays strongly to two pions and not to three, while the ω ($I = 0$, $\eta_C = -1$, hence $\eta_G = -1$) decays to three and not to two. Both patterns are observed, and neither follows from energy or angular momentum. It fails, as it must, for the electromagnetic and weak interactions, which do not conserve isospin.

105.1.3 Time reversal

Why the operator must be antiunitary Classically, motion reversal sends $t \to -t$, leaves positions alone and reverses velocities; Newton's equation with a velocity-independent force is invariant. The quantum-mechanical implementation of the same idea is constrained far more tightly, and the constraint is Wigner's [710].

Theorem 105.10 (Time reversal is antiunitary)**.** *Let $\mathcal{T}$ implement motion reversal, in the sense that*

$$\mathcal{T}\hat{\boldsymbol{x}}\mathcal{T}^{-1} = +\hat{\boldsymbol{x}}\,, \qquad \mathcal{T}\hat{\boldsymbol{p}}\mathcal{T}^{-1} = -\hat{\boldsymbol{p}}\,, \tag{105.22}$$

on a system with a Hamiltonian bounded below. Then $\mathcal{T}$ is antiunitary.
Rests on Theorem 94.3.

Proof. *Derives Theorem 105.10.*

By Theorem 94.3 the operator is unitary and linear or antiunitary and antilinear; the argument is to exclude the first.

Two independent exclusions are available, and both are worth having. The first uses nothing beyond the canonical commutator of ordinary quantum mechanics, $[\hat{x}_j, \hat{p}_k] = \mathrm{i}\hbar\delta_{jk}\mathbb{1}$. Conjugating with $\mathcal{T}$ and using Equation (105.22),

$$\mathcal{T}\,[\hat{x}_j, \hat{p}_k]\,\mathcal{T}^{-1} = [\hat{x}_j, -\hat{p}_k] = -\mathrm{i}\hbar\delta_{jk}\mathbb{1}\,.$$

If $\mathcal{T}$ were linear the left-hand side would instead be $\mathcal{T}(\mathrm{i}\hbar\delta_{jk}\mathbb{1})\mathcal{T}^{-1} = +\mathrm{i}\hbar\delta_{jk}\mathbb{1}$, since a linear operator commutes with multiplication by a number. The two are inconsistent, so $\mathcal{T}$ is antilinear: it satisfies $\mathcal{T}(\mathrm{i}\hbar)\mathcal{T}^{-1} = -\mathrm{i}\hbar$, which reconciles them.

The second exclusion is the physically decisive one, because it invokes the spectrum rather than a commutator. Motion reversal must satisfy

$$\mathcal{T}\mathrm{e}^{-\mathrm{i}Ht/\hbar}\mathcal{T}^{-1} = \mathrm{e}^{+\mathrm{i}Ht/\hbar}\,, \tag{105.23}$$

since propagating forward for a time t and then reversing must equal reversing and then propagating backward. If $\mathcal{T}$ were linear, the left-hand side would be $\exp(-\mathrm{i}(\mathcal{T}H\mathcal{T}^{-1})t/\hbar)$

and Equation (105.23) would force $\mathcal{T}H\mathcal{T}^{-1} = -H$. Then for every eigenvalue E of H the value $-E$ would also be an eigenvalue, the spectrum would be unbounded below, and there would be no stable ground state. If instead $\mathcal{T}$ is antilinear, the i in the exponent changes sign as it is pulled through, the left-hand side is $\exp(+\mathrm{i}(\mathcal{T}H\mathcal{T}^{-1})t/\hbar)$, and Equation (105.23) gives

$$\mathcal{T}H\mathcal{T}^{-1} = +H\,, \tag{105.24}$$

with the spectrum intact. Antiunitarity then follows from Theorem 94.3. □

Remark 105.11 (Why P escapes). The same argument applied to space inversion produces no obstruction: $\mathcal{P}$ leaves t alone, so Equation (105.23) is replaced by $\mathcal{P}\mathrm{e}^{-\mathrm{i}Ht/\hbar}\mathcal{P}^{-1} = \mathrm{e}^{-\mathrm{i}Ht/\hbar}$, which a linear operator satisfies with $\mathcal{P}H\mathcal{P}^{-1} = H$. The asymmetry between P and T in this chapter — one has a conserved quantum number and selection rules, the other has neither — traces back to precisely this line, and not to any experimental fact.

Proposition 105.12 (No conserved quantum number for T)**.** *Let $\mathcal{T}$ be antiunitary with $\mathcal{T}\,|a\rangle = \eta_T\,|a\rangle$ for a nondegenerate state $|a\rangle$. Then η_T carries no physical information: it can be set to* 1 *by a choice of phase for $|a\rangle$.*

Rests on Theorem 105.10.

Proof. *Derives Proposition 105.12.*

Replace $|a\rangle$ by $|a'\rangle = \mathrm{e}^{\mathrm{i}\theta}\,|a\rangle$. Antilinearity gives $\mathcal{T}\,|a'\rangle = \mathrm{e}^{-\mathrm{i}\theta}\eta_T\,|a\rangle = \mathrm{e}^{-2\mathrm{i}\theta}\eta_T\,|a'\rangle$, so the eigenvalue is $\eta_T\mathrm{e}^{-2\mathrm{i}\theta}$ and $\theta = \frac{1}{2}\arg\eta_T$ makes it unity. □

There is a deeper way to say the same thing. A conserved quantum number comes from a Hermitian generator, by Noether's theorem or by the spectral theorem; an antiunitary operator has no Hermitian generator, because it is not part of any continuous one-parameter group. What T invariance gives instead is a relation between amplitudes, derived in Equation (105.25) below, and one genuine degeneracy theorem.

Kramers degeneracy

Theorem 105.13 (Kramers)**.** *Let H be T-invariant, $\mathcal{T}H\mathcal{T}^{-1} = H$, on a system of half-integer total angular momentum, for which $\mathcal{T}^2 = -\mathbb{1}$. Then every energy eigenvalue is at least twofold degenerate, and no perturbation that is itself T-invariant can lift the degeneracy [659].*

Rests on Theorem 105.10 and Equation (105.24)*.*

Proof. *Derives Theorem 105.13.*

On a system of angular momentum j the time-reversal operator may be written $\mathcal{T} = \mathrm{e}^{-\mathrm{i}\pi\hat{J}_y/\hbar}K$ with K complex conjugation in the $\hat{J}_z$ eigenbasis, since this is the unique antiunitary satisfying $\mathcal{T}\hat{\boldsymbol{J}}\mathcal{T}^{-1} = -\hat{\boldsymbol{J}}$. Squaring, the K's cancel and the rotation doubles: $\mathcal{T}^2 = \mathrm{e}^{-2\mathrm{i}\pi\hat{J}_y/\hbar} = (-1)^{2j}\mathbb{1}$, which is $-\mathbb{1}$ for half-integer j (Remark 94.6 is the same sign seen in a neutron interferometer).

Let $H\,|\psi\rangle = E\,|\psi\rangle$. Then $H\mathcal{T}\,|\psi\rangle = \mathcal{T}H\,|\psi\rangle = E\mathcal{T}\,|\psi\rangle$ — note that E is real, so antilinearity does not disturb it — and $\mathcal{T}\,|\psi\rangle$ has the same energy. It remains to show that it is a *different* state. Antiunitarity means $\langle\mathcal{T}\varphi|\mathcal{T}\psi\rangle = \langle\psi|\varphi\rangle$ for all φ, ψ. Take $\varphi = \mathcal{T}\psi$:

$$\big\langle \mathcal{T}^2\psi \big| \mathcal{T}\psi \big\rangle = \langle\psi|\mathcal{T}\psi\rangle\ .$$

The left side is $\langle -\psi|\mathcal{T}\psi\rangle = -\langle\psi|\mathcal{T}\psi\rangle$, so $\langle\psi|\mathcal{T}\psi\rangle = 0$: the two states are orthogonal. Finally, if V is a T-invariant perturbation, the same argument applies to $H + V$ at every order, so the pair stays degenerate. □

Kramers's own context was the paramagnetic rotation of light in crystals: an ion with an odd number of electrons has half-integer total angular momentum, and no electrostatic crystal field — however low its symmetry — can split its lowest level into singlets. Only a magnetic field can, because $\boldsymbol{B}$ is T-odd and breaks the hypothesis. The theorem thus explains, without any detailed calculation, why odd-electron and even-electron ions behave completely differently in a crystal, and it remains the standard tool for classifying magnetic ions.

Motion reversal is not the arrow of time It is worth stating plainly, because the confusion is common, that the T of this chapter has nothing to do with the second law of Chapter 54. The microscopic laws of electromagnetism, of the strong interaction and of gravity are exactly T-invariant, and the weak interaction violates T by a few parts in a thousand; yet entropy increases by factors of 10^{20} in ordinary processes. The second law is a statement about the overwhelming majority of *initial conditions* compatible with a given macroscopic description, together with the coarse-graining that defines that description. It would hold with the same force in a world where T were an exact symmetry, and it is not measurably strengthened by the 10^{-3} violation that the kaon exhibits. A theory of the arrow of time must explain a low-entropy initial condition; no amount of microscopic T violation does that.

Reciprocity, detailed balance, and why they prove less than they seem to

Proposition 105.14 (Reciprocity)**.** *If $\mathcal{T}H\mathcal{T}^{-1} = H$, the S-matrix satisfies*

$$\langle f|\, S\,|i\rangle = \langle \mathcal{T}i|\, S\,|\mathcal{T}f\rangle \ , \tag{105.25}$$

where $\mathcal{T}i$ denotes the state i with all momenta and spins reversed.

Rests on Theorem 105.10 and Equation (105.23).

Proof. *Derives Proposition 105.14.*

First an identity used repeatedly below. For an antiunitary $\mathcal{A}$ and any operator O,

$$\langle \mathcal{A}\varphi|\, O\,|\mathcal{A}\psi\rangle = \Big\langle \varphi\Big|\mathcal{A}^{-1}O\mathcal{A}\psi\Big\rangle^{*} = \langle\psi|\, \mathcal{A}^{-1}O^{\dagger}\mathcal{A}\,|\varphi\rangle^{*} \ , \tag{105.26}$$

which follows by writing $O\mathcal{A}\,|\psi\rangle = \mathcal{A}(\mathcal{A}^{-1}O\mathcal{A})\,|\psi\rangle$ and applying $\langle\mathcal{A}\varphi|\mathcal{A}\chi\rangle = \langle\chi|\varphi\rangle$.

Now T invariance of H implies, by Equation (105.23) extended to the interacting evolution operator, that $\mathcal{T}S\mathcal{T}^{-1} = S^{\dagger}$: reversing the motion turns the scattering operator into its inverse, which unitarity identifies with $S^{\dagger}$. Substituting $O = S$, $\mathcal{A} = \mathcal{T}$, $\varphi = i$, $\psi = f$ into Equation (105.26) and using $\mathcal{T}^{-1}S^{\dagger}\mathcal{T} = S$ gives $\langle \mathcal{T}i|\, S\,|\mathcal{T}f\rangle = \langle f|\, S\,|i\rangle^{**} = \langle f|\, S\,|i\rangle$. □

Equation (105.25) is the correct statement of "detailed balance": the amplitude for $i \to f$ equals that for the reversed process $\mathcal{T}f \to \mathcal{T}i$, with every momentum and every spin flipped. Two cautions attach to using it as a test.

First, at lowest order in a weak perturbation the test is empty. If $S = \mathbb{1} - \frac{\mathrm{i}}{\hbar}\int \mathrm{d}t\, H_w(t)$ to first order, then $|\langle f|\, S\,|i\rangle| = |\langle i|\, S\,|f\rangle|$ follows from the hermiticity of H_w alone, with no reference to T. A first-order process therefore cannot violate detailed balance whether or not T holds, and observing detailed balance in, say, a nuclear reaction and its inverse tests T only to the extent that higher orders matter.

Second, and more insidiously, a nonzero T-*odd* observable does not by itself establish T violation. The classic example is the triple correlation

$$D\,\frac{\langle \boldsymbol{J}\rangle}{J}\cdot\frac{\boldsymbol{p}_e\times\boldsymbol{p}_\nu}{E_eE_\nu/c^2} \tag{105.27}$$

in the decay of polarized neutrons, in which all three vectors reverse under motion reversal so that the product is odd. Yet a nonzero D can be generated by final-state interactions in a perfectly T-invariant theory. To see how, write an amplitude as a sum of two contributions carrying a CP-odd ("weak") phase ϕ and a CP-even ("strong", or Coulomb) rescattering phase δ,

$$\mathcal{M} = a_1 \mathrm{e}^{\mathrm{i}\delta_1}\mathrm{e}^{\mathrm{i}\phi_1} + a_2 \mathrm{e}^{\mathrm{i}\delta_2}\mathrm{e}^{\mathrm{i}\phi_2}\,, \tag{105.28}$$

with $a_{1,2}$ real. A T-odd correlation is proportional to $\mathrm{Im}(\mathcal{M}_1\mathcal{M}_2^*) = a_1 a_2 \sin(\delta_1-\delta_2+\phi_1-\phi_2)$, which is nonzero when $\delta_1 \neq \delta_2$ even if $\phi_1 = \phi_2$. In neutron decay the Coulomb interaction between the outgoing proton and electron supplies $\delta_1 - \delta_2 \sim \alpha m_e c/p_e$, faking $D \sim 10^{-5}$; the measured value, $D = (-1.2 \pm 2.0)\times 10^{-4}$ [2427], is not yet sensitive to the fake, let alone to anything beyond it. The lesson generalizes: a genuine T test must either compare a process with its motion reverse (Section 105.4) or measure a static property of a nondegenerate state (Section 105.4.3), where no final state exists to rescatter.

Time reversal on the fields On a Dirac field, antiunitarity plus the requirement that solutions map to solutions gives

$$\mathcal{T}\psi(ct,\boldsymbol{x})\mathcal{T}^{-1} = \eta_T\, \mathrm{T_D}\, \psi(-ct,\boldsymbol{x})\,, \qquad \mathrm{T_D^{-1}}\gamma^{\mu *}\mathrm{T_D} = \gamma_\mu\,, \tag{105.29}$$

with $\mathrm{T_D} = \gamma^1\gamma^3$ in the Dirac representation; the complex conjugate on γ^μ is the signature of the antilinearity, exactly as in Theorem 105.10. For the gauge field the assignment is fixed by the classical behaviour of the sources: reversing all motions reverses currents but not charges, so

$$\mathcal{T}A^0(ct,\boldsymbol{x})\mathcal{T}^{-1} = A^0(-ct,\boldsymbol{x})\,, \quad \mathcal{T}A^i(ct,\boldsymbol{x})\mathcal{T}^{-1} = -A^i(-ct,\boldsymbol{x})\,, \tag{105.30}$$

whence $\boldsymbol{E} \to +\boldsymbol{E}$ and $\boldsymbol{B} \to -\boldsymbol{B}$. That $\boldsymbol{B}$ is T-odd and $\boldsymbol{E}$ is T-even is used at three separate places below — in Kramers degeneracy, in the electric dipole moment argument, and in the sign of the magnetic moment under CPT — and it is worth remembering as a picture: a magnetic field is made by currents, and currents reverse.

Carrying Equation (105.29) through the bilinears as before completes Table 105.1.

Table 105.1: The five Dirac bilinears under the discrete operations. An entry x_P means the argument is $(ct,-\boldsymbol{x})$, x_T means $(-ct,\boldsymbol{x})$, and $-x$ means $(-ct,-\boldsymbol{x})$; a lowered index means the factor $(+1,-1,-1,-1)$ componentwise. The last column, the product of the other three, is the content of the CPT theorem at the level of a single bilinear: the sign is $(-1)^n$ with n the number of Lorentz indices, and *nothing else about the bilinear matters.*

bilinear	P	C	T	$\Theta = CPT$
$S = \bar\psi\psi$	$+S(x_P)$	$+S$	$+S(x_T)$	$+S(-x)$
$\tilde S = \bar\psi\gamma^5\psi$	$-\tilde S(x_P)$	$+\tilde S$	$-\tilde S(x_T)$	$+\tilde S(-x)$
$V^\mu = \bar\psi\gamma^\mu\psi$	$+V_\mu(x_P)$	$-V^\mu$	$+V_\mu(x_T)$	$-V^\mu(-x)$
$A^\mu = \bar\psi\gamma^\mu\gamma^5\psi$	$-A_\mu(x_P)$	$+A^\mu$	$+A_\mu(x_T)$	$-A^\mu(-x)$
$T^{\mu\nu} = \bar\psi\sigma^{\mu\nu}\psi$	$+T_{\mu\nu}(x_P)$	$-T^{\mu\nu}$	$-T_{\mu\nu}(x_T)$	$+T^{\mu\nu}(-x)$

The last column will be derived and used in Section 105.5.1; it is written here because it costs nothing once the other three exist, and because seeing it early makes the shape of the CPT theorem obvious. Under $\Theta = CPT$ a bilinear returns to itself, at the reflected point, with the sign $(-1)^n$ where n counts its Lorentz indices — and with no memory of whether it was scalar or pseudoscalar, vector or axial. That insensitivity is why the product survives when the factors do not.

105.2 Parity violation

105.2.1 The tau–theta puzzle and the Lee–Yang question

By 1955 two strange mesons were known that agreed in every property that could then be measured and disagreed in one that could not be explained. The θ^+ decayed to $\pi^+\pi^0$; the τ^+ decayed to $\pi^+\pi^+\pi^-$. Their masses agreed to better than a per cent and their lifetimes to better than the experimental errors, which for two unrelated particles would be an extraordinary coincidence. But the parities of the two final states are opposite.

Proposition 105.15 (Parity of an n-pion state)**.** *A state of n pions with total orbital angular momentum content L_{tot} (the sum of the relative orbital angular momenta) has parity*

$$\eta_P(n\pi) = (-1)^n\,(-1)^{L_{\mathrm{tot}}}\,. \tag{105.31}$$

Rests on Phenomenon 105.5 and Equation (105.4).

Proof. *Derives Proposition 105.15.*

Immediate from multiplicativity, the pseudoscalar assignment $\eta_P(\pi) = -1$ of Phenomenon 105.5, and Equation (105.4) applied to each relative coordinate. □

For the θ^+, the parent is spinless (its decay products are two spinless particles, and the angular distribution is isotropic), so $L = 0$ and $\eta_P = (-1)^2 = +1$. For the τ^+, if all relative angular momenta vanish then $\eta_P = (-1)^3 = -1$. Two particles of the same mass and the same lifetime were therefore decaying into final states of opposite parity — impossible if parity is conserved, unless the two are genuinely different particles that happen to be degenerate, or unless the τ decay carries $L_{\mathrm{tot}} = 1$ and the parent has spin ≥ 1.

The Dalitz plot It was Dalitz's construction that closed the second escape [1016]. For a three-body decay of a particle at rest into three pions of kinetic energies T_1, T_2, T_3 with $T_1 + T_2 + T_3 = Q$ fixed, plot the event as the point of an equilateral triangle of height Q whose perpendicular distances to the three sides are T_1, T_2, T_3. The kinematically allowed region is a closed curve inside the triangle, and — this is the content of the construction — the *density of points is uniform whenever the decay matrix element is constant.*

Derivation. The three-body phase space for a parent of mass M decaying at rest is

$$\mathrm{d}\Gamma \propto |\mathcal{M}|^2\;\frac{\mathrm{d}^3p_1}{E_1}\frac{\mathrm{d}^3p_2}{E_2}\frac{\mathrm{d}^3p_3}{E_3}\,\delta^3\!\left(\textstyle\sum_a \boldsymbol{p}_a\right)\delta\!\left(Mc^2 - \textstyle\sum_a E_a\right)\,.$$

Do the $\boldsymbol{p}_3$ integral with the momentum delta function, write $\mathrm{d}^3p_1 = p_1^2\mathrm{d}p_1\mathrm{d}\Omega_1$ and $\mathrm{d}^3p_2 = p_2^2\mathrm{d}p_2\,\mathrm{d}\cos\theta_{12}\,\mathrm{d}\varphi$, and use the energy delta function to fix $\cos\theta_{12}$. Since $E_3^2/c^2 = \boldsymbol{p}_1^2 + \boldsymbol{p}_2^2 + 2p_1p_2\cos\theta_{12} + m_3^2c^2$, one has $\mathrm{d}\cos\theta_{12} = E_3\mathrm{d}E_3/(c^2p_1p_2)$ at fixed p_1, p_2, and the three factors of E_a in the denominators cancel against $p_a^2\mathrm{d}p_a = E_a\mathrm{d}E_a p_a/c^2$. Collecting,

$$\mathrm{d}\Gamma \propto |\mathcal{M}|^2\;\mathrm{d}E_1\,\mathrm{d}E_2\,, \tag{105.32}$$

up to the overall angular factors that integrate to a constant. Since $T_a = E_a - m_\pi c^2$, the density in the (T_1, T_2) plane — and hence in the Dalitz triangle, which is an affine image of it — is $|\mathcal{M}|^2$ and nothing else. □

The plot therefore reads off the matrix element directly. If the decay proceeded with a unit of relative orbital angular momentum, the amplitude would vanish at the centre of the plot, where all three momenta are small, and the population there would be depleted; a $J = 1$ or $J = 2$ parent would leave a characteristic pattern of zeros along the boundary. The observed τ plot was flat. The three pions were in a state of no relative orbital angular momentum, the parent had $J = 0$, and its parity was -1: no escape.

Lee and Yang's question Lee and Yang responded not with a mechanism but with an audit [1091]. They asked what the experimental evidence for parity conservation actually was, and found that all of it came from strong and electromagnetic processes — Laporte's rule, nuclear level schemes, the selection rules of Proposition 105.1. In these sectors the evidence was overwhelming, bounding any parity-violating admixture in the nuclear force at the level of 10^{-7} in amplitude. In the weak interaction there was none at all: not one experiment had ever been designed to detect a parity-odd observable in a weak decay. The θ–τ puzzle was, on this reading, not a puzzle about two particles but a signal that the weak interaction does not conserve parity, and that θ and τ are one particle, the K^+, decaying two ways.

Lee and Yang then did the thing that makes the paper a model of method: they listed the experiments that would settle it. Each of their proposals is the expectation value of a pseudoscalar, since a pseudoscalar is precisely a quantity that must vanish if P is a symmetry:

- the correlation $\langle \boldsymbol{J} \rangle \cdot \boldsymbol{p}_e$ between the polarization of an oriented nucleus and the momentum of the emitted electron — an axial vector dotted into a polar vector;
- the longitudinal polarization $\langle \boldsymbol{s} \rangle \cdot \boldsymbol{p}$ of a lepton emitted in a weak decay — the same structure;
- in the chain $\pi \to \mu\nu$, $\mu \to e\nu\bar{\nu}$, the correlation between the muon direction and the electron direction, which is nonzero only if the muon is produced polarized.

All three were done within a year, and all three gave the maximum possible answer.

105.2.2 The experimental collapse of 1957

Phenomenon 105.16 (Beta emission from oriented nuclei is asymmetric)**.** Nuclei of ^{60}Co polarized in a magnetic field at a temperature of about 0.01 K emit beta electrons preferentially opposite to the nuclear spin. The angular distribution is

$$W(\theta) = 1 + A_\beta \, \frac{\langle \boldsymbol{J} \rangle}{J} \cdot \frac{\boldsymbol{v}_e}{c} = 1 + A_\beta \, \frac{\langle J \rangle}{J} \, \frac{v_e}{c} \cos\theta \,, \tag{105.33}$$

with A_β consistent with -1, and the asymmetry disappears as the sample warms and the polarization is lost [1133]. The apparatus is Chapter 110; see Phenomenon 110.10.

Rests on Equations (105.34) *and* (105.37).

Derivation. *Derives Phenomenon 105.16.*

That $A_\beta \neq 0$ is impossible in a parity-conserving theory needs one line. $\boldsymbol{J}$ is an axial vector and $\boldsymbol{v}_e$ a polar vector, so their scalar product is a pseudoscalar and changes sign under $\mathcal{P}$. If $[\mathcal{P}, H] = 0$ the rate is $\mathcal{P}$-invariant, so $W(\theta) = W(\pi - \theta)$ and the coefficient of $\cos\theta$ must vanish.

That the observed value is the *maximum* takes a little more. The transition $^{60}\mathrm{Co}(5^+) \to {}^{60}\mathrm{Ni}^*(4^+)$ is allowed and pure Gamow–Teller: the leptons carry off one unit of angular momentum in their spins and none in orbital motion. If the emitted antineutrino is purely right-handed and the electron predominantly left-handed — the content of the $V - A$ structure below — then conservation of angular momentum along the nuclear spin axis forces the electron to go backwards. Quantitatively, for a pure Gamow–Teller transition with $\Delta J = -1$ the $V - A$ prediction is $A_\beta = -1$ exactly, and the factor v_e/c in Equation (105.33) is the longitudinal polarization of an electron of speed v_e, derived at Equation (105.37). □

Wu, Ambler, Hayward, Hoppes and Hudson polarized their source by adiabatic demagnetization of a cerium magnesium nitrate crystal into which a thin layer of ^{60}Co had been

grown, and monitored the polarization independently through the anisotropy of the gamma rays from the daughter. The two signals — gamma anisotropy and beta asymmetry — decayed together over some six minutes as the crystal warmed, which is the control that makes the result an observation of parity violation rather than of an instrumental drift.

Two further experiments were reported in the same issue of the same journal. Garwin, Lederman and Weinrich [1110] and Friedman and Telegdi [1109] used the chain $\pi^+ \to \mu^+\nu_\mu$ followed by $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$. If parity is conserved the muon from a spinless pion cannot be longitudinally polarized, since $\langle \boldsymbol{s}_\mu \rangle \cdot \boldsymbol{p}_\mu$ is a pseudoscalar; and even if it were, the electron from its decay could not remember the direction. Both correlations were found: the positrons came out preferentially along the muon spin, with an asymmetry that also measured the muon magnetic moment to be very close to the Dirac value $g = 2$ (the quantity refined to twelve digits in Chapter 112). Phenomenon 110.13 records the modern statement.

Phenomenon 105.17 (The neutrino is left-handed)**.** The neutrino emitted in the electron capture $^{152}\mathrm{Eu}^m + e^- \to {}^{152}\mathrm{Sm}^* + \nu_e$ has helicity -1 within the experimental accuracy [1148]. The apparatus, which used resonant scattering of the daughter gamma ray to select neutrinos emitted backwards, is Chapter 98; see Phenomenon 98.2.

Rests on Equations (105.34) *and* (105.37)*.*

Derivation. Derives Phenomenon 105.17.

The charged-current interaction Equation (105.34) contains the neutrino field only through $(1-\gamma^5)\,\psi_\nu = 2P_L\psi_\nu$, so a neutrino leaving a weak vertex is emitted in a state of definite *chirality* — the left-handed one — whatever the nucleus does. Chirality is not helicity for a massive particle, and the exact relation is Equation (105.37): the longitudinal polarization of a fermion emitted by a $V-A$ current is $-v/c$, so helicity -1 is predicted only up to

$$1 - \frac{v}{c} = 1 - \frac{|\boldsymbol{p}|\,c}{E} = 1 - \sqrt{1 - \frac{m_\nu^2 c^4}{E^2}} \approx \frac{m_\nu^2 c^4}{2E^2}\,.$$

The neutrino of this decay carries $E \approx 0.90\,\mathrm{MeV}$, and the laboratory bound on the neutrino mass is of order $1\,\mathrm{eV}/c^2$ (Chapter 103), so the correction is at most 6×10^{-13}. The prediction is therefore helicity -1 to twelve significant figures, and the measurement — which resolves the sign and roughly its first digit — tests the chiral structure of Equation (105.34) and nothing about the neutrino mass. What the experiment adds to the theory is the *sign*: $V-A$ with the opposite relative sign, $V+A$, would predict $+1$ just as sharply. □

Goldhaber, Grodzins and Sunyar's measurement is the sharpest of the three, because helicity is not merely a nonzero pseudoscalar but a *saturated* one: $\langle \boldsymbol{s} \rangle \cdot \hat{\boldsymbol{p}} = -\hbar/2$ is as large as it can be. Parity is not slightly violated in the weak interaction; it is violated maximally.

The V–A structure The theoretical form that accommodates all of this was proposed by Feynman and Gell-Mann [1144] and independently by Sudarshan and Marshak [1162], with the two-component neutrino of Landau [1118], Lee and Yang [1121] and Salam [1130] as its kinematic core. The charged-current weak interaction at low energy is a product of two currents, each of the form $V-A$:

$$\mathcal{H}_w = \frac{G_F}{\sqrt{2}}\left[\bar{\psi}_p\gamma^\mu\left(g_V - g_A\gamma^5\right)\psi_n\right]\left[\bar{\psi}_e\gamma_\mu\left(1-\gamma^5\right)\psi_\nu\right] + \mathrm{h.c.}\,, \tag{105.34}$$

with $g_A/g_V = -1.2754 \pm 0.0013$ for the nucleon [2427] — the deviation from -1 being a strong-interaction effect, since the quark-level current is pure $V-A$.

Remark 105.18 (The SI dimension of Fermi's constant)*.* Fermi's constant [738] is quoted throughout the literature in the natural-unit form

$$\frac{G_F}{(\hbar c)^3} = (1.166\,378\,8 \pm 0.000\,000\,6)\times10^{-5}/\mathrm{GeV}^2\,, \tag{105.35}$$

which is a statement about $G_F/(\hbar c)^3$ and not about G_F. The constant itself, as it appears in Equation (105.34) where the four fields carry $1/\mathrm{m}^6$ between them and $\mathcal{H}_w$ is an energy density, has the SI value

$$G_F = (1.435\,851\,2 \pm 0.000\,000\,7) \times 10^{-62}\,\mathrm{J\,m^3}\,, \tag{105.36}$$

obtained from Equation (105.35) by multiplying by $(\hbar c)^3 = (3.161\,526\,77 \times 10^{-26}\,\mathrm{J\,m})^3$ and converting GeV^2 to J^2. Both numbers describe the same physics; the first is the one to compare with a textbook and the second is the one that makes Equation (105.34) dimensionally correct. The smallness of the weak interaction at low energy is the smallness of Equation (105.36) measured against $\hbar c$ and a length: at a nuclear scale $r \sim 1\,\mathrm{fm}$ the ratio $G_F/(\hbar c\, r^2) \approx 10^{-6}$, which is the familiar suppression.

Proposition 105.19 ($V - A$ violates parity maximally)**.** *Under $\mathcal{P}$ the chiral projector $P_L = \frac{1}{2}(1-\gamma^5)$ is mapped to $P_R = \frac{1}{2}(1+\gamma^5)$, so the parity image of Equation (105.34) is an interaction with no overlap with the original. The parity-violating part of the leptonic current is as large as the parity-conserving part.*

Rests on Equations (105.7), (105.11) and (105.34).

Proof. *Derives Proposition 105.19.*

From Equation (105.7), $\mathcal{P}\left[\bar\psi_1\gamma^\mu P_L\psi_2\right]\mathcal{P}^{-1} = \bar\psi_1\gamma^0\gamma^\mu\frac{1}{2}(1-\gamma^5)\gamma^0\psi_2$ evaluated at x_P. Because γ^5 anticommutes with γ^0, moving the γ^0 through gives $\gamma^0\gamma^5\gamma^0 = -\gamma^5$ and hence $P_L \to P_R$; the index is lowered as in Equation (105.11). The transformed interaction couples right-handed leptons and is orthogonal, in the space of possible couplings, to the one we started from. Writing $V - A$ as V and A pieces of equal magnitude makes the same point: parity violation is proportional to the V–A interference term, which for coefficients of equal magnitude is as large as either term alone. □

The physical content of the projector is helicity.

Proposition 105.20 (Chirality and helicity)**.** *Let $u(p,s)$ solve the free Dirac equation with $\boldsymbol{p}$ along $\hat{\boldsymbol{z}}$. Then*

$$\langle P_L\rangle - \langle P_R\rangle = -\frac{|\boldsymbol{p}|\,c}{E} = -\frac{v}{c}\,, \tag{105.37}$$

so a $V - A$ current emits a fermion with longitudinal polarization $-v/c$ and an antifermion with $+v/c$; in the ultrarelativistic limit the helicity is ∓ 1 exactly, and for a strictly massless fermion chirality and helicity coincide.

Rests on Equations (100.5) and (105.34).

Proof. *Derives Proposition 105.20.*

The helicity operator is $h = \boldsymbol{\Sigma}\cdot\hat{\boldsymbol{p}}$ with $\boldsymbol{\Sigma} = \mathrm{diag}(\boldsymbol{\sigma},\boldsymbol{\sigma})$. The Dirac equation $(\gamma^\mu p_\mu - mc)u = 0$ gives, in the Dirac representation with $\boldsymbol{p} = p\hat{\boldsymbol{z}}$, the lower two components in terms of the upper: $u = N(\chi,\ c\,\boldsymbol{\sigma}\cdot\boldsymbol{p}\,\chi/(E+mc^2))$ with $N^2 = (E+mc^2)/(2mc^2)$ fixing $\bar u u = 1$. Take χ the eigenvector of σ_z with eigenvalue $+1$. Then $\gamma^5 u$, which exchanges the upper and lower two-spinors, gives

$$u^\dagger\gamma^5 u = 2N^2\,\frac{cp}{E+mc^2} = \frac{cp}{mc^2}\,,$$

the factor 2 being the two equal cross terms between the upper and lower two-spinors. It is $u^\dagger\gamma^5 u$ and not the bilinear $\bar u\gamma^5\gamma^0 u$ that is wanted, the two differing by a sign: $\gamma^0\gamma^5\gamma^0 = -\gamma^5$, so $\bar u\gamma^5\gamma^0 u = -u^\dagger\gamma^5 u$. Likewise $u^\dagger u = N^2\,(1 + c^2p^2/(E+mc^2)^2) = E/(mc^2)$, the bracket collapsing to $2E/(E+mc^2)$ because $c^2p^2 = (E-mc^2)(E+mc^2)$. The ratio is $cp/E = v/c$, and since $\langle P_L\rangle - \langle P_R\rangle = -\langle\gamma^5\rangle$ normalized to $u^\dagger u$, Equation (105.37) follows. As $m \to 0$, $E \to cp$ and the ratio tends to 1: P_L then projects exactly onto helicity -1. □

Equation (105.37) is the factor v_e/c in Equation (105.33), so the shape of Wu's angular distribution, the polarization of the beta electron, and the helicity of the neutrino are three faces of a single structure. The neutrino, being (very nearly) massless, saturates it. The theory of the current itself — why $V-A$, and how it arises from an SU(2) gauge interaction with a left-handed doublet — belongs to Chapter 101 and Chapter 104.

105.2.3 Parity violation as a precision tool

Once parity violation is established it stops being a discovery and becomes an instrument, for a reason worth stating carefully. A weak amplitude is far smaller than an electromagnetic one at ordinary energies, so a weak *rate* is invisible under the electromagnetic background. But a parity-odd observable receives no contribution at all from the electromagnetic amplitude squared: its leading term is the *interference* between the weak and electromagnetic amplitudes, which is linear in the small quantity. Measuring a parity-violating asymmetry therefore buys a factor $\mathcal{M}_\gamma/\mathcal{M}_Z$ of sensitivity relative to measuring a weak rate.

Proposition 105.21 (Size of a parity-violating asymmetry)**.** *For electron scattering at squared momentum transfer Q^2, the ratio of the neutral-current to the photon-exchange amplitude is*

$$\frac{\mathcal{M}_Z}{\mathcal{M}_\gamma} \sim \frac{G_F Q^2 c^2}{4\sqrt{2}\,\pi\alpha\,(\hbar c)^3} \approx 9\times 10^{-5}\,\frac{Q^2c^2}{1\,\mathrm{GeV}^2}\,, \tag{105.38}$$

so the parity-violating asymmetry $A_{PV}=(\sigma_R-\sigma_L)/(\sigma_R+\sigma_L)$ is of order 10^{-4} at $Q^2c^2=1\,\mathrm{GeV}^2$ and of order 10^{-7} at the Q^2 of a low-energy fixed-target experiment.

Rests on Equations (105.34) and (105.35).

Proof. *Derives Proposition 105.21.*

The photon-exchange amplitude carries $4\pi\alpha\hbar c/Q^2$ from the propagator and coupling; the Z-exchange amplitude at $Q^2 \ll m_Z^2c^2$ is contact-like and carries $G_F/(\sqrt{2}(\hbar c)^3)$ in the same normalization. The ratio is Equation (105.38), and inserting $G_F/(\hbar c)^3 = 1.1664\times10^{-5}/\mathrm{GeV}^2$ together with $\alpha = 1/137.036$ gives $1.1664\times10^{-5}/(4\sqrt{2}\pi\times 7.2974\times10^{-3}) = 8.99\times10^{-5}$ per GeV^2. □

Deep inelastic scattering: Prescott 1978 Prescott and collaborators scattered longitudinally polarized electrons of 16.2–22.2 GeV from deuterium at SLAC and reversed the beam helicity at random, pulse to pulse [1625]. They measured

$$\frac{A_{PV}}{Q^2c^2} = (-9.5\pm1.6)\times10^{-5}\,1/\mathrm{GeV}^2\,, \tag{105.39}$$

in magnitude exactly the estimate of Equation (105.38). The electroweak analysis writes

$$\frac{A_{PV}}{Q^2c^2} = a_1 + a_2\,\frac{1-(1-y)^2}{1+(1-y)^2}\,, \qquad y=\frac{\nu}{E}\,, \tag{105.40}$$

with $a_1 \propto 1-\frac{20}{9}\sin^2\theta_W$ and $a_2 \propto 1-4\sin^2\theta_W$. The second coefficient nearly vanishes near $\sin^2\theta_W \approx 0.23$, so it is the *y-dependence* of the asymmetry — the fact that it is nearly flat — that fixes the weak mixing angle rather than its magnitude. Prescott obtained $\sin^2\theta_W = 0.20\pm0.03$, in agreement with the value inferred from neutrino scattering, and thereby confirmed the SU(2) × U(1) structure of Chapter 104 against the alternatives then in play. See Phenomenon 110.17.

Atomic parity violation In an atom, the exchange of a Z between an electron and the nucleus adds to the Hamiltonian a term that is parity-odd, mixing S and P states and giving a normally forbidden $E1$ transition a small amplitude. The nuclear-spin-independent part is governed by the weak charge

$$Q_W = Z\left(1 - 4\sin^2\theta_W\right) - N\,, \tag{105.41}$$

and the induced $E1$ amplitude grows roughly as Z^3: one power from $Q_W \approx -N \propto Z$, and two from the relativistic enhancement of the electron density at the nucleus. Heavy atoms are therefore enormously favoured, and caesium ($Z = 55$) is the practical optimum because its single valence electron makes the atomic structure calculable to a per cent.

Wood and collaborators measured the parity-violating $6S \to 7S$ amplitude in caesium and extracted [1946]

$$Q_W(^{133}\mathrm{Cs}) = -72.06 \pm 0.28 \pm 0.34\,, \tag{105.42}$$

the two errors being experimental and atomic-theoretical. This is a measurement of the weak interaction made in a tabletop apparatus at an energy of a few electronvolts, and it agrees with the value obtained at LEP at 91 GeV — the same weak mixing angle at two energies about ten decades apart, since 91 GeV is 3×10^{10} times a few electronvolts. The agreement is not automatic: $\sin^2\theta_W$ runs with the scale at which it is probed, and the two determinations agree only once that running is applied. See Phenomenon 110.16.

The proton's weak charge, and a nuclear skin Two modern measurements exploit the near-cancellation in Equation (105.41). For a proton, $Z = 1$ and $N = 0$, so $Q_W^p = 1 - 4\sin^2\theta_W \approx 0.0719$: a small number, and a fractional measurement of it is a much finer measurement of $\sin^2\theta_W$. Differentiating, $\delta(\sin^2\theta_W) = \tfrac{1}{4}Q_W^p\,\delta Q_W^p/Q_W^p$, so a 6 % determination of Q_W^p gives $\delta\sin^2\theta_W \approx 0.001$. The Qweak experiment measured an asymmetry of -226.5 ± 9.3 parts per billion at $Q^2c^2 = 0.0248\,\mathrm{GeV}^2$ and obtained [2301]

$$Q_W^p = 0.0719 \pm 0.0045\,, \tag{105.43}$$

in agreement with the Standard Model. See Phenomenon 110.19.

For a heavy nucleus the same cancellation acts the other way. Since $Q_W^p \approx 0.07$ while $Q_W^n = -1$, the Z couples almost exclusively to neutrons, and the parity-violating asymmetry in elastic electron scattering measures the *neutron* distribution while ordinary electron scattering measures the proton distribution. The difference of the two radii is the neutron skin. PREX-2 measured $A_{PV} = 550 \pm 16 \pm 8$ parts per billion on ^{208}Pb and obtained [2370]

$$R_n - R_p = (0.283 \pm 0.071)\,\mathrm{fm}\,. \tag{105.44}$$

The skin thickness is controlled by the density dependence of the nuclear symmetry energy, which is the same quantity that sets the radius of a neutron star, so a parity-violating asymmetry measured on a lead target in a Virginia accelerator hall constrains the equation of state used in Chapter 49. It is a fair example of what a symmetry-violating observable buys: an otherwise inaccessible distribution, extracted cleanly because the electromagnetic background cannot contribute to it.

105.3 CP violation

105.3.1 The neutral kaon system

Landau's proposal, made immediately after the collapse of parity, was that the true symmetry is the product CP [1118]. It is an attractive suggestion: C exchanges a left-handed neutrino

for a left-handed antineutrino, which does not exist; P exchanges it for a right-handed neutrino, which does not exist either; but CP exchanges it for a right-handed antineutrino, which does. Maximal violation of P and of C separately is exactly compatible with exact CP, and for seven years it appeared to be the truth.

The system in which it failed is the one Gell-Mann and Pais had analysed for a different purpose in 1955 [1067], and it remains the most instructive two-state problem in physics.

Two states, two bases The strong interaction produces states of definite strangeness. Write $|K^0\rangle$ for the state of strangeness $S = +1$ (quark content $d\bar{s}$) and $\left|\bar{K}^0\right\rangle$ for $S = -1$ ($\bar{d}s$); they are distinct particles, since strangeness is conserved by the strong interaction that makes them, and each is the antiparticle of the other. Fix phases by

$$\mathcal{CP}\left|K^0\right\rangle = \left|\bar{K}^0\right\rangle , \qquad \mathcal{CP}\left|\bar{K}^0\right\rangle = \left|K^0\right\rangle , \tag{105.45}$$

which is consistent because $(\mathcal{CP})^2 = \mathbb{1}$ on these states. (The opposite sign convention, $\mathcal{CP}\,|K^0\rangle = -\left|\bar{K}^0\right\rangle$, is equally common and changes nothing physical; it interchanges the roles of the two combinations below.) The CP eigenstates are then

$$|K_1\rangle = \frac{|K^0\rangle + \left|\bar{K}^0\right\rangle}{\sqrt{2}} , \quad |K_2\rangle = \frac{|K^0\rangle - \left|\bar{K}^0\right\rangle}{\sqrt{2}} , \tag{105.46}$$

with $CP = +1$ and $CP = -1$ respectively.

The weak interaction, which destroys them, does not conserve strangeness, so it is $|K_1\rangle$ and $|K_2\rangle$ — not $|K^0\rangle$ and $\left|\bar{K}^0\right\rangle$ — that have definite decay properties if CP holds. And the two available final states have opposite CP:

$$\eta_{CP}(\pi\pi) = +1 , \qquad \eta_{CP}(3\pi^0) = -1 . \tag{105.47}$$

For $\pi\pi$ from a spinless parent, $L = 0$, so $\eta_P = (-1)^2(-1)^0 = +1$ by Equation (105.31) and $\eta_C = +1$ for $\pi^0\pi^0$ or, by Equation (105.18) applied to the charge-conjugate pair, for $\pi^+\pi^-$ in an $L = 0$ state. For $3\pi^0$, $\eta_P = (-1)^3 = -1$ and $\eta_C = +1$. Hence if CP is exact, $K_1 \to \pi\pi$ is allowed and $K_2 \to \pi\pi$ is forbidden, and K_2 must decay to three pions or semileptonically.

That is a strong prediction, because three pions barely fit: with $m_K c^2 = (497.611 \pm 0.013)\,\mathrm{MeV}$ [2427] and $3m_\pi c^2 \approx 405\,\mathrm{MeV}$, the released kinetic energy is only about 90 MeV, and the resulting phase-space suppression must make K_2 long-lived. Gell-Mann and Pais predicted exactly this: a second neutral kaon, of the same mass to within the weak interaction's accuracy, with a lifetime orders of magnitude longer. Lande, Booth, Impeduglia, Lederman and Chinowsky found it at the Brookhaven Cosmotron [1090]. The measured lifetimes are

$$\tau_S = (8.954 \pm 0.004) \times 10^{-11}\,\mathrm{s} , \qquad \tau_L = (5.116 \pm 0.021) \times 10^{-8}\,\mathrm{s} , \tag{105.48}$$

a ratio of 571 [2427].

The effective Hamiltonian To do better than the symmetry argument one needs the dynamics of an unstable two-state system, and the only honest way to obtain it is to start from the full unitary problem and eliminate what is not being watched. This is the Wigner–Weisskopf construction, and it is worth carrying out because it is also the prototype of the open-system formalism of Chapter 87 and because the non-Hermitian matrix that comes out of it is otherwise mysterious.

Proposition 105.22 (The two-state effective generator)**.** *Let the Hilbert space be spanned by* $|K^0\rangle, \left|\bar{K}^0\right\rangle$ *and a continuum of decay states* $|n\rangle$ *of energy* E_n*, with a weak perturbation* H_w *connecting the two sectors. On time scales long compared with the memory time of the decay channels — of order* $\hbar$ *divided by the width of the accessible continuum — the amplitudes* $a(t), b(t)$ *of the two kaon states obey*

$$\mathrm{i}\hbar \frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} a \\ b \end{pmatrix} = \mathbf{H}\begin{pmatrix} a \\ b \end{pmatrix}, \qquad \mathbf{H} = \mathbf{M} - \frac{\mathrm{i}\hbar}{2}\mathbf{\Gamma}, \tag{105.49}$$

where $\mathbf{M}$ *and* $\mathbf{\Gamma}$ *are Hermitian* 2×2 *matrices,*

$$M_{ij} = m_K c^2 \delta_{ij} + \langle i|\, H_w\, |j\rangle + \mathrm{P}\sum_n \frac{\langle i|\, H_w\, |n\rangle \langle n|\, H_w\, |j\rangle}{m_K c^2 - E_n}, \tag{105.50}$$

$$\Gamma_{ij} = \frac{2\pi}{\hbar}\sum_n \langle i|\, H_w\, |n\rangle \langle n|\, H_w\, |j\rangle\ \delta\!\left(m_K c^2 - E_n\right), \tag{105.51}$$

P *denoting the principal value.* $\mathbf{M}$ *has the SI dimension of energy and* $\mathbf{\Gamma}$ *of inverse time.*
Rests on Proposition 17.42.

Proof. *Derives Proposition 105.22.*

Write $|\psi(t)\rangle = a\,|K^0\rangle + b\left|\bar{K}^0\right\rangle + \sum_n c_n\,|n\rangle$ and project the Schrödinger equation $\mathrm{i}\hbar\partial_t\,|\psi\rangle = (H_0 + H_w)\,|\psi\rangle$ onto each sector. For the continuum,

$$\mathrm{i}\hbar \dot{c}_n = E_n c_n + \sum_j \langle n|\, H_w\, |j\rangle\ \psi_j(t),$$

with $\psi_1 = a$, $\psi_2 = b$. Integrate with $c_n(0) = 0$:

$$c_n(t) = -\frac{\mathrm{i}}{\hbar}\sum_j \langle n|\, H_w\, |j\rangle \int_0^t \mathrm{d}t'\, \mathrm{e}^{-\mathrm{i}E_n(t-t')/\hbar}\psi_j(t').$$

Substituting into the equation for the two-dimensional sector gives an exact integro-differential equation with a memory kernel. The Wigner–Weisskopf approximation is to note that the kernel is sharply peaked in $t - t'$ on the scale $\hbar/\Delta E$ set by the width of the continuum, which for a hadronic decay is far shorter than the kaon lifetime, so that $\psi_j(t')$ may be replaced by $\psi_j(t)\mathrm{e}^{\mathrm{i}m_K c^2 (t-t')/\hbar}$ and the upper limit sent to infinity. The remaining integral is

$$\int_0^\infty \mathrm{d}s\, \mathrm{e}^{\mathrm{i}\left(m_K c^2 - E_n + \mathrm{i}0\right)s/\hbar} = \mathrm{i}\hbar\,\frac{1}{m_K c^2 - E_n + \mathrm{i}0} = \mathrm{i}\hbar\left[\mathrm{P}\frac{1}{m_K c^2 - E_n} - \mathrm{i}\pi\delta\!\left(m_K c^2 - E_n\right)\right],$$

using the Sokhotski–Plemelj identity, Proposition 17.42. Collecting the real and imaginary parts reproduces Equations (105.50) and (105.51). That $\mathbf{M}$ and $\mathbf{\Gamma}$ are separately Hermitian is manifest: each is built from $\langle i|\, H_w\, |n\rangle\,\overline{\langle j|\, H_w\, |n\rangle}$ with a real weight, since H_w is Hermitian. □

Two structural consequences follow at once. First, $\mathbf{\Gamma}$ is positive semidefinite, being of the form $\sum_n v_n v_n^\dagger$ with $v_{n,i} = \langle i|\, H_w\, |n\rangle$ weighted by a positive delta function; hence

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(|a|^2 + |b|^2\right) = -\psi^\dagger \mathbf{\Gamma}\psi \le 0, \tag{105.52}$$

and probability leaks out of the two-dimensional space at exactly the rate at which decay products appear. Second, $\mathbf{H}$ is not Hermitian, so its eigenvectors need not be orthogonal — and in the presence of CP violation they are not. This is not a pathology; it is what an open subsystem looks like.

What the discrete symmetries impose

Proposition 105.23 (Symmetry constraints on the mass matrix)**.** *With the phase convention Equation* (105.45)*:*

1. *CPT invariance implies $H_{11} = H_{22}$, that is $M_{11} = M_{22}$ and $\Gamma_{11} = \Gamma_{22}$;*
2. *T invariance implies $\mathrm{Im}\,(M_{12}\hbar\Gamma_{12}^{*}) = 0$, equivalently $|H_{12}| = |H_{21}|$;*
3. *CP invariance implies both.*

Rests on Equations (105.26) *and* (105.45) *and Proposition 105.22.*

Proof. *Derives Proposition 105.23.*

(i) Let Θ be the antiunitary CPT operator, so that $\Theta\,|K^0\rangle = \left|\bar{K}^0\right\rangle$ up to a phase and $\Theta H_w \Theta^{-1} = H_w$, $\Theta H_0 \Theta^{-1} = H_0$. Apply Equation (105.26) to $M_{11} = \langle K^0|\,\mathbf{M}\,|K^0\rangle$: since $\mathbf{M}$ is built from H_w, H_0 and real weights, $\Theta\mathbf{M}\Theta^{-1} = \mathbf{M}$, and Equation (105.26) gives $\left\langle \bar{K}^0\right|\mathbf{M}\left|\bar{K}^0\right\rangle = \langle K^0|\,\mathbf{M}\,|K^0\rangle^{*}$. But $\mathbf{M}$ is Hermitian, so its diagonal elements are real, and $M_{22} = M_{11}$. The same argument on $\mathbf{\Gamma}$ gives $\Gamma_{22} = \Gamma_{11}$. Note that Θ maps the state to its *antiparticle* without reversing momentum (the kaon is at rest), which is exactly what makes this constraint a relation between the two diagonal entries.

(ii) T invariance means $\mathcal{T} H_w \mathcal{T}^{-1} = H_w$ with $\mathcal{T}$ antiunitary and, for kaons at rest, $\mathcal{T}\,|K^0\rangle = \mathrm{e}^{\mathrm{i}\alpha}\,|K^0\rangle$. Applying Equation (105.26) to the off-diagonal element gives $M_{12} = \mathrm{e}^{-2\mathrm{i}\alpha} M_{12}^{*}$ and likewise $\Gamma_{12} = \mathrm{e}^{-2\mathrm{i}\alpha}\Gamma_{12}^{*}$: both off-diagonal elements carry the *same* phase α, which the phase freedom of $|K^0\rangle$ can then remove. The convention-independent content is that their relative phase vanishes, $\mathrm{Im}(M_{12}\hbar\Gamma_{12}^{*}) = 0$, whereupon $H_{21} = H_{12}^{*}$ with H_{12} of a removable phase, so $|H_{12}| = |H_{21}|$.

(iii) $CP = T^{-1}\cdot CPT$ up to the phases already fixed, so it imposes the union of (i) and (ii). □

The three constraints are logically independent, and that is the architecture of the whole subject: the diagonal of $\mathbf{H}$ tests CPT, the moduli of its off-diagonal elements test T, and CP tests both at once. Experiment finds (i) satisfied to the accuracy of Section 105.5.3 and (ii) violated at the 10^{-3} level.

Diagonalization, and the definition of epsilon Assume CPT, so $H_{11} = H_{22} =: H_0$ and

$$\mathbf{H} = \begin{pmatrix} H_0 & H_{12} \\ H_{21} & H_0 \end{pmatrix}. \tag{105.53}$$

The characteristic equation gives eigenvalues $\lambda_{\pm} = H_0 \pm \sqrt{H_{12}H_{21}}$ with right eigenvectors proportional to $(\sqrt{H_{12}}, \pm\sqrt{H_{21}})$. Define the complex number ϵ by

$$\frac{1-\epsilon}{1+\epsilon} = \sqrt{\frac{H_{21}}{H_{12}}}, \qquad \epsilon = \frac{\sqrt{H_{12}} - \sqrt{H_{21}}}{\sqrt{H_{12}} + \sqrt{H_{21}}}, \tag{105.54}$$

so that the two physical states are

$$|K_S\rangle = \frac{(1+\epsilon)\,|K^0\rangle + (1-\epsilon)\left|\bar{K}^0\right\rangle}{\sqrt{2\left(1+|\epsilon|^2\right)}} = \frac{|K_1\rangle + \epsilon\,|K_2\rangle}{\sqrt{1+|\epsilon|^2}}, \tag{105.55}$$

$$|K_L\rangle = \frac{(1+\epsilon)\,|K^0\rangle - (1-\epsilon)\left|\bar{K}^0\right\rangle}{\sqrt{2\left(1+|\epsilon|^2\right)}} = \frac{|K_2\rangle + \epsilon\,|K_1\rangle}{\sqrt{1+|\epsilon|^2}}, \tag{105.56}$$

with eigenvalues written as

$$\lambda_{S,L} = m_{S,L}c^2 - \frac{\mathrm{i}\hbar}{2}\Gamma_{S,L}\,. \tag{105.57}$$

Equation (105.54) is the whole of CP violation in the mixing: $\epsilon = 0$ if and only if $H_{12} = H_{21}$, which by Proposition 105.23 holds if and only if T (and, given CPT, CP) is a symmetry of the mass matrix. It is also manifest that $|K_S\rangle$ and $|K_L\rangle$ are *not* orthogonal: $\langle K_S|K_L\rangle = 2\mathrm{Re}\,\epsilon/(1+|\epsilon|^2) \neq 0$.

To first order in the small asymmetry, write Equation (105.54) as $\epsilon = (H_{12}-H_{21})/[(H_{12}+H_{21}) + 2\sqrt{H_{12}H_{21}}]$ and use $H_{12}+H_{21} \approx 2\sqrt{H_{12}H_{21}}$, so that the whole denominator is $4\sqrt{H_{12}H_{21}} = 2(\lambda_S - \lambda_L)$. The sign of that difference is not free, and it is where a factor of -1 is most easily lost: Equation (105.57) gives $\lambda_S - \lambda_L = -\Delta m\,c^2 - \frac{\mathrm{i}\hbar}{2}(\Gamma_S - \Gamma_L)$, with *both* terms negative, because K_S is at once the lighter state and the broader one. With $H_{21} = M_{12}^* - \frac{\mathrm{i}\hbar}{2}\Gamma_{12}^*$ the numerator is $H_{12} - H_{21} = 2\mathrm{i}\,\mathrm{Im}\,M_{12} + \hbar\,\mathrm{Im}\,\Gamma_{12}$, whence

$$\epsilon \approx \frac{\mathrm{i}\,\mathrm{Im}\,M_{12} + \frac{1}{2}\hbar\,\mathrm{Im}\,\Gamma_{12}}{-\Delta m\,c^2 - \mathrm{i}\frac{\hbar}{2}\Gamma_S}\,, \qquad \Delta m := m_L - m_S\,, \tag{105.58}$$

where $\Gamma_L \ll \Gamma_S$ has been used. Both numerator terms vanish in a T-invariant theory, as they must.

Equation (105.58) makes a prediction that is one of the most satisfying numerical accidents in physics. The $\pi\pi$ channel dominates Γ_S and hence Γ_{12}, and it carries essentially the phase of M_{12}, so $\mathrm{Im}\,\Gamma_{12}$ is negligible next to $\mathrm{Im}\,M_{12}$. The phase of ϵ is then fixed by the denominator alone, up to the 180° carried by the sign of $\mathrm{Im}\,M_{12}$:

$$\arg\epsilon \approx \arctan\frac{2\,\Delta m\,c^2}{\hbar\Gamma_S} = \arctan\frac{2\,\Delta m\,c^2\,\tau_S}{\hbar}\,. \tag{105.59}$$

With the measured [2427]

$$\Delta m\,c^2 = (3.484 \pm 0.006)\times 10^{-6}\,\mathrm{eV}\,, \qquad \frac{\hbar}{2\tau_S} = 3.676\times 10^{-6}\,\mathrm{eV}\,, \tag{105.60}$$

this gives $\arg\epsilon = \arctan(0.948) = 43.5^\circ$, and the measured value is $(43.5 \pm 0.5)^\circ$ — which also settles the branch, since $+43.5^\circ$ rather than -136.5° requires $\mathrm{Im}\,M_{12} < 0$ in the phase convention of Equation (105.45). The agreement is a check on the whole construction, and the near-equality $\Delta m\,c^2 \approx \hbar\Gamma_S/2$ that produces it is, so far as anyone knows, a coincidence.

Strangeness oscillation Because $|K^0\rangle$ is not an eigenstate of $\mathbf{H}$, a beam produced as pure K^0 develops a $\bar{K}^0$ component. Neglecting ϵ (a 10^{-3} correction) and using $|K^0\rangle = (|K_S\rangle + |K_L\rangle)/\sqrt{2}$,

$$\left|K^0(t)\right\rangle = \frac{1}{\sqrt{2}}\left(\mathrm{e}^{-\mathrm{i}\lambda_S t/\hbar}\,|K_S\rangle + \mathrm{e}^{-\mathrm{i}\lambda_L t/\hbar}\,|K_L\rangle\right)\,,$$

so that, projecting back onto the strangeness basis,

$$P\left(K^0 \to \bar{K}^0\right)(t) = \frac{1}{4}\left[\mathrm{e}^{-\Gamma_S t} + \mathrm{e}^{-\Gamma_L t} - 2\mathrm{e}^{-(\Gamma_S+\Gamma_L)t/2}\cos\frac{\Delta m\,c^2 t}{\hbar}\right]\,, \tag{105.61}$$

$$P\left(K^0 \to K^0\right)(t) = \frac{1}{4}\left[\mathrm{e}^{-\Gamma_S t} + \mathrm{e}^{-\Gamma_L t} + 2\mathrm{e}^{-(\Gamma_S+\Gamma_L)t/2}\cos\frac{\Delta m\,c^2 t}{\hbar}\right]\,. \tag{105.62}$$

The oscillation frequency is $\Delta m\,c^2/\hbar = 5.29\times 10^9/\mathrm{s}$, comparable to $1/\tau_S$, so the interference term is observable over the first few τ_S and then dies, leaving equal K^0 and $\bar{K}^0$ content in the surviving K_L beam.

It is worth pausing on what Equation (105.61) makes measurable. A mass difference of $3.5\,\mu\mathrm{eV}/c^2$ is being read off a particle of mass $497.6\,\mathrm{MeV}/c^2$:

$$\frac{\Delta m}{m_K} = 7.0 \times 10^{-15}\,. \tag{105.63}$$

No spectrometer resolves that. The interferometer does, because the observable is a phase accumulated over a macroscopic flight path, and this is the same trick that makes the neutral-meson systems the sharpest CPT laboratories in Section 105.5.3.

Regeneration A K_L beam traversing matter emerges with a K_S component [1077]. The reason is that the strong interaction sees strangeness, not CP: the forward scattering amplitude f for K^0 on a nucleus differs from the amplitude $\bar{f}$ for $\bar{K}^0$, because $\bar{K}^0$ can convert a nucleon into a hyperon while K^0 cannot. Writing the transmitted state through a slab of N scatterers per unit volume and thickness ℓ, each strangeness component picks up its own index of refraction, and the regenerated amplitude is

$$\rho = \frac{\mathrm{i}\pi N\hbar^2\left(f-\bar{f}\right)}{p\,(\lambda_S-\lambda_L)/c}\left(1-\mathrm{e}^{\mathrm{i}(\lambda_S-\lambda_L)\ell/(\hbar v)}\right), \tag{105.64}$$

proportional to $f-\bar{f}$ and therefore vanishing if the medium cannot distinguish the two. Coherent regeneration is the standard tool for producing a K_S beam far from the target; it is also the background that any claim of $K_L \to \pi\pi$ must exclude, and excluding it was the principal experimental burden of Chapter 111.

105.3.2 The 1964 discovery

Christenson, Cronin, Fitch and Turlay put a two-arm spectrometer at the end of a 17 m helium-filled decay volume at the Brookhaven AGS, far enough downstream that every K_S had decayed, and looked for two-body decays of the surviving beam [1274]. They found 45 events with the reconstructed invariant mass of the kaon and with the reconstructed parent momentum collinear with the beam, over a background of about 12. The branching fraction was about 2×10^{-3}; the modern value is $(1.967\pm0.010)\times10^{-3}$ [2427]. The collinearity is what kills regeneration — a regenerated K_S from the residual gas would produce a non-collinear parent — and the substance of the apparatus and its controls is Chapter 111; see Phenomenon 111.8.

The immediate reading of the result is Equation (105.56): the long-lived state is not the CP eigenstate $|K_2\rangle$ but carries an admixture $\epsilon\,|K_1\rangle$, and the CP-even component decays to two pions. Quantitatively,

$$\eta_{+-} := \frac{\mathcal{A}\left(K_L\to\pi^+\pi^-\right)}{\mathcal{A}\left(K_S\to\pi^+\pi^-\right)}, \qquad \eta_{00} := \frac{\mathcal{A}\left(K_L\to\pi^0\pi^0\right)}{\mathcal{A}\left(K_S\to\pi^0\pi^0\right)}, \tag{105.65}$$

and if the only source of CP violation were the mixing, both would equal ϵ. The measured magnitude is

$$|\epsilon| = (2.228\pm0.011)\times10^{-3}, \qquad \arg\epsilon = (43.5\pm0.5)^\circ, \tag{105.66}$$

consistent with Equation (105.59).

Indirect and direct violation The distinction that took thirty-five years to settle is whether CP violation lives only in the mass matrix — in the *state* — or also in the decay amplitudes. Decompose the two-pion final state by isospin. Two pions in a relative S wave from a spinless parent must have a symmetric isospin wavefunction, because the spatial part is symmetric and pions are bosons; of the three combinations $I=0,1,2$ available to two

isospin-1 particles, $I = 1$ is antisymmetric and is therefore forbidden. Write the amplitudes for the two allowed channels as

$$\mathcal{A}\left(K^0 \to (\pi\pi)_I\right) = A_I\, \mathrm{e}^{\mathrm{i}\delta_I}\,, \qquad \mathcal{A}\left(\bar{K}^0 \to (\pi\pi)_I\right) = A_I^*\, \mathrm{e}^{\mathrm{i}\delta_I}\,, \tag{105.67}$$

where δ_I is the $\pi\pi$ strong rescattering phase — real and identical for the two, since the strong interaction conserves CP — and any CP violation in the decay resides in $\operatorname{Im} A_I$. The relative sign of the two conjugate amplitudes is fixed by Equation (105.45).

The observed states are recovered from the isospin eigenstates by the Clebsch–Gordan coefficients of $1 \otimes 1$ in the $I_3 = 0$ sector. Writing $|m_1, m_2\rangle$ for the product state of two pions of third components m_1, m_2, those coefficients are

$$|2\rangle = \tfrac{1}{\sqrt{6}}\,|+,-\rangle + \sqrt{\tfrac{2}{3}}\,|0,0\rangle + \tfrac{1}{\sqrt{6}}\,|-,+\rangle\,, \tag{105.68}$$

$$|0\rangle = \tfrac{1}{\sqrt{3}}\,|+,-\rangle - \tfrac{1}{\sqrt{3}}\,|0,0\rangle + \tfrac{1}{\sqrt{3}}\,|-,+\rangle\,, \tag{105.69}$$

the third combination $|1\rangle = \left(|+,-\rangle - |-,+\rangle\right)/\sqrt{2}$ being the antisymmetric one already excluded. Since $\left|\pi^+\pi^-\right\rangle$ in an S wave *is* the normalized symmetric combination $\left(|+,-\rangle + |-,+\rangle\right)/\sqrt{2}$, while $\left|\pi^0\pi^0\right\rangle = |0,0\rangle$, projecting gives

$$\left|\pi^+\pi^-\right\rangle = \sqrt{\tfrac{1}{3}}\,|2\rangle + \sqrt{\tfrac{2}{3}}\,|0\rangle\,, \qquad \left|\pi^0\pi^0\right\rangle = \sqrt{\tfrac{2}{3}}\,|2\rangle - \sqrt{\tfrac{1}{3}}\,|0\rangle\,. \tag{105.70}$$

The two are orthogonal and normalized, as they must be. The weight of A_2 relative to A_0 is $1/\sqrt{2}$ in the charged channel and $-\sqrt{2}$ in the neutral one, the second being -2 times the first, and that single ratio is the entire origin of the factor -2 below. Carrying Equation (105.70) through gives

$$\eta_{+-} = \epsilon + \epsilon'\,, \qquad \eta_{00} = \epsilon - 2\epsilon'\,, \tag{105.71}$$

with

$$\epsilon' = \frac{\mathrm{i}}{\sqrt{2}}\, \mathrm{e}^{\mathrm{i}(\delta_2 - \delta_0)}\, \frac{\operatorname{Re} A_2}{\operatorname{Re} A_0} \left[\frac{\operatorname{Im} A_2}{\operatorname{Re} A_2} - \frac{\operatorname{Im} A_0}{\operatorname{Re} A_0}\right]. \tag{105.72}$$

Everything in Equation (105.72) is a statement about the decay amplitudes and none of it about the mass matrix, so $\epsilon' \neq 0$ is CP violation *in the decay*: direct CP violation. Note the structure of the bracket — a *difference* of two phases. If the two isospin amplitudes carried a common CP-odd phase it could be rotated away, and ϵ' would vanish; direct CP violation requires two interfering amplitudes with different weak phases, a point proved in general at Proposition 105.39.

The observable is the double ratio.

Proposition 105.24 (The double ratio)**.**

$$\frac{\Gamma(K_L \to \pi^0\pi^0)\,\Gamma(K_S \to \pi^+\pi^-)}{\Gamma(K_L \to \pi^+\pi^-)\,\Gamma(K_S \to \pi^0\pi^0)} = \left|\frac{\eta_{00}}{\eta_{+-}}\right|^2 \approx 1 - 6\operatorname{Re}\frac{\epsilon'}{\epsilon}\,. \tag{105.73}$$

Rests on Equation (105.71).

Proof. *Derives Proposition 105.24.*

From Equation (105.71), $\eta_{00}/\eta_{+-} = (1 - 2\epsilon'/\epsilon)/(1 + \epsilon'/\epsilon)$. With $|\epsilon'/\epsilon| \sim 10^{-3}$, expand to first order: $\eta_{00}/\eta_{+-} \approx 1 - 3\epsilon'/\epsilon$, whose squared modulus is $1 - 6\mathrm{Re}(\epsilon'/\epsilon)$. □

The double ratio is designed so that every quantity that is common to the four channels — kaon flux, detector solid angle, most of the efficiency — cancels. NA48 at CERN [1973] and KTeV at Fermilab [1965] measured it with independent systematics, and the world average is [2427]

$$\operatorname{Re}\frac{\epsilon'}{\epsilon} = (1.66 \pm 0.23) \times 10^{-3}\,. \tag{105.74}$$

See Phenomenon 111.11. A hypothetical superweak $\Delta S = 2$ interaction acting only in the mass matrix reproduces ϵ exactly and predicts $\epsilon' = 0$; Equation (105.74) excludes it. That ϵ'/ϵ is itself of order 10^{-3} rather than order unity is largely the $\Delta I = \tfrac{1}{2}$ rule, the empirical fact that $|A_0/A_2| \approx 22$, which enhances ϵ and suppresses the $I = 2$ amplitude appearing in Equation (105.72).

An absolute definition of matter The semileptonic decays give the cleanest statement of what CP violation means. The rule $\Delta S = \Delta Q$, which holds because the strange quark decays to an up quark by emitting a W^-, allows $K^0 \to \pi^- e^+ \nu_e$ and forbids $K^0 \to \pi^+ e^- \bar{\nu}_e$; the conjugate statements hold for $\bar{K}^0$. From Equation (105.56) the K^0 content of K_L carries amplitude $(1+\epsilon)$ and the $\bar{K}^0$ content $-(1-\epsilon)$, so

$$\delta_L = \frac{\Gamma(\pi^- e^+ \nu_e) - \Gamma(\pi^+ e^- \bar{\nu}_e)}{\Gamma(\pi^- e^+ \nu_e) + \Gamma(\pi^+ e^- \bar{\nu}_e)} = \frac{|1+\epsilon|^2 - |1-\epsilon|^2}{|1+\epsilon|^2 + |1-\epsilon|^2} = \frac{2\mathrm{Re}\,\epsilon}{1+|\epsilon|^2}\,. \tag{105.75}$$

Numerically $2\,|\epsilon|\cos 43.5^\circ = 3.23 \times 10^{-3}$, against the measured $(3.32 \pm 0.06) \times 10^{-3}$ [2427]; see Phenomenon 111.9. The significance is not the number but its status. Instruct a correspondent, with whom no sample and no convention has been shared, to prepare a long-lived neutral kaon beam and count the charge of the emitted lepton: the commoner sign defines the positron, and therefore matter, absolutely. Before 1964 no such instruction existed — C and P violation alone leave the labelling conventional, since one can compensate a mirror reflection by an exchange of matter and antimatter. Only CP violation makes "matter" an objective term.

105.3.3 The CKM phase

Kobayashi and Maskawa asked, in 1973, what the minimal modification of the Standard Model would be that admits CP violation at all [1505]. Their answer is a counting argument, and it predicted a third generation of quarks from a single measured asymmetry of 2×10^{-3}.

Theorem 105.25 (Number of physical phases)**.** *Let there be N generations of quarks. After diagonalizing the mass matrices, the charged-current interaction is governed by a unitary $N \times N$ matrix V, of which*

$$n_{angles} = \frac{N(N-1)}{2}\,, \qquad n_{phases} = \frac{(N-1)(N-2)}{2} \tag{105.76}$$

parameters are physical. There is no CP-violating phase for $N \le 2$ and exactly one for $N = 3$.

Rests on Equation (104.46).

Proof. *Derives Theorem 105.25.*

The Yukawa couplings of Chapter 104 give arbitrary complex mass matrices M_u and M_d; each is brought to positive diagonal form by a bi-unitary transformation $M = U_L^\dagger M_{\mathrm{diag}} U_R$, and the charged current, which couples $\bar{u}_L \gamma^\mu d_L$, retains the combination $V = U_L^{u\dagger} U_L^d$, a general $N \times N$ unitary matrix.

A unitary $N \times N$ matrix depends on N^2 real parameters (the condition $V^\dagger V = \mathbb{1}$ imposes N^2 real conditions on $2N^2$ real entries). Of these, an orthogonal $N \times N$ matrix would use $N(N-1)/2$; the remainder, $N^2 - N(N-1)/2 = N(N+1)/2$, are phases.

Not all phases are physical. The quark fields may be rephased, $u_j \to \mathrm{e}^{\mathrm{i}\alpha_j} u_j$ and $d_k \to \mathrm{e}^{\mathrm{i}\beta_k} d_k$, which changes $V_{jk} \to \mathrm{e}^{-\mathrm{i}\alpha_j} V_{jk} \mathrm{e}^{\mathrm{i}\beta_k}$ without touching the diagonal mass terms. That is $2N$ phases, but the overall common phase $\alpha_j = \beta_k = \theta$ leaves V unchanged, so only $2N - 1$ are usable. Hence

$$n_{\mathrm{phases}} = \frac{N(N+1)}{2} - (2N-1) = \frac{N^2 - 3N + 2}{2} = \frac{(N-1)(N-2)}{2}\,.$$

For $N = 2$ this is zero: the two-generation mixing matrix is a real rotation through the Cabibbo angle [1248], and no phase survives. For $N = 3$ it is one. □

The argument's force is that it is a counting theorem, not a model. Given that CP violation exists and that the Standard Model gauge structure is right, three generations are the minimum. In 1973 three quarks were known, the fourth was conjectural, and the fifth and sixth were found in 1977 and 1995.

Definition 105.26 (The Jarlskog invariant)**.** For any $i \neq k$ and $j \neq l$,

$$\operatorname{Im}\left(V_{ij} V_{kl} V_{il}^{*} V_{kj}^{*}\right) = J \sum_{m,n} \varepsilon_{ikm} \varepsilon_{jln} \,, \tag{105.77}$$

defining a single real number J independent of which quartet is chosen [1756].

The quartet in Equation (105.77) is invariant under the rephasing $V_{jk} \to \mathrm{e}^{-\mathrm{i}\alpha_j} V_{jk} \mathrm{e}^{\mathrm{i}\beta_k}$, since each index appears once with a phase and once with its conjugate; J is therefore a physical observable and not a parametrization artefact. Unitarity makes all nine quartets equal up to sign, which is what Equation (105.77) records. The measured value is [2074, 2427]

$$J = \left(3.08^{+0.15}_{-0.13}\right) \times 10^{-5} \,, \tag{105.78}$$

a small number whose smallness is a fact about the mixing angles and not about the phase, which is of order unity.

Proposition 105.27 (When CP violation is possible)**.** *CP is violated in the quark sector if and only if*

$$\det\left[M_u M_u^{\dagger} c^4, M_d M_d^{\dagger} c^4\right] = 2\mathrm{i} J \prod_{i>j} \left[\left(m_{u_i}^2 - m_{u_j}^2\right) c^4\right] \prod_{i>j} \left[\left(m_{d_i}^2 - m_{d_j}^2\right) c^4\right] \tag{105.79}$$

is nonzero. In particular CP is conserved if any two quarks of the same charge are degenerate, or if $J = 0$.

Rests on Definition 105.26 and Theorem 105.25.

Derivation. *Derives Proposition 105.27.*

The left-hand side is invariant under the field redefinitions that leave the physics alone, and it vanishes identically if the two Hermitian matrices commute, which happens exactly when they are simultaneously diagonalizable — i.e. when V can be taken real. Evaluating the determinant in the basis where $M_u M_u^{\dagger}$ is diagonal, each entry of the commutator is $(m_{u_i}^2 - m_{u_j}^2)c^4$ times the corresponding entry of $V\ \mathrm{diag}(m_d^2 c^4)\, V^{\dagger}$, and expanding the 3×3 determinant collects the six mass differences together with the imaginary part of a quartet, which is J by Definition 105.26. That last step is where the sign on the right is fixed, and it is fixed by a convention worth stating: V is the matrix whose (u, d) entry is V_{ud}, so that in the up-diagonal basis $M_d M_d^{\dagger} c^4 = V\, \mathrm{diag}(m_d^2 c^4) V^{\dagger}$, and J is the quartet of Definition 105.26; with the opposite convention for V both J and the sign reverse together, and the statement is unchanged.

The factors of c^4 in Equation (105.79) are not decoration. $M_u M_u^{\dagger}$ is a squared mass, kg^2, so $M_u M_u^{\dagger} c^4$ is a squared energy; each entry of the commutator of two such matrices carries J^4 and the 3×3 determinant J^{12}, which is also what the right-hand side's six factors of J^2 come to. Written without them the left-hand side would be kg^{12} and the two sides would not have the same dimension at all. □

If two up-type quarks had equal mass, the freedom to rotate between them could be used to make V real; the phase would be unphysical. CP violation in the Standard Model therefore requires three *non-degenerate* generations, and the extreme hierarchy of

the observed masses is precisely what makes Equation (105.79) numerically tiny — the fact that returns, with consequences, in Section 105.6.2.

Unitarity of V gives six orthogonality relations, of which

$$V_{ud}V_{ub}^{*} + V_{cd}V_{cb}^{*} + V_{td}V_{tb}^{*} = 0 \tag{105.80}$$

has three terms of comparable magnitude and so draws a non-degenerate triangle in the complex plane. Its area is $J/2$: for any three complex numbers summing to zero, the triangle they close has area $\frac{1}{2}\,|\mathrm{Im}(z_1 z_2^{*})|$, and that imaginary part is a Jarlskog quartet. The angles are conventionally α, β, γ, and the programme of flavour physics is to measure the sides and the angles by independent means and ask whether they close. They do, at the few-per-cent level, which is the quantitative statement that one phase accounts for all observed CP violation in the quark sector; the detailed over-determination belongs to Chapter 103.

105.3.4 CP violation beyond the kaon

The B factories If one phase controls everything, the kaon's 10^{-3} effect and a possible order-unity effect elsewhere are the same physics. The Standard Model predicts the latter in $B^0 \to J/\psi\, K_S^0$, where the interference is between decay after mixing and decay without mixing, and no small ratio of amplitudes suppresses it.

Proposition 105.28 (Time-dependent asymmetry)**.** *For a final state f that is a CP eigenstate accessible to both B^0 and $\bar{B}^0$, define $\lambda = (q/p)\left(\bar{\mathcal{A}}_f/\mathcal{A}_f\right)$, with q/p the mixing parameter analogous to $(1-\epsilon)/(1+\epsilon)$. Then*

$$\frac{\Gamma(\bar{B}^0(t)\to f) - \Gamma(B^0(t)\to f)}{\Gamma(\bar{B}^0(t)\to f) + \Gamma(B^0(t)\to f)} = S_f \sin\frac{\Delta m_d c^2 t}{\hbar} - C_f \cos\frac{\Delta m_d c^2 t}{\hbar}\,, \tag{105.81}$$

with $S_f = 2\mathrm{Im}\,\lambda/(1+|\lambda|^2)$ and $C_f = (1-|\lambda|^2)/(1+|\lambda|^2)$.

Rests on Equations (105.53), (105.55) and (105.56).

Derivation. Derives Proposition 105.28.

The B system has $\Delta\Gamma \approx 0$, so the two mass eigenstates share a width and the time evolution of an initially pure B^0 is $|B^0(t)\rangle = g_+(t)\,|B^0\rangle + (q/p)g_-(t)\left|\bar{B}^0\right\rangle$ with $g_\pm(t) = \mathrm{e}^{-\Gamma t/2}\mathrm{e}^{-\mathrm{i}\bar{m}c^2 t/\hbar}$ times cos or $+\mathrm{i}\sin$ of $\Delta m_d c^2 t/(2\hbar)$ respectively, $\bar{m}$ being the mean of the two masses, obtained by diagonalizing Equation (105.53) exactly as in Equations (105.55) and (105.56).

That sign in g_- is not free, and it is the one place the derivation can silently go wrong. The eigenvector $p\,|B^0\rangle + q\left|\bar{B}^0\right\rangle$ is the *light* state, exactly as $|K_S\rangle$ is in Equation (105.55), so writing $\Delta m_d = m_H - m_L > 0$ gives $g_\pm = \frac{1}{2}\left(\mathrm{e}^{-\mathrm{i}\lambda_L t/\hbar} \pm \mathrm{e}^{-\mathrm{i}\lambda_H t/\hbar}\right)$ and hence $+\mathrm{i}\sin$ and not $-\mathrm{i}\sin$; taking the other sign reverses the coefficient of $\sin\Delta m_d c^2 t/\hbar$ in Equation (105.81), which is the whole measurement. Then $\mathcal{A}(B^0(t)\to f) = \mathcal{A}_f\,[g_+ + \lambda g_-]$ and $\mathcal{A}(\bar{B}^0(t)\to f) = (p/q)\mathcal{A}_f\,[g_- + \lambda g_+]$. Squaring, using $|g_\pm|^2 = \frac{1}{2}\mathrm{e}^{-\Gamma t}(1 \pm \cos\Delta m_d c^2 t/\hbar)$ and $g_+^{*}g_- = \frac{\mathrm{i}}{2}\mathrm{e}^{-\Gamma t}\sin\Delta m_d c^2 t/\hbar$, and forming the asymmetry gives Equation (105.81). □

For $f = J/\psi\, K_S^0$ the decay proceeds through a single dominant amplitude, so $|\lambda| = 1$, $C_f = 0$, and the phase of λ is the mixing phase $\mathrm{e}^{-2\mathrm{i}\beta}$ of Equation (105.80); hence

$$S_{J/\psi K_S} = \sin 2\beta\,. \tag{105.82}$$

The measurement requires knowing which meson was which at production, and the B factories solved this by producing the pair coherently from the $\Upsilon(4S)$: the two mesons are in a C-odd, $L = 1$ state, so until one decays there is exactly one B^0 and one $\bar{B}^0$,

and a flavour-specific decay of one tags the other. Belle [2005] and BaBar [2010] reported simultaneously, with $\sin 2\beta = 0.99 \pm 0.14 \pm 0.06$ and $0.59 \pm 0.14 \pm 0.05$ respectively — two values differing by about two standard deviations, which is a useful reminder that first measurements scatter. The world average has since settled at $\sin 2\beta = 0.708 \pm 0.011$ [2427], and $\Delta m_d c^2 = (3.334 \pm 0.013) \times 10^{-4}\,\text{eV}$. See Phenomenon 111.13.

The effect is of order unity. CP violation is therefore not intrinsically small: it is small in the kaon because the kaon system happens to sit where the interfering amplitudes are unequal, and large in this B channel because they are not.

Charm The up-type sector was the last to yield. LHCb measured the difference of the time-integrated CP asymmetries of two singly Cabibbo-suppressed charm decays [2323],

$$\Delta A_{CP} = A_{CP}(D^0 \to K^- K^+) - A_{CP}(D^0 \to \pi^- \pi^+) = (-15.4 \pm 2.9) \times 10^{-4}\,, \qquad (105.83)$$

nonzero at 5.3 standard deviations. The difference is taken because production and detection asymmetries cancel in it. The effect requires interference of tree and loop ("penguin") amplitudes with different strong phases, per Proposition 105.39, and the long-distance strong phases are not calculable, so the measurement establishes the phenomenon without sharply testing the CKM prediction. See Phenomenon 111.15.

Leptons The mixing matrix of the leptons admits the same counting as Theorem 105.25, so with three neutrino generations there is one Dirac phase δ_{CP}. T2K, comparing $\nu_\mu \to \nu_e$ with $\bar{\nu}_\mu \to \bar{\nu}_e$ over a 295 km baseline, finds the data preferring values of δ_{CP} near $-\pi/2$ and excluding CP conservation ($\delta_{CP} = 0$ or π) at the 95 % confidence level [2345]. This is a constraint and not a discovery: the exclusion is a two-sigma statement resting on a comparison of two event samples of a few tens of events each, and it depends on the mass ordering, which is not yet settled. The apparatus and the oscillation formalism are Chapter 114; the honest summary is that leptonic CP violation is likely and unproven.

105.4 Direct tests of time reversal

Everything in Section 105.3 tests CP. Given the CPT theorem, CP violation is T violation, and one might think nothing remains to be measured. But that inference *assumes* the theorem whose hypotheses are the deepest in the subject, and a test of T that does not assume CPT is a genuinely independent piece of information — indeed it is the only way to separate the three symmetries experimentally. This section describes the two measurements that compare a process directly with its motion reverse, and the static observable that needs no process at all.

105.4.1 The CPLEAR asymmetry

Kabir's observation is that the neutral kaon offers a transition and its exact reverse [1426]. The process $K^0 \to \bar{K}^0$ and the process $\bar{K}^0 \to K^0$ are related by exchanging initial and final state; both particles are at rest, so no momenta or spins need reversing, and motion reversal is nothing but the exchange. Define

$$A_T(t) = \frac{P\left(\bar{K}^0 \to K^0\right)(t) - P\left(K^0 \to \bar{K}^0\right)(t)}{P\left(\bar{K}^0 \to K^0\right)(t) + P\left(K^0 \to \bar{K}^0\right)(t)}\,. \qquad (105.84)$$

If T is a symmetry, Equation (105.25) forces $A_T = 0$ identically.

Proposition 105.29 (The Kabir asymmetry measures the real part of epsilon)**.** *To first order in ϵ,*

$$A_T = 4\,\mathrm{Re}\,\epsilon\,, \tag{105.85}$$

independent of t.

Rests on Equations (105.55)*,* (105.56) *and* (105.84)*.*

Proof. *Derives Proposition 105.29.*

Invert Equations (105.55) and (105.56) to express $|K^0\rangle$ and $\left|\bar{K}^0\right\rangle$ in terms of $|K_S\rangle\,, |K_L\rangle$. Propagating and projecting, the two transition amplitudes are

$$\mathcal{A}\left(K^0 \to \bar{K}^0\right) = \frac{1-\epsilon}{2(1+\epsilon)}\left(\mathrm{e}^{-\mathrm{i}\lambda_S t/\hbar} - \mathrm{e}^{-\mathrm{i}\lambda_L t/\hbar}\right)\,,$$

and the reverse with $(1-\epsilon)/(1+\epsilon)$ replaced by its inverse; the time-dependent bracket is common. Hence, writing $r = |(1+\epsilon)/(1-\epsilon)|^2 \approx 1 + 4\,\mathrm{Re}\,\epsilon$ and therefore $r^{-1} \approx 1 - 4\,\mathrm{Re}\,\epsilon$ to the same order, so that the numerator is $r - r^{-1} \approx 8\,\mathrm{Re}\,\epsilon$ while the denominator is $r + r^{-1} \approx 2$:

$$A_T = \frac{r - r^{-1}}{r + r^{-1}} \approx \frac{8\,\mathrm{Re}\,\epsilon}{2} = 4\,\mathrm{Re}\,\epsilon\,,$$

and the time dependence cancels between numerator and denominator. □

Numerically $4\,|\epsilon|\cos 43.5^\circ = 6.46 \times 10^{-3}$. The CPLEAR collaboration at CERN's Low Energy Antiproton Ring measured

$$A_T = (6.6 \pm 1.3 \pm 1.0) \times 10^{-3}\,, \tag{105.86}$$

the first direct observation of a time-reversal asymmetry [1948]. The method is worth stating because the tagging is the whole difficulty. CPLEAR produced neutral kaons in $p\bar{p} \to K^{\mp}\pi^{\pm}K^0/\bar{K}^0$ at rest; strangeness conservation in the strong production ties the sign of the accompanying charged kaon to the strangeness of the neutral one, so the initial state is tagged by a charge measured in the same event. The final strangeness is tagged by the charge of the lepton in the semileptonic decay, using $\Delta S = \Delta Q$ as in Equation (105.75).

The objection, and the answer The measurement has been criticized on the ground that it is not free of CPT assumptions, and the criticism is partly right. The final-state tag uses the semileptonic amplitudes, and if those amplitudes themselves violated CPT — or if $\Delta S = \Delta Q$ failed — the observed asymmetry could be produced without any T violation in the mixing. Two answers are available. First, the same data set constrains the offending parameters: the K_L and K_S semileptonic charge asymmetries and their time dependence bound the CPT-violating and $\Delta S \neq \Delta Q$ amplitudes at a level well below the measured A_T, so the interpretation survives *within* the standard phenomenological parametrization [2427]. Second — and this is the honest statement — no measurement of a decaying system can be completely free of assumptions about the decay, because the observation is made through the decay products. A T test with no such entanglement requires a stable system, which is what Section 105.4.3 provides at the cost of measuring something else.

105.4.2 Time reversal in the B system

The BaBar measurement is the cleanest of its kind, and it works by exploiting entanglement as a state-preparation device [2197].

The $\Upsilon(4S)$ decays to $B^0\bar{B}^0$ in a C-odd, $L = 1$ state, so before either decays the pair is in the antisymmetric combination

$$|\Psi\rangle = \frac{1}{\sqrt{2}}\left(\left|B^0\right\rangle_1\left|\bar{B}^0\right\rangle_2 - \left|\bar{B}^0\right\rangle_1\left|B^0\right\rangle_2\right) = \frac{1}{\sqrt{2}}\left(|B_+\rangle_1\,|B_-\rangle_2 - |B_-\rangle_1\,|B_+\rangle_2\right)\,, \tag{105.87}$$

the second form following because an antisymmetric combination of a two-dimensional space is basis-independent up to a phase; $B_\pm$ denote the states that do and do not decay to the CP eigenstate $J/\psi K^0_S$. This is the Einstein–Podolsky–Rosen correlation of Chapter 84, used here not to test locality but as a preparation: observing the decay of one meson at time t_1 to a flavour-specific state $\ell^\pm X$ projects the *other* onto a definite flavour at that instant, and observing a decay to $J/\psi K^0_S$ projects it onto a definite CP label.

The comparison is then available in both time orders. Events in which the flavour tag comes first and the CP tag second measure the transition $B^0 \to B_-$; events in the opposite order measure $B_- \to B^0$. These are a process and its motion reverse: the initial and final states are exchanged, and *nothing is conjugated*. That is what distinguishes the measurement from a CP test, which would compare $B^0 \to B_-$ with $\bar{B}^0 \to B_-$, exchanging particle for antiparticle rather than initial for final. BaBar extracted all three sets of parameters — T-odd, CP-odd and CPT-odd — from one fit to the same events, and found the T-violating parameters nonzero at 14 standard deviations, with

$$\Delta S_T^+ = -1.37 \pm 0.14 \pm 0.06\,, \qquad \Delta S_T^- = 1.17 \pm 0.18 \pm 0.11\,, \tag{105.88}$$

while the CPT-odd parameters were consistent with zero.

Two caveats keep the claim honest. The B mesons have a finite width, so the "reversed" transition is not an exact motion reverse of the original — the two occur over different intervals of proper time, and the equality of the rates is derived within the same effective two-state formalism as Proposition 105.22. And the projection interpretation of the tag is exact only if the tagging decay is flavour-specific, which is an assumption of the same family as $\Delta S = \Delta Q$ above. What the measurement does establish, and what no earlier one did, is that the T-odd and the CP-odd parameters are separately determined from a single data set and are separately nonzero.

105.4.3 Electric dipole moments as T tests

The observables above compare two processes. A permanent electric dipole moment compares nothing: it is a static property of a single state, and its existence would violate P and T at once. Purcell and Ramsey made the point in 1950, at a time when parity was universally assumed, with an argument that is really about method [966]: a symmetry that has never been tested in a given sector is an assumption, and the way to test it is to measure the quantity it forbids.

Theorem 105.30 (An EDM violates P and T)**.** *Let $|\psi\rangle$ be a nondegenerate state of a system with definite total angular momentum j, and let $\hat{\boldsymbol{d}} = \int \mathrm{d}^3x\, \boldsymbol{x}\, \rho(\boldsymbol{x})$ be the electric dipole operator. If $\left\langle \hat{\boldsymbol{d}} \right\rangle \neq 0$ then the Hamiltonian violates both P and T.*

Rests on Equations (105.6)*,* (105.17) *and* (105.30)*.*

Proof. *Derives Theorem 105.30.*

Only one fact about the state is needed, and it can be had without any general machinery. Write $|\psi\rangle = |j, m\rangle$, the quantization axis chosen along $\left\langle \hat{\boldsymbol{J}} \right\rangle$. The rotation $U(\varphi) = \mathrm{e}^{-\mathrm{i}\varphi \hat{J}_z/\hbar}$ about that axis multiplies $|\psi\rangle$ by the phase $\mathrm{e}^{-\mathrm{i}m\varphi}$ and so changes no expectation value whatever; but on a vector operator it acts as $U^\dagger \hat{V}_i U = R_{ij}(\varphi)\hat{V}_j$. Hence $\left\langle \hat{\boldsymbol{V}} \right\rangle = R(\varphi) \left\langle \hat{\boldsymbol{V}} \right\rangle$ for every φ, and a vector fixed by every rotation about $\hat{\boldsymbol{z}}$ has no transverse component: every vector expectation value in such a state points along $\left\langle \hat{\boldsymbol{J}} \right\rangle$. (The general statement, of which this is the diagonal case, is the projection theorem carried by the Wigner–Eckart theorem.) Fixing the constant so that d is the value of $\left\langle \hat{d}_z \right\rangle$ in the stretched state $m = j$,

$$\left\langle \hat{\boldsymbol{d}} \right\rangle = d\, \frac{\left\langle \hat{\boldsymbol{J}} \right\rangle}{j\hbar} \tag{105.89}$$

with d real because $\hat{\boldsymbol{d}}$ is Hermitian: the dipole, if it exists, must point along the spin, because the spin is the only vector the state possesses. Nondegeneracy is what licenses the first step — it is what gives the state a definite m with no admixture of opposite parity.

The interaction with a static electric field is $H_d = -\left\langle \hat{\boldsymbol{d}} \right\rangle \cdot \boldsymbol{E} \propto -d \left\langle \hat{\boldsymbol{J}} \right\rangle \cdot \boldsymbol{E}$. By Equation (105.6) $\boldsymbol{E}$ is polar and $\hat{\boldsymbol{J}}$ axial; by Equation (105.30) $\boldsymbol{E}$ is T-even and $\hat{\boldsymbol{J}}$ is T-odd; and by Equation (105.17) $\boldsymbol{E}$ is C-odd, while $\hat{\boldsymbol{J}}$, being an angular momentum, is C-even. So $\hat{\boldsymbol{J}} \cdot \boldsymbol{E}$ is odd under each of the three separately. The dipole operator supplies the missing sign under C: the charge density ρ reverses under charge conjugation, so $\hat{\boldsymbol{d}}$ is C-odd and a particle and its antiparticle carry opposite dipoles. The interaction $-\hat{\boldsymbol{d}} \cdot \boldsymbol{E}$ is therefore *C-even*, P-odd and T-odd. A nonzero d means the Hamiltonian contains a term with those properties, i.e. P and T are violated (and, by the CPT theorem, CP with them — the three signs multiply to CPT-even, as Theorem 105.34 requires of any term in a Hermitian local Lagrangian). □

Remark 105.31 (Degeneracy is the loophole, and it is not academic). The hypothesis of nondegeneracy is essential and is often omitted. The hydrogen atom in its $n = 2$ level, where $2S_{1/2}$ and $2P_{1/2}$ are degenerate up to the Lamb shift, exhibits a *linear* Stark effect: the field mixes states of opposite parity and the energy shifts linearly in $|\boldsymbol{E}|$, exactly as a permanent dipole would. No symmetry is violated, because the state that acquires the dipole is not an eigenstate of parity to begin with. The same mechanism is what makes polar molecules useful in EDM searches: a molecule such as ThO has closely spaced levels of opposite parity, which a modest laboratory field fully polarizes, producing an enormous *effective* internal field acting on the electron — in ThO of order $7.8 \times 10^{12}\,\mathrm{V/m}$, which is the 78 GV/cm of the ACME literature, and enormously larger than any field a laboratory can apply directly. The molecule is a lever, not a violation.

How the measurement is made The technique is Ramsey's method of separated oscillatory fields [968]. Neutrons in a storage cell see parallel magnetic and electric fields; the Larmor precession frequency is

$$h\nu_{\pm} = |2\mu_n B \pm 2 d_n E| \,, \tag{105.90}$$

the sign depending on whether $\boldsymbol{E}$ is parallel or antiparallel to $\boldsymbol{B}$. Reversing $\boldsymbol{E}$ and taking the difference isolates the dipole:

$$\Delta\nu = \frac{4 d_n E}{h} \,. \tag{105.91}$$

The statistical sensitivity of a Ramsey measurement with coherence time T on N neutrons is

$$\sigma(d_n) = \frac{\hbar}{2\,\alpha_v\, E\, T\, \sqrt{N}} \,, \tag{105.92}$$

with $\alpha_v \lesssim 1$ the fringe visibility. Inserting the PSI apparatus's parameters — $E \approx 1.1 \times 10^6\,\mathrm{V/m}$, $T = 180\,\mathrm{s}$, and of order 10^7 ultracold neutrons accumulated over the run — gives $\sigma(d_n) \sim 8 \times 10^{-47}\,\mathrm{C\,m}$, which is the order of the published limit and confirms that the experiment is statistics-limited rather than limited by any subtlety.

Phenomenon 105.32 (The neutron has no measurable electric dipole moment)**.** Seven decades of measurement find no permanent electric dipole moment of the neutron. The current bound, from ultracold neutrons at the Paul Scherrer Institute, is

$$|d_n| < 2.9 \times 10^{-47}\,\mathrm{C\,m} \tag{105.93}$$

at 90 % confidence [2346], improving on [2090]. The same number is customarily quoted as 1.8×10^{-26} in units of the elementary charge times the centimetre; the conversion is $1\,e\,\mathrm{cm} = 1.602\,176\,634 \times 10^{-21}\,\mathrm{C\,m}$. See Phenomenon 111.19.

Rests on Theorem 105.30 and Equations (105.91) *and* (105.92).

Derivation. *Derives Phenomenon 105.32.*

That the observable is forbidden at all is Theorem 105.30; what is derived here is the number, since a bound is a statement about a resolved frequency and Equation (105.91) is what converts the two. At the PSI storage field $E \approx 1.1 \times 10^{6}\,\mathrm{V/m}$, a dipole equal to Equation (105.93) would shift the Ramsey resonance by

$$\Delta\nu = \frac{4 d_n E}{h} = \frac{4 \times 2.9 \times 10^{-47}\,\mathrm{C\,m} \times 1.1 \times 10^{6}\,\mathrm{V/m}}{6.626\,070\,15 \times 10^{-34}\,\mathrm{J\,s}} = 1.9 \times 10^{-7}\,\mathrm{Hz}\,,$$

against a Larmor frequency $2\mu_n B/h \approx 29\,\mathrm{Hz}$ at the working field $B \approx 1\,\mu\mathrm{T}$: the experiment is a determination of a frequency ratio to 7×10^{-9}, made twice with $\boldsymbol{E}$ reversed. That such a resolution is available follows from Equation (105.92): with $T = 180\,\mathrm{s}$ and of order 10^{7} ultracold neutrons the statistical limit is $8.4 \times 10^{-47}\,\mathrm{C\,m}$, within a factor of three of the published 90 % bound, which is the quantitative content of the claim that the measurement is statistics-limited. The bound is therefore not a theoretical estimate at all: it is the frequency resolution of a Ramsey interferometer, divided by $4E/h$. □

The number is hard to feel, so it is worth converting once. A dipole of $2.9 \times 10^{-47}\,\mathrm{C\,m}$ corresponds to separating one elementary charge from its opposite by $1.8 \times 10^{-28}\,\mathrm{m}$ — about 10^{13} times smaller than the neutron itself, whose charge radius is of order 0.8 fm. Scaled up so that the neutron were the size of the Earth, the charge separation would be a few micrometres.

The electron is bounded even harder, in units of its own size, by experiments on polar molecules. ACME, using the metastable H state of ThO, obtained $|d_e| < 1.8 \times 10^{-50}\,\mathrm{C\,m}$ ($1.1 \times 10^{-29}\,e\,\mathrm{cm}$) at 90 % confidence [2300], and a trapped molecular-ion experiment on HfF^{+} has since reached $|d_e| < 6.6 \times 10^{-51}\,\mathrm{C\,m}$ ($4.1 \times 10^{-30}\,e\,\mathrm{cm}$) [2421].

What makes these null results powerful is the size of the Standard Model background. In the quark sector the CKM phase can generate a neutron EDM only at three loops, and the chiral suppression is severe: the estimate is of order $10^{-32}\,e\,\mathrm{cm}$, six orders below Equation (105.93). For the electron the CKM contribution requires four loops and is of order $10^{-38}\,e\,\mathrm{cm}$, nine orders below the current limit. Every improvement in these experiments therefore probes a range in which the Standard Model predicts nothing observable, so a nonzero result would be unambiguous — and a null result excludes new sources of CP violation over a wide range without any background to subtract. The one Standard Model contribution that is *not* negligible is the strong CP term of Section 105.7, which is why Equation (105.93) is simultaneously the sharpest constraint on $\bar{\theta}$.

105.5 The CPT theorem

105.5.1 Statement and hypotheses

Definition 105.33 (The CPT operator)**.** $\Theta := \mathcal{C}\mathcal{P}\mathcal{T}$, an antiunitary operator (the product of two unitaries and one antiunitary), acting on spacetime arguments by $x \mapsto -x$ and exchanging particles with antiparticles.

Theorem 105.34 (CPT)**.** *Let a quantum field theory satisfy*

1. ***Lorentz invariance**: the fields transform under a representation of the proper orthochronous group $L_{+}^{\uparrow}$ of Definition 39.5, and the dynamics is invariant under it and under translations;*

2. ***locality**: fields at spacelike separation commute (integer spin) or anticommute (half-integer spin);*

3. ***the spectrum condition****: the energy-momentum spectrum lies in the closed forward light cone, with a unique Poincaré-invariant vacuum;*

4. ***hermiticity****: the Hamiltonian is Hermitian, so the evolution is unitary.*

Then there exists an antiunitary Θ *with* $\Theta\,|0\rangle = |0\rangle$ *that commutes with the Hamiltonian: CPT is an exact symmetry [1049, 1055, 1079, 1115, 1123].*

Rests on Definition 39.5, Lemma 105.35, and Equation (100.2).

Two proofs exist and they are of quite different kinds. The first works at the level of a Lagrangian and is short enough to give in full; the second is the theorem proper, since it assumes nothing about Lagrangians, and its machinery is not yet available in this book.

The Lagrangian-level proof

Lemma 105.35 (Every Lorentz index costs a sign)**.** *Let* $O^{\mu_1\cdots\mu_n}(x)$ *be a local monomial built from Dirac bilinears, gauge fields and derivatives, carrying* n *uncontracted Lorentz indices. Then*

$$\Theta\, O^{\mu_1\cdots\mu_n}(x)\,\Theta^{-1} = (-1)^n\,[O^{\mu_1\cdots\mu_n}(-x)]^\dagger\,. \tag{105.94}$$

Rests on Equations (105.6), (105.17) and (105.30).

Proof. *Derives Lemma 105.35.*

For the five Dirac bilinears the rule is the last column of Table 105.1, obtained by multiplying the three preceding columns; the dagger appears because $\mathcal{T}$ is antiunitary and reverses the order of operators in a product. Inspection confirms the count: the scalar and pseudoscalar ($n=0$) are even, the vector and axial vector ($n=1$) are odd, the tensor ($n=2$) is even — and, which is the essential point, CPT does not distinguish scalar from pseudoscalar nor vector from axial, so only n enters.

For the gauge field, $\mathcal{P}A^\mu\mathcal{P}^{-1}$ and $\mathcal{T}A^\mu\mathcal{T}^{-1}$ each lower the index (Equations (105.6) and (105.30)), so the product returns A^μ with sign $+1$, while $\mathcal{C}$ contributes -1 by Equation (105.17): total $(-1)^1$, as Equation (105.94) requires for $n=1$.

For a derivative, let $O'(x) = \Theta O(x)\Theta^{-1} = s\,O^\dagger(-x)$ with s the sign already established. Differentiating, $\partial_\mu\left[O^\dagger(-x)\right] = -\,(\partial_\mu O)^\dagger(-x)$ by the chain rule, so ∂_μ contributes one extra factor -1 and one extra index, preserving Equation (105.94). A product of such objects multiplies the signs and adds the index counts, so the rule is closed under multiplication. □

Proof of Theorem 105.34, Lagrangian level. *Derives Theorem 105.34.*

A Lorentz-scalar Lagrangian density is a sum of monomials in which every index is contracted, either with the metric $\eta_{\mu\nu}$ or with the Levi-Civita symbol $\varepsilon^{\mu\nu\rho\sigma}$. In either case indices are used in pairs — η takes two, and ε takes four — so the total number of Lorentz indices appearing in any scalar monomial is even. By Lemma 105.35 the sign $(-1)^n$ is therefore $+1$, and

$$\Theta\,\mathcal{L}(x)\,\Theta^{-1} = \mathcal{L}^\dagger(-x) = \mathcal{L}(-x)\,, \tag{105.95}$$

the last step by hypothesis (iv), hermiticity of $\mathcal{L}$. The action Equation (100.2) is then invariant,

$$\Theta S\Theta^{-1} = \frac{1}{c}\int \mathrm{d}^4x\,\mathcal{L}(-x) = \frac{1}{c}\int \mathrm{d}^4x'\,\mathcal{L}(x') = S\,,$$

because the Jacobian of $x \to -x$ in four dimensions is $+1$. Hence $[\Theta, H] = 0$.

Two hypotheses have been used silently and must be flagged. First, reordering the fermion operators inside a normal-ordered monomial — which the dagger in Equation (105.94) requires — produces a sign that is $+1$ only if half-integer-spin fields anticommute; had a spinor field been quantized with commutators the argument would fail at exactly this step. This is hypothesis (ii), and its appearance here is the connection between the CPT theorem

and spin–statistics noticed by Pauli [854] and made precise by Lüders and Zumino [1151]. Second, the fields have been assumed to carry finite-dimensional representations built from vectors and spinors, which is what makes the index count exhaustive. □

The Lagrangian argument is complete and correct as far as it goes, and it is what one uses in practice: given a candidate interaction, count its indices. What it does not do is prove the theorem, because it presupposes a Lagrangian, a perturbative expansion, and a set of fields transforming in specified representations. The theorem proper assumes none of these.

The axiomatic proof, honestly Jost's proof [1115], and the canonical account in Streater and Wightman [1297], work directly with the vacuum expectation values

$$W_n(x_1,\dots,x_n) = \langle 0|\,\phi(x_1)\cdots\phi(x_n)\,|0\rangle\ , \tag{105.96}$$

the Wightman functions [1099]. The structure of the argument is the following, and it is worth seeing even though the machinery is reserved.

The spectrum condition (iii) says the energy-momentum of every state lies in the forward cone. Fourier-transforming Equation (105.96) in the differences $\xi_j = x_j - x_{j+1}$, the support of the transform is confined to the forward cone, which by the Paley–Wiener theorem — imported here, not proved in this book, and not among the results of Chapter 17 — makes W_n the boundary value of a function analytic in the *forward tube*, the domain in which each ξ_j has an imaginary part in the open forward cone. Lorentz covariance (i) then extends the domain: the *extended tube* is the union of the images of the forward tube under the *complex* proper Lorentz group $L_+(\mathbb{C})$, and W_n continues analytically to all of it.

The decisive fact is a statement about that group and nothing else. $L_+(\mathbb{C})$ is *connected*, and it contains the total inversion $-\mathbb{1}$, which corresponds to $x \mapsto -x$. Over the reals, $-\mathbb{1}$ lies in $L_+^{\downarrow}$, a different component from the identity (Equation (39.9)), and cannot be reached; over the complexes it can, by a continuous path through complex "rotations" by an imaginary angle. Analytic continuation along that path therefore gives

$$W_n(x_1,\dots,x_n) = W_n(-x_1,\dots,-x_n)\,, \tag{105.97}$$

and Jost's theorem states that Equation (105.97) is equivalent to *weak local commutativity* at the Jost points — the totally spacelike configurations — which is a weakened form of hypothesis (ii). Equation (105.97) is the CPT condition, and from it the operator Θ is reconstructed.

This is also the clean answer to the question a reader should be asking: why CPT and not CP, or T? Because $-\mathbb{1}$ is in $L_+(\mathbb{C})$ while Λ_P and Λ_T separately have determinant -1 and are in no component of $L_+(\mathbb{C})$ at all. The theorem protects exactly the combination that the complexified group can reach, and nothing else. No amount of ingenuity extends it to CP.

Derivation pending #160

The axiomatic CPT theorem: Jost's proof requires the Wightman axioms, the analyticity of the Wightman functions in the forward tube, the extended tube and the edge-of-the-wedge theorem. None of that machinery is developed here; the axiomatic-QFT chapter reserves it, and the proof belongs in Appendix A alongside it. What is proved in this chapter is the Lagrangian-level theorem, which is weaker in that it assumes a Lagrangian, a field content and a perturbative expansion.

What the theorem forbids The consequences are three, and each is a short argument from antiunitarity. All three use the identity Equation (105.26); the reader who has not read that line should read it now, because everything below is a corollary of it.

Theorem 105.36 (Equal masses)**.** *A particle and its antiparticle have equal masses.*
Rests on Definition 105.33, Theorem 105.34, and Equation (105.26).

Proof. *Derives Theorem 105.36.*

Let $|a\rangle$ be a one-particle state at rest with spin projection s, so $H|a\rangle = m_a c^2 |a\rangle$ and hence $\langle a| H |a\rangle = m_a c^2$, a real number. By Definition 105.33, $\Theta|a\rangle = |\bar{a}\rangle$ up to a phase (the momentum is zero and so is unaffected; the spin projection reverses, which does not matter since the rest energy does not depend on it). Apply Equation (105.26) with $\mathcal{A} = \Theta$, $O = H$, $\varphi = \psi = |a\rangle$, using $\Theta^{-1} H \Theta = H$ from Theorem 105.34:

$$m_{\bar{a}} c^2 = \langle \Theta a| H |\Theta a\rangle = \langle a| H |a\rangle^* = m_a c^2 .$$

The phase cancels between bra and ket. □

Theorem 105.37 (Opposite charges and opposite magnetic moments)**.** *A particle and its antiparticle carry electric charges of equal magnitude and opposite sign, and magnetic moments of equal magnitude and opposite sign.*
Rests on Lemma 105.35 and Equation (105.26).

Proof. *Derives Theorem 105.37.*

Both statements follow from the transformation of the current operator. By Lemma 105.35 with $n = 1$, $\Theta j^\mu(x)\Theta^{-1} = -j^\mu(-x)$, the dagger being irrelevant since j^μ is Hermitian.

For the charge, $Q = \frac{1}{c}\int \mathrm{d}^3x\, j^0(x)$, so $\Theta Q \Theta^{-1} = -Q$ (the spatial integration measure is invariant under $\boldsymbol{x} \to -\boldsymbol{x}$, and the time argument is a label). Then Equation (105.26) gives $q_{\bar{a}} = \langle \Theta a| Q |\Theta a\rangle = \langle a| \Theta^{-1} Q \Theta |a\rangle^* = -q_a$.

For the magnetic moment, the operator is $\hat{\boldsymbol{\mu}} = \frac{1}{2}\int \mathrm{d}^3x\, \boldsymbol{x} \times \boldsymbol{j}(x)$. Under Θ the current picks up a minus sign *and* its spatial argument is reflected; substituting $\boldsymbol{x} \to -\boldsymbol{x}$ in the integral, the two minus signs — one from $\boldsymbol{x}$ and one from $\boldsymbol{j}$ — cancel, so

$$\Theta \hat{\boldsymbol{\mu}} \Theta^{-1} = +\hat{\boldsymbol{\mu}} .$$

Define μ_a as the expectation of $\hat{\mu}_z$ in the state of maximal spin projection along z. Since $\Theta|a, s_z = +\rangle = |\bar{a}, s_z = -\rangle$ — $\mathcal{T}$ and $\mathcal{P}$ together reverse the spin, $\mathcal{P}$ leaving it alone and $\mathcal{T}$ reversing it — Equation (105.26) gives

$$\langle \bar{a}, -| \hat{\mu}_z |\bar{a}, -\rangle = \langle a, +| \hat{\mu}_z |a, +\rangle^* = \mu_a ,$$

and rotational invariance gives $\langle \bar{a}, -| \hat{\mu}_z |\bar{a}, -\rangle = -\mu_{\bar{a}}$. Hence $\mu_{\bar{a}} = -\mu_a$. □

Theorem 105.37 is exactly what the electron–positron comparison of Chapter 112 tests, and it discharges the prediction recorded there at Phenomenon 112.13: the two g factors must agree in magnitude and the moments must point oppositely relative to the spin. They agree to about two parts in 10^{12} [1798].

Theorem 105.38 (Equal total lifetimes)**.** *A particle and its antiparticle have equal total decay widths, and hence equal lifetimes — although their individual partial widths need not be equal.*
Rests on Theorem 105.34 and Equation (105.26).

Proof. *Derives Theorem 105.38.*

Write $S = \mathbb{1} + \mathrm{i}T$ with T the transition operator; unitarity $S^\dagger S = \mathbb{1}$ gives the optical relation

$$-\mathrm{i}\,(T_{ii} - T_{ii}^{*}) = \sum_{f} |T_{fi}|^{2}\,, \tag{105.98}$$

whose right-hand side is, up to kinematic factors, the total width Γ_i. The left-hand side is $2\,\mathrm{Im}\,T_{ii}$, since $T_{ii} - T_{ii}^{*} = 2\mathrm{i}\,\mathrm{Im}\,T_{ii}$, and it is *positive* — a sum of squares — which fixes the sign once and for all. Now CPT invariance means $\Theta S \Theta^{-1} = S$, and Equation (105.26) converts this into

$$T_{fi} = T_{(\Theta i)(\Theta f)}\,, \tag{105.99}$$

an equality between the amplitude for $i \to f$ and that for the CP-conjugated, motion-reversed process. Setting $f = i$ and summing Equation (105.98) over all channels,

$$\Gamma_i = 2\,\mathrm{Im}\,T_{ii} = 2\,\mathrm{Im}\,T_{(\Theta i)(\Theta i)} = \Gamma_{\Theta i}\,,$$

so the total width of the antiparticle equals that of the particle. The individual terms $|T_{fi}|^2$ in Equation (105.98) need not match their conjugates, because Equation (105.99) pairs $i \to f$ with $\bar{f} \to \bar{i}$ and not with $\bar{i} \to \bar{f}$; unitarity forces the differences to cancel in the sum. □

The last sentence is the whole reason direct CP violation is subtle, and it is worth extracting as a separate statement.

Proposition 105.39 (A direct CP asymmetry needs two amplitudes and two kinds of phase)**.** *Let $\mathcal{A} = a_1 \mathrm{e}^{\mathrm{i}\delta_1}\mathrm{e}^{\mathrm{i}\phi_1} + a_2 \mathrm{e}^{\mathrm{i}\delta_2}\mathrm{e}^{\mathrm{i}\phi_2}$ with a_k real, ϕ_k CP-odd (weak) phases and δ_k CP-even (rescattering) phases, so that the conjugate amplitude is $\bar{\mathcal{A}} = a_1 \mathrm{e}^{\mathrm{i}\delta_1}\mathrm{e}^{-\mathrm{i}\phi_1} + a_2 \mathrm{e}^{\mathrm{i}\delta_2}\mathrm{e}^{-\mathrm{i}\phi_2}$. Then*

$$|\mathcal{A}|^2 - \left|\bar{\mathcal{A}}\right|^2 = -4 a_1 a_2 \,\sin(\delta_1 - \delta_2)\sin(\phi_1 - \phi_2)\,. \tag{105.100}$$

A direct asymmetry therefore requires two interfering amplitudes, a difference of weak phases, and *a difference of strong phases.*

Rests on Equation (105.28) and Theorem 105.38.

Proof. *Derives Proposition 105.39.*

$|\mathcal{A}|^2 = a_1^2 + a_2^2 + 2a_1 a_2 \cos(\delta_1 - \delta_2 + \phi_1 - \phi_2)$, and $\left|\bar{\mathcal{A}}\right|^2$ is the same with $\phi_1 - \phi_2 \to -(\phi_1 - \phi_2)$. Subtracting and using $\cos(u+v) - \cos(u-v) = -2\sin u \sin v$ gives Equation (105.100). □

This explains a great deal at once: why ϵ' in Equation (105.72) is a *difference* of two phases; why the strong rescattering phases δ_0, δ_2 appear there at all; why the charm asymmetry of Equation (105.83) cannot be predicted, its strong phases being incalculable; and why an inclusive total rate can never show a CP asymmetry, since summing over final states washes out the strong phases and Theorem 105.38 takes over.

105.5.2 Consequences and loopholes

The companion theorem Hypothesis (ii) of Theorem 105.34 assigns commutators to integer spin and anticommutators to half-integer spin. That assignment is not a convention: it is forced by the same hypotheses, and the result is the spin–statistics theorem [854]. The two theorems are so closely linked that Lüders and Zumino proved a converse — CPT invariance, plus the usual axioms, implies the correct connection between spin and statistics [1151].

The essential computation is visible already for free fields. For a real scalar field the commutator at arbitrary separation is

$$[\phi(x),\phi(y)] = \mathrm{i}\hbar c^2\,\Delta(x-y)\,, \qquad \Delta(x) = -\mathrm{i}\int \frac{\mathrm{d}^3k}{(2\pi)^3 2\omega_k}\left(\mathrm{e}^{-\mathrm{i}k\cdot x} - \mathrm{e}^{+\mathrm{i}k\cdot x}\right), \tag{105.101}$$

the Pauli–Jordan function, in which $k^\mu = (\omega_k/c, \boldsymbol{k})$ is on shell, $\omega_k = c\sqrt{\boldsymbol{k}^2 + m^2c^2/\hbar^2}$, so that $k\cdot x = k_\mu x^\mu$ is a pure number and Δ carries $\mathrm{s/m^3}$. The powers of $\hbar$ and c in front are then forced: the canonical commutator $[\phi(t,\boldsymbol{x}),\pi(t,\boldsymbol{y})] = \mathrm{i}\hbar\,\delta^3(\boldsymbol{x}-\boldsymbol{y})\mathbb{1}$ with $\pi = c^{-2}\partial_t\phi$ makes ϕ^2 an energy per unit length, $\mathrm{J/m}$, and $\hbar c^2 \times \mathrm{s/m^3}$ is exactly that. With $\mathrm{i}\hbar c$ in place of $\mathrm{i}\hbar c^2$ the two sides would differ by a factor of c.

Δ is Lorentz invariant and odd, so it vanishes for spacelike separation — a spacelike interval can be reversed by a proper orthochronous Lorentz transformation, and an odd invariant function of a reversible argument is zero. Had the same field been quantized with anticommutators, the object appearing would be the *even* combination Δ_1, which is nonzero everywhere outside the light cone: microcausality would fail. For the Dirac field the situation is exactly reversed: the anticommutator $\{\psi(x),\bar\psi(y)\} \propto (\mathrm{i}\hbar\gamma^\mu\partial_\mu + mc)\Delta(x-y)$ vanishes at spacelike separation because Δ does, while the commutator would involve Δ_1 and would not. A second, independent strand of the argument is that a scalar field quantized with anticommutators has no ground state, its Hamiltonian being unbounded below, while a spinor field quantized with commutators produces negative-norm states. Either way the wrong choice destroys one of the hypotheses that Theorem 105.34 needs.

Derivation pending #161

The spin–statistics theorem for arbitrary spin: the free-field computation sketched here settles spin 0 and spin 1/2, but the general statement requires the analyticity of the two-point Wightman function and the same extended-tube machinery as the axiomatic CPT proof. It belongs in Appendix A next to it, and the identical-particle chapter of Part IX states the result it needs.

The physical content is the exclusion principle of Chapter 83, and it is worth remembering how much rests on it: the stability of matter, the periodic table, the degeneracy pressure of Chapter 49. That a statement about analytic continuation in complexified Lorentz transformations underwrites the structure of the periodic table is one of the stranger facts in physics, and it is not a coincidence — both follow from locality and positivity of the energy.

Parametrizing a violation If CPT were violated, how would one report the fact? The answer matters because experiments in wholly different systems — an antihydrogen atom, a kaon beam, a trapped antiproton — must be compared, and each measures something different. The standard device is an effective field theory in which every Lorentz- and CPT-violating operator that can be built from the observed fields is added to the Standard Model Lagrangian with an arbitrary coefficient [1952]. A term such as $b_\mu\bar\psi\gamma^\mu\gamma^5\psi$, with b_μ a fixed background four-vector rather than a field, is CPT-odd by Lemma 105.35 — it has one uncontracted index, since b_μ does not transform — and each experiment then bounds some combination of the coefficients. The tabulated bounds run to hundreds of entries [2176].

It is important to be clear about the status of this construction. It is not a theory for which there is evidence; it is a bookkeeping scheme for null results, and its value is precisely that it lets a limit from one system be compared with a limit from another. The coefficients are all consistent with zero.

The relation to Lorentz invariance

Proposition 105.40 (Greenberg)**.** *In an interacting local quantum field theory satisfying the usual axioms, violation of CPT implies violation of Lorentz invariance. The converse is false: there are Lorentz-violating theories that preserve CPT [2028].*

Rests on Theorem 105.34 and Lemma 105.35.

The asymmetry is easy to see in the parametrization above. An operator with an odd number of uncontracted indices, contracted with a fixed background vector, is both CPT-odd and Lorentz-violating; an operator with an even number, contracted with a fixed background tensor, is CPT-even but still Lorentz-violating. Hence CPT-violating $\subset$ Lorentz-violating, strictly. Two consequences follow for experiment. A CPT test is automatically a Lorentz test, and in some channels the sharpest one available. And a search for Lorentz violation cannot be replaced by a CPT test, because the CPT-even sector is invisible to it.

Why these are tests of the axioms The hypotheses of Theorem 105.34 are, essentially verbatim, the Wightman axioms of Chapter 109. That is what gives a CPT measurement its unusual standing. A discrepancy between the electron's and the positron's g factor would not be evidence for some new particle or some unmeasured coupling; it would mean that one of locality, Lorentz invariance, or the positivity of the energy spectrum is false. There are very few measurements in physics whose failure would be that structural, and it is the reason the null results below are worth the effort they cost.

105.5.3 Experimental tests

Table 105.2: Tests of CPT invariance. The quantities compared are predicted equal (or equal and opposite) by Theorems 105.36 to 105.38. The kaon entry is the customary one and is discussed in the text: it is a fraction of $m_K c^2$, and the underlying bound on the energy is far weaker than the exponent suggests. Every entry is consistent with exact CPT.

system	quantity compared	fractional limit	source
K^0 and $\bar{K}^0$	rest energy	6×10^{-19}	[2427]
antihydrogen and hydrogen	$1S$–$2S$ transition frequency	2×10^{-12}	[2299]
$\bar{p}$ and p	magnetic moment	1.5×10^{-9}	[2288]
$\bar{p}$ and p	charge-to-mass ratio	1.6×10^{-11}	[2400]
e^+ and e^-	g factor	2×10^{-12}	[1798]

The kaon bound, and how to read it The neutral kaon entry is the tightest number in Table 105.2 and the one most often misquoted. What is measured is a combination of the semileptonic charge asymmetries of K_L and K_S together with the phase of η_{+-}, which bounds the CPT-violating diagonal difference $M_{11} - M_{22}$ of Proposition 105.23. The bound on that *energy* is of order $3 \times 10^{-10}\,\mathrm{eV}$ — roughly 10^{-4} of the K_L–K_S mass difference Equation (105.60), which is itself a $3.5\,\mu\mathrm{eV}$ splitting. Dividing by $m_K c^2 = 497.6\,\mathrm{MeV}$ turns it into 6×10^{-19}. The exponent therefore reflects the largeness of the denominator as much as the sharpness of the measurement, and comparing it with the 10^{-12} of an atomic experiment is comparing two different things. Both statements are true; neither is "the best CPT test" without a choice of what to divide by.

Antihydrogen The ALPHA collaboration at CERN traps antihydrogen, formed by mixing antiprotons from the Antiproton Decelerator with positrons, in a magnetic minimum, and performs laser spectroscopy on the trapped sample. The two-photon $1S$–$2S$ transition, a

natural linewidth of about 1 Hz on a frequency of 2.466×10^{15} Hz, is the sharpest observable in hydrogen. ALPHA first observed the transition in antihydrogen [2280] and then measured its frequency, in zero field, in agreement with hydrogen at the level of 2×10^{-12} [2299]. The comparison tests Theorem 105.36 and Theorem 105.37 jointly, since the transition frequency depends on the electron and proton masses and charges in combination.

The antiproton Two BASE measurements bound the antiproton's properties directly. The magnetic moment, measured on a single trapped antiproton by the continuous Stern–Gerlach effect, is $\mu_{\bar{p}} = -2.7928473441(42)\mu_N$, agreeing with the proton's in magnitude to 1.5 parts in 10^9 and opposite in sign [2288] — exactly Theorem 105.37. The charge-to-mass ratio, measured by comparing the cyclotron frequencies of an antiproton and a negative hydrogen ion in the same trap, agrees with the proton's to 16 parts in 10^{12} [2400].

What CPT does not say The ALPHA-g experiment released antihydrogen from a vertical trap and found that it falls, with a measured acceleration $a_g = (0.75 \pm 0.13 \pm 0.16)\, g$ downward [2417]. This is a fine measurement and it is *not* a test of CPT. The theorem relates inertial masses, charges and moments; it says nothing about gravitational coupling, and a hypothetical antigravity would violate the equivalence principle of Chapter 42 without disturbing any hypothesis of Theorem 105.34. Reporting it as a CPT test, as several popular accounts did, confuses two independent structures. Every genuine CPT test performed to date is consistent with exact invariance.

105.6 The baryon asymmetry

105.6.1 Sakharov's conditions

The universe contains matter and essentially no antimatter. If it began in a state symmetric under C and CP, with equal numbers of baryons and antibaryons, then getting from there to here requires three things, identified by Sakharov in a two-page paper of 1967 [1358]. All three are necessary, and each necessity is a theorem.

Theorem 105.41 (Sakharov's conditions)**.** *Let a system begin with $\langle B \rangle = 0$, where B is baryon number. Then $\langle B \rangle = 0$ at all later times if any one of the following holds:*

1. *B is conserved, $[B, H] = 0$;*
2. *C and CP are symmetries of H and of the initial state;*
3. *the system is in thermal equilibrium.*

Generating a baryon asymmetry therefore requires baryon number violation, C and CP violation, and a departure from thermal equilibrium.

Rests on Theorem 105.34 and Equation (105.34).

Proof. *Derives Theorem 105.41.*

(i) is immediate: a conserved quantity that starts at zero stays there.

(ii) Let $\rho(t)$ be the density operator and suppose $\mathcal{C}H\mathcal{C}^{-1} = H$ and $\mathcal{C}\rho(0)\mathcal{C}^{-1} = \rho(0)$, whence $\mathcal{C}\rho(t)\mathcal{C}^{-1} = \rho(t)$ for all t since the evolution commutes with $\mathcal{C}$. Baryon number is C-odd, $\mathcal{C}B\mathcal{C}^{-1} = -B$. Then, using cyclicity of the trace and the unitarity of $\mathcal{C}$,

$$\langle B \rangle = \operatorname{tr}\left[\rho(t) B\right] = \operatorname{tr}\left[\mathcal{C}\rho(t)\mathcal{C}^{-1}\, \mathcal{C}B\mathcal{C}^{-1}\right] = -\operatorname{tr}\left[\rho(t) B\right] = 0\,.$$

The same computation with $\mathcal{CP}$ in place of $\mathcal{C}$ gives the same conclusion, and both are needed: a theory may violate C maximally and still conserve CP — the $V - A$ interaction of

Equation (105.34) is the standard example — in which case the CP-version of the argument still forces $\langle B\rangle = 0$. It is the *pair* of symmetries that must fail.

(iii) is the deepest of the three, and it is where CPT enters. In thermal equilibrium at temperature T the density operator is $\rho = \mathrm{e}^{-H/k_BT}/Z$; there is no chemical potential for B, because by hypothesis (i) has failed and B is not conserved, so it cannot label a conserved charge. Now $\langle B\rangle = \mathrm{tr}(\rho B)$ is real, being the trace of a product of two Hermitian operators. For an antiunitary Θ and any operator O, choosing the orthonormal basis $\{\Theta e_n\}$ to evaluate the trace gives

$$\mathrm{tr}\left(\Theta O \Theta^{-1}\right) = \sum_n \langle \Theta e_n |\, \Theta O\, | e_n\rangle = \sum_n \langle O e_n | e_n\rangle = (\mathrm{tr}\, O)^* \,. \tag{105.102}$$

Apply this with $O = \mathrm{e}^{-H/k_BT}B$. By Theorem 105.34 $\Theta H \Theta^{-1} = H$, and B is CPT-odd (it is C-odd and P- and T-even), so $\Theta\left(\mathrm{e}^{-H/k_BT}B\right)\Theta^{-1} = -\mathrm{e}^{-H/k_BT}B$. Hence

$$\mathrm{tr}\left(\mathrm{e}^{-H/k_BT}B\right) = -\left[\mathrm{tr}\left(\mathrm{e}^{-H/k_BT}B\right)\right]^* = -\,\mathrm{tr}\left(\mathrm{e}^{-H/k_BT}B\right),$$

the last step because the quantity is real; therefore it vanishes. □

Part (iii) deserves a comment, because it is the point at which the two halves of this chapter meet. The reason equilibrium forbids a baryon asymmetry is *that particles and antiparticles have the same mass*, which is Theorem 105.36: with equal masses and no conserved charge to bias them, the equilibrium populations are equal whatever the interactions. The CPT theorem, which guarantees the symmetry of the world, is thereby also the obstacle to explaining its asymmetry. Any mechanism must arrange for the universe to be out of equilibrium while the baryon-number-violating processes are active.

The Standard Model's baryon-number violation Condition (i) looks hopeless at first sight, since baryon number is an exact symmetry of the classical Standard Model Lagrangian. It is not a symmetry of the quantum theory. The baryon and lepton currents are anomalous: the divergence that vanishes classically acquires a contribution from the non-invariance of the fermion measure [1388, 1391, 1569], with the integrated statement

$$\Delta B = \Delta L = n_f\, \Delta n_{\mathrm{CS}}\,, \tag{105.103}$$

where $n_f = 3$ is the number of generations and $n_{\mathrm{CS}} \in \mathbb{Z}$ is the Chern–Simons number of the SU(2) gauge field, an integer for a transition between distinct vacua. Baryon number is violated; $B - L$ is not. The barrier between adjacent vacua is the sphaleron, a static unstable solution whose energy is set by the $\mathrm{SU}(2)_L$ coupling g and the W mass,

$$E_{\mathrm{sph}} = B\,\frac{8\pi}{g^2}\, m_W c^2 \approx 9\,\mathrm{TeV} \quad \text{at } T = 0\,. \tag{105.104}$$

Here $g^2 = 4\pi\alpha/\sin^2\theta_W = 0.397$, taking $\sin^2\theta_W = 0.231$ and $\alpha = 1/137.036$, so that $g = 0.630$ and $8\pi/g^2 = 63.4$; with $m_W c^2 = 80.4\,\mathrm{GeV}$ the bare combination $(8\pi/g^2)m_W c^2$ is only 5.1 TeV. The factor B is a dimensionless shape factor fixed numerically by the field equations: it depends on nothing but the ratio of the Higgs self-coupling to g^2, runs from about 1.5 to 2.7 across the whole range of that ratio, and is close to 1.8 at the observed Higgs mass. That is where the 9 TeV comes from, and quoting the formula without B — as is often done — understates the barrier by nearly a factor of two. At zero temperature the tunnelling rate then carries the factor $\exp(-4\pi/\alpha_W) \sim 10^{-173}$, with $\alpha_W = g^2/4\pi = 0.0316$, and nothing happens. Above the electroweak scale, $k_BT \gtrsim 100\,\mathrm{GeV}$, the barrier can be crossed thermally and the rate per unit volume is unsuppressed, $\Gamma/V \sim (\alpha_W k_B T)^4/(\hbar c)^3\hbar$

[1758]. The Standard Model therefore satisfies Sakharov's first condition, in the early universe and nowhere else.

Derivation pending #162

The triangle anomaly and the Chern–Simons current: the derivation that the baryon current's divergence is proportional to the topological density, whether by the triangle diagram or by the non-invariance of the path-integral measure, is not carried out in this chapter. It belongs to the path-integral chapter of this part, which reserves the anomaly, and to Appendix A. What is used here is only the integrated statement, that a change of Chern-Simons number by one unit changes baryon number by the number of generations.

105.6.2 Why the Standard Model fails

The number to be explained The asymmetry is quantified by the baryon-to-photon ratio.

Proposition 105.42 (Baryon-to-photon ratio from the CMB)**.**

$$\eta = \frac{n_B - n_{\bar{B}}}{n_\gamma} = 2.74 \times 10^{-8}\, \Omega_b h^2 = (6.12 \pm 0.04) \times 10^{-10}\,, \tag{105.105}$$

using $\Omega_b h^2 = 0.02237 \pm 0.00015$ *from Planck [2348].*
Rests on Equation (68.5) and Phenomenon 51.3.

Derivation. *Derives Proposition 105.42.*
The photon number density of a blackbody at temperature T is

$$n_\gamma = \frac{2\zeta(3)}{\pi^2}\left(\frac{k_B T}{\hbar c}\right)^3 = 4.107 \times 10^8/\mathrm{m}^3$$

at $T_0 = 2.7255\,\mathrm{K}$. The baryon number density is $\Omega_b \rho_c/\bar{m}$ with $\rho_c = 3H_0^2/(8\pi G) = 1.878\,34 \times 10^{-26}\,\mathrm{kg/m^3}\,h^2$ and $\bar{m}$ the mean mass per baryon, close to the proton mass $1.672\,62 \times 10^{-27}\,\mathrm{kg}$; hence $n_B = 11.23/\mathrm{m}^3\,\Omega_b h^2$. The ratio is $11.23/4.107 \times 10^8 = 2.74 \times 10^{-8}$ per unit of $\Omega_b h^2$. □

The same number follows independently from the light-element abundances produced in primordial nucleosynthesis, which depend on η through the neutron-to-proton ratio at freeze-out; the two determinations agree, which is what makes Equation (105.105) a measurement rather than a fit. No antimatter region has been found: a matter–antimatter boundary anywhere within the observable universe would radiate annihilation gamma rays at a level long since excluded, and the antinuclei searched for in the cosmic radiation (Chapter 115) are consistent with secondary production. See Phenomenon 111.17.

The CKM phase is far too small By Proposition 105.27, the strength of Standard Model CP violation is measured by the invariant Equation (105.79). Made dimensionless at the temperature $k_B T \approx 100\,\mathrm{GeV}$ where sphalerons are active, it is

$$d_{CP} = \frac{J \prod_{i>j} \left(m_{u_i}^2 - m_{u_j}^2\right) c^4 \prod_{i>j} \left(m_{d_i}^2 - m_{d_j}^2\right) c^4}{(k_B T)^{12}}\,. \tag{105.106}$$

Inserting the running quark masses at that scale — $m_t c^2 \approx 170\,\mathrm{GeV}$, $m_b c^2 \approx 2.9\,\mathrm{GeV}$, $m_c c^2 \approx 0.6\,\mathrm{GeV}$, $m_s c^2 \approx 50\,\mathrm{MeV}$, $m_d c^2 \approx 3\,\mathrm{MeV}$, $m_u c^2 \approx 1.5\,\mathrm{MeV}$ — and Equation (105.78) gives

$$d_{CP} \approx 2 \times 10^{-21}\,. \tag{105.107}$$

The observed η is 6×10^{-10}. Detailed calculations of what the Standard Model would actually produce, which involve more than this crude ratio, arrive at asymmetries of order 10^{-20} or smaller [1882]: the shortfall is at least eight orders of magnitude and on the standard estimates ten or more. The reason is structural and worth stating: CP violation in the Standard Model requires all six quark masses to be distinct (Proposition 105.27), and at a temperature of 100 GeV five of the six are negligible compared with the temperature, so the effect is suppressed by twelve powers of small mass ratios. The phase itself is of order unity; it is the masses that kill it.

And the third condition fails too Even a larger phase would not help, because the Standard Model does not depart from thermal equilibrium at the electroweak scale. A departure would require a first-order phase transition, proceeding by the nucleation of bubbles of the broken phase whose walls sweep through the plasma; and it would have to be *strongly* first order, since after the transition the sphaleron processes must switch off fast enough not to erase the asymmetry just created. The washout condition is

$$\frac{v(T_c)}{T_c} \gtrsim 1 \tag{105.108}$$

in the customary units, v being the Higgs expectation value at the critical temperature — a requirement that the broken-phase sphaleron energy Equation (105.104) exceed the thermal energy by enough that the Boltzmann factor quenches the rate.

Lattice studies settled the question. The electroweak transition is first order only for a light Higgs; the line of first-order transitions ends at a critical endpoint near $m_H c^2 \approx 72 - -80\,\mathrm{GeV}$, and beyond it the change from the symmetric to the broken phase is a smooth crossover with no bubbles, no walls and no departure from equilibrium [1925]. The measured Higgs mass is $m_H c^2 = (125.20 \pm 0.11)\,\mathrm{GeV}$ [2427], far above the endpoint (Chapter 104). Two of Sakharov's three conditions therefore fail in the Standard Model, one by ten orders of magnitude and one outright.

This is recorded as an open problem, not a solved one: see Section 133.5 in Chapter 133. The measurement — Equation (105.105) — is secure; the mechanism is unknown. It is worth being precise about what is and is not established, because the literature contains many proposals and no evidence for any of them. What is established: baryon number is not conserved in the Standard Model at high temperature; CP is violated by the CKM phase; the observed asymmetry exceeds what those two can produce by a very large factor; and the electroweak transition is a crossover. What is not established: anything about where the missing asymmetry came from.

105.7 The strong CP problem

105.7.1 The theta term

Section 105.1.1 showed that the quark–gluon coupling, being a vector current, conserves P, C and T. That argument is incomplete, because it enumerated only the terms one would think to write. There is one more term allowed by every symmetry that QCD is supposed to have — gauge invariance, Lorentz invariance, locality and renormalizability — and it violates P and T.

Definition 105.43 (The topological term)**.** Let $q(x)$ denote the topological charge density of the gluon field, normalized so that

$$\int \mathrm{d}t\, \mathrm{d}^3x\, q(x) = n \in \mathbb{Z} \tag{105.109}$$

for any finite-action field configuration, n being its winding number; q therefore carries the SI dimension $1/(\mathrm{m}^3\,\mathrm{s})$. The QCD Lagrangian density may contain

$$\mathcal{L}_\theta = \theta\,\hbar\,q(x)\,, \tag{105.110}$$

with θ a dimensionless number. Its contribution to the action is $S_\theta = \theta\hbar n$, so it enters the path-integral weight $\exp(\mathrm{i}S/\hbar)$ of Chapter 106 only through the phase $\mathrm{e}^{\mathrm{i}\theta n}$, and θ is periodic with period 2π.

In terms of the gluon field strengths, q is proportional to $\sum_a \boldsymbol{E}^a \cdot \boldsymbol{B}^a$, the colour analogue of the electromagnetic invariant $\boldsymbol{E}\cdot\boldsymbol{B}$; the constant of proportionality is fixed by Equation (105.109) and involves g_s^2 and $\hbar$ but nothing else. That representation is all that is needed for the symmetry properties.

Proposition 105.44 (The theta term is P-odd, T-odd and C-even)**.** *$\mathcal{L}_\theta$ is odd under P and under T, even under C, and therefore odd under CP and even under CPT.*
Rests on Equations (105.6), (105.17) and (105.30).

Proof. *Derives Proposition 105.44.*
Use the abelian analogue, which carries the same index structure. By Equation (105.6), $\boldsymbol{E}$ is a polar vector and $\boldsymbol{B}$ an axial vector, so $\boldsymbol{E}\cdot\boldsymbol{B}$ is a pseudoscalar: P-odd. By Equation (105.30), $\boldsymbol{E}$ is T-even and $\boldsymbol{B}$ is T-odd, so the product is T-odd. Under C, both fields reverse (Equation (105.17)), so the product is even. Hence CP-odd and, as Theorem 105.34 requires of any term in a Hermitian local Lagrangian, CPT-even. The same signs hold for the non-abelian $\sum_a \boldsymbol{E}^a \cdot \boldsymbol{B}^a$, since the colour index is inert under all three operations. □

Two facts then make the term a problem rather than a curiosity.

First, q is a total derivative: $q = \partial_\mu K^\mu$ for the Chern–Simons current K^μ. A total derivative contributes nothing in perturbation theory, which is why θ never appears in a Feynman diagram; but K^μ is not gauge invariant, and for field configurations with nontrivial topology at infinity — the instantons of [1569, 1573, 1582] — the surface term is the nonzero integer of Equation (105.109). The term is therefore invisible perturbatively and physical nonperturbatively, which is the worst combination for anyone hoping to argue it away.

Second, θ is not by itself observable. A chiral rotation of the quark fields, $\psi_j \to \mathrm{e}^{\mathrm{i}\alpha\gamma^5}\psi_j$, changes the phase of the quark mass matrix and, because the fermion measure is not invariant under it [1388, 1391], shifts θ by a compensating amount. Only the combination

$$\bar\theta = \theta + \arg\det M_q \tag{105.111}$$

is invariant, and it is $\bar\theta$ that is measurable. The strong and Yukawa sectors are thereby tied together: a quantity of the gluon sector can be cancelled against a quantity of the Higgs sector, and no symmetry of the Standard Model relates them.

There is exactly one way the problem could evaporate. If any quark were massless, $\det M_q = 0$, $\arg\det M_q$ would be undefined, and the chiral rotation could be used to set $\bar\theta = 0$ with no cost. That escape is closed by measurement: lattice determinations give $m_u c^2 = (2.16 \pm 0.07)\,\mathrm{MeV}$ at the customary renormalization point [2427], tens of standard deviations from zero.

Proposition 105.45 (The induced neutron electric dipole moment)**.** *A nonzero $\bar\theta$ generates a neutron electric dipole moment*

$$d_n \approx \bar\theta \times 1.6 \times 10^{-37} - -6.4 \times 10^{-37}\,\mathrm{C\,m}\,, \tag{105.112}$$

equivalently $(1\text{–}4) \times 10^{-16}\,\bar\theta\,e\,\mathrm{cm}$ *[1633, 1637].*
Rests on Proposition 105.44, Equation (105.111), and Theorem 105.30.

Derivation. *Derives Proposition 105.45.*

The parametric form follows from dimensional analysis plus chiral counting, and is worth doing because it explains the size. A neutron EDM requires the violation of P and T, which $\bar{\theta}$ supplies; it requires a charge, which supplies e; and it requires a length, for which the only candidates are the nucleon Compton wavelength $\hbar/(m_N c) = 0.21\,\mathrm{fm}$ and the pion's. Chiral symmetry supplies a further suppression: in the limit of vanishing quark masses the θ term is unobservable, so the answer must be proportional to the reduced quark mass $m_* = m_u m_d/(m_u + m_d) \approx 1.5\,\mathrm{MeV}/c^2$ measured against the nucleon mass. Hence

$$d_n \sim e\,\bar{\theta}\,\frac{\hbar}{m_N c}\,\frac{m_*}{m_N} \approx \bar{\theta} \times 5 \times 10^{-38}\,\mathrm{C\,m}\,,$$

that is $3 \times 10^{-17}\,\bar{\theta}\,e\,\mathrm{cm}$. The chiral-loop calculations of Baluni [1633] and of Crewther, Di Vecchia, Veneziano and Witten [1637] supply the coefficient, and it is between about three and thirteen times larger than this estimate — $1.6 \times 10^{-37}\,\mathrm{C\,m}/5 \times 10^{-38}\,\mathrm{C\,m} = 3.2$ at one end and 12.8 at the other — because the dominant contribution is a chiral logarithm from the pion cloud rather than a contact term; modern lattice determinations also fall inside Equation (105.112). That spread — a factor of a few in the coefficient — is the dominant uncertainty in the bound on $\bar{\theta}$ below, and it is why the bound is quoted as an order of magnitude and not as a number. □

105.7.2 The experimental bound and its status

Combining Equation (105.93) — the ultracold-neutron measurement at the Paul Scherrer Institute, whose Ramsey technique is described at Equation (105.91) — with Equation (105.112) gives

$$\left|\bar{\theta}\right| \lesssim \frac{2.9 \times 10^{-47}\,\mathrm{C\,m}}{1.6 \times 10^{-37}\,\mathrm{C\,m}} \approx 1.8 \times 10^{-10}\,, \tag{105.113}$$

so $\left|\bar{\theta}\right| \lesssim 10^{-10}$, with the factor-of-a-few uncertainty inherited from Proposition 105.45.

This is the strong CP problem, and it is worth stating exactly what kind of problem it is. $\bar{\theta}$ is a free dimensionless parameter of the Standard Model. It is periodic with period 2π, so there is no sense in which small values are "near a boundary" of its range; a value of order unity is the natural expectation for a number about which nothing else is known. It is measured to be smaller than 10^{-10}. No symmetry of the Standard Model requires it to vanish — the one candidate, a massless quark, is excluded by measurement — and no dynamical mechanism within the Standard Model relaxes it. The problem is therefore an *observation*: a parameter that could have been anything is measured to be extraordinarily small, and nothing in the accepted theory explains why. It is recorded as such in Section 133.1.

The Peccei–Quinn proposal, and its status The best-known response is to make $\bar{\theta}$ dynamical. Peccei and Quinn observed that if the Standard Model is extended by a global U(1) symmetry that is spontaneously broken and itself anomalous, then $\bar{\theta}$ is replaced by a field whose potential — generated by the same instanton effects that make θ physical — is minimized at zero [1609]. The spontaneously broken symmetry implies a light pseudo-Goldstone boson, the axion, as Weinberg [1628] and Wilczek [1630] pointed out at once. Its mass is tied to the symmetry-breaking scale f_a by

$$m_a c^2 \approx 5.7\,\mu\mathrm{eV} \times \frac{1 \times 10^{12}\,\mathrm{GeV}}{f_a c^2}\,, \tag{105.114}$$

so that a very weakly coupled axion is a very light one.

The chapter states the position plainly. No axion has been observed. The haloscope searches, of which ADMX is the most sensitive, look for the resonant conversion of a galactic-halo axion into a microwave photon in a strong magnetic field; the reported results are

exclusions, covering a band of couplings in a narrow mass window around 2.66–2.81 μeV [2355]. Helioscopes and light-shining-through-walls experiments likewise report null results. The Peccei–Quinn mechanism is a hypothesis with an attractive structure and no experimental support, and Section 133.7 lists it accordingly. What this chapter records as physics is the measurement, Equation (105.113): a dimensionless parameter of the Standard Model, free to be of order unity, is smaller than 10^{-10}, and no one knows why.

Chapter 106

Path-Integral Quantization

The canonical quantization of Chapter 99 promotes coordinates to operators and privileges a time coordinate; the path integral does neither. It computes an amplitude as a sum over every history weighted by $\exp(\mathrm{i}S/\hbar)$, with S the classical action of Chapter 16, so the Lorentz invariance of the Lagrangian is manifest at every step. The idea is Dirac's [718] and its execution Feynman's [911, 930]. This chapter develops it from non-relativistic quantum mechanics through the functional quantization of fields: generating functionals, the Euclidean continuation, the LSZ reduction [1073], Feynman rules and the one-particle-irreducible effective action. It therefore follows Chapter 64 and supplies the machinery used throughout Chapters 102 and 104 and Chapter 108.

Three things make the path integral more than a restatement. Gauge theories require it: the Faddeev–Popov construction [1347] and the BRST symmetry that organizes it [1564, 1571] have no simple canonical counterpart, and Gribov showed that the gauge-fixing is not globally well posed [1623]. Non-perturbative physics requires it: Wilson's lattice formulation [1537] turns the Euclidean integral into a finite-dimensional one that a computer can sample, which is how the hadron spectrum of Chapter 102 is computed from first principles [2122]. And it explains anomalies: a classical symmetry can fail to survive quantization because the functional measure is not invariant [1638] — a statement with a measured consequence, the decay rate of the neutral pion [1388, 1391, 2361]. The canonical monographs are [1306, 1751, 1933].

Conventions are those of Section 100.1.1 without exception. The metric is $\eta_{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$; coordinates are $x^\mu = (ct, \boldsymbol{x})$, so d^4x has SI dimension m^4; four-momenta are $p^\mu = (E/c, \boldsymbol{p})$ of dimension $\mathrm{kg\,m/s}$, and the mass shell is $p^2 = m^2c^2$ as in Equation (100.1), so every propagator denominator reads $p^2 - m^2c^2$ and never $p^2 - m^2$. The action is $S = c^{-1}\int \mathrm{d}^4x\,\mathcal{L}$ as in Equation (100.2), with $\mathcal{L}$ an energy density; the Fourier convention is Equation (100.14). Every $\hbar$ and every c is written out, and here that is not a matter of taste: the expansion parameter of this whole chapter *is* $\hbar$. The loop expansion of Section 106.3.4 is an expansion in $\hbar$ and in nothing else, and the semiclassical limit of Section 106.1.3 is the statement that $\hbar$ is small compared with the classical action. A treatment that puts the reduced Planck constant equal to unity erases the very quantity whose smallness is being exploited. Readers coming from the standard references should use the translation rule of Remark 100.4, which is the only place in this part where that convention is discussed.

Five symbols carry more than one standard meaning in the material of this chapter, and the collisions are settled here rather than in passing. The *electric charge* of a particle or a field is written Q throughout, never q: the letter q is the mechanical coordinate of Section 106.1 and the topological charge density of Definition 106.79, and both meet a charge on the same page. The *BRST charge* of Definition 106.59 is therefore written Q_B. The *ghost* fields are c^a and $\bar{c}^a$, always carrying an adjoint index or an explicit generator, so

a bare c is the speed of light and nothing else. The lattice coupling β of Equation (106.81) is not the inverse temperature β of Equation (106.27); each name is fixed by its own literature, and they never enter the same equation here. And Γ is the effective action of Definition 106.41 everywhere except in Section 106.7.2, where it is a decay width, and at one step of Proposition 106.45, where it is the Euler function and is flagged as such on the spot.

106.1 The path integral in quantum mechanics

106.1.1 Dirac's Lagrangian formulation

Take one degree of freedom q with Hamiltonian $H = p^2/2m + V(q)$, both operators, and write the finite-time propagator

$$K(q'', t''; q', t') := \langle q'' | \, U(t'', t') \, | q' \rangle \,, \qquad U(t'', t') = \exp\!\left[-\frac{\mathrm{i}}{\hbar} H (t'' - t') \right] , \tag{106.1}$$

for a time-independent H. Since $\langle q'' | q' \rangle = \delta(q'' - q')$, the states $|q\rangle$ carry dimension $1/\mathrm{m}^{1/2}$ and K carries $1/\mathrm{m}$. Everything about the dynamics is in K: given $\psi(q', t')$, the wavefunction at any later time is $\psi(q'', t'') = \int \mathrm{d}q' \, K(q'', t''; q', t') \psi(q', t')$.

The classical object that propagates a mechanical system from (q', t') to (q'', t'') is Hamilton's principal function — the value of the action along the classical path,

$$S_{\mathrm{cl}}(q'', t''; q', t') = \int_{t'}^{t''} \mathrm{d}t \; L(q_{\mathrm{cl}}, \dot{q}_{\mathrm{cl}}, t) \,, \tag{106.2}$$

of dimension J s. It is the type-one generating function of the canonical transformation that maps the state at t' onto the state at t'' (Chapter 23), obeying

$$\frac{\partial S_{\mathrm{cl}}}{\partial q''} = p'' \,, \qquad \frac{\partial S_{\mathrm{cl}}}{\partial q'} = -p' \,, \qquad \frac{\partial S_{\mathrm{cl}}}{\partial t''} + H\!\left(q'', \frac{\partial S_{\mathrm{cl}}}{\partial q''} \right) = 0 \,. \tag{106.3}$$

Dirac's observation [718] was that the quantum object Equation (106.1) and the classical object Equation (106.2) are related by

$$\langle q'' | \, U(t'', t') \, | q' \rangle \quad \text{“corresponds to”} \quad \exp\!\left[\frac{\mathrm{i}}{\hbar} S_{\mathrm{cl}}(q'', t''; q', t') \right] . \tag{106.4}$$

The scare quotes are Dirac's own. He did not claim an equality, and he was right not to: the two sides do not even have the same dimension, the left-hand side carrying $1/\mathrm{m}$ and the right-hand side being a pure phase. What he had was the observation that a canonical transformation is implemented in quantum mechanics by a unitary operator, that the generating function of the classical transformation therefore ought to control the phase of the quantum kernel, and that in the classical limit Equation (106.3) is exactly the eikonal relation satisfied by the phase of a rapidly oscillating wave.

What Feynman added is that Equation (106.4) becomes an *equality* in the infinitesimal case, up to a normalization that carries the missing dimension, and that finite times then follow by composition. The infinitesimal statement is a short computation.

Lemma 106.1 (The short-time kernel)**.** *Let $H = p^2/2m + V(q)$ with V bounded and continuous. Then, for $\Delta t \to 0$,*

$$\langle q'' | \, \mathrm{e}^{-\mathrm{i} H \Delta t / \hbar} \, | q' \rangle = \sqrt{\frac{m}{2\pi \mathrm{i} \hbar \Delta t}} \, \exp\!\left\{ \frac{\mathrm{i} \Delta t}{\hbar} \left[\frac{m}{2} \left(\frac{q'' - q'}{\Delta t} \right)^2 - V\!\left(\frac{q'' + q'}{2} \right) \right] \right\} \left[1 + O((\Delta t)^2) \right] . \tag{106.5}$$

The prefactor carries $1/\mathrm{m}$, the exponent is dimensionless, and the bracket in the exponent is the Lagrangian $L = \tfrac{1}{2} m \dot{q}^2 - V$ evaluated on the straight segment joining the endpoints.

Rests on Lemma 106.2 and Corollary 8.15.

Derivation. *Derives Lemma 106.1.*

The two terms of H do not commute, but over a time Δt the error of separating them is second order: by the Baker–Campbell–Hausdorff expansion,

$$\mathrm{e}^{-\mathrm{i}(T+V)\Delta t/\hbar} = \mathrm{e}^{-\mathrm{i}T\Delta t/\hbar}\,\mathrm{e}^{-\mathrm{i}V\Delta t/\hbar}\exp\!\left[-\frac{(\Delta t)^2}{2\hbar^2}\,[T,V] + O((\Delta t)^3)\right],$$

with $T = p^2/2m$. Dropping the correction and inserting the momentum-space resolution of the identity $\mathbb{1} = \int \mathrm{d}p\;|p\rangle\langle p|$ with $\langle q|p\rangle = (2\pi\hbar)^{-1/2}\mathrm{e}^{\mathrm{i}pq/\hbar}$,

$$\begin{aligned}\langle q''|\,\mathrm{e}^{-\mathrm{i}T\Delta t/\hbar}\mathrm{e}^{-\mathrm{i}V\Delta t/\hbar}\,|q'\rangle &= \mathrm{e}^{-\mathrm{i}\Delta t V(q')/\hbar}\int\frac{\mathrm{d}p}{2\pi\hbar}\,\exp\!\left[\frac{\mathrm{i}}{\hbar}p(q''-q') - \frac{\mathrm{i}\Delta t p^2}{2m\hbar}\right]\\ &= \mathrm{e}^{-\mathrm{i}\Delta t V(q')/\hbar}\sqrt{\frac{m}{2\pi\mathrm{i}\hbar\Delta t}}\,\exp\!\left[\frac{\mathrm{i}m(q''-q')^2}{2\hbar\Delta t}\right], \qquad (106.6)\end{aligned}$$

the p integral being the Gaussian $\int \mathrm{d}p\,\mathrm{e}^{-ap^2/2+bp} = \sqrt{2\pi/a}\,\mathrm{e}^{b^2/2a}$ of Lemma 106.2 below, analytically continued to $a = \mathrm{i}\Delta t/(m\hbar)$ on the boundary of its domain of convergence — legitimate because the integrand is the boundary value of a function holomorphic in $\Re a > 0$ and the contour may be rotated by Corollary 8.15. The square root is the principal branch, $\sqrt{\mathrm{i}} = \mathrm{e}^{\mathrm{i}\pi/4}$.

Finally $V(q')$ may be replaced by $V\big((q''+q')/2\big)$: the two differ by $\tfrac12(q''-q')V' + O((q''-q')^2)$, and the prefactor confines $|q''-q'|$ to order $\sqrt{\hbar\Delta t/m}$, so the change in the exponent is of order $(\Delta t)^{3/2}$; it cancels against its mirror image on symmetrizing, leaving an error $O((\Delta t)^2)$. The midpoint form is not an aesthetic choice, and Section 106.1.3 shows where it becomes compulsory.

The prefactor's dimension is $[\,m/(\hbar\Delta t)\,]^{1/2} = [\mathrm{kg}/(\mathrm{J\,s}^2)]^{1/2} = 1/\mathrm{m}$, as K requires. □

So Dirac's correspondence is an equality once the normalization $(m/2\pi\mathrm{i}\hbar\Delta t)^{1/2}$ is supplied, and once the principal function is read as the action of the *straight* segment, which for infinitesimal times is the classical path to the accuracy retained. The whole of the next subsection is the observation that finite times are built out of infinitesimal ones, and that when they are, the straight segments become arbitrary paths.

106.1.2 Feynman's sum over histories

The Gaussian integral, once and for all Every explicit evaluation in this chapter reduces to one integral, so it is worth recording in the generality that will be needed.

Lemma 106.2 (Gaussian integrals)**.** *Let A be a real symmetric positive-definite $n\times n$ matrix and $b\in\mathbb{R}^n$. Then*

$$\int_{\mathbb{R}^n}\mathrm{d}^n x\;\exp\!\Big(-\tfrac12 x^{\mathsf T}Ax + b^{\mathsf T}x\Big) = \frac{(2\pi)^{n/2}}{\sqrt{\det A}}\;\exp\!\Big(\tfrac12 b^{\mathsf T}A^{-1}b\Big)\,. \qquad (106.7)$$

The identity extends by analytic continuation to every complex symmetric A with positive-definite real part, and to the boundary case $A = -\mathrm{i}M$ with M real symmetric and non-singular, where

$$\int_{\mathbb{R}^n}\mathrm{d}^n x\;\exp\!\Big(\tfrac{\mathrm{i}}{2}x^{\mathsf T}Mx\Big) = \frac{(2\pi)^{n/2}}{|\det M|^{1/2}}\;\mathrm{e}^{\mathrm{i}\pi\sigma(M)/4}\,, \qquad (106.8)$$

$\sigma(M)$ being the signature of M, i.e. the number of positive minus the number of negative eigenvalues.

Rests on Equation (17.42) and Lemma 8.9.

Derivation. *Derives Lemma 106.2.*

Diagonalize: $A = O^{\mathsf{T}} D O$ with O orthogonal and $D = \operatorname{diag}(a_1, \dots, a_n)$, $a_i > 0$, which is possible by the finite-dimensional spectral theorem for real symmetric matrices. That theorem is quoted here from textbook linear algebra and is not proved anywhere in this book: the subsection it belongs to is Section 12.4.2, and Remark 11.86 records the same import where it is made in the probability chapter. The substitution $y = Ox$ has unit Jacobian and factorizes the integral into n copies of the one-dimensional case. Completing the square in one dimension, $-\tfrac{1}{2}ay^2 + \beta y = -\tfrac{1}{2}a(y - \beta/a)^2 + \beta^2/(2a)$, and $\int \mathrm{d}u\, \mathrm{e}^{-au^2/2} = \sqrt{2\pi/a}$ — the Gauss integral, which is Equation (17.42) of Chapter 17 evaluated at zero frequency. Reassembling, $\prod_i a_i = \det A$ and $\sum_i \beta_i^2/a_i = b^{\mathsf{T}} A^{-1} b$, which is Equation (106.7).

Both sides of Equation (106.7) are holomorphic in the entries of A on the domain $\Re A > 0$ — the left-hand side because the integral converges absolutely and uniformly there, the right-hand side because $\det A \neq 0$ — so they agree throughout it by the identity theorem (Chapter 8). For the purely imaginary boundary case, diagonalize M and rotate each contour: for $a > 0$,

$$\int_{-\infty}^{\infty} \mathrm{d}u\, \mathrm{e}^{\mathrm{i}au^2/2} = \lim_{\delta \to 0^+} \int_{-\infty}^{\infty} \mathrm{d}u\, \mathrm{e}^{-(\delta - \mathrm{i}a)u^2/2} = \lim_{\delta \to 0^+} \sqrt{\frac{2\pi}{\delta - \mathrm{i}a}} = \sqrt{\frac{2\pi}{a}}\, \mathrm{e}^{\mathrm{i}\pi/4},$$

the limit being uniform on compacta by Cauchy's theorem applied to the wedge $0 \le \arg u \le \pi/4$, whose arc contribution vanishes by the estimation lemma Lemma 8.9. A negative eigenvalue rotates the other way and contributes $\mathrm{e}^{-\mathrm{i}\pi/4}$; collecting the phases gives the signature. □

The phase $\mathrm{e}^{\mathrm{i}\pi\sigma/4}$ in Equation (106.8) is not decoration. It is the origin of the Maslov index, which is what makes the semiclassical propagator of Section 106.1.3 agree with the turning-point counting of Remark 9.79.

Composition

Theorem 106.3 (Feynman's sum over histories)**.** *Let $H = p^2/2m + V(q)$ as above and let $t'' > t'$. Divide the interval into N steps of length $\Delta t = (t'' - t')/N$ and write $q_k = q(t' + k\Delta t)$, $q_0 = q'$, $q_N = q''$. Then*

$$K(q'', t''; q', t') = \lim_{N \to \infty} \left(\frac{m}{2\pi \mathrm{i}\hbar \Delta t} \right)^{N/2} \int \prod_{k=1}^{N-1} \mathrm{d}q_k\, \exp\left[\frac{\mathrm{i}}{\hbar} \sum_{k=1}^{N} \Delta t L_k \right], \tag{106.9}$$

with $L_k = \frac{m}{2}\big((q_k - q_{k-1})/\Delta t\big)^2 - V\big((q_k + q_{k-1})/2\big)$. Written compactly,

$$K(q'', t''; q', t') = \int_{q(t')=q'}^{q(t'')=q''} \mathcal{D}q\, \exp\left(\frac{\mathrm{i}}{\hbar} S[q] \right), \tag{106.10}$$

where $\mathcal{D}q$ denotes the limit in Equation (106.9) and nothing else.
Rests on Equation (106.1) and Lemma 106.1.

Derivation. *Derives Theorem 106.3.*

The evolution operator composes exactly, $U(t'', t') = U(t'', t_{N-1}) \cdots U(t_1, t')$, because H is time-independent. Insert $\mathbb{1} = \int \mathrm{d}q_k\, |q_k\rangle\langle q_k|$ between consecutive factors:

$$K = \int \prod_{k=1}^{N-1} \mathrm{d}q_k \prod_{k=1}^{N} \langle q_k |\, \mathrm{e}^{-\mathrm{i}H\Delta t/\hbar}\, | q_{k-1} \rangle ,$$

which is exact for every N. Now apply Lemma 106.1 to each factor. Each contributes the normalization $(m/2\pi\mathrm{i}\hbar\Delta t)^{1/2}$ — there are N of them, one per step, against $N - 1$

integrations — and the phase $\mathrm{e}^{\mathrm{i}\Delta t L_k/\hbar}$, and the individual errors $O((\Delta t)^2)$ accumulate to $N\cdot O((\Delta t)^2) = O(\Delta t)$, which vanishes with $N\to\infty$. The exponents add, giving the Riemann sum $\sum_k \Delta t L_k$ for the action $S[q]=\int_{t'}^{t''}\mathrm{d}t\,L$ of the piecewise-linear path through the sampled points. □

Three features of Equation (106.9) deserve emphasis, because they are what makes the formalism different from Chapter 99 rather than equivalent to it in disguise.

First, *every* path contributes, and every path contributes with the same magnitude. The integrand's modulus is one; only the phase $S[q]/\hbar$ distinguishes paths. There is no sense in which the classical path is weighted more heavily. Its distinction is that its neighbours share its phase — $\delta S=0$ means precisely that S is stationary — so that contributions near it add coherently while contributions elsewhere cancel. That is the content of Section 106.1.3.

Second, the paths summed over are not classical trajectories and are not even differentiable. The measure concentrates $|q_k-q_{k-1}|$ on $\sqrt{\hbar\Delta t/m}$, so the typical increment scales as $(\Delta t)^{1/2}$ and the typical "velocity" as $(\Delta t)^{-1/2}$, which diverges. The paths dominating Equation (106.9) are continuous and nowhere differentiable, the same class that carries Wiener measure in Section 106.2.2.

Third, the object $S[q]$ is the classical action — a Lorentz scalar in the relativistic case, a functional of the path and of nothing else. No operator ordering appears in Equation (106.10), no Hilbert space, no choice of time slicing beyond the one used to define the limit. That is why the formalism generalizes to gauge fields, where the operator formulation must first solve a constraint problem (Chapter 26) before it can begin.

Equivalence with the Schrödinger equation

Proposition 106.4 (From the kernel to the Schrödinger equation)**.** *Let ψ evolve by $\psi(q,t+\Delta t)=\int\mathrm{d}q'\,K(q,t+\Delta t;q',t)\psi(q',t)$ with K given by Equation (106.5). Then to first order in Δt,*

$$\mathrm{i}\hbar\,\frac{\partial\psi}{\partial t} = -\frac{\hbar^2}{2m}\,\frac{\partial^2\psi}{\partial q^2} + V(q)\psi\,. \tag{106.11}$$

Rests on Equations (106.5) and (106.8).

Derivation. *Derives Proposition 106.4.*

Write $q'=q+\eta$. Then

$$\psi(q,t+\Delta t)=\sqrt{\frac{m}{2\pi\mathrm{i}\hbar\Delta t}}\int\mathrm{d}\eta\;\exp\!\left[\frac{\mathrm{i}m\eta^2}{2\hbar\Delta t}-\frac{\mathrm{i}\Delta t}{\hbar}V\!\left(q+\tfrac{\eta}{2}\right)\right]\psi(q+\eta,t)\,.$$

The Gaussian factor suppresses all but $\eta=O(\sqrt{\hbar\Delta t/m})$, so expanding to the order that survives means keeping η^0,η^1,η^2 in ψ and $(\Delta t)^0,(\Delta t)^1$ elsewhere:

$$\mathrm{e}^{-\mathrm{i}\Delta t V/\hbar}\approx 1-\frac{\mathrm{i}\Delta t}{\hbar}V(q)\,,\qquad \psi(q+\eta)\approx\psi+\eta\,\frac{\partial\psi}{\partial q}+\frac{\eta^2}{2}\,\frac{\partial^2\psi}{\partial q^2}\,.$$

By Equation (106.8) with $M=m/(\hbar\Delta t)$,

$$\sqrt{\frac{m}{2\pi\mathrm{i}\hbar\Delta t}}\int\mathrm{d}\eta\,\mathrm{e}^{\mathrm{i}m\eta^2/2\hbar\Delta t}=1\,,\qquad \int\mathrm{d}\eta\,\eta\,\mathrm{e}^{\mathrm{i}m\eta^2/2\hbar\Delta t}=0\,,$$

by parity, and differentiating the first with respect to $m/(\hbar\Delta t)$ gives the second moment

$$\sqrt{\frac{m}{2\pi\mathrm{i}\hbar\Delta t}}\int\mathrm{d}\eta\,\eta^2\,\mathrm{e}^{\mathrm{i}m\eta^2/2\hbar\Delta t}=\frac{\mathrm{i}\hbar\Delta t}{m}\,.$$

Collecting,

$$\psi(q,t+\Delta t)=\psi-\frac{\mathrm{i}\Delta t}{\hbar}V\psi+\frac{\mathrm{i}\hbar\Delta t}{2m}\frac{\partial^2\psi}{\partial q^2}+O((\Delta t)^2)\,,$$

and $(\psi(q,t+\Delta t)-\psi(q,t))/\Delta t\to\partial\psi/\partial t$ gives Equation (106.11) after multiplication by $\mathrm{i}\hbar$. Note where the two derivatives came from: the potential from the first-order term of the exponential, the kinetic operator from the *second moment of the Gaussian*, which is why the dimensionless combination controlling the expansion is $\hbar\Delta t/m$ and why the paths have the roughness they do. □

Interference, and the evidence that the action is primitive The two-slit experiment is the elementary case of Theorem 106.3: the paths from source to detector fall into two homotopy classes, one through each slit, and within each class the contributions add coherently around the stationary path. Writing the two class sums as A_1 and A_2, the probability density on the screen is $|A_1+A_2|^2=|A_1|^2+|A_2|^2+2\Re(A_1^*A_2)$, and the phase of $A_1^*A_2$ is $(S_2-S_1)/\hbar$. For a free particle of momentum p the stationary paths are straight, $S=p\ell$ along a segment of length ℓ, so slits separated by d and a screen at distance $L\gg d$ give a path difference $\ell_2-\ell_1\approx dx/L$ and fringes wherever $p\,dx/(L\hbar)$ is a multiple of 2π: the spacing is $2\pi\hbar L/(pd)=hL/(pd)$, the de Broglie result of Chapter 71. That the pattern is built out of individual particles, each of which arrives at one point and none of which "goes through both slits", was shown directly by Tonomura and co-workers, who recorded the electron-by-electron accumulation of the interference pattern from a biprism [1826].

The sharpest evidence that the path integral's primitive quantity is the action, and not the force, is the Aharonov–Bohm effect.

Phenomenon 106.5 (The Aharonov–Bohm effect)**.** An electron beam split into two arms that enclose a magnetic flux Φ confined entirely to a region the beam never enters shows an interference pattern whose fringes shift with Φ, periodically with period

$$\Phi_0=\frac{h}{e}=4.135\,667\,696\times10^{-15}\,\mathrm{Wb}\,,\tag{106.12}$$

even though the electric and magnetic fields vanish identically along both arms [1164].

Rests on Theorem 106.3 and Equation (100.8)*.*

Derivation. *Derives Phenomenon 106.5.*

The Lagrangian of a particle of charge Q in an electromagnetic field is $L=\frac12 m\dot{\boldsymbol{x}}^2+Q\,\dot{\boldsymbol{x}}\cdot\boldsymbol{A}-Q\phi$, whose Euler–Lagrange equation is $m\ddot{\boldsymbol{x}}=Q(\boldsymbol{E}+\dot{\boldsymbol{x}}\times\boldsymbol{B})$, the Lorentz force; that derivation belongs to Chapter 64, with the covariant coupling $-A_\mu J^\mu$, and is not repeated here. Along any path γ the action therefore contains the term

$$S_{\mathrm{mag}}[\gamma]=Q\int_\gamma \mathrm{d}t\;\dot{\boldsymbol{x}}\cdot\boldsymbol{A}=Q\int_\gamma \boldsymbol{A}\cdot\mathrm{d}\boldsymbol{x}\,,$$

which depends on the path but not on its parametrization. For two paths γ_1,γ_2 with the same endpoints, the difference of the two actions is the circulation around the closed loop $\gamma_2-\gamma_1$,

$$S_{\mathrm{mag}}[\gamma_2]-S_{\mathrm{mag}}[\gamma_1]=Q\oint\boldsymbol{A}\cdot\mathrm{d}\boldsymbol{x}=Q\int_\Sigma\boldsymbol{B}\cdot\mathrm{d}\boldsymbol{S}=Q\Phi\,,$$

by Stokes's theorem, Σ being any surface spanning the loop. The interference term in Theorem 106.3 therefore acquires the phase

$$\Delta\varphi=\frac{Q\Phi}{\hbar}\,,\tag{106.13}$$

and for the electron, $Q=-e$, the pattern repeats when $e\Phi/\hbar = 2\pi$, that is when Φ advances by h/e. The numerical value in Equation (106.12) is exact in the present SI, both h and e being defined constants [2431].

The point is the one Aharonov and Bohm made. The surface Σ necessarily passes through the solenoid, where $\boldsymbol{B}\neq 0$; the paths do not. In a formulation whose primitive quantities are the fields, the effect is impossible; in a formulation whose primitive quantity is $\int \boldsymbol{A}\cdot \mathrm{d}\boldsymbol{x}$, it is the first thing one would predict. What is measurable is not $\boldsymbol{A}$, which is gauge dependent, but the loop integral $\oint \boldsymbol{A}\cdot \mathrm{d}\boldsymbol{x}$, which is not — a gauge transformation Equation (100.8) changes it by $\oint \partial_\mu \Lambda \,\mathrm{d}x^\mu = 0$ for a single-valued Λ. The gauge-invariant content of the potential is exactly its holonomy, and Section 106.5.1 is built on that observation. □

Remark 106.6 (Two flux quanta, and which is which). The period Equation (106.12) is h/e because the interfering object carries charge e. The superconducting flux quantum is $h/2e = 2.067\,833\,848\times 10^{-15}\,\mathrm{Wb}$, half as large, because the interfering object there is a Cooper pair of charge $2e$. Neither number is a property of the electromagnetic field; both are properties of the charge of the thing whose phase is being compared.

106.1.3 Time slicing, the measure and the classical limit

Convergence of the product formula Theorem 106.3 took the splitting $\mathrm{e}^{-\mathrm{i}(T+V)\Delta t/\hbar}\approx \mathrm{e}^{-\mathrm{i}T\Delta t/\hbar}\mathrm{e}^{-\mathrm{i}V\Delta t/\hbar}$ on the strength of a formal expansion. That the product converges as $N\to\infty$ is a theorem about operator semigroups, not about exponentials of numbers, and it is due to Trotter [1175].

Theorem 106.7 (Trotter product formula)**.** *Let T and V be self-adjoint operators on a Hilbert space such that $T+V$ is essentially self-adjoint on the intersection of their domains. Then, in the strong operator topology,*

$$\mathrm{e}^{-\mathrm{i}(T+V)t/\hbar}=\lim_{N\to\infty}\left(\mathrm{e}^{-\mathrm{i}Tt/N\hbar}\,\mathrm{e}^{-\mathrm{i}Vt/N\hbar}\right)^N . \tag{106.14}$$

Rests on Equation (106.1).

Derivation, bounded case. *Derives Theorem 106.7.*

Let T and V be bounded operators, write $\Delta t=t/N$, $X_N=\mathrm{e}^{-\mathrm{i}(T+V)\Delta t/\hbar}$ and $Y_N=\mathrm{e}^{-\mathrm{i}T\Delta t/\hbar}\mathrm{e}^{-\mathrm{i}V\Delta t/\hbar}$. Both are contractions, $\|X_N\|\le 1$ and $\|Y_N\|\le 1$, and expanding both exponentials gives $\|X_N-Y_N\|\le K(\Delta t)^2$ with $K=\|[T,V]\|/2\hbar^2$, since the terms of order Δt^0 and Δt^1 agree. The telescoping identity

$$X_N^N-Y_N^N=\sum_{k=0}^{N-1}X_N^{N-1-k}(X_N-Y_N)Y_N^k$$

then bounds $\left\|X_N^N-Y_N^N\right\|\le N\,\|X_N-Y_N\|\le Kt^2/N\to 0$. Unbounded T and V — the physical case, since p^2 is unbounded — require the strong-topology argument of Trotter [1175], whose extension to operators bounded relative to T is Kato's [1335]; the mechanism is the same telescoping, applied to the resolvents. □

The hypothesis is met for $T=p^2/2m$ and any V that is Kato-small with respect to T, which includes every potential of physical interest here, the Coulomb potential among them [1335]. This matters more than it looks: without Theorem 106.7 the sliced expression Equation (106.9) would be a mnemonic, and its limit would have no reason to be the propagator of the theory one started from.

What $\mathcal{D}q$ is not

Remark 106.8 (There is no Feynman measure). The symbol $\mathcal{D}q$ in Equation (106.10) is not a measure. There is no countably additive complex measure of finite total variation on the space of continuous paths that reproduces Equation (106.9), and the obstruction is not technical: a measure with the required translation and scaling behaviour would have to assign every cylinder set a weight of unit modulus, and the total variation of such an object over the N-fold product diverges like $|2\pi\mathrm{i}\hbar\Delta t/m|^{-N/2}$. The precise statement and its consequences are Nelson's [1292]. The Euclidean continuation of Section 106.2 repairs exactly this: the weight there is real and positive, the total variation is finite, and the measure exists — it is Wiener's [507].

This is not a licence to be careless. It means that every manipulation of $\mathcal{D}q$ in this chapter is shorthand for a manipulation of the finite-dimensional integral in Equation (106.9), to be justified there. The two places where the difference bites are the ordering ambiguity below and the Jacobian of a change of variables, which is the subject of Section 106.7.3.

Ordering, and the midpoint rule Lemma 106.1 placed V at the midpoint and remarked that for a potential the choice is immaterial at the order retained. It is not immaterial when the Hamiltonian depends on momentum beyond p^2, and the case that matters physically is the magnetic one.

Proposition 106.9 (The midpoint rule is forced by gauge invariance)**.** *For* $H = (\boldsymbol{p} - Q\boldsymbol{A}(\boldsymbol{x}))^2/2m$ *the short-time kernel is*

$$\langle \boldsymbol{x}'' | \, \mathrm{e}^{-\mathrm{i}H\Delta t/\hbar} \, | \boldsymbol{x}' \rangle = \left(\frac{m}{2\pi\mathrm{i}\hbar\Delta t} \right)^{3/2} \exp\left\{ \frac{\mathrm{i}}{\hbar} \left[\frac{m(\boldsymbol{x}'' - \boldsymbol{x}')^2}{2\Delta t} + Q\,(\boldsymbol{x}'' - \boldsymbol{x}') \cdot \boldsymbol{A}\!\left(\frac{\boldsymbol{x}'' + \boldsymbol{x}'}{2} \right) \right] \right\}, \tag{106.15}$$

to the accuracy of Equation (106.5)*. Evaluating* $\boldsymbol{A}$ *at either endpoint instead gives an answer that differs at order* Δt *and does not reproduce the Schrödinger equation.*

Rests on Equations (106.5) *and* (106.6)*.*

Derivation. *Derives Proposition 106.9.*

Repeat the momentum-space computation Equation (106.6) with H quadratic in $\boldsymbol{p} - Q\boldsymbol{A}$. Writing $\boldsymbol{A}$ at a fixed point $\boldsymbol{x}_*$ inside the segment, the $\boldsymbol{p}$ integral is Gaussian with a shifted centre and gives Equation (106.15) with $\boldsymbol{A}(\boldsymbol{x}_*)$ in place of the midpoint value. To fix $\boldsymbol{x}_*$, demand that the kernel transform correctly under a gauge transformation $\boldsymbol{A} \to \boldsymbol{A} + \nabla\Lambda$, under which the wavefunction acquires the phase $\mathrm{e}^{\mathrm{i}Q\Lambda(\boldsymbol{x})/\hbar}$ and hence the kernel must acquire $\mathrm{e}^{\mathrm{i}Q[\Lambda(\boldsymbol{x}'') - \Lambda(\boldsymbol{x}')]/\hbar}$. The exponent in Equation (106.15) changes by $(\mathrm{i}Q/\hbar)(\boldsymbol{x}'' - \boldsymbol{x}') \cdot \nabla\Lambda(\boldsymbol{x}_*)$, and

$$\Lambda(\boldsymbol{x}'') - \Lambda(\boldsymbol{x}') = (\boldsymbol{x}'' - \boldsymbol{x}') \cdot \nabla\Lambda(\boldsymbol{x}_*) + O\big(|\boldsymbol{x}'' - \boldsymbol{x}'|^3\big)$$

holds *only* for the midpoint $\boldsymbol{x}_* = (\boldsymbol{x}'' + \boldsymbol{x}')/2$; at any other point the error is quadratic, i.e. of order $\hbar\Delta t/m$ in the exponent, which survives the limit. Endpoint prescriptions therefore quantize a different Hamiltonian, differing from H by a term proportional to $\nabla \cdot \boldsymbol{A}$. □

The moral generalizes: the time-sliced integral is a definition, and different discretizations of the same classical Lagrangian can define different quantum theories. What selects the right one is a symmetry that must survive — gauge invariance here, and in Section 106.7.3 chiral symmetry, where the answer turns out to be that no discretization preserves it and the failure is observable.

The classical limit

Theorem 106.10 (Stationary phase)**.** *Let $f:\mathbb{R}^n\to\mathbb{R}$ be smooth with a single non-degenerate critical point x_0, $\nabla f(x_0)=0$ and $\det f''(x_0)\neq 0$, and let g be smooth and compactly supported near x_0. Then as $\hbar\to 0^+$*

$$\int \mathrm{d}^n x\; g(x)\,\mathrm{e}^{\mathrm{i}f(x)/\hbar} = \frac{(2\pi\hbar)^{n/2}\,g(x_0)}{|\det f''(x_0)|^{1/2}}\,\mathrm{e}^{\mathrm{i}f(x_0)/\hbar}\,\mathrm{e}^{\mathrm{i}\pi\sigma/4}\big[1+O(\hbar)\big]\,, \tag{106.16}$$

with σ the signature of $f''(x_0)$.

Rests on Equation (106.8)*.*

Derivation. *Derives Theorem 106.10.*

Away from x_0 the integrand oscillates: writing $\mathrm{e}^{\mathrm{i}f/\hbar}=(\hbar/\mathrm{i})\nabla f\cdot\nabla \mathrm{e}^{\mathrm{i}f/\hbar}/|\nabla f|^2$ and integrating by parts k times produces a factor $\hbar^k$, so those regions contribute beyond all orders. Near x_0, substitute $x=x_0+\sqrt{\hbar}\,u$ and expand $f(x)=f(x_0)+\frac{\hbar}{2}u^{\mathsf{T}}f''(x_0)u+O(\hbar^{3/2})$. The measure supplies $\hbar^{n/2}$, the exponent becomes $\mathrm{i}f(x_0)/\hbar+\frac{\mathrm{i}}{2}u^{\mathsf{T}}f''u$, and Equation (106.8) evaluates the remaining integral. □

Apply this to Equation (106.9), whose integration variables are the $N-1$ intermediate positions and whose phase is the discretized action. The critical point of S is the path satisfying $\partial S/\partial q_k=0$ for every k, which is the discretized Euler–Lagrange equation, i.e. Hamilton's principle (Chapter 16); in the limit it is the classical trajectory. Therefore

$$K(q'',t'';q',t') \underset{\hbar\to 0}{\longrightarrow} \sqrt{\frac{1}{2\pi\mathrm{i}\hbar}\left(-\frac{\partial^2 S_{\mathrm{cl}}}{\partial q''\partial q'}\right)}\;\exp\!\left[\frac{\mathrm{i}}{\hbar}S_{\mathrm{cl}}(q'',t'';q',t')-\frac{\mathrm{i}\pi\nu}{2}\right], \tag{106.17}$$

the Van Vleck form, with ν the number of conjugate points passed — the Maslov index, the accumulated signature phase of Equation (106.8). Dirac's correspondence Equation (106.4) is recovered as the leading term, with the normalization now derived rather than guessed.

Proposition 106.11 (The semiclassical propagator is the WKB wavefunction)**.** *For a particle of energy E in one dimension, the Fourier transform of Equation (106.17) with respect to $t''-t'$ has stationary phase at the classical time of flight and gives, up to normalization,*

$$\psi(q)\propto\frac{1}{\sqrt{p(q)}}\,\exp\!\left[\pm\frac{\mathrm{i}}{\hbar}\int^{q}p(u)\,\mathrm{d}u\right], \qquad p(q)=\sqrt{2m\big(E-V(q)\big)}\,, \tag{106.18}$$

which is the semiclassical wave Equation (9.69) of Corollary 9.62, where the local momentum is written P and the amplitude factor $P^{-1/2}$ is derived from the transport equation rather than from a stationary phase.

Rests on Equations (106.3) *and* (106.17) *and Theorem 106.10.*

Derivation. *Derives Proposition 106.11.*

The energy eigenfunctions are obtained from K by $\int \mathrm{d}t\,\mathrm{e}^{\mathrm{i}Et/\hbar}K(q,t;q',0)$, a Fourier transform of the type of Chapter 17. Applying Theorem 106.10 in the single variable t, the stationary point is where $\partial S_{\mathrm{cl}}/\partial t=-E$ by Equation (106.3), i.e. at the classical time of flight at energy E, and the phase there becomes the Legendre transform $W(q,q'';E)=S_{\mathrm{cl}}+Et=\int p\,\mathrm{d}q$, Hamilton's characteristic function. The prefactor collects $(\partial^2 W/\partial q\partial q'')^{1/2}$, which for one degree of freedom is $(\partial p/\partial q'')^{1/2}\propto p(q)^{-1/2}$ after the reciprocity relation. This is Equation (106.18). □

Proposition 106.11 is the exact junction between this chapter and Section 9.6: the WKB ansatz $\psi=\exp(\mathrm{i}S/\hbar)$ of Equation (9.62) and the path-integral weight $\exp(\mathrm{i}S/\hbar)$ of Equation (106.10) are the same object seen from two sides, and the expansion of the exponent in powers of $\hbar$ in Equation (9.64) is the loop expansion of Section 106.3.4. In particular the $\hbar^1$ term of the WKB series, which produces the $p^{-1/2}$ amplitude, is the one-loop determinant, and the failure of the expansion at a turning point (Remark 9.66) is the failure of Theorem 106.10 at a degenerate critical point.

106.2 Euclidean formulation

106.2.1 Wick rotation

Remark 106.8 recorded that the oscillatory weight $\mathrm{e}^{\mathrm{i}S/\hbar}$ defines no measure. The remedy is to continue the time variable into the complex plane until the weight becomes real and decaying. The substitution is Wick's [1053].

Definition 106.12 (Euclidean time)**.** Set $t = -\mathrm{i}\tau$ with τ real, of SI dimension s. Equivalently $x^0 = ct \mapsto -\mathrm{i}x^4$ with $x^4 = c\tau$, and the metric $\eta_{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$ becomes $-\delta_{\mu\nu}$: squared four-vectors change sign, $p^2 \mapsto -p_E^2$ with $p_E^2 = (p^4)^2 + \boldsymbol{p}^2 \geq 0$.

Proposition 106.13 (The Euclidean weight)**.** *Under Definition 106.12 the action of a particle in a potential becomes $S = \mathrm{i}S_E$ with*

$$S_E[q] = \int \mathrm{d}\tau \left[\frac{m}{2} \left(\frac{\mathrm{d}q}{\mathrm{d}\tau} \right)^2 + V(q) \right] , \tag{106.19}$$

of dimension J s*, so the path-integral weight is*

$$\exp\!\left(\frac{\mathrm{i}}{\hbar} S \right) \longmapsto \exp\!\left(-\frac{1}{\hbar} S_E \right) , \tag{106.20}$$

real, positive and bounded by one, since $S_E \geq 0$ for $V \geq 0$. The Euclidean action is the sum, not the difference, of kinetic and potential terms: the Euclidean motion takes place in the inverted potential $-V$.

Rests on Definition 106.12.

Derivation. *Derives Proposition 106.13.*

With $t = -\mathrm{i}\tau$, $\mathrm{d}t = -\mathrm{i}\,\mathrm{d}\tau$ and $\mathrm{d}q/\mathrm{d}t = \mathrm{i}\,\mathrm{d}q/\mathrm{d}\tau$, so $\frac{m}{2}(\mathrm{d}q/\mathrm{d}t)^2 = -\frac{m}{2}(\mathrm{d}q/\mathrm{d}\tau)^2$ and

$$S = \int \mathrm{d}t \left[\frac{m}{2} \left(\frac{\mathrm{d}q}{\mathrm{d}t} \right)^2 - V \right] = \int (-\mathrm{i}\,\mathrm{d}\tau) \left[-\frac{m}{2} \left(\frac{\mathrm{d}q}{\mathrm{d}\tau} \right)^2 - V \right] = \mathrm{i} \int \mathrm{d}\tau \left[\frac{m}{2} \left(\frac{\mathrm{d}q}{\mathrm{d}\tau} \right)^2 + V \right] ,$$

whence $\mathrm{i}S/\hbar = \mathrm{i} \cdot \mathrm{i}S_E/\hbar = -S_E/\hbar$. □

The Euclidean weight is a genuine probability density on path space once normalized — that is the subject of Section 106.2.2 — and it is what makes the numerical work of Section 106.5.2 possible at all. What must be established is that the continuation is legitimate: that the Minkowski amplitude may be recovered from the Euclidean one by rotating back.

The pole structure that licenses the rotation

Proposition 106.14 (The Feynman contour permits the rotation)**.** *Let $f(p^0)$ be a product of Feynman propagators Equation (100.23) and scalar propagators $\mathrm{i}\hbar^3 c/(p^2 - m^2c^2 + \mathrm{i}\epsilon)$ and let the integrand fall faster than $|p^0|^{-1}$ at infinity. Then*

$$\int_{-\infty}^{\infty} \mathrm{d}p^0 \, f(p^0) = \mathrm{i} \int_{-\infty}^{\infty} \mathrm{d}p^4 \, f(\mathrm{i}p^4) , \tag{106.21}$$

the contour being rotated counterclockwise from the real to the imaginary axis.

Rests on Equation (100.23), Theorem 8.12, and Lemma 8.9.

Derivation. *Derives Proposition 106.14.*

A propagator denominator $p^2 - m^2c^2 + \mathrm{i}\epsilon = (p^0)^2 - \boldsymbol{p}^2 - m^2c^2 + \mathrm{i}\epsilon$ vanishes at

$$p^0 = \pm\left(\sqrt{\boldsymbol{p}^2 + m^2c^2} - \mathrm{i}\epsilon'\right), \qquad \epsilon' > 0\,,$$

to first order in ϵ: the positive-energy pole sits just *below* the positive real axis and the negative-energy pole just *above* the negative real axis, i.e. in the fourth and second quadrants respectively. The first and third quadrants are therefore free of singularities, and the closed contour consisting of the real axis, the imaginary axis traversed downwards, and the two connecting arcs in those quadrants encloses no pole. By Cauchy's theorem (Theorem 8.12) its integral vanishes; the arcs contribute nothing by the estimation lemma Lemma 8.9 given the assumed fall-off. Rotating $p^0 = \mathrm{e}^{\mathrm{i}\theta}\,|p^0|$ from $\theta = 0$ to $\theta = \pi/2$ and writing $p^0 = \mathrm{i}p^4$ gives $\mathrm{d}p^0 = \mathrm{i}\,\mathrm{d}p^4$, which is Equation (106.21). Under it $p^2 = (p^0)^2 - \boldsymbol{p}^2 \mapsto -(p^4)^2 - \boldsymbol{p}^2 = -p_E^2$, so the denominator becomes $-(p_E^2 + m^2c^2)$, which never vanishes for real p_E: the Euclidean propagator has no poles at all, and no $\mathrm{i}\epsilon$ is needed. □

The $\mathrm{i}\epsilon$ prescription of Equation (100.23) is thus not a computational convenience but the statement of which boundary value of an analytic function the theory picks — and it is exactly the choice that puts the poles out of the way of the rotation. That is the same fact seen twice: the Feynman propagator is the one whose Euclidean continuation exists.

Remark 106.15 (What the rotation costs). Three things are lost or endangered.

Real-time information. The Euclidean correlator determines the Minkowski one only through an analytic continuation, and continuing numerical data from a finite set of Euclidean times back to real time is an ill-posed inverse problem: two spectral functions differing by an oscillation of high frequency give Euclidean correlators differing by less than the statistical error. This is why the lattice computes masses and matrix elements well and transport coefficients badly.

Positivity of the weight, at finite chemical potential. Introducing a chemical potential μ for a conserved charge adds μ to the time component of the covariant derivative in the fermion operator; after the rotation this term is imaginary relative to the rest, the determinant $\det(\mathrm{i}\hbar\gamma^\mu D_\mu - mc)$ of Section 106.3.3 becomes complex, and $\mathrm{e}^{-S_E/\hbar}$ is no longer a probability. This is the *sign problem.* It is not a difficulty of technique: no reweighting scheme has been found whose cost is not exponential in the volume, and the phase diagram of QCD at large baryon density is consequently not known from first principles. The honest position is that Section 106.5.2's successes are successes at zero or small chemical potential.

Nothing else. At zero chemical potential the rotation is exact, and Section 106.2.3 states the conditions under which the Euclidean theory contains the whole of the Minkowski one.

106.2.2 The Feynman–Kac formula

Theorem 106.16 (Feynman–Kac)**.** *Let $H = p^2/2m + V(q)$ with V bounded below and continuous. Then for $\tau > 0$*

$$\langle q''|\,\mathrm{e}^{-H\tau/\hbar}\,|q'\rangle = \int_{q(0)=q'}^{q(\tau)=q''} \mathcal{D}q\;\mathrm{e}^{-S_E[q]/\hbar} = \rho_\tau(q''-q')\;\mathbb{E}_{q'\to q''}\left[\exp\left(-\frac{1}{\hbar}\int_0^\tau V(q(s))\,\mathrm{d}s\right)\right], \tag{106.22}$$

where the expectation is over the Wiener measure of Brownian bridges from q' to q'' with diffusion constant

$$D = \frac{\hbar}{2m}\,, \qquad [D] = \mathrm{m}^2/\mathrm{s}\,, \tag{106.23}$$

and $\rho_\tau(x) = (4\pi D\tau)^{-1/2}\mathrm{e}^{-x^2/4D\tau}$ is the free heat kernel.

Rests on Theorem 106.3 and Proposition 106.13.

Derivation. *Derives Theorem 106.16.*

Repeat the slicing of Theorem 106.3 with $\mathrm{e}^{-H\tau/\hbar}$ in place of $\mathrm{e}^{-\mathrm{i}Ht/\hbar}$; every step goes through with $\mathrm{i}\varepsilon \mapsto \Delta\tau$, giving

$$\langle q''|\,\mathrm{e}^{-H\tau/\hbar}\,|q'\rangle = \lim_{N\to\infty}\left(\frac{m}{2\pi\hbar\Delta\tau}\right)^{N/2}\int\prod_{k=1}^{N-1}\mathrm{d}q_k\;\exp\!\left\{-\frac{1}{\hbar}\sum_{k=1}^{N}\Delta\tau\left[\frac{m}{2}\left(\frac{q_k-q_{k-1}}{\Delta\tau}\right)^2+V\right]\right\}.$$

Now the prefactor and the kinetic term together are $\prod_k \rho_{\Delta\tau}(q_k-q_{k-1})$ with ρ as stated, because $m/(2\hbar\Delta\tau) = 1/(4D\Delta\tau)$ with D of Equation (106.23). That product is precisely the finite-dimensional distribution of Brownian motion of diffusion constant D sampled at the times $k\Delta\tau$, and by Kolmogorov's extension theorem it defines a genuine countably additive probability measure on continuous paths — Wiener's measure [507]. What remains in the exponent is $-\frac{1}{\hbar}\sum\Delta\tau\,V$, the Riemann sum for $\frac{1}{\hbar}\int V$, and the identification of the limit with the expectation is Kac's theorem [935]. Conditioning on the endpoint $q(\tau)=q''$ produces the bridge and the explicit factor $\rho_\tau(q''-q')$. □

That $D=\hbar/2m$ is worth pausing over. The Euclidean quantum mechanics of a particle of mass m *is* a diffusion process whose diffusion constant is set by $\hbar$; the classical limit $\hbar\to 0$ is the limit of vanishing diffusion, in which the paths collapse onto the single deterministic solution. For an electron, $D=\hbar/2m_e = 5.79\times10^{-5}\,\mathrm{m^2/s}$. The roughness noted after Theorem 106.3 is now a theorem rather than an estimate: Wiener paths are almost surely continuous, almost surely nowhere differentiable, and almost surely Hölder continuous of every exponent below $1/2$.

Spectral consequences

Proposition 106.17 (Euclidean time projects onto the ground state)**.** *Let H have discrete spectrum $E_0<E_1\le\cdots$ with eigenfunctions ψ_n. Then*

$$\langle q''|\,\mathrm{e}^{-H\tau/\hbar}\,|q'\rangle = \sum_n \psi_n(q'')\psi_n^*(q')\,\mathrm{e}^{-E_n\tau/\hbar} \;\xrightarrow[\tau\to\infty]{}\; \psi_0(q'')\psi_0^*(q')\,\mathrm{e}^{-E_0\tau/\hbar}, \tag{106.24}$$

so the large-τ decay rate of a Euclidean correlator measures an energy, and the gap E_1-E_0 governs the leading correction.

Rests on Theorem 106.16.

Derivation. *Derives Proposition 106.17.*

Insert the resolution of the identity in energy eigenstates into $\mathrm{e}^{-H\tau/\hbar}$; each term carries $\mathrm{e}^{-E_n\tau/\hbar}$ and the smallest exponent dominates. The subleading term is suppressed by $\mathrm{e}^{-(E_1-E_0)\tau/\hbar}$. □

Equation (106.24) is the entire basis of hadron spectroscopy on the lattice. A field theory correlator of an operator carrying the quantum numbers of a particle of mass m decays in Euclidean time as $\mathrm{e}^{-mc^2\tau/\hbar}$, and fitting that exponential to Monte Carlo data is how the numbers of Section 106.5.2 are obtained. The correlation *length* in the fourth direction is

$$\xi = c\tau_{\mathrm{corr}} = \frac{\hbar}{mc}, \tag{106.25}$$

the Compton wavelength: a mass gap in the quantum theory is a finite correlation length in the statistical one, and a massless particle is a critical point.

Finite temperature

Theorem 106.18 (The partition function is a periodic path integral)**.** *The canonical partition function of a system with Hamiltonian H at temperature T is*

$$Z(T) = \operatorname{tr} \mathrm{e}^{-H/k_B T} = \oint_{q(0)=q(\beta\hbar)} \mathcal{D}q \, \mathrm{e}^{-S_E[q]/\hbar}, \qquad \beta = \frac{1}{k_B T}, \tag{106.26}$$

the integral running over paths periodic in Euclidean time with period

$$\tau_\beta = \beta\hbar = \frac{\hbar}{k_B T}, \qquad [\tau_\beta] = \mathrm{s}. \tag{106.27}$$

Rests on Equation (106.22).

Derivation. *Derives Theorem 106.18.*

Take Equation (106.22) at $\tau = \beta\hbar$, set $q'' = q' = q$ and integrate over q: the left-hand side becomes $\int \mathrm{d}q \, \langle q| \, \mathrm{e}^{-\beta H} \, |q\rangle = \operatorname{tr} \mathrm{e}^{-\beta H}$, and the right-hand side becomes the path integral restricted to closed paths. Fermionic degrees of freedom acquire antiperiodic boundary conditions instead, because the trace of a Grassmann bilinear picks up a sign; that computation is Section 106.3.3. □

The thermal circumference Equation (106.27) is a length in Euclidean spacetime, $c\tau_\beta = \hbar c/k_B T$. At room temperature, $T = 300\,\mathrm{K}$,

$$\tau_\beta = \frac{\hbar}{k_B T} = \frac{1.054\,571\,817 \times 10^{-34}\,\mathrm{J\,s}}{1.380\,649 \times 10^{-23}\,\mathrm{J/K} \times 300\,\mathrm{K}} = 2.55 \times 10^{-14}\,\mathrm{s}, \tag{106.28}$$

using the exactly defined Boltzmann constant [2431]; at the temperature $k_B T = 150\,\mathrm{MeV}$ characteristic of the quark–hadron transition, $\tau_\beta = 4.39 \times 10^{-24}\,\mathrm{s}$ and $c\tau_\beta = 1.32\,\mathrm{fm}$, comparable with the size of a hadron — which is why finite-temperature QCD is a strongly coupled problem and not a small correction.

Table 106.1: The Euclidean dictionary. A quantum field theory in $3+1$ spacetime dimensions, continued to imaginary time, is a classical statistical system in four Euclidean dimensions; a quantum system at temperature T is the same system on a slab of thickness $\hbar/k_B T$. Every entry is an identity between the two columns after Theorems 106.16 and 106.18, not an analogy.

Euclidean field theory	**Classical statistical mechanics**
Weight $\mathrm{e}^{-S_E/\hbar}$	Boltzmann factor $\mathrm{e}^{-\mathcal{H}/k_B T}$
$\hbar$	$k_B T$
Euclidean action S_E	energy $\mathcal{H}$ of a configuration
Generating functional $Z[0]$	partition function
Mass m of the lightest state	inverse correlation length, $\xi = \hbar/mc$
Massless particle	critical point, $\xi \to \infty$
Continuum limit $a \to 0$	second-order critical point
Vacuum expectation value	thermal average
Temperature T of the quantum system	circumference $\hbar/k_B T$ of the fourth direction

Table 106.1 is the reason this chapter sits next to Chapter 118 in the architecture of the book, and why the renormalization group of Chapter 108 is the same construction as the one applied to critical phenomena in Chapter 123. The identification $\hbar \leftrightarrow k_B T$ fixes the direction of the loop expansion of Section 106.3.4: it is an expansion in *powers* of $\hbar$,

hence in powers of $k_B T$, and so a *low*-temperature expansion of the statistical system — the saddle-point expansion about the configuration of least energy, with each loop one power of $k_B T$ smaller than the last. The classical limit $\hbar \to 0$ is correspondingly its zero-temperature limit, in which fluctuations are frozen and the configuration of least energy is the only one. A genuine high-temperature expansion of the statistical system is an expansion in $1/k_B T$ and is the strong-coupling expansion of Theorem 106.72, at the opposite end of the same axis.

106.2.3 Reconstruction of the real-time theory

The Euclidean theory is a computational device only if the Minkowski theory can be recovered from it. Osterwalder and Schrader gave necessary and sufficient conditions [1510, 1555].

Definition 106.19 (Schwinger functions)**.** The Euclidean correlation functions of a scalar field,

$$S_n(x_1, \dots, x_n) = \frac{1}{Z} \int \mathcal{D}\phi \; \phi(x_1) \cdots \phi(x_n) \, \mathrm{e}^{-S_E[\phi]/\hbar} \,, \tag{106.29}$$

with all x_i in Euclidean $\mathbb{R}^4$ and distinct.

Theorem 106.20 (Osterwalder–Schrader reconstruction)**.** *Let a family $\{S_n\}$ satisfy*

1. regularity*: each S_n is a tempered distribution, with growth in n bounded so that the reconstructed fields are operator-valued distributions;*
2. Euclidean invariance*: S_n is invariant under the rotations and translations of* $\mathrm{SO}(4) \ltimes \mathbb{R}^4$*;*
3. reflection positivity*: for the reflection $\theta : (x^4, \boldsymbol{x}) \mapsto (-x^4, \boldsymbol{x})$ and any finite family of test functions f_k supported in $x^4 > 0$,*
$$\sum_{j,k} \bar{c}_j c_k \, S(\theta \bar{f}_j \otimes f_k) \geq 0 \,, \tag{106.30}$$
4. symmetry*: S_n is invariant under permutations of its arguments;*
5. cluster decomposition*: $S_{n+m}(x_1, \dots, x_n, y_1 + a, \dots) \to S_n S_m$ as the Euclidean separation $|a| \to \infty$;*

then there is a Wightman quantum field theory in $3+1$ Minkowski dimensions — a Hilbert space with a positive-definite inner product, a unitary representation of the Poincaré group with spectrum in the forward cone, a unique vacuum, and local fields — whose vacuum correlators continue to the S_n. Conversely, the Schwinger functions of any Wightman theory satisfy (i)–(v). The Wightman axioms so reconstructed are the subject of Chapter 109.

Rests on Definition 106.19.

Of the five, reflection positivity is the one that carries the physics, and it is worth seeing why in the simplest case, where the whole content is visible.

Proposition 106.21 (Reflection positivity is the positivity of the Hilbert space)**.** *In Euclidean quantum mechanics, let F be any functional of the path depending only on $q(s)$ for $s > 0$, and let θF be its reflection, depending only on $s < 0$. Then*

$$\left\langle \overline{\theta F} \, F \right\rangle = \| \Psi_F \|^2 \geq 0 \,, \tag{106.31}$$

where Ψ_F is a vector in the Hilbert space of the theory built from F and the ground state $|\Omega\rangle$ by Theorem 106.16.

Rests on Theorem 106.16 and Equation (106.30).

Derivation. *Derives Proposition 106.21.*

Take $F = \prod_i f_i(q(s_i))$ with $0 < s_1 < \cdots < s_n$. By Theorem 106.16 the Euclidean expectation of a product of such factors is a time-ordered chain of operators separated by Euclidean evolutions,

$$\left\langle \overline{\theta F}\, F \right\rangle = \langle \Omega |\, \hat{f}_n^\dagger \mathrm{e}^{-H(s_n - s_{n-1})/\hbar} \cdots \hat{f}_1^\dagger\, \hat{f}_1 \cdots \mathrm{e}^{-H(s_n - s_{n-1})/\hbar} \hat{f}_n\, |\Omega\rangle \ ,$$

because reflecting $s \mapsto -s$ reverses the order of the factors and conjugates them, while the intervening evolution operators $\mathrm{e}^{-H\Delta s/\hbar}$ are positive and self-adjoint. The whole expression is therefore $\|\Psi\|^2$ with $\Psi = \hat{f}_1 \mathrm{e}^{-H(s_2 - s_1)/\hbar} \cdots |\Omega\rangle$, manifestly non-negative. Linear combinations give Equation (106.30).

Read backwards, this is the content of the axiom: the Euclidean functional integral supplies a bilinear form on functionals of the positive-time half-path, and reflection positivity says exactly that this form is a non-negative inner product. The physical Hilbert space is the completion of that space modulo null vectors, the operator $\mathrm{e}^{-H\tau/\hbar}$ is the translation in Euclidean time, and H is self-adjoint and bounded below because it generates a contraction semigroup. Without Equation (106.30) one obtains a vector space with an indefinite form and no probability interpretation — and no amount of Euclidean invariance repairs it. □

Remark 106.22 (Reflection positivity on the lattice). The lattice discretization of Section 106.5.1 must inherit Equation (106.30) or it is not the Euclidean form of any quantum theory, however well it reproduces the classical action. Wilson's plaquette action does inherit it, because it couples only nearest-neighbour time slices, so the transfer operator constructed above exists and is positive. Actions "improved" by adding couplings between next-to-nearest time slices generally do not: they can produce a transfer matrix with negative eigenvalues, whose signature is a correlator that oscillates in Euclidean time and which cannot be fitted by Equation (106.24) with any real spectrum. Improvement schemes are therefore constructed to act within a time slice, or their violation is arranged to vanish faster than the discretization errors they remove. This is a working constraint on the design of a lattice action, not a foundational nicety.

Derivation pending #163

Osterwalder–Schrader reconstruction: the derivation above establishes the easy half in quantum mechanics — that reflection positivity is the positivity of the reconstructed inner product — and states the field-theoretic theorem. The construction of the Wightman functions from the Schwinger functions by analytic continuation in the time arguments, and the verification of the spectrum condition and locality, are not carried out here; they belong in Appendix A, alongside the axiomatic material of the axiomatic quantum field theory chapter of this part.

106.3 Functional quantization of fields

106.3.1 Generating functionals

A field is a mechanical system with one degree of freedom per point of space, so Theorem 106.3 carries over with $q(t)$ replaced by $\phi(x)$ and the time slicing replaced by a slicing in x^0. The one thing that must be fixed first is dimensions, because the whole chapter turns on the exponent $S/\hbar$ being a pure number.

Notation 106.23 (The scalar field and its source). For a single real scalar field the Lagrangian density is

$$\mathcal{L} = \frac{1}{2}\partial_\mu\phi\, \partial^\mu\phi - \frac{1}{2}\left(\frac{mc}{\hbar}\right)^2 \phi^2 - \frac{g}{4!}\phi^4 \, , \tag{106.32}$$

of dimension $\mathrm{J/m^3}$ by Equation (100.2). Since ∂_μ carries $1/\mathrm{m}$, the field carries

$$[\phi] = \mathrm{J}^{1/2}/\mathrm{m}^{1/2} = \mathrm{kg}^{1/2}\,\mathrm{m}^{1/2}/\mathrm{s}\,, \tag{106.33}$$

the mass term carries $(mc/\hbar)^2$ of dimension $1/\mathrm{m}^2$ — the inverse squared Compton wavelength, so that the field equation is $(\Box + (mc/\hbar)^2)\phi = 0$ — and the quartic coupling carries

$$[g] = 1/(\mathrm{J\,m})\,, \qquad \hat{g} := g\hbar c \ \text{ dimensionless}\,. \tag{106.34}$$

The source J is coupled by adding $c^{-1}\int \mathrm{d}^4x\, J\phi$ to the action, so $[J] = \mathrm{J}^{1/2}/\mathrm{m}^{5/2}$.

That $\hat{g} = g\hbar c$ and not g is the dimensionless coupling is not bookkeeping. It says that the strength of a quartic self-interaction is measured against $\hbar c = 3.161\,53 \times 10^{-26}\,\mathrm{J\,m}$, the only quantity in the theory with the dimension of an energy times a length, exactly as the electromagnetic coupling is measured against it in Equation (100.3). A "dimensionless coupling" is always a ratio to $\hbar c$, and saying so is what makes the classical limit visible: as $\hbar \to 0$ at fixed g, every dimensionless coupling goes to zero and the theory becomes free and classical.

Definition 106.24 (The generating functional)**.**

$$Z[J] = \int \mathcal{D}\phi\, \exp\!\left\{\frac{\mathrm{i}}{\hbar}\left(S[\phi] + \frac{1}{c}\int \mathrm{d}^4x\; J(x)\phi(x)\right)\right\}, \tag{106.35}$$

with $S[\phi] = c^{-1}\int \mathrm{d}^4x\,\mathcal{L}$ and $\mathcal{D}\phi$ the slicing limit of Equation (106.9) applied to each mode. It is dimensionless, and $Z[0]$ is the vacuum persistence amplitude $\langle 0, +\infty | 0, -\infty\rangle$: $|Z[0]|^2$ is the probability that a system prepared in the vacuum is found in the vacuum, which is unity for a stable theory and less than unity when the external conditions can create particles.

Schwinger's insight, which is what makes Equation (106.35) the master object of the subject, is that all correlation functions are encoded in the response of the vacuum amplitude to an external source [989].

Theorem 106.25 (Correlators as functional derivatives)**.** *The time-ordered vacuum correlation functions are*

$$\langle 0|\,T\,\phi(x_1)\cdots\phi(x_n)\,|0\rangle = \frac{1}{Z[0]}\prod_{k=1}^{n}\left(\frac{\hbar c}{\mathrm{i}}\,\frac{\delta}{\delta J(x_k)}\right) Z[J]\Big|_{J=0}\,, \tag{106.36}$$

each functional derivative carrying the factor $\hbar c/\mathrm{i}$ so that the result has dimension $[\phi]^n$.
Rests on Equations (106.9) and (106.35).

Derivation. *Derives Theorem 106.25.*
Differentiating Equation (106.35),

$$\frac{\delta Z}{\delta J(x)} = \int \mathcal{D}\phi\, \frac{\mathrm{i}}{\hbar c}\,\phi(x)\,\mathrm{e}^{\mathrm{i}(S + c^{-1}\int J\phi)/\hbar}\,,$$

so multiplying by $\hbar c/\mathrm{i}$ inserts one factor of $\phi(x)$ into the integrand. Repeating gives n insertions; dividing by $Z[0]$ normalizes. That the insertions come out *time-ordered* is a property of the slicing: the fields in Equation (106.9) are c-numbers attached to time slices, and reassembling them into operators reinstates them in the order of their time arguments, whatever order they were written in. This is the technical advantage of the formalism — the object it computes naturally is the object that appears in the Dyson series Equation (100.25) — and also its limitation, since it does not directly give an unordered product. □

Proposition 106.26 (Connected correlators and the linked-cluster theorem)**.** *Define*

$$W[J] := -\mathrm{i}\hbar \ln Z[J]\,, \tag{106.37}$$

of dimension J s*. Then* W *generates the* connected *correlation functions: in particular*

$$\langle \phi(x) \rangle_J = c\,\frac{\delta W}{\delta J(x)}\,, \qquad \langle T\phi(x)\phi(y)\rangle_{\mathrm{conn}} = \frac{\hbar c^2}{\mathrm{i}}\,\frac{\delta^2 W}{\delta J(x)\,\delta J(y)}\,. \tag{106.38}$$

Moreover $Z[J] = \exp(\mathrm{i}W[J]/\hbar)$ *states that the sum of all diagrams is the exponential of the sum of the connected ones.*

Rests on Equations (106.35) *and* (106.36)*.*

Derivation. *Derives Proposition 106.26.*

From $Z = \mathrm{e}^{\mathrm{i}W/\hbar}$, $\delta Z/\delta J = (\mathrm{i}/\hbar)(\delta W/\delta J)Z$, and combining with Equation (106.36) for $n = 1$ gives $\langle\phi\rangle = (\hbar c/\mathrm{i})(\mathrm{i}/\hbar)\delta W/\delta J = c\,\delta W/\delta J$. Differentiating once more,

$$\frac{\delta^2 Z}{\delta J_1 \delta J_2} = \left[\frac{\mathrm{i}}{\hbar}\frac{\delta^2 W}{\delta J_1 \delta J_2} + \left(\frac{\mathrm{i}}{\hbar}\right)^2 \frac{\delta W}{\delta J_1}\frac{\delta W}{\delta J_2}\right] Z\,,$$

so that, multiplying by $(\hbar c/\mathrm{i})^2 = -\hbar^2 c^2$,

$$\langle T\phi_1\phi_2\rangle = -\mathrm{i}\hbar c^2 \frac{\delta^2 W}{\delta J_1 \delta J_2} + \langle\phi_1\rangle\,\langle\phi_2\rangle\ ,$$

and the first term is by definition the connected part.

For the general statement, argue combinatorially. Let the connected diagrams (with sources attached) be indexed by i with values C_i. A general diagram is a disjoint union of connected pieces; if it contains n_i copies of the connected diagram i, its symmetry factor includes $1/n_i!$ from the permutations of identical components, because the Wick contractions that produce it differ only by relabelling those components. Summing over all multiplicities independently,

$$Z = Z_{\mathrm{free}} \sum_{\{n_i\}} \prod_i \frac{C_i^{n_i}}{n_i!} = Z_{\mathrm{free}} \prod_i \mathrm{e}^{C_i} = Z_{\mathrm{free}}\,\exp\!\left(\sum_i C_i\right)\ ,$$

so $\ln Z$ is the sum of connected diagrams alone. That is the linked-cluster theorem, and it is why the vacuum diagrams — those with no external source — cancel between numerator and denominator in Equation (106.36): they exponentiate into an overall factor $Z[0]$. □

The linked-cluster theorem has a consequence worth stating separately, because it is the reason the formalism is usable at all. The connected correlators are extensive: $\ln Z$ is proportional to the spacetime volume, whereas Z itself is exponentially large in it. Any expansion organized around W rather than Z therefore has coefficients with a finite thermodynamic limit. In the Euclidean language of Table 106.1 this is the statement that the free energy is extensive while the partition function is not.

106.3.2 Free fields and the perturbative expansion

The Gaussian theory, solved exactly

Theorem 106.27 (The free generating functional and the Feynman propagator)**.** *For* $g = 0$ *in Equation* (106.32)*,*

$$Z_0[J] = Z_0[0]\,\exp\!\left\{-\frac{\mathrm{i}}{2\hbar c}\int \mathrm{d}^4x\,\mathrm{d}^4y\; J(x)\,G(x-y)\,J(y)\right\}\ , \tag{106.39}$$

where G is the Green function of the Klein–Gordon operator,

$$-\left(\Box_x + \left(\frac{mc}{\hbar}\right)^2\right) G(x-y) = \delta^4(x-y)\,, \qquad [G] = 1/\mathrm{m}^2\,. \tag{106.40}$$

The two-point function is

$$\Delta_F(x-y) := \langle 0|\, T\phi(x)\phi(y)\,|0\rangle = \mathrm{i}\hbar c\, G(x-y)\,, \qquad \widetilde{\Delta}_F(p) = \frac{\mathrm{i}\hbar^3 c}{p^2 - m^2c^2 + \mathrm{i}\epsilon}\,, \tag{106.41}$$

of dimension $\mathrm{J/m}$ *in position space and* $\mathrm{J\,m^3}$ *in momentum space.*
Rests on Equations (106.32) *and* (106.35) *and Lemma 106.2.*

Derivation. *Derives Theorem 106.27.*

Integrate the kinetic term by parts, discarding the surface term:

$$S_0[\phi] = \frac{1}{c}\int \mathrm{d}^4x\, \frac{1}{2}\left[\partial_\mu\phi\partial^\mu\phi - \left(\frac{mc}{\hbar}\right)^2\phi^2\right] = \frac{1}{2c}\int \mathrm{d}^4x\, \phi\,\mathcal{K}\phi\,, \qquad \mathcal{K} = -\left(\Box + \left(\frac{mc}{\hbar}\right)^2\right).$$

The exponent of Equation (106.35) is then $\frac{\mathrm{i}}{\hbar c}\left[\frac{1}{2}\int \phi\mathcal{K}\phi + \int J\phi\right]$, a quadratic form in ϕ, and Lemma 106.2 applies once the square is completed. Put $\phi = \phi_0 + \chi$ with $\phi_0(x) = -\int \mathrm{d}^4y\, G(x-y)J(y)$, so that $\mathcal{K}\phi_0 = -J$ by Equation (106.40). Then

$$\frac{1}{2}\phi\mathcal{K}\phi + J\phi = \frac{1}{2}\chi\mathcal{K}\chi + \chi(\mathcal{K}\phi_0 + J) + \frac{1}{2}\phi_0\mathcal{K}\phi_0 + J\phi_0 = \frac{1}{2}\chi\mathcal{K}\chi - \frac{1}{2}\iint J\,G\,J\,,$$

the cross term vanishing by construction. The shift $\phi \mapsto \chi$ is a translation of the integration variable and leaves $\mathcal{D}\phi$ invariant — this is a property of the sliced definition, each $\mathrm{d}\phi_k$ being a Lebesgue measure on $\mathbb{R}$ — so the χ integral is the J-independent constant $Z_0[0]$ and what remains is Equation (106.39).

By Equation (106.37), $W_0[J] = -\frac{1}{2c}\iint JGJ$, and Equation (106.38) gives $\langle T\phi_1\phi_2\rangle = (\hbar c^2/\mathrm{i})(-G/c) = \mathrm{i}\hbar c G$.

In momentum space, with the convention Equation (100.14), $\partial_\mu \mapsto -\mathrm{i}p_\mu/\hbar$ and $\Box \mapsto -p^2/\hbar^2$, so $\mathcal{K} \mapsto (p^2 - m^2c^2)/\hbar^2$ and $\widetilde{G}(p) = \hbar^2/(p^2 - m^2c^2)$. The pole on the real axis is resolved by the Feynman prescription $m^2c^2 \to m^2c^2 - \mathrm{i}\epsilon$, which is the choice singled out by Proposition 106.14. Multiplying by $\mathrm{i}\hbar c$ gives Equation (106.41). The result has exactly the structure of the photon propagator Equation (100.17), the factor $\hbar^3 c$ being common to both. □

Corollary 106.28 (Wick's theorem)**.** *In the free theory, correlators of an odd number of fields vanish, and*

$$\langle 0|\, T\phi(x_1)\cdots\phi(x_{2n})\,|0\rangle = \sum_{\text{pairings}}\ \prod_{\text{pairs }(i,j)} \Delta_F(x_i - x_j)\,, \tag{106.42}$$

the sum running over all $(2n-1)!!$ *ways of partitioning the arguments into pairs.*
Rests on Equations (106.36) *and* (106.39).

Derivation. *Derives Corollary 106.28.*

Apply Equation (106.36) to Equation (106.39). Each derivative $\hbar c\,\delta/(\mathrm{i}\delta J)$ acting on the exponential brings down one factor $-(\mathrm{i}/\hbar c)\int GJ$ times $\hbar c/\mathrm{i}$, i.e. $-\int GJ$, which is set to zero at $J = 0$ unless a later derivative acts on it. A non-vanishing term therefore requires the derivatives to be used in pairs: one to bring down the bilinear, one to remove the surviving J. The pair (i,j) contributes $(\hbar c/\mathrm{i})^2 \times (-\mathrm{i}/\hbar c)G = \mathrm{i}\hbar c G = \Delta_F$, and the number of ways of pairing $2n$ objects is $(2n-1)!!$. An odd number of derivatives always leaves one J unpaired. □

Corollary 106.28 is the same statement as the operator Wick theorem [974] invoked in Proposition 100.14. In the operator formalism it is a statement about normal-ordering products of creation and annihilation operators, and that chapter quotes it from Wick's paper rather than proving it; here it is a property of the Gaussian integral, derived above, and no operators appear. That is the second road promised in the introduction.

Perturbation theory and the Feynman rules

Proposition 106.29 (Feynman rules from the functional integral)**.** *Write $S = S_0 + S_{\mathrm{int}}$ with $S_{\mathrm{int}} = -\frac{1}{c}\int \mathrm{d}^4x\, \frac{g}{4!}\phi^4$. Then*

$$Z[J] = \exp\!\left\{ \frac{\mathrm{i}}{\hbar} S_{\mathrm{int}}\!\left[\frac{\hbar c}{\mathrm{i}} \frac{\delta}{\delta J} \right] \right\} Z_0[J]\,, \tag{106.43}$$

and expanding the outer exponential generates, order by order in $\hat{g} = g\hbar c$, the diagrammatic rules: a line for each propagator Equation (106.41), a four-point vertex carrying

$$-\frac{\mathrm{i}g}{\hbar c}\int \mathrm{d}^4x \quad \leftrightarrow \quad -\frac{\mathrm{i}g}{\hbar c}\,(2\pi\hbar)^4\,\delta^4\!\left(\textstyle\sum_k p_k\right) \quad \text{in momentum space,} \tag{106.44}$$

one integration $\int \mathrm{d}^4\ell/(2\pi\hbar)^4$ per loop, and the symmetry factor of the diagram.
Rests on Equation (106.35), Theorem 106.25, and Corollary 106.28.

Derivation. *Derives Proposition 106.29.*

Every occurrence of $\phi(x)$ in S_{int} may be replaced by $(\hbar c/\mathrm{i})\delta/\delta J(x)$ acting on the integrand of Equation (106.35), by the computation in Theorem 106.25; the resulting operator may then be pulled outside the ϕ integral, leaving $Z_0[J]$. That is Equation (106.43), which is exact. Expanding $\exp(\mathrm{i}S_{\mathrm{int}}/\hbar)$ in powers and applying Corollary 106.28 to each term produces sums of products of propagators with four lines meeting at each vertex position, each vertex carrying $(\mathrm{i}/\hbar)\times(-1/c)\times(g/4!)$ and an integration $\int \mathrm{d}^4x$; the 4! is cancelled by the number of ways of assigning the four lines to the four fields, except when a symmetry of the diagram leaves some of those assignments equivalent, which is the origin of the symmetry factor. Fourier transforming each propagator by Equation (100.14) turns the position integrals into the momentum-conserving delta functions of Equation (106.44), leaving one free integration per independent loop. □

Theorem 106.30 (The loop expansion is the expansion in $\hbar$)**.** *A connected diagram with V vertices, I internal lines and L independent loops carries the factor*

$$\hbar^{I-V} = \hbar^{L-1}\,, \qquad L = I - V + 1\,, \tag{106.45}$$

counting the vertices and the internal lines alone. A tree graph has $L = 0$ and therefore carries $\hbar^{-1}$; relative to it an L-loop graph is suppressed by $\hbar^{L}$. The two statements are the same one and must not be added: $\hbar^{L-1}$ is the absolute power, $\hbar^{L}$ the power relative to the classical contribution. The perturbative expansion in the number of loops is therefore an expansion in powers of $\hbar$, and in nothing else.
Rests on Proposition 106.29 and Equation (106.40).

Derivation. *Derives Theorem 106.30.*

By Proposition 106.29 each vertex carries an explicit $\hbar^{-1}$ (from $\mathrm{i}S_{\mathrm{int}}/\hbar$) and each internal line one factor of $\hbar$ (the propagator $\mathrm{i}\hbar cG$ is linear in $\hbar$, G being $\hbar$-independent by Equation (106.40) once $mc/\hbar$ is regarded as the fixed inverse Compton wavelength). A diagram therefore carries $\hbar^{I-V}$. The second relation of Equation (106.45) is Euler's relation for a connected graph: each internal line carries one momentum, the V vertices impose V delta functions of which one is the overall momentum conservation, leaving $I-(V-1)$ undetermined loop momenta. Hence $\hbar^{I-V} = \hbar^{L-1}$, and a tree, having $L = 0$, sets the reference power $\hbar^{-1}$ against which the loops are counted. □

Theorem 106.30 is the reason this chapter refuses to drop $\hbar$ from its formulae. In the standard presentation the loop counting is a combinatorial fact about graphs; here it is a physical statement — a one-loop correction is the first quantum correction, suppressed relative to the classical answer by one power of the quantity whose smallness defines the classical limit, and the tree diagrams alone reproduce classical field theory exactly. This will be made precise in Section 106.3.4, where the tree approximation to Γ is shown to be the classical action.

The series does not converge

Proposition 106.31 (Dyson's argument)**.** *The perturbation series of quantum electrodynamics in powers of e^2 has zero radius of convergence [998].*

Rests on Proposition 106.29.

Derivation. *Derives Proposition 106.31.*

Suppose the series converged in some disc $|e^2| < r$. Then it would converge for real negative e^2, that is for an imaginary charge, and by analyticity the sum would be the physical quantity of that theory. But with $e^2 < 0$ like charges attract: the vacuum is unstable against the spontaneous creation of a large number of electron–positron pairs, which segregate into two clouds of like charge whose negative potential energy exceeds their rest energy once enough pairs are made. No lowest-energy state exists, so the theory has no ground state, no S-matrix, and no analytic continuation of the physical quantities to compare with. Hence the radius of convergence is zero.

Dyson's argument is physical, not a theorem: it establishes that the theory at $e^2 < 0$ is pathological, and infers from this that the function of e^2 cannot be analytic at the origin. □

The concrete form of the divergence is visible in a single ordinary integral, which is the whole of the phenomenon with none of the field theory.

Example 106.32 (The zero-dimensional model)**.** Let $Z(\hat g) = \int_{-\infty}^{\infty} \mathrm{d}x\ \mathrm{e}^{-x^2/2 - \hat g x^4/4!}$, the $0+0$-dimensional version of Equation (106.32) after Wick rotation. Expanding the quartic term and using $\langle x^{4n}\rangle = (4n-1)!!$ from Lemma 106.2,

$$\frac{Z(\hat g)}{Z(0)} = \sum_{n=0}^{\infty} \frac{(-\hat g)^n}{n!\,(4!)^n}\,(4n-1)!! = 1 - \frac{\hat g}{8} + \frac{35\hat g^2}{384} - \frac{385\hat g^3}{3072} + \cdots . \tag{106.46}$$

The coefficients grow factorially. Writing $(4n-1)!! = (4n)!/(2^{2n}(2n)!)$ and applying Stirling's formula to each factorial gives

$$|a_n| = \frac{(4n-1)!!}{n!\,(4!)^n} \sim \frac{n!}{\sqrt{2}\,\pi n}\left(\frac{2}{3}\right)^n \qquad (n\to\infty)\,, \tag{106.47}$$

so the series diverges for every $\hat g \neq 0$ although the integral it came from is perfectly finite and analytic in $\hat g$ on the cut plane. The best one can do is truncate at the smallest term, $n \approx 3/(2\hat g)$, with an error of order $\mathrm{e}^{-3/(2\hat g)}$: an *asymptotic* series.

The same estimate applied to quantum electrodynamics with $\alpha = 1/137.036$ puts the optimal truncation near order $1/\alpha \approx 137$ and the irreducible error near $\mathrm{e}^{-1/\alpha} \approx 10^{-60}$ — some fifty orders of magnitude below the precision of the most accurate measurement in physics (Section 100.8.2). The non-convergence of the series is therefore a statement about the far tail of a computation nobody will ever do, not a defect of the predictions. What it does mean is that perturbation theory alone cannot define the theory: quantities of the size $\mathrm{e}^{-1/\alpha}$, or $\mathrm{e}^{-1/\hat g}$, are invisible to it, and those are exactly the instanton effects of Section 106.6.1 and the confining physics of Section 106.5. The Euclidean path integral, defined non-perturbatively on a lattice, is at present the only construction that reaches them.

106.3.3 Fermions and Grassmann integration

Why the classical fields must anticommute The construction of Theorem 106.3 inserted a resolution of the identity built from eigenstates of the coordinate operator. For a field theory the corresponding step inserts eigenstates of the field operator, $\hat{\phi}(\boldsymbol{x})\,|\phi\rangle = \phi(\boldsymbol{x})\,|\phi\rangle$ at fixed time, and the eigenvalues $\phi(\boldsymbol{x})$ are the integration variables. For a Dirac field this is impossible with ordinary numbers.

Proposition 106.33 (Field eigenvalues inherit the statistics)**.** *Let $\hat{\psi}_\alpha(\boldsymbol{x})$ satisfy the equal-time anticommutation relations $\{\hat{\psi}_\alpha(\boldsymbol{x}), \hat{\psi}_\beta(\boldsymbol{y})\} = 0$ required by the spin–statistics connection of Chapter 83, and let $|\psi\rangle$ be a simultaneous eigenstate, $\hat{\psi}_\alpha(\boldsymbol{x})\,|\psi\rangle = \psi_\alpha(\boldsymbol{x})\,|\psi\rangle$. Then the eigenvalues satisfy*

$$\psi_\alpha(\boldsymbol{x})\psi_\beta(\boldsymbol{y}) = -\psi_\beta(\boldsymbol{y})\psi_\alpha(\boldsymbol{x})\,, \tag{106.48}$$

and in particular $\psi_\alpha(\boldsymbol{x})^2 = 0$: they are Grassmann *numbers, generators of an exterior algebra, not elements of $\mathbb{R}$ or $\mathbb{C}$.*

Rests on Theorem 99.46.

Derivation. *Derives Proposition 106.33.*

Apply the two operators in both orders to the eigenstate: $\hat{\psi}_\alpha(\boldsymbol{x})\hat{\psi}_\beta(\boldsymbol{y})\,|\psi\rangle = \psi_\beta(\boldsymbol{y})\psi_\alpha(\boldsymbol{x})\,|\psi\rangle$ — reading the operators from right to left — while the anticommutator gives $\hat{\psi}_\alpha\hat{\psi}_\beta = -\hat{\psi}_\beta\hat{\psi}_\alpha$, whose eigenvalue is $-\psi_\alpha(\boldsymbol{x})\psi_\beta(\boldsymbol{y})$. Equating the two gives Equation (106.48). Setting $\alpha = \beta$, $\boldsymbol{x} = \boldsymbol{y}$ gives $\psi^2 = -\psi^2 = 0$. □

Nothing was assumed here beyond the anticommutation relations themselves. The Grassmann variables of the fermionic path integral are not a formal device chosen for convenience: they are what the eigenvalues of an anticommuting operator are. What remains is to say what it means to integrate over them, and Berezin's answer [1325] is not a postulate either — it is forced by two requirements.

Berezin's rules, derived

Definition 106.34 (Grassmann algebra)**.** Let $\theta_1, \dots, \theta_n$ generate an associative algebra over $\mathbb{C}$ with $\theta_i\theta_j = -\theta_j\theta_i$, hence $\theta_i^2 = 0$. Every element is a finite sum $f = \sum_S c_S \prod_{i\in S} \theta_i$ over subsets $S \subseteq \{1, \dots, n\}$; there are 2^n terms and the algebra is finite-dimensional. In one generator the general element is simply $f(\theta) = a + b\theta$.

Theorem 106.35 (The Berezin integral)**.** *Suppose a linear functional $f \mapsto \int \mathrm{d}\theta\, f(\theta)$ on the one-generator algebra is required to be*

1. linear*, and*
2. translation invariant*: $\int \mathrm{d}\theta\, f(\theta+\eta) = \int \mathrm{d}\theta\, f(\theta)$ for every Grassmann η.*

Then it is determined up to normalization, and with the normalization $\int \mathrm{d}\theta\, \theta = 1$,

$$\int \mathrm{d}\theta\; 1 = 0\,, \qquad \int \mathrm{d}\theta\; \theta = 1\,, \qquad \textit{hence} \qquad \int \mathrm{d}\theta\, f(\theta) = \frac{\partial f}{\partial \theta}\,. \tag{106.49}$$

Integration over a Grassmann variable is *differentiation with respect to it.*

Rests on Definition 106.34.

Derivation. *Derives Theorem 106.35.*

By linearity the functional is fixed by the two numbers $I_0 = \int \mathrm{d}\theta\, 1$ and $I_1 = \int \mathrm{d}\theta\, \theta$. Apply translation invariance to $f = a + b\theta$:

$$\int \mathrm{d}\theta\,(a + b\theta + b\eta) = aI_0 + bI_1 + b\eta I_0 \quad \text{must equal} \quad aI_0 + bI_1\,,$$

for every b and every η, which forces $I_0 = 0$. Normalizing $I_1 = 1$ then gives Equation (106.49), and since $\partial(a + b\theta)/\partial\theta = b = aI_0 + bI_1$, integration and differentiation coincide.

Translation invariance is not a technical convenience: it is exactly the property used in Theorem 106.27 to complete the square, and without it there would be no fermionic Gaussian integral and hence no fermionic path integral. It is also the property whose *failure* under a chiral rotation produces the anomaly of Section 106.7.3 — there the transformation is linear but not a translation, and its Jacobian is the whole story. □

Corollary 106.36 (Change of variables inverts)**.** *For an invertible linear change of Grassmann variables $\theta'_i = A_{ij}\theta_j$,*

$$\mathrm{d}^n\theta' = (\det A)^{-1}\mathrm{d}^n\theta\,, \tag{106.50}$$

the determinant appearing with the opposite *power to the ordinary case.*

Rests on Definition 106.34 and Theorem 106.35.

Derivation. *Derives Corollary 106.36.*

Only the top monomial survives an n-fold integration, so the rule is fixed by $\int \mathrm{d}^n\theta'\,\theta'_1\cdots\theta'_n = 1$. Expanding, $\theta'_1\cdots\theta'_n = A_{1j_1}\cdots A_{nj_n}\theta_{j_1}\cdots\theta_{j_n} = (\det A)\,\theta_1\cdots\theta_n$, since reordering the θ's into canonical order produces the sign of the permutation and the sum over permutations with signs is the Leibniz formula for the determinant. To keep the normalization, $\mathrm{d}^n\theta'$ must carry $(\det A)^{-1}$. □

Theorem 106.37 (The Grassmann Gaussian is a determinant)**.** *Let $\theta_i, \bar\theta_i$, $i = 1,\dots,n$, be independent Grassmann generators, with the convention $\int \mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i\;\theta_i\bar\theta_i = 1$. Then for any $n\times n$ matrix A,*

$$\int \prod_{i=1}^{n} \mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i\;\exp\!\Big(-\bar\theta_i A_{ij}\theta_j\Big) = \det A\,, \tag{106.51}$$

to be compared with the bosonic $\int \mathrm{d}^n x\,\mathrm{e}^{-x^{\mathsf T}Ax/2} = (2\pi)^{n/2}(\det A)^{-1/2}$ of Equation (106.7). With sources,

$$\int \prod_{i} \mathrm{d}\bar\theta_i\,\mathrm{d}\theta_i\;\exp\!\Big(-\bar\theta A\theta + \bar\eta\theta + \bar\theta\eta\Big) = \det A\;\exp\!\Big(\bar\eta A^{-1}\eta\Big)\,. \tag{106.52}$$

Rests on Equation (106.7) and Theorem 106.35.

Derivation. *Derives Theorem 106.37.*

Expand the exponential. Because each generator squares to zero, the only term that survives the $2n$-fold integration is the one containing each of $\theta_1,\dots,\theta_n$ and each of $\bar\theta_1,\dots,\bar\theta_n$ exactly once, namely

$$\frac{(-1)^n}{n!}\Big(\bar\theta_i A_{ij}\theta_j\Big)^n = (-1)^n\sum_{\sigma\in S_n} A_{1\sigma(1)}\cdots A_{n\sigma(n)}\,\bar\theta_1\theta_{\sigma(1)}\cdots\bar\theta_n\theta_{\sigma(n)}\,,$$

the $n!$ cancelling against the $n!$ orderings of the identical factors. Reordering each $\bar\theta_k\theta_{\sigma(k)}$ pair into the canonical order $\theta_k\bar\theta_k$ produces $\operatorname{sgn}(\sigma)$ together with $(-1)^n$, and the surviving sum is $\sum_\sigma \operatorname{sgn}(\sigma)\prod_k A_{k\sigma(k)} = \det A$. The sourced version follows by the shift $\theta \to \theta + A^{-1}\eta$, $\bar\theta \to \bar\theta + \bar\eta A^{-1}$, which is legitimate by Theorem 106.35(ii) and has unit Jacobian, being a translation. □

Equation (106.51) and Equation (106.7) differ in exactly one place — the sign of the exponent of the determinant — and every distinctive feature of fermions in the path integral follows from it.

The fermion determinant

Proposition 106.38 (Integrating out the fermions)**.** *For a Dirac field coupled to a gauge field A_μ with the Lagrangian density $\mathcal{L}_\psi = \bar\psi(\mathrm{i}\hbar c\,\gamma^\mu D_\mu - mc^2)\psi$ of Equation (100.5),*

$$\int \mathcal{D}\bar\psi\,\mathcal{D}\psi\ \exp\!\left\{\frac{\mathrm{i}}{\hbar c}\int \mathrm{d}^4x\ \bar\psi(\mathrm{i}\hbar c\gamma^\mu D_\mu - mc^2)\psi\right\}\ \propto\ \det(\mathrm{i}\hbar\gamma^\mu D_\mu - mc)\ , \tag{106.53}$$

the constant of proportionality being field-independent. Each entry of the operator carries the dimension of a momentum, so the determinant must be normalized against its free value to be a number; only ratios appear in physical quantities.

Rests on Equations (100.5) *and* (106.51)*.*

Derivation. *Derives Proposition 106.38.*

The exponent is $\mathrm{i}S/\hbar$ with $S = c^{-1}\int \mathrm{d}^4x\,\mathcal{L}_\psi$, which is a Grassmann bilinear $-\bar\psi\mathcal{A}\psi$ with $\mathcal{A} = -(\mathrm{i}/\hbar c)(\mathrm{i}\hbar c\gamma^\mu D_\mu - mc^2) = -(\mathrm{i}/\hbar)(\mathrm{i}\hbar\gamma^\mu D_\mu - mc)$ after extracting the common factor c. Apply Equation (106.51) mode by mode: the answer is $\det\mathcal{A}$, and the field-independent factors $-\mathrm{i}/\hbar$ per mode contribute an infinite but A-independent constant, absorbed into the normalization. □

Corollary 106.39 (The minus sign of a closed fermion loop)**.** *Write $\det\mathcal{A} = \exp\operatorname{tr}\ln\mathcal{A}$ and expand in powers of the gauge field. The resulting contribution to the effective action is $-\mathrm{i}\hbar\operatorname{tr}\ln\mathcal{A}$, whereas a boson of the same coupling gives $+\frac{\mathrm{i}\hbar}{2}\operatorname{tr}\ln$ by Equation (106.7). Hence every closed fermion loop carries a factor (-1) relative to the corresponding boson loop, together with a Dirac trace — which is rule five of Proposition 100.14, here derived rather than imposed.*

Rests on Proposition 106.38 and Equations (106.7) *and* (106.37)*.*

Derivation. *Derives Corollary 106.39.*

By Proposition 106.38, integrating out the fermions contributes $\det\mathcal{A}$ to Z, hence $\operatorname{tr}\ln\mathcal{A}$ to $\ln Z$ and $-\mathrm{i}\hbar\operatorname{tr}\ln\mathcal{A}$ to W by Equation (106.37). Expanding $\operatorname{tr}\ln(\mathcal{A}_0+\delta\mathcal{A}) = \operatorname{tr}\ln\mathcal{A}_0 + \sum_{k\ge1}\frac{(-1)^{k+1}}{k}\operatorname{tr}\big[(\mathcal{A}_0^{-1}\delta\mathcal{A})^k\big]$ produces, at order k, a single trace around a closed chain of k propagators and k vertices: a one-loop diagram with k external legs. For a real boson the same manipulation applied to $(\det)^{-1/2}$ gives $+\frac12\operatorname{tr}\ln$, so the fermion loop differs by the factor $-2\times\frac12 = -1$ per loop and by the appearance of a Dirac trace, the boson having no spinor index. The factor $1/2$ absent in the fermionic case is the symmetry factor of a loop of a real field, which a complex fermion loop does not have because its two orientations are distinct. □

Remark 106.40 (Quenching, and why it was abandoned)*.* The determinant Equation (106.53) is a non-local functional of the gauge field: changing a link far away changes it. Early lattice computations therefore replaced it by a constant — the *quenched* approximation, equivalent to omitting all internal quark loops — because the cost of evaluating it repeatedly exceeded the machines of the time by orders of magnitude. The approximation is not controlled: it has no small parameter, its error was estimated empirically at ten to twenty percent for typical hadronic quantities, and in some channels it is qualitatively wrong, since a quenched theory has no two-particle thresholds from sea quarks and hence a different analytic structure. It is no longer used for results that are quoted with error bars; the computation of Section 106.5.2 includes the determinant of two degenerate light flavours and one strange flavour [2122]. Squaring the determinant of the degenerate pair is what keeps the Euclidean weight positive, which is the practical form of Remark 106.15.

106.3.4 The effective action

Definition 106.41 (Effective action)**.** Let $\phi_c(x) := c\,\delta W/\delta J(x) = \langle\phi(x)\rangle_J$ be the field expectation value in the presence of the source. The effective action is the Legendre transform

$$\Gamma[\phi_c] := W[J] - \frac{1}{c}\int \mathrm{d}^4x\; J(x)\phi_c(x)\,, \tag{106.54}$$

with J eliminated in favour of ϕ_c. It has the dimension of an action, J s.

The construction is Jona-Lasinio's [1286], who introduced it precisely to have a functional whose stationary points locate the vacuum: a symmetry of the action that is not a symmetry of the minimising ϕ_c is a symmetry broken by the state and not by the dynamics, which is the situation Chapter 104 turns into masses.

Proposition 106.42 (The quantum equation of motion)**.**

$$\frac{\delta\Gamma}{\delta\phi_c(x)} = -\frac{1}{c}J(x)\,, \tag{106.55}$$

so that in the absence of a source the physical field configurations are the stationary points of Γ*, exactly as the classical ones are the stationary points of* S*.*

Rests on Equation (106.54)*.*

Derivation. *Derives Proposition 106.42.*

Vary Equation (106.54) with respect to ϕ_c, allowing J to vary with it:

$$\delta\Gamma = \int \mathrm{d}^4x\left[\frac{\delta W}{\delta J}\,\delta J - \frac{1}{c}\phi_c\,\delta J - \frac{1}{c}J\,\delta\phi_c\right] = -\frac{1}{c}\int \mathrm{d}^4x\; J\,\delta\phi_c\,,$$

the first two terms cancelling by the definition of ϕ_c. □

Theorem 106.43 (The effective action generates 1PI vertices)**.** *Write* $W_{x_1\cdots x_n}$ *and* $\Gamma_{x_1\cdots x_n}$ *for the functional derivatives of* W *with respect to* J *and of* Γ *with respect to* ϕ_c*. Then*

$$\int \mathrm{d}^4z\; W_{xz}\,\Gamma_{zy} = -\frac{1}{c^2}\,\delta^4(x-y)\,, \tag{106.56}$$

so Γ_{xy} *is, up to the factor* $-c^{-2}$*, the inverse of the full connected propagator; and*

$$W_{xyz} = c^3\int \mathrm{d}^4a\,\mathrm{d}^4b\,\mathrm{d}^4d\; W_{xa}W_{yb}W_{zd}\,\Gamma_{abd}\,, \tag{106.57}$$

so the connected three-point function is the third derivative of Γ *dressed with a full propagator on each leg. In general the* n*-th derivative of* Γ *is the amputated one-particle-irreducible* n*-point vertex.*

Rests on Definition 106.41 and Equation (106.55)*.*

Derivation. *Derives Theorem 106.43.*

By definition $\phi_c = c\,\delta W/\delta J$ and, by Equation (106.55), $J = -c\,\delta\Gamma/\delta\phi_c$. The two are inverse maps, so by the chain rule

$$\delta^4(x-y) = \int \mathrm{d}^4z\;\frac{\delta\phi_c(x)}{\delta J(z)}\,\frac{\delta J(z)}{\delta\phi_c(y)} = \int \mathrm{d}^4z\;(cW_{xz})(-c\Gamma_{zy})\,,$$

which is Equation (106.56). Differentiate it with respect to $J(w)$, using $\delta/\delta J(w) = c\int \mathrm{d}^4u\; W_{uw}\,\delta/\delta\phi_c(u)$:

$$\int \mathrm{d}^4z\; W_{xzw}\Gamma_{zy} = -c\int \mathrm{d}^4z\,\mathrm{d}^4u\; W_{xz}W_{uw}\Gamma_{zyu}\,.$$

Contract with $-c^2 W_{yb}$ and integrate over y; the left-hand side collapses by Equation (106.56) to W_{xbw}, and the right-hand side becomes $c^3 \int W_{xz} W_{by} W_{wu} \Gamma_{zyu}$, which is Equation (106.57) after renaming.

A connected three-point function with a full propagator removed from each external leg cannot be cut into two pieces by severing one internal line, since any such cut would isolate one external leg and the piece so isolated is precisely the propagator already amputated. Hence Γ_{abd} is one-particle irreducible. Differentiating Equation (106.57) once more produces

$$W_4 = c^4 \Big[WWWW\,\Gamma_4 + (\text{three channels}) WWWWW\,\Gamma_3 \Gamma_3 \Big] ,$$

in which the second group of terms is exactly the set of one-particle-*reducible* tree graphs built from two cubic vertices joined by one full propagator. The pattern repeats: at each order the new derivative of Γ supplies the irreducible part and the terms generated by differentiating the propagators supply all the reducible trees. Induction on n gives the general statement. □

Theorem 106.43 is what makes Γ the practical object. Since it generates the irreducible vertices and the exact propagator, knowing Γ is knowing the theory: every connected amplitude is assembled from it by tree graphs alone.

The loop expansion of Γ

Theorem 106.44 (One loop)**.**

$$\Gamma[\phi_c] = S[\phi_c] + \frac{\mathrm{i}\hbar}{2}\,\operatorname{tr}\ln\left(\frac{\delta^2 S}{\delta\phi\,\delta\phi}\Big|_{\phi=\phi_c} \right) + O(\hbar^2) , \tag{106.58}$$

so the classical action is the tree approximation to Γ *and the first quantum correction is one power of* $\hbar$ *smaller, in accord with Theorem 106.30.*

Rests on Equations (106.7)*,* (106.54) *and* (106.55)*.*

Derivation. Derives Theorem 106.44.

Combining Equations (106.35), (106.37) and (106.54),

$$\exp\!\left(\frac{\mathrm{i}}{\hbar}\Gamma[\phi_c]\right) = \int \mathcal{D}\phi\, \exp\!\left\{ \frac{\mathrm{i}}{\hbar}\left(S[\phi] - \frac{1}{c}\int \mathrm{d}^4x\, \frac{\delta\Gamma}{\delta\phi_c}\,(\phi-\phi_c) \right) \right\} ,$$

using Equation (106.55) to eliminate J. Substitute $\phi = \phi_c + \sqrt{\hbar}\,\chi$ and expand:

$$S[\phi_c + \sqrt{\hbar}\chi] = S[\phi_c] + \sqrt{\hbar}\int \frac{\delta S}{\delta\phi}\chi + \frac{\hbar}{2}\iint \chi\,\frac{\delta^2 S}{\delta\phi\delta\phi}\,\chi + O(\hbar^{3/2}) .$$

At order $\sqrt{\hbar}$ the term linear in χ cancels against the source term, because $\delta\Gamma/\delta\phi_c = \delta S/\delta\phi_c + O(\hbar)$; what remains is a Gaussian integral over χ, evaluated by Equation (106.7) in the form $(\det)^{-1/2} = \exp(-\tfrac{1}{2}\operatorname{tr}\ln)$. Multiplying by $\hbar/\mathrm{i}$ to extract Γ turns $-\tfrac{1}{2}\operatorname{tr}\ln$ into $+\tfrac{\mathrm{i}\hbar}{2}\operatorname{tr}\ln$, which is Equation (106.58). The substitution $\phi = \phi_c + \sqrt{\hbar}\chi$ is what makes the $\hbar$ counting automatic: each additional vertex in the expansion brings $\hbar^{1/2}$ per field beyond the second, and the Gaussian contractions pair them up. □

The effective potential For a constant ϕ_c the effective action reduces to a function of one variable. Writing $V_4 = \int \mathrm{d}^4x$,

$$\Gamma[\phi_c] = -\frac{V_4}{c}\,U(\phi_c) , \tag{106.59}$$

which defines the effective potential U, of dimension $\mathrm{J/m^3}$; at tree level U is the classical potential $U_0 = \tfrac{1}{2}(mc/\hbar)^2\phi_c^2 + \tfrac{g}{4!}\phi_c^4$.

Proposition 106.45 (One-loop effective potential)**.** *Define the field-dependent mass* $M(\phi_c)$ *by* $(Mc/\hbar)^2 = (mc/\hbar)^2 + \frac{g}{2}\phi_c^2$*. Then, in the minimal-subtraction scheme of Definition 100.54 at renormalization energy* $\mathcal{E}$*,*

$$U_1(\phi_c) = \frac{(Mc^2)^4}{64\pi^2(\hbar c)^3}\left[\ln\frac{(Mc^2)^2}{\mathcal{E}^2} - \frac{3}{2}\right], \tag{106.60}$$

of dimension $\mathrm{J/m^3}$ *as required, since* $(Mc^2)^4/(\hbar c)^3$ *is an energy divided by a volume.*
Rests on Equations (106.58) and (106.59) and Lemma 100.28.

Derivation. *Derives Proposition 106.45.*

By Equation (106.58) the one-loop term is $\frac{\mathrm{i}\hbar}{2}\operatorname{tr}\ln\mathcal{K}_\phi$ with $\mathcal{K}_\phi = -(\Box + M^2c^2/\hbar^2)$ read off from the second variation of Equation (106.32). For a translation-invariant kernel the trace is $V_4\int \mathrm{d}^4p\,(2\pi\hbar)^{-4}$ of the momentum-space symbol, so

$$\Gamma_1 = \frac{\mathrm{i}\hbar V_4}{2}\int\frac{\mathrm{d}^4p}{(2\pi\hbar)^4}\,\ln\frac{p^2 - M^2c^2 + \mathrm{i}\epsilon}{\hbar^2},$$

and Equation (106.59) gives $U_1 = -c\Gamma_1/V_4$. Rotate by Proposition 106.14, $\mathrm{d}^4p = \mathrm{i}\,\mathrm{d}^4p_E$ and $p^2 = -p_E^2$:

$$U_1 = \frac{\hbar c}{2}\int\frac{\mathrm{d}^4p_E}{(2\pi\hbar)^4}\,\ln\frac{p_E^2 + M^2c^2}{\hbar^2},$$

up to a field-independent constant. The integral is quartically divergent and is evaluated in $d = 4 - 2\varepsilon$ dimensions by Lemma 100.28. Writing $\Lambda^2 = M^2c^2$ for the mass-squared parameter, the standard d-dimensional result is

$$\int\frac{\mathrm{d}^dp_E}{(2\pi)^d}\,\ln(p_E^2 + \Lambda^2) = -\frac{1}{(4\pi)^{d/2}}\,\frac{(\Lambda^2)^{d/2}}{\Gamma(1)}\,\Gamma\!\left(-\frac{d}{2}\right),$$

Γ here denoting the Euler gamma function and not the effective action. Expanding its pole at $d = 4$ by Lemma 100.29 and discarding that pole together with the $-\gamma_{\mathrm{E}} + \ln 4\pi$ which accompanies it — the definition of minimal subtraction, Equation (100.75) — leaves $(\Lambda^2)^2[\ln(\Lambda^2/\mu^2) - 3/2]/(32\pi^2)$. Restoring the $\hbar^{-4}$ of the measure and the prefactor $\hbar c/2$ gives Equation (106.60) with $\mathcal{E} = \mu c$. □

The physical content of Equation (106.60) is Coleman and Weinberg's [1495]: a theory whose classical potential has its minimum at the origin can have its *effective* potential minimized away from it, so that a symmetry unbroken classically is broken by radiative corrections alone. The mechanism is real and is used in Chapter 104 as one of the two possible origins of a scalar expectation value; whether it is the origin of the electroweak one is settled by measurement, and the measured Higgs and top masses say that it is not. The one-loop potential also generates the vacuum-stability question of that chapter, since Equation (106.60) turns negative at large field when the fermion loops dominate.

Remark 106.46 (The exact effective potential is convex). The one-loop potential can have two minima; the exact one cannot have the shape between them that Equation (106.60) suggests. In the Euclidean formulation $W[J]$ is a convex functional of J, because

$$\frac{\delta^2 W_E}{\delta J(x)\delta J(y)} \propto \langle\phi(x)\phi(y)\rangle - \langle\phi(x)\rangle\,\langle\phi(y)\rangle$$

is a covariance matrix, hence positive semidefinite — and it is positive by reflection positivity Equation (106.30). The Legendre transform of a convex function is convex, so Γ, and with it U, is convex exactly. The apparent non-convex region between two degenerate minima is therefore replaced in the exact theory by the straight segment joining them —

the Maxwell equal-area construction, the same object that replaces the unphysical loop of the van der Waals isotherm in Chapter 123. Physically, a constrained expectation value ϕ_c intermediate between the two minima is realized not by a homogeneous state of that field value but by a mixture — domains of one vacuum and of the other, in the proportion that gives the average. The loop expansion does not see this because it expands about a single homogeneous configuration. The non-convex one-loop potential is nonetheless the right object for computing the physics of a single phase, which is what it is used for in Chapter 104; the convexity statement is about a question the loop expansion was not asked.

106.3.5 The LSZ reduction formula

The path integral computes time-ordered correlation functions of fields. Experiments measure the probabilities of scattering processes. Lehmann, Symanzik and Zimmermann supplied the bridge [1073], and its content is that the S-matrix lives in the poles of the correlators.

Proposition 106.47 (Källén–Lehmann representation)**.** *For an interacting scalar theory the exact two-point function is*

$$\widetilde{\Delta}(p) = \frac{\mathrm{i}\hbar^3 c Z}{p^2 - m^2c^2 + \mathrm{i}\epsilon} + \int_{(2mc)^2}^{\infty} \mathrm{d}s\, \rho(s)\, \frac{\mathrm{i}\hbar^3 c}{p^2 - s + \mathrm{i}\epsilon}\,, \tag{106.61}$$

where m is the physical mass of the one-particle state, s is a squared momentum, $\rho \geq 0$ is the spectral density of the multiparticle continuum, and the field-strength renormalization *$Z = |\langle 0|\,\phi(0)\,|p\rangle|^2 \,/\, |\langle 0|\,\phi_{\mathrm{free}}(0)\,|p\rangle|^2$ is a dimensionless number with $0 \leq Z \leq 1$.*

Rests on Theorem 106.20 and Equation (106.30).

Derivation. *Derives Proposition 106.47.*

Insert a complete set of eigenstates of the four-momentum operator between the two fields in $\langle 0|\,T\phi(x)\phi(y)\,|0\rangle$. Poincaré invariance and the spectrum condition (Theorem 105.34) organize them into the vacuum, which contributes only $|\langle 0|\,\phi\,|0\rangle|^2$ and is removed by normal-ordering the field; the one-particle states of mass m, whose contribution is fixed by Lorentz invariance to be that of a free field of mass m times a constant Z; and states whose invariant mass is at least $2m$, summarized by a density $\rho(s) \geq 0$ supported on $s \geq (2mc)^2$. The positivity of ρ is the positivity of the Hilbert-space norm, i.e. Equation (106.30) once more, and the sum of all contributions must reproduce the canonical equal-time commutator, which gives $Z + \int \rho = 1$ and hence $Z \leq 1$. □

Theorem 106.48 (LSZ reduction)**.** *Let $\widetilde{G}_n(p_1, \dots, p_n)$ be the momentum-space connected correlator of n fields, all momenta incoming. Then the S-matrix element for the process in which the momenta with $p_k^0 < 0$ are incoming particles and the rest outgoing is*

$$\mathrm{i}\mathcal{M}\,(2\pi\hbar)^4 \delta^4\!\left(\textstyle\sum_k p_k\right) = \lim_{p_k^2 \to m^2c^2} \prod_{k=1}^{n} \frac{p_k^2 - m^2c^2}{\mathrm{i}\hbar^3 c\sqrt{Z}}\; \widetilde{G}_n(p_1, \dots, p_n)\,, \tag{106.62}$$

that is: put each external leg on its mass shell, divide out the full propagator, and take one factor $\sqrt{Z}$ off each leg.

Rests on Proposition 106.47.

Derivation. *Derives Theorem 106.48.*

Consider the dependence of $\widetilde{G}_n$ on one momentum p_1. By Proposition 106.47 applied to the leg carrying p_1, the correlator has a simple pole at $p_1^2 = m^2c^2$ whose residue is $\mathrm{i}\hbar^3 c Z$ times the matrix element of the remaining fields between the vacuum and the one-particle state $|p_1\rangle$, divided by $\sqrt{Z}$ — one factor of $\sqrt{Z}$ being consumed by the overlap $\langle 0|\,\phi(0)\,|p_1\rangle$ and the other remaining in the residue. Multiplying by $(p_1^2 - m^2c^2)$ and taking the limit isolates that residue and discards the multiparticle continuum, which has only a branch cut

starting at $(2mc)^2$ and is regular at the pole. Repeating for each leg replaces every field by an asymptotic one-particle state; what remains between them is by definition the S-matrix element, which carries the overall momentum-conserving delta function.

The physical statement behind the algebra is that an asymptotic particle is a pole in a correlation function, and nothing else: the interacting field ϕ need not create a one-particle state cleanly, and generically it creates a superposition of one-particle and multiparticle states. The prescription discards the second because it is analytically distinguishable from the first. □

Corollary 106.49 (Any interpolating field will do)**.** *Let $\mathcal{O}(x)$ be any local operator with the quantum numbers of the particle and with $\langle 0|\,\mathcal{O}(0)\,|p\rangle \neq 0$. Then Equation (106.62) holds with ϕ replaced by $\mathcal{O}$ and $\sqrt{Z}$ replaced by $\langle 0|\,\mathcal{O}(0)\,|p\rangle$ appropriately normalized, and the S-matrix element obtained is the same.*

Rests on Theorem 106.48 and Equation (106.61).

Derivation. Derives Corollary 106.49.

The derivation above used only two properties of ϕ: that it is local, so the spectral decomposition Equation (106.61) applies to it; and that it has non-zero overlap with the one-particle state, so the pole is present. Any $\mathcal{O}$ with those properties has the same pole at $p^2 = m^2c^2$, differing only in its residue, and the prescription divides that residue out. The S-matrix element is a property of the states, not of the operator used to reach them. □

Corollary 106.49 is why lattice computations may use whatever operator is numerically convenient to create a proton — any gauge-invariant combination of three quark fields with the right quantum numbers — and still measure the same mass. It is also the reason the composite pion field and the quark bilinear $\bar{d}\gamma^5 u$ give the same $\pi \to \mu\nu$ amplitude, which the weak-interaction phenomenology of Chapter 101 takes for granted. The scattering formalism into which Equation (106.62) feeds is Chapter 86, and the analyticity assumptions under which the pole structure used here is guaranteed belong to Chapter 109.

106.4 Gauge fields

106.4.1 Faddeev–Popov ghosts

Notation for the non-abelian case

Notation 106.50 (Absorbing the coupling into the potential). Let T^a be Hermitian generators of a compact simple Lie group with $\left[T^a, T^b\right] = \mathrm{i} f^{abc} T^c$ and $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ (Section 14.3). Write

$$\mathcal{A}_\mu := \frac{g}{\hbar} A^a_\mu T^a\,, \qquad [\mathcal{A}_\mu] = 1/\mathrm{m}\,, \tag{106.63}$$

so that the covariant derivative is $D_\mu = \partial_\mu + \mathrm{i}\mathcal{A}_\mu$ — which for one abelian generator is exactly Equation (100.9) with $\mathcal{A}_\mu = QA_\mu/\hbar$ for a field of charge Q — and the field strength is

$$\mathcal{F}_{\mu\nu} := \frac{1}{\mathrm{i}}\,[D_\mu, D_\nu] = \partial_\mu \mathcal{A}_\nu - \partial_\nu \mathcal{A}_\mu + \mathrm{i}\,[\mathcal{A}_\mu, \mathcal{A}_\nu]\,, \qquad [\mathcal{F}_{\mu\nu}] = 1/\mathrm{m}^2\,. \tag{106.64}$$

The Yang–Mills Lagrangian density is then

$$\mathcal{L}_{\mathrm{YM}} = -\frac{\hbar c}{2\hat{g}^2}\,\mathrm{tr}(\mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu}) = -\frac{\hbar c}{4\hat{g}^2}\,\mathcal{F}^a_{\mu\nu}\mathcal{F}^{a\,\mu\nu}\,, \tag{106.65}$$

of dimension $\mathrm{J/m^3}$, since $\hbar c = 3.161\,53 \times 10^{-26}\,\mathrm{J\,m}$ and $\mathcal{F}^2$ carries $1/\mathrm{m}^4$. The number $\hat{g}^2$ is the *dimensionless* coupling,

$$\hat{g}^2 := 4\pi\alpha_s\,, \tag{106.66}$$

in exact parallel with Equation (100.3): for electromagnetism $\hat{g}^2 = \mu_0 c e^2/\hbar = 4\pi\alpha$ by Equation (100.4), $\mathcal{F}_{\mu\nu} = eF_{\mu\nu}/\hbar$, and Equation (106.65) collapses to $-F_{\mu\nu}F^{\mu\nu}/4\mu_0$, which is Equation (100.12). For the strong interaction α_s is the running coupling measured in Equation (102.47). Infinitesimal gauge transformations are

$$\delta\mathcal{A}_\mu = D_\mu\omega := \partial_\mu\omega + \mathrm{i}\,[\mathcal{A}_\mu, \omega]\ , \tag{106.67}$$

with $\omega = \omega^a T^a$ dimensionless ($\omega^a = g\Lambda^a/\hbar$ in the notation of Equation (100.8)).

Every formula of this section is therefore free of g and $\hbar$ except through the single dimensionless number $\hat{g}^2$, and the factor $\hbar c/\hat{g}^2$ multiplying the action. That is not a retreat into natural units: $\mathcal{A}$, $\mathcal{F}$ and ω have been given SI dimensions above, and the action $S_{\mathrm{YM}} = c^{-1}\int \mathrm{d}^4x\,\mathcal{L}_{\mathrm{YM}} = -\hbar\hat{g}^{-2}\int \mathrm{d}^4x\,\mathcal{F}^a_{\mu\nu}\mathcal{F}^{a\mu\nu}/4$ carries J s because $\hbar$ stands in front of a dimensionless integral. It is precisely this form that makes $S/\hbar$ visibly equal to a pure number divided by $\hat{g}^2$, which is the origin of the $\mathrm{e}^{-8\pi^2/\hat{g}^2}$ of Section 106.6.1.

The redundancy, and the divergence it causes Section 100.1.3 showed that the quadratic form of the photon action is singular: $\widetilde{M}_{\mu\nu}p^\nu = 0$ in Equation (100.15). In the functional integral the same fact appears as an infinite factor.

Proposition 106.51 (The naive integral diverges by the volume of the gauge group)**.** *The integrand of $\int \mathcal{D}\mathcal{A}\,\mathrm{e}^{\mathrm{i}S_{\mathrm{YM}}/\hbar}$ is constant along each gauge orbit $\{\mathcal{A}^\omega : \omega \in \mathcal{G}\}$, so the integral contains an overall factor equal to the volume of the group $\mathcal{G}$ of gauge transformations — an infinite constant, independent of the physics but not factorizable in the presence of sources, since the source term is not gauge invariant.*

Rests on Equations (106.65) and (106.67).

Derivation. Derives Proposition 106.51.

S_{YM} is invariant under Equation (106.67) by construction, and the measure $\mathcal{D}\mathcal{A}$ is invariant because Equation (106.67) is, at each point, a translation of $\mathcal{A}_\mu$ by $\partial_\mu\omega$ plus a rotation in the adjoint index, and both preserve the Lebesgue measure on the fibre. The integral therefore factorizes as $\left(\int_{\mathcal{G}} \mathcal{D}\omega\right) \times \left(\int_{\mathcal{A}/\mathcal{G}} \mathrm{e}^{\mathrm{i}S/\hbar}\right)$, the first factor being the divergent volume. □

Faddeev and Popov's device [1347] is to insert a resolution of unity that selects one representative from each orbit and supplies the Jacobian of that choice.

Theorem 106.52 (Faddeev–Popov)**.** *Let $G^a[\mathcal{A}](x)$ be a gauge-fixing function — for the covariant family, $G^a = \partial^\mu\mathcal{A}^a_\mu$ — such that $G^a[\mathcal{A}^\omega] = \sigma^a$ has exactly one solution ω on each orbit. Then*

$$\int \mathcal{D}\mathcal{A}\,\mathrm{e}^{\mathrm{i}S_{\mathrm{YM}}/\hbar} = \left(\int_{\mathcal{G}} \mathcal{D}\omega\right)\int \mathcal{D}\mathcal{A}\,\delta\big[G[\mathcal{A}] - \sigma\big]\,\det\mathcal{M}[\mathcal{A}]\,\mathrm{e}^{\mathrm{i}S_{\mathrm{YM}}/\hbar}\,, \tag{106.68}$$

with the Faddeev–Popov operator

$$\mathcal{M}^{ab}(x,y) = \left.\frac{\delta G^a[\mathcal{A}^\omega](x)}{\delta\omega^b(y)}\right|_{\omega=0} = \partial^\mu\left(D_\mu\right)^{ab}\delta^4(x-y)\,, \qquad \left(D_\mu\right)^{ab} = \delta^{ab}\partial_\mu + f^{abc}\mathcal{A}^c_\mu\,, \tag{106.69}$$

for the covariant gauge condition; the sign of the second term is fixed by $\left[T^a, T^b\right] = \mathrm{i}f^{abc}T^c$ together with $D_\mu = \partial_\mu + \mathrm{i}\mathcal{A}_\mu$ and is derived below. The divergent factor now stands outside and cancels in every normalized expectation value.

Rests on Proposition 106.51 and Equation (106.67).

Derivation. *Derives Theorem 106.52.*

For each $\mathcal{A}$ define $\Delta[\mathcal{A}]$ by

$$\Delta[\mathcal{A}]^{-1} := \int_{\mathcal{G}} \mathcal{D}\omega \; \delta\big[G[\mathcal{A}^{\omega}] - \sigma\big] \, .$$

By hypothesis the delta functional is supported at a single ω_*, and the one-dimensional identity $\int \mathrm{d}x \, \delta(f(x)) = |f'(x_*)|^{-1}$ generalizes to $\Delta[\mathcal{A}] = |\det(\delta G/\delta\omega)|_{\omega_*} = |\det \mathcal{M}|$. Also Δ is gauge invariant, since $\mathcal{D}\omega$ is a left- and right-invariant Haar measure on $\mathcal{G}$ and the defining integral is unchanged by relabelling the orbit representative. Insert $1 = \Delta[\mathcal{A}] \int \mathcal{D}\omega \, \delta[G[\mathcal{A}^{\omega}] - \sigma]$ into the left-hand side of Equation (106.68), exchange the order of integration, and change variables $\mathcal{A} \to \mathcal{A}^{-\omega}$; the action, the measure and Δ are all invariant, so the ω integral factorizes out as the group volume and what remains is the right-hand side.

For the covariant condition, $G^a[\mathcal{A}^{\omega}] = \partial^{\mu}(\mathcal{A}^a_{\mu} + (D_{\mu}\omega)^a)$ by Equation (106.67), whose derivative with respect to ω^b is $\partial^{\mu}(D_{\mu})^{ab}$, i.e. Equation (106.69). The component form of the adjoint covariant derivative follows from $\mathrm{i}\,[\mathcal{A}_{\mu}, \omega] = \mathrm{i}\mathcal{A}^c_{\mu}\omega^b \mathrm{i} f^{cba} T^a = -f^{cba}\mathcal{A}^c_{\mu}\omega^b T^a$, and $f^{cba} = -f^{bca} = -f^{abc}$ by total antisymmetry and cyclicity, so that $(D_{\mu}\omega)^a = \partial_{\mu}\omega^a + f^{abc}\mathcal{A}^c_{\mu}\omega^b$ — the plus sign of Equation (106.69). Equivalently, the adjoint generators are $(T^a_{\mathrm{adj}})^{bc} = -\mathrm{i}f^{abc}$, as they are for SU(3) in Proposition 14.55, and $\delta^{bc}\partial_{\mu} + \mathrm{i}\mathcal{A}^a_{\mu}(T^a_{\mathrm{adj}})^{bc} = \delta^{bc}\partial_{\mu} + f^{abc}\mathcal{A}^a_{\mu}$ is the same operator with the summed index moved by one cyclic step. □

Corollary 106.53 (Why electrodynamics has no ghosts)**.** *For an abelian group $f^{abc} = 0$, so $\mathcal{M} = \partial^{\mu}\partial_{\mu} = \Box$ is independent of $\mathcal{A}$; $\det \mathcal{M}$ is then a constant that cancels between numerator and denominator, and the Faddeev–Popov procedure reduces to the gauge-fixing term Equation (100.16) alone. This is the derivation of a fact that Section 100.1.3 could only assert.*

Rests on Theorem 106.52 and Equations (100.16) and (106.69).

Exponentiating the determinant: ghosts The delta functional is inconvenient and the determinant is not a local object. Both are repaired at once, and it is Section 106.3.3 that repairs them.

Theorem 106.54 (The gauge-fixed action)**.** *Averaging Equation (106.68) over the arbitrary function σ with the Gaussian weight $\exp\{-\frac{\mathrm{i}}{2\hat{g}^2\xi}\int \mathrm{d}^4x \, \sigma^a\sigma^a\}$ — dimensionless, since σ carries $1/\mathrm{m}^2$ — and writing the determinant as a Grassmann integral by Equation (106.51) gives*

$$Z = \int \mathcal{D}\mathcal{A}\,\mathcal{D}\bar{c}\,\mathcal{D}c \; \exp\!\Big\{\frac{\mathrm{i}}{\hbar}(S_{\mathrm{YM}} + S_{\mathrm{gf}})\Big\} \exp\!\Big\{-\int \mathrm{d}^4x \; \bar{c}^a (\partial^{\mu} D_{\mu})^{ab} c^b\Big\} \, , \tag{106.70}$$

with

$$S_{\mathrm{gf}} = -\frac{\hbar}{2\hat{g}^2\xi}\int \mathrm{d}^4x \; (\partial^{\mu}\mathcal{A}^a_{\mu})^2 \, , \tag{106.71}$$

the R_{ξ} family, ξ dimensionless. The ghost *fields $c^a, \bar{c}^a$ are anticommuting, carry dimension $1/\mathrm{m}$, are scalars under the Lorentz group, and transform in the adjoint representation of the gauge group.*

Rests on Equations (106.51) and (106.68) and Lemma 106.2.

Derivation. *Derives Theorem 106.54.*

The left-hand side of Equation (106.68) does not depend on σ, so it may be averaged over σ with any normalized weight; the Gaussian one converts $\delta[G - \sigma]$ into $\exp(\mathrm{i}S_{\mathrm{gf}}/\hbar)$ with S_{gf} as stated, by Lemma 106.2. The determinant is written as a Grassmann integral by reading Equation (106.51) from right to left with $A = \mathcal{M}$ — and it is worth noting that this is the one place in physics where the exponent of a determinant being $+1$ rather than $-\frac{1}{2}$ decides the statistics of a field: the Jacobian sits in the numerator, so the field

that represents it must be the one whose Gaussian integral gives det and not $(\det)^{-1/2}$, i.e. an anticommuting one, by Theorem 106.37. The ghosts are spin-zero fields obeying Fermi statistics, which is why they cannot be physical: they violate the spin–statistics connection of Chapter 83.

Written as a single exponent $\mathrm{i}S_{\mathrm{tot}}/\hbar$, the ghost term is $S_{\mathrm{gh}} = \mathrm{i}\hbar \int \mathrm{d}^4x\, \bar{c}^a (\partial^\mu D_\mu)^{ab} c^b$, whose explicit factor of i records that the ghost action is not real. Nothing is wrong: an action is required to be real only when its exponential must be a phase for physical configurations, and the ghosts have no physical configurations. The dimension assignment follows from requiring the exponent in Equation (106.70) to be a pure number: $\int \mathrm{d}^4x$ supplies m^4, $\partial^\mu D_\mu$ supplies $1/\mathrm{m}^2$, so $\bar{c}c$ must supply $1/\mathrm{m}^2$. □

Proposition 106.55 (Ghosts are required by unitarity)**.** *In a non-abelian theory the ghost loop is not optional. Cutting a one-loop gluon self-energy diagram with the covariant polarization sum $-\eta^{\mu\nu}$ counts four intermediate polarizations where the physical theory has two; the ghost loop, carrying (-1) by Corollary 106.39 and running over a pair $(c, \bar{c})$, subtracts exactly the two unphysical ones, and the optical theorem is restored.*

Rests on Theorem 106.54 and Corollary 106.39.

Derivation. *Derives Proposition 106.55.*

A massless vector of momentum k has two physical transverse polarizations, whose sum is $\sum_{\lambda=1,2} \varepsilon^\mu_{(\lambda)} \varepsilon^{*\nu}_{(\lambda)} = -\eta^{\mu\nu} + (k^\mu n^\nu + n^\mu k^\nu)/(k\cdot n)$ for a lightlike auxiliary n. In a covariant gauge the propagator supplies $-\eta^{\mu\nu}$, which is the same object plus the longitudinal and timelike pair; those two do not cancel of their own accord when the external current is not conserved, and in a non-abelian theory it is not conserved diagram by diagram, because the gluon carries colour and its own current is only covariantly conserved. The discrepancy is a two-state contribution of positive norm. The ghost loop supplies two scalar states (c and $\bar{c}$) with the sign (-1) of a closed anticommuting loop, i.e. -2 states, which cancels it identically. The all-orders statement — that the cancellation holds to every order and for every process — is the Kugo–Ojima quartet mechanism of Section 106.4.2, and it is a theorem about the BRST cohomology rather than a diagrammatic accident. □

The same construction can be reached from the Hamiltonian side. Gauge invariance makes the Yang–Mills Lagrangian singular in Dirac's sense: the momentum conjugate to $\mathcal{A}_0$ vanishes identically, so the system carries first-class constraints and its quantization requires the Dirac-bracket apparatus of Chapter 26. Carrying that programme through and then integrating out the non-dynamical components reproduces Equation (106.70), ghosts and all. The functional route is shorter and manifestly covariant, which is why it is the one used; the Hamiltonian route is what shows that the answer is not an artefact of the trick.

106.4.2 BRST symmetry

The gauge-fixed action Equation (106.70) is not gauge invariant — that was the point of fixing the gauge. Becchi, Rouet and Stora [1518, 1571], and independently Tyutin [1564], found that it retains an exact global symmetry whose parameter is anticommuting, and that this residual symmetry carries everything the lost gauge invariance was doing.

Definition 106.56 (The BRST operator)**.** Introduce the auxiliary Nakanishi–Lautrup field $B = B^a T^a$, of dimension $1/\mathrm{m}^2$, and define a Grassmann-odd derivation s by

$$s\mathcal{A}_\mu = D_\mu c\,, \qquad sc = -\mathrm{i}c^2\,, \qquad s\bar{c} = B\,, \qquad sB = 0\,, \tag{106.72}$$

where $c = c^a T^a$, $\bar{c} = \bar{c}^a T^a$, and $c^2 = \tfrac{1}{2}\{c, c\}$ is non-zero because the components anticommute while the matrices do not. On a matter field ψ transforming in a representation R, $s\psi = -\mathrm{i}c\psi$. The operator acts on products by $s(XY) = (sX)Y + (-1)^{|X|}X(sY)$.

Theorem 106.57 (Nilpotency)**.** $s^2 = 0$ *on every field of Equation* (106.72)*.*
Rests on Equation (106.72)*.*

Derivation. *Derives Theorem 106.57.*

On the ghost: $s^2 c = -\mathrm{i}\big[(sc)c - c(sc)\big] = -\mathrm{i}\big[(-\mathrm{i}c^2)c - c(-\mathrm{i}c^2)\big] = -c^3 + c^3 = 0$, the sign in the middle being that of s passing the odd c. Associativity of matrix multiplication has done here exactly the work that the Jacobi identity does in component notation, which is the reason for writing the algebra in matrix form.

On the connection, expand $s^2\mathcal{A}_\mu = s(\partial_\mu c + \mathrm{i}\,[\mathcal{A}_\mu, c])$. Since $\mathcal{A}$ is even and c odd, $s\,[\mathcal{A}_\mu, c] = \{s\mathcal{A}_\mu, c\} + [\mathcal{A}_\mu, sc]$, so

$$s^2\mathcal{A}_\mu = \partial_\mu(sc) + \mathrm{i}\,\{D_\mu c, c\} + \mathrm{i}\,[\mathcal{A}_\mu, sc]\ .$$

Insert $sc = -\mathrm{i}c^2$ and use $\partial_\mu(c^2) = \{\partial_\mu c, c\}$ and $\{[\mathcal{A}_\mu, c]\,, c\} = [\mathcal{A}_\mu, c^2]$:

$$s^2\mathcal{A}_\mu = -\mathrm{i}\,\{\partial_\mu c, c\} + \mathrm{i}\,\{\partial_\mu c, c\} - \Big[\mathcal{A}_\mu, c^2\Big] + \Big[\mathcal{A}_\mu, c^2\Big] = 0\,.$$

On $\bar c$ and B nilpotency is immediate from $sB = 0$. Since s is a derivation and vanishes on the square of every generator, $s^2 = 0$ on any polynomial in the fields. □

Theorem 106.58 (The gauge-fixing sector is BRST-exact)**.** *With the gauge fermion*

$$\Psi = -\frac{\hbar}{\hat g^2}\int \mathrm{d}^4x\ \bar c^a\left(\partial^\mu \mathcal{A}^a_\mu - \frac{\xi}{2}B^a\right)\,, \tag{106.73}$$

the total action is

$$S_{\mathrm{tot}} = S_{\mathrm{YM}} + s\Psi\,, \tag{106.74}$$

and $sS_{\mathrm{tot}} = 0$*, since* S_{YM} *is gauge invariant and* $s^2 = 0$*.*
Rests on Equations (106.71) *and* (106.72) *and Theorem 106.57.*

Derivation. *Derives Theorem 106.58.*

Applying s to Equation (106.73) and using Equation (106.72),

$$s\Psi = -\frac{\hbar}{\hat g^2}\int \mathrm{d}^4x\left[B^a\left(\partial^\mu\mathcal{A}^a_\mu - \frac{\xi}{2}B^a\right) - \bar c^a\,\partial^\mu(D_\mu c)^a\right]\,,$$

the sign of the second term coming from s passing the odd $\bar c$. The auxiliary field is algebraic and may be integrated out, its equation of motion being $B^a = \partial^\mu\mathcal{A}^a_\mu/\xi$; the first bracket then becomes $(\partial^\mu\mathcal{A}^a_\mu)^2/2\xi$ and, with the prefactor, is exactly S_{gf} of Equation (106.71). The second term is $+(\hbar/\hat g^2)\int \mathrm{d}^4x\,\bar c^a\partial^\mu(D_\mu c)^a$, which enters the weight $\exp(\mathrm{i}S_{\mathrm{tot}}/\hbar)$ as $\exp\big[(\mathrm{i}/\hat g^2)\int \bar c\,\partial^\mu D_\mu c\big]$, whereas Equation (106.70) carries $\exp\big[-\int \bar c\,\partial^\mu D_\mu c\big]$. The two differ by the constant factor $-\mathrm{i}/\hat g^2$ multiplying the ghost bilinear, and are brought into coincidence by rescaling the pair, $c \mapsto \kappa c$ *and* $\bar c \mapsto \kappa\bar c$ with $\kappa^2 = \mathrm{i}\hat g^2$. It must be the pair and not one against the other: the ghosts enter only through the product $\bar c c$, so a rescaling $c \mapsto \kappa c$, $\bar c \mapsto \bar c/\kappa$ leaves the ghost term exactly as it was and cannot fix a normalization. The rescaling used here multiplies the Grassmann measure by a field-independent constant, by Corollary 106.36, which cancels between numerator and denominator in every normalized expectation value — equivalently, $\det(\lambda\mathcal{M}) = \lambda^n \det\mathcal{M}$ and only ratios of determinants are ever used. Finally $sS_{\mathrm{YM}} = 0$ because s acts on $\mathcal{A}$ as a gauge transformation with parameter c, and $s(s\Psi) = s^2\Psi = 0$ by Theorem 106.57. □

Definition 106.59 (BRST charge and physical states)**.** Let Q_B be the conserved charge generating s through the graded commutator, $sX = \mathrm{i}\hbar^{-1}\,[Q_B, X]_\pm$; nilpotency of s makes $Q_B^2 = 0$. A state is *physical* when it is annihilated by Q_B, and two physical states differing by Q_B applied to something are identified:

$$\mathcal{H}_{\mathrm{phys}} := \frac{\ker Q_B}{\mathrm{im}\,Q_B}\,. \tag{106.75}$$

The construction is the standard one for any nilpotent operator: Q_B is a differential, $\ker Q_B / \operatorname{im} Q_B$ its cohomology, and the physical Hilbert space is a cohomology class rather than a subspace. The differential-geometric setting in which that pattern is usually met — connections and curvature on a principal bundle — belongs to Section 14.6, which at present fixes the notation used by Theorem 14.111 and leaves the underlying definitions owed. Two facts make the construction work, and both are checkable.

Proposition 106.60 (The quartet mechanism)**.** *The unphysical modes of a gauge field organize into quartets: for each colour and momentum, the longitudinal and timelike polarizations together with the ghost and antighost form a set of four states on which Q_B acts by mapping two into the other two. Every such quartet contributes zero to any matrix element between states of* $\ker Q_B$*, so unphysical states cancel in pairs [1641].*

Rests on Equation (106.72) *and Definition 106.59.*

Derivation. *Derives Proposition 106.60.*

From Equation (106.72) the free-field limit of the transformations is $s\mathcal{A}_\mu = \partial_\mu c$, $sc = 0$, $s\bar{c} = B$, $sB = 0$: the ghost c is Q_B-closed and maps the longitudinal polarization; the antighost $\bar{c}$ maps onto B, which is the timelike combination on shell. So among the four states $\{\mathcal{A}_L, \mathcal{A}_0, c, \bar{c}\}$, two are Q_B-exact and two are not Q_B-closed. A physical state, being Q_B-closed, has zero inner product with a Q_B-exact one (since $\langle \Phi | Q_B \Lambda \rangle = \langle Q_B \Phi | \Lambda \rangle = 0$ by the hermiticity of Q_B), and the states that are not Q_B-closed are excluded from $\mathcal{H}_{\text{phys}}$ by definition. Hence the quartet decouples entirely, leaving the two transverse polarizations, which is Proposition 106.55 at all orders. The inner product induced on $\mathcal{H}_{\text{phys}}$ is therefore positive definite and the S-matrix restricted to it is unitary [1641]. □

Theorem 106.61 (Gauge-parameter independence)**.** *Any expectation value of a Q_B-closed operator is independent of the gauge parameter ξ and of the choice of gauge-fixing function altogether.*

Rests on Equation (106.74) *and Theorem 106.58.*

Derivation. *Derives Theorem 106.61.*

By Equation (106.74) the entire dependence on the gauge-fixing choice is in Ψ. Let $\mathcal{O}$ satisfy $s\mathcal{O} = 0$ and vary $\Psi \to \Psi + \delta\Psi$. Then

$$\delta \langle \mathcal{O} \rangle = \frac{\mathrm{i}}{\hbar} \langle \mathcal{O}\, s\, \delta\Psi \rangle = \frac{\mathrm{i}}{\hbar} \langle s(\mathcal{O}\, \delta\Psi) \rangle = 0 \,,$$

the second step because $s\mathcal{O} = 0$ and the last because the expectation value of a BRST variation vanishes: the measure and the action are s-invariant, so $\langle sX \rangle = 0$ for every X, by the same argument that gives a Ward identity from any symmetry of the functional integral. In particular the ξ-dependence of Equation (106.71) cancels out of every physical quantity, which is the checkable statement quoted at Equation (100.18). □

That is what BRST buys, and it is worth listing plainly because the formalism can look like machinery for its own sake. It supplies (i) a definition of the physical state space in a manifestly covariant gauge, Equation (106.75); (ii) a proof that the unphysical states decouple to all orders, Proposition 106.60; (iii) a one-line proof of gauge-parameter independence, Theorem 106.61, replacing an order-by-order diagrammatic check; and (iv) the functional identities of Section 106.4.3, which are what makes renormalizability provable. The generalization to gauge algebras that close only on shell is the antifield construction of Batalin and Vilkovisky [1664], in which s is generated by an antibracket and nilpotency becomes a master equation; it is not needed for the Standard Model, whose gauge algebra closes off shell, and it is mentioned here only because Section 106.4.3 states its identity in that language.

106.4.3 Slavnov–Taylor identities

Theorem 106.62 (Slavnov–Taylor)**.** *For every functional X of the fields,*

$$\langle sX \rangle = 0\,, \tag{106.76}$$

and the resulting relations among Green functions are the Slavnov–Taylor identities [1458, 1484]. In the abelian case they reduce to the Ward–Takahashi identity Equation (100.71).

Rests on Equations (106.70) and (106.72) and Theorem 106.58.

Derivation. *Derives Theorem 106.62.*

Change variables in Equation (106.70) by an infinitesimal BRST transformation with a constant anticommuting parameter ζ: $\Phi \to \Phi + \zeta\, s\Phi$ for every field Φ. The action is invariant by Theorem 106.58. The measure is invariant too, and this requires proof rather than assertion: the Jacobian of the transformation is $\det(1 + \zeta\, \partial(s\Phi)/\partial\Phi) = 1 + \zeta\ \mathrm{tr}(\partial(s\Phi)/\partial\Phi)$ with a sign for each Grassmann direction, and the bosonic and fermionic traces cancel — the $\mathcal{A}$–c block against the c–c block — because s maps a boson to a ghost and a ghost to a ghost bilinear with matched coefficients. (This cancellation is exactly what fails for a chiral rotation of the fermion measure, and its failure is the anomaly of Section 106.7.3; a gauge anomaly is the statement that it fails here too, and Section 106.7.4 is the condition that it does not.) With action and measure invariant, the integral of a total BRST variation vanishes, which is Equation (106.76).

In the abelian case the ghosts decouple by Corollary 106.53 and Equation (106.72) collapses to $s\mathcal{A}_\mu = \partial_\mu c$ with c a free field, so that a BRST variation is a gauge transformation whose parameter is an anticommuting constant times that free field. Taking $X = \bar{c}(y)\,\psi(x_1)\bar{\psi}(x_2)$ then turns Equation (106.76) into the relation between the vertex function and the inverse propagator, $q_\mu \Gamma^\mu(p', p) = S^{-1}(p') - S^{-1}(p)$, whose derivation is carried out in full at Theorem 100.48. □

Corollary 106.63 (The Zinn-Justin equation)**.** *Coupling sources K^μ_a, L_a to the composite operators $s\mathcal{A}^a_\mu$ and sc^a and Legendre-transforming as in Definition 106.41, the whole family Equation (106.76) collapses into the single bilinear equation*

$$\int \mathrm{d}^4x \left[\frac{\delta\Gamma}{\delta K^\mu_a} \frac{\delta\Gamma}{\delta \mathcal{A}^a_\mu} + \frac{\delta\Gamma}{\delta L_a} \frac{\delta\Gamma}{\delta c^a} \right] = 0\,, \tag{106.77}$$

which is the statement that the effective action is BRST invariant with the quantum-corrected transformation law.

Rests on Definition 106.41, Equation (106.76), and Theorem 106.57.

Derivation. *Derives Corollary 106.63.*

Add to the action the terms $\int \mathrm{d}^4x\, (K^\mu_a\, s\mathcal{A}^a_\mu + L_a\, sc^a)$. They are BRST invariant by Theorem 106.57, since s applied to them gives $K\, s^2\mathcal{A} + L\, s^2 c = 0$, so the extended action is still s-invariant and Equation (106.76) still holds. Take $X = \Phi$ for each field in turn: the resulting identities say that W is annihilated by the operator $\int \mathrm{d}^4x\, [(\delta W/\delta K^\mu_a)(\delta/\delta j^a_\mu) + \cdots]$ acting on the sources. Legendre-transforming in the field variables only — K and L are carried along untouched, so that $\delta\Gamma/\delta K = \delta W/\delta K$ — converts the source derivatives into field derivatives of Γ and produces Equation (106.77). The equation is bilinear in Γ because the composite operators $s\mathcal{A}$ and sc are themselves products of two fields, so their sources cannot be eliminated linearly. □

The identities do three jobs. First, they constrain the divergences: the counterterms needed to renormalize a gauge theory must themselves satisfy Equation (106.77), which forces the gauge coupling appearing in the three-gluon, four-gluon, ghost and matter vertices to renormalize by the same factor — the non-abelian generalization of $Z_1 = Z_2$

(Corollary 100.49). Without that, a single coupling constant would not stay single, and the theory would not be renormalizable with finitely many parameters. This is the role the identities play in 't Hooft's proof [1448, 1449], completed with the dimensional-regularization technique that respects them [1463] — and the fact that dimensional regularization respects gauge invariance, where a momentum cutoff does not, is why Definition 100.30 is the scheme of choice throughout this part.

Second, they give the practical check of Theorem 106.61: a physical quantity computed in Feynman gauge $\xi = 1$ and in Landau gauge $\xi = 0$ must agree, while the individual propagators and vertices do not. Every serious calculation in this part is done twice for that reason.

Third, they are the object that a gauge anomaly destroys, which is the subject of Section 106.7.4.

106.4.4 The Gribov ambiguity

Theorem 106.52 assumed that $G[\mathcal{A}^\omega] = \sigma$ has *exactly one* solution on each orbit. Gribov showed that for the Coulomb and Landau conditions it does not [1623].

Proposition 106.64 (Gribov copies exist)**.** *Let $\mathcal{A}$ satisfy the Landau condition $\partial^\mu \mathcal{A}_\mu = 0$. A gauge-equivalent field $\mathcal{A}^\omega$ satisfies the same condition, to first order in ω, if and only if*

$$\mathcal{M}^{ab}\omega^b = \partial^\mu (D_\mu)^{ab}\omega^b = 0\,, \tag{106.78}$$

i.e. if and only if the Faddeev–Popov operator has a normalizable zero mode. Since $\mathcal{M} = \Box + O(\mathcal{A})$ is positive for small $\mathcal{A}$ and its lowest eigenvalue decreases continuously as $\mathcal{A}$ grows, there is a surface in field space — the Gribov horizon *— on which the lowest eigenvalue first vanishes, and beyond it copies exist.*

Rests on Equations (106.67) and (106.69).

Derivation. Derives Proposition 106.64.

Under Equation (106.67), $\partial^\mu \mathcal{A}^\omega_\mu = \partial^\mu \mathcal{A}_\mu + \partial^\mu (D_\mu \omega)$, so preserving the condition requires Equation (106.78). In the Euclidean theory the Landau condition $\partial^\mu \mathcal{A}_\mu = 0$ makes $-\mathcal{M}$ Hermitian on square-integrable functions, with $-\mathcal{M}^{ab} = -\delta^{ab}\partial^2 - f^{abc}\mathcal{A}^{c\mu}\partial_\mu$ by Equation (106.69), so its spectrum is real; at $\mathcal{A} = 0$ it is the positive operator $-\partial^2$ on non-constant modes. As the amplitude of $\mathcal{A}$ is increased along any ray in field space the eigenvalues move continuously, and Gribov exhibited explicit configurations for which the lowest one crosses zero, at which point Equation (106.78) has a solution and the orbit meets the gauge-fixing surface again. □

The failure is therefore not perturbative: it occurs only for fields of amplitude of order $1/\hat{g}$, which is invisible to any finite order in $\hat{g}^2$. Everything computed in Sections 100.4 and 106.4.3 is unaffected. What is affected is any statement about the infrared behaviour of the non-abelian theory, which is where the large-amplitude configurations live.

Theorem 106.65 (Singer)**.** *For a non-abelian structure group there is no continuous gauge-fixing prescription that works globally: no continuous section of the principal bundle of gauge fields over the space of orbits exists, for gauge fields on S^4 or on S^3 [1626].*

Rests on Proposition 106.64.

Singer's statement is not about the particular choice $\partial^\mu \mathcal{A}_\mu = 0$; it says that *every* choice fails. The obstruction is topological: a gauge-fixing prescription is a section of the principal bundle whose base is the space of orbits, a principal bundle admits a global section if and only if it is trivial, and this one is not. Both statements are quoted here from [1626]; the bundle language they are written in belongs to Section 14.6, which so far carries only the notation that Theorem 14.111 needs and reserves the definition of a section itself. The

Faddeev–Popov construction is therefore a local construction that has been used globally, and Theorem 106.52 is exactly true only in a neighbourhood of $\mathcal{A} = 0$.

Two responses exist, and the honest position is that neither is closed.

Restrict the integration region. The *Gribov region* Ω is the set of transverse fields on which $\mathcal{M}$ is positive; it is convex and bounded in every direction, and every orbit meets it. It still contains copies, and the *fundamental modular region* $\Lambda \subset \Omega$, defined by minimizing $\int \mathrm{d}^4x\, \mathcal{A}^a_\mu \mathcal{A}^{a\mu}$ along the orbit, contains exactly one representative of each orbit except on its boundary. Restricting the functional integral to Ω modifies the infrared behaviour of the gluon propagator, and the two candidate answers in the literature — a propagator vanishing at zero momentum and one approaching a finite constant — correspond to different treatments of the boundary. Which is right is not settled.

Do not fix a gauge at all. On the lattice (Section 106.5.1) the integration variables are group elements and the group volume per link is finite, so Proposition 106.51 does not arise: the integral over gauge orbits contributes a finite constant and is simply left in. No gauge fixing means no Faddeev–Popov determinant, no ghosts and no Gribov copies. This is the strongest practical argument for the lattice formulation, and it is why the results of Section 106.5.2 are free of the ambiguity entirely.

Derivation pending #164

The Gribov horizon and Singer's obstruction: the derivation above establishes the criterion — a copy exists exactly when the Faddeev–Popov operator acquires a normalizable zero mode — and states that configurations reaching it exist. Gribov's explicit spherically symmetric family, the proof that the Gribov region is convex and bounded, and Singer's theorem that the bundle of gauge fields over the orbit space admits no continuous global section are stated here and not proved; all three belong in Appendix A.

106.5 The lattice

106.5.1 Wilson's lattice gauge theory

Everything so far has been perturbative, and Proposition 106.31 showed that perturbation theory cannot be the definition of the theory. Wilson supplied a definition [1537]: replace Euclidean spacetime by a finite hypercubic lattice of spacing a, so that the functional integral becomes an ordinary integral of finite dimension, and choose the variables so that gauge invariance is exact at finite a rather than only in the limit.

Definition 106.66 (Link variables and the plaquette)**.** Let the sites be $x = an$, $n \in \mathbb{Z}^4$. The dynamical variable on the link from n to $n + \hat{\mu}$ is the group element

$$U_\mu(n) = \exp\!\left[\mathrm{i}a\, \mathcal{A}^a_\mu \left(n + \tfrac{1}{2}\hat{\mu}\right) T^a\right] \in G\,, \tag{106.79}$$

dimensionless because $\mathcal{A}$ carries $1/\mathrm{m}$ by Equation (106.63) — the same product $\mathcal{A} \cdot \mathrm{d}x$ that appeared as the Aharonov–Bohm phase in Equation (106.13). The elementary closed loop, the *plaquette*, is

$$U_p = U_\mu(n)\, U_\nu(n+\hat{\mu})\, U^\dagger_\mu(n+\hat{\nu})\, U^\dagger_\nu(n)\,. \tag{106.80}$$

Proposition 106.67 (Exact gauge invariance at finite spacing)**.** *Under* $U_\mu(n) \mapsto \Omega(n) U_\mu(n) \Omega^\dagger(n+\hat{\mu})$ *with* $\Omega(n) \in G$ *arbitrary at each site, the trace of any closed loop of links is invariant. In particular* $\operatorname{tr} U_p$ *is invariant.*

Rests on Definition 106.66 and Equation (106.80).

Derivation. *Derives Proposition 106.67.*

Each link carries Ω at its start and $\Omega^\dagger$ at its end, so in a product of links forming a path the factors at every interior site cancel, $\Omega^\dagger(m)\Omega(m) = 1$. For a closed path the two remaining factors sit at the same site and are removed by the cyclicity of the trace. □

This is the decisive structural point. The gauge field lives in the *group*, not in the algebra, and gauge invariance is therefore an exact symmetry of a finite-dimensional integral rather than a property that survives only in the continuum. There is no gauge fixing, hence no Faddeev–Popov determinant, no ghosts and — as Section 106.4.4 noted — no Gribov problem: the volume of the gauge group is $(\mathrm{vol}\, G)^{\text{sites}}$, a finite constant.

Theorem 106.68 (The Wilson action and its continuum limit)**.** *Let*

$$S_W = \beta \sum_p \left(1 - \frac{1}{N} \Re\, \mathrm{tr}\, U_p\right), \qquad \beta = \frac{2N}{\hat{g}^2}, \tag{106.81}$$

the sum running over all plaquettes of the lattice, N the dimension of the fundamental representation, and β dimensionless. Then as $a \to 0$

$$S_W \longrightarrow \frac{1}{4\hat{g}^2} \int \mathrm{d}^4 x_E \; \mathcal{F}^a_{\mu\nu} \mathcal{F}^a_{\mu\nu} = \frac{S_E}{\hbar}, \tag{106.82}$$

with S_E the Euclidean Yang–Mills action of Equation (106.65). For SU(3)*, $\beta = 6/\hat{g}^2 = 6/(4\pi\alpha_s)$. This β is the lattice coupling and not the inverse temperature of Equation (106.27); under the dictionary of Table 106.1 it does play the role of an inverse temperature for the four-dimensional statistical system, which is why strong coupling is that system's high-temperature regime.*

Rests on Equations (106.64), (106.65) and (106.80).

Derivation. *Derives Theorem 106.68.*

Multiplying the four exponentials of Equation (106.80) and applying the Baker–Campbell–Hausdorff formula, the leading term of the exponent is the discrete curl of $\mathcal{A}$, so $U_p = \exp\!\left[\mathrm{i} a^2 \mathcal{F}_{\mu\nu} + O(a^3)\right]$ with $\mathcal{F}_{\mu\nu} = \mathcal{F}^a_{\mu\nu} T^a$ evaluated at the centre of the plaquette — this is the finite version of Equation (106.64), and the commutator term of Equation (106.64) arises here from the non-commutativity of the four link matrices. Expanding,

$$1 - \frac{1}{N} \Re\, \mathrm{tr}\, U_p = \frac{1}{2N}\, \mathrm{tr}\Big(a^2 \mathcal{F}_{\mu\nu}\Big)^2 + O(a^6) = \frac{a^4}{4N}\, \mathcal{F}^a_{\mu\nu} \mathcal{F}^a_{\mu\nu} + O(a^6),$$

with no sum over μ, ν, using $\mathrm{tr}(T^a T^b) = \tfrac{1}{2}\delta^{ab}$. The sum over plaquettes is a sum over sites and over $\mu < \nu$, which becomes $a^{-4} \int \mathrm{d}^4 x_E \, \tfrac{1}{2} \sum_{\mu\nu}$; hence $S_W \to (\beta/8N) \int \mathrm{d}^4 x_E \, \mathcal{F}^a_{\mu\nu} \mathcal{F}^a_{\mu\nu}$, and matching to Equation (106.82) gives $\beta = 2N/\hat{g}^2$. □

Remark 106.69 (A regulator, and a critical continuum limit)*.* Momenta on the lattice are bounded, $|p_\mu| \le \pi\hbar/a$, so the theory is finite: the spacing is an ultraviolet cutoff and no divergence occurs at any order. Recovering continuum physics requires the physical correlation length to be large in lattice units, $\xi/a \to \infty$, and by Equation (106.25) $\xi = \hbar/mc$, so $a \to 0$ at fixed physical mass means $mac/\hbar \to 0$: in the language of Table 106.1, the continuum limit is a second-order critical point of the four-dimensional statistical system defined by Equation (106.81). Asymptotic freedom says where that point is — at $\hat{g} \to 0$, i.e. $\beta \to \infty$ — and the rate of approach is fixed by the beta function of Chapter 108, which is what makes the extrapolation controlled rather than a guess.

Confinement as an area law

Definition 106.70 (Wilson loop)**.** For a closed contour C of links, $W(C) = \frac{1}{N}\,\langle \operatorname{tr} \prod_{\ell \in C} U_\ell \rangle$, the continuum form being the trace of the path-ordered exponential $\frac{1}{N}\,\big\langle \operatorname{tr} P \exp\!\big(\mathrm{i} \oint_C \mathcal{A}_\mu \mathrm{d}x^\mu\big)\big\rangle$.

Proposition 106.71 (The Wilson loop measures the static potential)**.** *For a rectangular contour of spatial extent R and Euclidean time extent τ, with $\tau \gg R/c$,*

$$W(R,\tau) \;\sim\; \exp\!\left[-\frac{V(R)\,\tau}{\hbar}\right], \tag{106.83}$$

where $V(R)$ is the energy of a static quark–antiquark pair at separation R. An area law*, $W \sim \exp[-\sigma R c\tau/(\hbar c)]$, is therefore equivalent to a linearly rising potential $V(R) = \sigma R$, i.e. to confinement; a* perimeter law *corresponds to a potential approaching a constant, i.e. to a screened, deconfined phase.*

Rests on Definition 106.70 and Proposition 106.17.

Derivation. *Derives Proposition 106.71.*

The two timelike sides of the rectangle are the parallel transporters that carry a static colour source forward in Euclidean time; the two spacelike sides create and annihilate the pair. By Proposition 106.17 the correlator of a creation and an annihilation operator separated by Euclidean time τ decays as $\mathrm{e}^{-E_0\tau/\hbar}$, with E_0 the lowest energy in the sector created — here the energy of the static pair, $V(R)$, measured from the vacuum. Substituting $A = Rc\tau$ for the enclosed area converts an exponential in the area into an exponential in $V\tau$ with $V = \sigma R$. Dimensions: σ carries N, so $\sigma A/(\hbar c)$ is dimensionless. □

Theorem 106.72 (Confinement at strong coupling)**.** *For $\beta \ll 1$ the Wilson loop of a planar rectangle obeys an area law. For* SU(N) *with $N \geq 3$,*

$$W(C) = \left(\frac{\beta}{2N^2}\right)^{A/a^2} \big[1 + O(\beta)\big], \qquad \sigma = \frac{\hbar c}{a^2}\,\ln\!\frac{2N^2}{\beta}, \tag{106.84}$$

A being the minimal area spanned by C. For SU(2) *every plaquette contributes twice as much,*

$$W(C) = \left(\frac{\beta}{4}\right)^{A/a^2} \big[1 + O(\beta)\big], \qquad \sigma = \frac{\hbar c}{a^2}\,\ln\!\frac{4}{\beta}, \tag{106.85}$$

and not the $\beta/2N^2 = \beta/8$ that Equation (106.84) would give: the fundamental representation of SU(2) *is pseudo-real, so U and $U^\dagger$ are not independent and the two orientations of a plaquette supply the same term rather than two different ones. The distinction is not academic here —* SU(2) *is the group of the measurement quoted in Section 106.5.2.*

Rests on Equations (106.81) and (106.83) and Theorem 5.153.

Derivation. *Derives Theorem 106.72.*

Expand e^{-S_W} in powers of β: for each plaquette, $\exp\!\big[(\beta/N)\Re\operatorname{tr} U_p\big] = 1 + \frac{\beta}{2N}\big(\operatorname{tr} U_p + \operatorname{tr} U_p^\dagger\big) + O(\beta^2)$. The integration is over independent Haar measures on each link, and the two identities that are needed are

$$\int \mathrm{d}U\; U_{ij} = 0\,, \qquad \int \mathrm{d}U\; U_{ij}\big(U^\dagger\big)_{kl} = \frac{1}{N}\delta_{il}\delta_{jk}\,,$$

the first because the integrand transforms in a non-trivial representation and the Haar measure is invariant, the second by Schur's first lemma (Theorem 5.153) applied to the invariant tensor. Every link of the contour must therefore be paired with a link of opposite orientation supplied by some plaquette; the cheapest way to do this is to tile the minimal surface spanned by C with A/a^2 plaquettes, each bringing $\beta/2N$ from the expansion and

each internal link contributing $1/N$ from the second identity. The single-plaquette case is exact and does the counting transparently:

$$\left\langle \tfrac{1}{N}\operatorname{tr} U_p \right\rangle = \frac{\beta}{2N}\cdot\frac{1}{N}\int \mathrm{d}U\ \operatorname{tr} U\ \operatorname{tr} U^{\dagger} + O(\beta^2) = \frac{\beta}{2N^2} + O(\beta^2)\,,$$

since $\int \mathrm{d}U\ \operatorname{tr} U \operatorname{tr} U^{\dagger} = \sum_{ij}\delta_{ij}\delta_{ij}/N = 1$. Iterating over the tiling gives Equation (106.84), and comparing with Equation (106.83) gives σ.

That counting used $\int \mathrm{d}U\, U_{ij}U_{kl} = 0$, i.e. $\int \mathrm{d}U\,(\operatorname{tr} U)^2 = 0$, which holds only when $\boldsymbol{N}\otimes\boldsymbol{N}$ contains no singlet. For $N \geq 3$ it splits into the symmetric and antisymmetric two-index representations and neither is trivial, so the identity holds. For SU(2), $\mathbf{2}\otimes\mathbf{2} = \mathbf{3}\oplus\mathbf{1}$ does contain the singlet, $\operatorname{tr} U$ is real, and orthogonality of characters gives $\int \mathrm{d}U\,(\operatorname{tr} U)^2 = 1$. The plaquette factor is then $(\beta/2N)(\operatorname{tr} U_p + \operatorname{tr} U_p^{\dagger}) = \frac{\beta}{2}\operatorname{tr} U_p$ and

$$\left\langle \tfrac{1}{2}\operatorname{tr} U_p \right\rangle = \frac{1}{2}\cdot\frac{\beta}{2}\int \mathrm{d}U\ (\operatorname{tr} U)^2 + O(\beta^2) = \frac{\beta}{4} + O(\beta^2)\,,$$

which is Equation (106.85): twice the value the generic formula assigns, hence $\ln(4/\beta)$ in place of $\ln(8/\beta)$ in the string tension. □

Remark 106.73 (What the strong-coupling result does and does not prove). Theorem 106.72 is a genuine derivation of confinement — of an area law with a computable string tension — but for the lattice theory at large $\hat{g}$, not for the continuum theory. The continuum limit lives at $\beta \to \infty$ (Remark 106.69), which is the opposite end, and the expansion Equation (106.84) says nothing about whether the area law survives to it. Worse, the expansion converges for compact U(1) too, and there confinement is known *not* to survive: the theory has a phase transition at intermediate β and its weak-coupling phase is ordinary massless electrodynamics. Whether SU(3) has such a transition — and the evidence is that it does not — is a question that only a numerical computation covering the whole range of β can answer, which is Section 106.5.2. The confinement of quarks remains, in the strict sense, unproved; what exists is a definition of the theory in which the question is well posed, and overwhelming numerical evidence about the answer.

For orientation, the customary phenomenological value of the string tension, obtained by matching the linear potential to the slope of the observed Regge trajectories, is $\sqrt{\sigma\hbar c} \approx 0.44\,\mathrm{GeV}$, i.e.

$$\sigma = \frac{(0.44\,\mathrm{GeV})^2}{\hbar c} \approx 1.6\times 10^{5}\,\mathrm{N}\,, \tag{106.86}$$

about the weight of sixteen tonnes, independent of separation. That number is the reason no free quark has been seen: separating a pair by one femtometre costs $\sigma\times 1\,\mathrm{fm} = 1.6\times10^{-10}\,\mathrm{J} \approx 1\,\mathrm{GeV}$, and by one metre would cost 10^{15} times more — long before which it is cheaper to create a quark–antiquark pair out of the vacuum and break the string.

Fermions on a lattice

Proposition 106.74 (Naive discretization doubles the species sixteen times)**.** *Replacing $\gamma^{\mu}\partial_{\mu}$ by the symmetric difference $\gamma^{\mu}[\psi(n+\hat{\mu}) - \psi(n-\hat{\mu})]/2a$ gives a momentum-space operator whose massless part is*

$$\widetilde{D}(p) = \frac{\mathrm{i}}{a}\sum_{\mu}\gamma^{\mu}\sin\!\left(\frac{ap_{\mu}}{\hbar}\right)\,, \tag{106.87}$$

which vanishes not only at $p_{\mu} = 0$ but at every corner of the Brillouin zone with $ap_{\mu}/\hbar \in \{0,\pi\}$: $2^4 = 16$ species where one was intended.

Rests on Definition 106.66 and Equation (100.5).

Derivation. *Derives Proposition 106.74.*

Fourier transform the difference operator: the shift $\psi(n \pm \hat{\mu})$ becomes $\mathrm{e}^{\pm \mathrm{i} a p_\mu/\hbar}\psi$, so the symmetric difference becomes $\mathrm{i}\sin(a p_\mu/\hbar)/a$, giving Equation (106.87). The propagator is $\widetilde{D}^{-1}$, and a pole occurs wherever $\widetilde{D}$ vanishes; $\sin(a p_\mu/\hbar) = 0$ has two solutions in the Brillouin zone $-\pi < a p_\mu/\hbar \le \pi$ for each of the four directions, hence 2^4 poles, each of which is a physical particle in the continuum limit. □

Theorem 106.75 (Nielsen–Ninomiya)**.** *No lattice Dirac operator can simultaneously (i) be local, (ii) possess the continuum chiral symmetry $\{D, \gamma^5\} = 0$, (iii) have the correct continuum limit, and (iv) describe a single species. One of the four must be given up [1673].*

Rests on Proposition 106.74.

The choices actually made are: Wilson's, which adds $-\frac{r a}{2}\partial^2$ to the operator, lifting the fifteen doublers to masses of order $\hbar/(ac)$ at the price of breaking chiral symmetry explicitly at finite a — the symmetry is recovered in the continuum limit, but only after an additive renormalization of the quark mass; and the staggered construction, which distributes the spinor components over the corners of a hypercube, retaining a remnant of chiral symmetry and reducing the doubling from sixteen to four. The computation of Section 106.5.2 uses the Wilson operator with smeared links [2122]. That a theorem of this kind exists at all is the sharpest illustration of the point made after Proposition 106.9: a discretization is a definition, and a symmetry of the classical Lagrangian need not survive it. Section 106.7.3 shows that for the axial symmetry the failure is not an artefact of any discretization but a property of the continuum theory itself, with a measured consequence.

Derivation pending #165

The Nielsen–Ninomiya theorem: the fermion doubling of the naive operator is derived above, but the no-go theorem itself — that no local, chirally symmetric, doubler-free operator exists, proved by counting the zeros of the energy–momentum relation as a topological invariant of the Brillouin torus — is stated and not proved here. It belongs in Appendix A.

106.5.2 Monte Carlo evidence

Why sampling, and why it works A lattice of $64^3 \times 128$ sites carries $33\,554\,432$ sites, $134\,217\,728$ links and, for SU(3) with eight parameters per link, about 1.1×10^9 real integration variables. No deterministic quadrature can touch an integral of that dimension: a product rule with k points per axis costs k^d evaluations. Monte Carlo integration does not degrade with dimension at all.

Proposition 106.76 (Importance sampling)**.** *Let configurations $\{U^{(i)}\}_{i=1}^{M}$ be drawn with probability proportional to $\mathrm{e}^{-S_E[U]/\hbar}$. Then*

$$\langle \mathcal{O} \rangle = \frac{\int \mathcal{D}U\; \mathcal{O}[U]\, \mathrm{e}^{-S_E/\hbar}}{\int \mathcal{D}U\; \mathrm{e}^{-S_E/\hbar}} = \lim_{M\to\infty} \frac{1}{M}\sum_{i=1}^{M} \mathcal{O}\big[U^{(i)}\big]\,, \tag{106.88}$$

with a statistical error falling as $M^{-1/2}$ independently of the dimension of the integral, by the central limit theorem.

Rests on Proposition 106.13 and Theorem 106.68.

Derivation. *Derives Proposition 106.76.*

The estimator is the sample mean of a random variable whose expectation is $\langle \mathcal{O} \rangle$ by construction, so it is unbiased; its variance is $\mathrm{Var}(\mathcal{O})/M$, and the central limit theorem gives the distribution of the error. Nothing in either statement refers to the dimension. What

replaces the dimension in the cost is the *autocorrelation* of the algorithm that generates the sample, since successive configurations are not independent. □

Two facts make Equation (106.88) legitimate, and both were established earlier in this chapter rather than assumed. Proposition 106.13 makes the weight real and positive, so that "probability proportional to $\mathrm{e}^{-S_E/\hbar}$" means something; and Remark 106.40 explains why the fermion determinant is included as $\det^2$ for the degenerate light pair, which keeps it positive. Where positivity fails — at non-zero baryon chemical potential — the method fails with it (Remark 106.15).

Confinement and asymptotic scaling Creutz's computation [1651] was the first to show that the lattice theory and the continuum theory are the same theory. He extracted the string tension of SU(2) gauge theory from ratios of Wilson loops,

$$\chi(I,J) = -\ln \frac{W(I,J)\,W(I-1,J-1)}{W(I-1,J)\,W(I,J-1)}\,, \tag{106.89}$$

a combination in which the perimeter and corner contributions cancel and only the area term survives, so that $\chi \to \sigma a^2/(\hbar c)$ for large loops. Measuring χ over a range of β, he found that it followed the asymptotic-freedom scaling law

$$\sqrt{\chi} \;\propto\; \exp\!\left[-\frac{4\pi^2\beta}{N b_0}\right], \qquad b_0 = \frac{11N}{3} - \frac{2n_f}{3}\,, \tag{106.90}$$

in which b_0 is the one-loop beta-function coefficient in the convention $\mu\,\mathrm{d}\hat{g}/\mathrm{d}\mu = -b_0\hat{g}^3/16\pi^2$ — $b_0 = 22/3$ for the pure SU(2) theory Creutz simulated, so that the exponent is $-3\pi^2\beta/11$. The exponent follows from $a\Lambda = \exp[-8\pi^2/(b_0\hat{g}^2)]$ with $\hat{g}^2 = 2N/\beta$, and the scaling law itself is the prediction of the renormalization group of Chapter 108 — that is, that the dimensionless lattice quantity ran with β exactly as a physical quantity held fixed in units of a continuum scale must. Confinement at strong coupling was already known from Theorem 106.72; what Creutz showed is that it persists into the region where the continuum limit is taken.

The hadron spectrum from three inputs

Phenomenon 106.77 (The light hadron spectrum is a prediction of QCD)**.** With the three free parameters of the light-quark sector fixed by three measured masses — those of the pion, the kaon and one baryon, which set the light-quark mass, the strange-quark mass and the overall scale — the Euclidean lattice path integral reproduces the masses of the remaining light hadrons, including the nucleon, to a few percent [2122]. Nothing else is put in: no potential, no constituent masses, no fitted form factors.

Rests on Equation (106.24)*, Corollary 106.49, and Proposition 106.17.*

Derivation. *Derives Phenomenon 106.77.*

The procedure is Equation (106.24) applied to a lattice correlator. Choose an interpolating operator $\mathcal{O}$ with the quantum numbers of the hadron — for the nucleon, a colour-singlet product of three quark fields; Corollary 106.49 guarantees that the choice does not affect the answer. Measure

$$C(\tau) = \left\langle \mathcal{O}(\tau)\,\mathcal{O}^\dagger(0)\right\rangle \underset{\tau\to\infty}{\longrightarrow} |\langle 0|\,\mathcal{O}\,|h\rangle|^2\;\mathrm{e}^{-m_h c^2\tau/\hbar}\,,$$

by Proposition 106.17, and read the mass off the exponential decay rate. Repeat at several lattice spacings, volumes and quark masses, and extrapolate.

The counting of inputs is what makes this a prediction rather than a fit. The Lagrangian of the light sector contains exactly three parameters that are not fixed by symmetry: $\hat{g}^2$,

the degenerate up–down mass, and the strange mass. Measuring m_π, m_K and one baryon mass fixes all three (the coupling enters only through the overall scale, by dimensional transmutation — Chapter 108). Every other hadron mass is then output. The masses to be reproduced include, from the shipped Particle Data Group compilation [2427], $m_p c^2 = 938.272\,\mathrm{MeV}$, $m_n c^2 = 939.565\,\mathrm{MeV}$, $m_\Lambda c^2 = 1115.683\,\mathrm{MeV}$ and $m_\Delta c^2 = (1232.0 \pm 2.0)\,\mathrm{MeV}$, together with the Σ, Ξ, Σ^*, Ξ^* and Ω; the computed values agree with all of them within the combined statistical and systematic uncertainties, which are at the level of a few percent [2122]. □

This is the strongest single piece of evidence that the quantization scheme of this chapter describes Nature and not merely a formal expansion. The perturbative successes of Chapter 100 test the theory where the coupling is small and the series is asymptotic; here the coupling is of order unity, no series is involved, and the answer still comes out right. It is also the answer to Remark 106.73: no phase transition intervenes between the strong-coupling region and the continuum limit, because if one did the spectrum would not come out.

Remark 106.78 (The systematics, and how they are quantified). A lattice result is not a measurement and its error budget is not statistical alone. Three systematic effects dominate, and each is controlled by computing at several values of the corresponding parameter and extrapolating rather than by estimating.

Finite spacing. The discretization error vanishes as a power of a — $O(a)$ for the unimproved Wilson operator, $O(a^2)$ after improvement. Computations are repeated at three or more spacings, in the range $a \approx 0.065 - -0.125\,\mathrm{fm}$ for [2122], and extrapolated to $a = 0$.

Finite volume. A box of side L with periodic boundaries distorts a hadron by the exchange of the lightest particle around the box, an effect falling as $\mathrm{e}^{-m_\pi c L/\hbar}$. The working rule is $m_\pi c L/\hbar \gtrsim 4$, i.e. $L \gtrsim 4\hbar/(m_\pi c)$, four reduced Compton wavelengths of the pion. At the physical charged-pion mass $m_\pi c^2 = 139.570\,39\,\mathrm{MeV}$ [2427] that wavelength is $\hbar c/(m_\pi c^2) = 1.414\,\mathrm{fm}$, so the rule demands $L \gtrsim 5.7\,\mathrm{fm}$ — a demanding box, which is why the requirement is usually met at a pion mass above the physical one, where the same rule costs less: at $m_\pi c^2 = 190\,\mathrm{MeV}$ it asks only for $L \gtrsim 4.2\,\mathrm{fm}$. The dependence is checked by running at two volumes.

Quark mass. Simulating at the physical light-quark mass is expensive because the algorithms slow down as the pion becomes light, so computations are done at larger masses and extrapolated using the functional form supplied by chiral perturbation theory. This was historically the largest uncertainty, and it is the one that has shrunk most as machines have grown.

Note that these are all controlled extrapolations in parameters the computation itself can vary, which is what distinguishes them from the uncontrolled quenched approximation of Remark 106.40. It is that difference, and not raw computer power, that turned lattice QCD from an illustration into a source of numbers with error bars.

106.6 Topology of the gauge vacuum

106.6.1 Instantons

The Euclidean action of Equation (106.82) has non-trivial finite-action stationary points, found by Belavin, Polyakov, Schwartz and Tyupkin [1539]. They contribute to the path integral factors of the form $\mathrm{e}^{-S_E/\hbar}$ which are invisible to every order of perturbation theory, and they are the mechanism by which the vacuum acquires structure.

Definition 106.79 (Topological charge)**.** For a Euclidean gauge field of finite action define the dual $\widetilde{\mathcal{F}}^a_{\mu\nu} = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}\mathcal{F}^a_{\rho\sigma}$ and

$$\nu := \frac{1}{32\pi^2}\int \mathrm{d}^4x_E\, \mathcal{F}^a_{\mu\nu}\widetilde{\mathcal{F}}^a_{\mu\nu} = \frac{1}{32\pi^2}\int \mathrm{d}^4x_E\, \epsilon_{\mu\nu\rho\sigma}\,\mathrm{tr}(\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma})\ , \tag{106.91}$$

dimensionless, since $\mathcal{F}$ carries $1/\mathrm{m}^2$ by Equation (106.64). This is the quantity denoted n in Equation (105.109), and the corresponding density $q(x) = (c/32\pi^2)\epsilon_{\mu\nu\rho\sigma}\,\mathrm{tr}(\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma})$, of dimension $1/(\mathrm{m}^3\,\mathrm{s})$, is the q of Definition 105.43.

Theorem 106.80 (Bogomolny bound and self-duality)**.** *For any Euclidean configuration,*

$$S_E \geq \frac{8\pi^2\hbar}{\hat{g}^2}\,|\nu|\ , \tag{106.92}$$

with equality if and only if the field is self-dual ($\mathcal{F} = \widetilde{\mathcal{F}}$, for $\nu > 0$) or anti-self-dual ($\mathcal{F} = -\widetilde{\mathcal{F}}$, for $\nu < 0$). A configuration saturating the bound with $\nu = 1$ is an instanton*, and its contribution to the path integral is weighted by*

$$\mathrm{e}^{-S_E/\hbar} = \exp\!\left(-\frac{8\pi^2}{\hat{g}^2}\right) = \exp\!\left(-\frac{2\pi}{\alpha_s}\right)\ , \tag{106.93}$$

which at $\alpha_s = 0.1180$ (Equation (102.47)) is 8×10^{-24} — a number with no expansion in powers of α_s at all.

Rests on Equations (106.82) *and* (106.91)*.*

Derivation. *Derives Theorem 106.80.*

The Euclidean action is $S_E = (\hbar/4\hat{g}^2)\int \mathrm{d}^4x_E\,\mathcal{F}^a_{\mu\nu}\mathcal{F}^a_{\mu\nu}$ by Equation (106.82), and the integrand is a sum of squares, hence non-negative. Consider

$$0 \leq \int \mathrm{d}^4x_E\ \left(\mathcal{F}^a_{\mu\nu} \mp \widetilde{\mathcal{F}}^a_{\mu\nu}\right)^2 = 2\int \mathrm{d}^4x_E\,\mathcal{F}^a_{\mu\nu}\mathcal{F}^a_{\mu\nu} \mp 2\int \mathrm{d}^4x_E\,\mathcal{F}^a_{\mu\nu}\widetilde{\mathcal{F}}^a_{\mu\nu}\,,$$

using $\widetilde{\mathcal{F}}\widetilde{\mathcal{F}} = \mathcal{F}\mathcal{F}$, which follows from $\epsilon_{\mu\nu\rho\sigma}\epsilon_{\mu\nu\alpha\beta} = 2(\delta_{\rho\alpha}\delta_{\sigma\beta} - \delta_{\rho\beta}\delta_{\sigma\alpha})$ in four Euclidean dimensions. Hence $\int \mathcal{F}\mathcal{F} \geq \left|\int \mathcal{F}\widetilde{\mathcal{F}}\right| = 32\pi^2\,|\nu|$ by Equation (106.91), with equality iff $\mathcal{F} = \pm\widetilde{\mathcal{F}}$. Multiplying by $\hbar/4\hat{g}^2$ gives Equation (106.92). A self-dual field automatically solves the Euclidean field equations, since $D_\mu\mathcal{F}_{\mu\nu} = D_\mu\widetilde{\mathcal{F}}_{\mu\nu} = 0$ by the Bianchi identity; self-duality, a first-order condition, therefore replaces the second-order equations of motion.

Numerically, $2\pi/0.1180 = 53.24$ and $\mathrm{e}^{-53.24} = 8\times10^{-24}$. □

Proposition 106.81 (The topological charge is an integer)**.** *Finiteness of the action forces $\mathcal{F}\to 0$ at infinity, hence $\mathcal{A}_\mu \to -\mathrm{i}\,g^{-1}\partial_\mu g$ for some map $g : S^3 \to G$ on the sphere at infinity. Then*

$$\nu = \frac{1}{24\pi^2}\int_{S^3} \mathrm{d}^3S_\mu\ \epsilon_{\mu\nu\rho\sigma}\ \mathrm{tr}\!\left(g^{-1}\partial_\nu g\ g^{-1}\partial_\rho g\ g^{-1}\partial_\sigma g\right)\ , \tag{106.94}$$

which is the degree of g as a map $S^3\to S^3$ — for $G = \mathrm{SU}(2)$, whose manifold is S^3 — and is therefore an integer.

Rests on Equations (14.155) *and* (106.91) *and Theorem 14.111.*

Derivation. *Derives Proposition 106.81.*

The integrand of Equation (106.91) is a total divergence, $\epsilon\,\mathrm{tr}(\mathcal{F}\mathcal{F}) = \partial_\mu K_\mu$ with the Chern–Simons current $K_\mu = 2\epsilon_{\mu\nu\rho\sigma}\,\mathrm{tr}(\mathcal{A}_\nu\partial_\rho\mathcal{A}_\sigma + \frac{2\mathrm{i}}{3}\mathcal{A}_\nu\mathcal{A}_\rho\mathcal{A}_\sigma)$; this is the transgression form of the second Chern class, and it is Equation (14.155) of Theorem 14.111 specialized to $r = 2$. The volume integral is therefore a surface integral over the sphere at infinity, where $\mathcal{A}$ is pure gauge; substituting $\mathcal{A}_\mu = -\mathrm{i}g^{-1}\partial_\mu g$ makes the first term of K_μ combine with the second into Equation (106.94).

That the resulting number is an integer is the degree theorem. Let y be a regular value of the smooth map $g : S^3 \to S^3$; its preimage is a finite set of points, and Equation (106.94) evaluates to the sum over those points of the sign of the Jacobian determinant of g, i.e. to the number of times g covers the target counted with orientation. That count is an integer, and it is unchanged under continuous deformation of g, since the preimages can only be created or destroyed in pairs of opposite sign. The map $g(x) = (x_4 + \mathrm{i}\,\boldsymbol{x}\cdot\boldsymbol{\tau})/|x|$, with $\boldsymbol{\tau}$ the Pauli matrices, covers $\mathrm{SU}(2) \cong S^3$ exactly once and has $\nu = 1$: it is the identity map, whose Jacobian is everywhere positive. □

Remark 106.82 (The dilute-gas approximation and its failure). Instantons come in a family: the classical equations are scale invariant, so a solution of size ρ costs the same action for every ρ. Integrating over the collective coordinates — position, size and global colour orientation — requires the determinant of the fluctuation operator about the instanton, computed by 't Hooft [1568]. The result is a density of instantons per unit four-volume of the form

$$\mathrm{d}n \;\propto\; \frac{\mathrm{d}\rho}{\rho^5}\,\left(\frac{1}{\hat{g}^2(\rho)}\right)^{2N} \exp\!\left(-\frac{8\pi^2}{\hat{g}^2(\rho)}\right),$$

in which the running of $\hat{g}$ with the scale $1/\rho$ turns the exponential into a power, ρ^{b_0} with $b_0 = 11N/3 - 2n_f/3$ the one-loop beta-function coefficient in the same convention as Equation (106.90), so that $8\pi^2/\hat{g}^2(\rho) = b_0 \ln(1/\rho\Lambda)$. For $\mathrm{SU}(3)$ with three light flavours $b_0 = 9$, so the density behaves as $\rho^4\mathrm{d}\rho$: the integral is dominated by *large* instantons, where the coupling is strong and the semiclassical approximation that produced the formula has failed. The honest conclusion is that the dilute-gas approximation is not a controlled calculation in QCD. What survives is the qualitative structure — the vacuum has topological sectors, they are populated, and the population is a non-perturbative effect — together with the one place where the counting is protected by an index theorem, which is Section 106.7.3. The quantitative statements about the topological susceptibility of the QCD vacuum come from the lattice, not from instanton calculus.

The physical use of all this in Chapter 102 is the mass of the η'. The nine light pseudoscalars would be the Goldstone bosons of a spontaneously broken $\mathrm{U}(3)_L \times \mathrm{U}(3)_R$, and eight of them — the pions, kaons and η — are light for that reason. The ninth is not: the singlet axial symmetry is broken by the anomaly of Section 106.7.1, and the topological configurations of this subsection are what make the anomaly have consequences rather than being a total derivative one can discard. That is the resolution of what was called the $\mathrm{U}(1)_A$ problem, and it is the reason the η' is heavier than the nucleon-scale expectation for a Goldstone boson.

Derivation pending #166

The instanton fluctuation determinant: the Bogomolny bound, the integrality of the winding number and the exponential weight are derived above, but the explicit self-dual solution of Belavin, Polyakov, Schwartz and Tyupkin and the one-loop determinant about it, which supply the measure over collective coordinates quoted in the dilute-gas remark, are not computed here. They belong in Appendix A.

106.6.2 Theta vacua

Proposition 106.83 (The vacuum is a superposition of winding sectors)**.** *Let $|n\rangle$ denote the state built on the classical vacuum of Chern–Simons number $n \in \mathbb{Z}$, and let T be the operator implementing a large gauge transformation, $T\,|n\rangle = |n+1\rangle$. Since T commutes with the Hamiltonian and with all local observables, the energy eigenstates are simultaneous*

eigenstates of T:

$$|\theta\rangle = \sum_{n\in\mathbb{Z}} \mathrm{e}^{\mathrm{i}n\theta}\,|n\rangle\ , \qquad T\,|\theta\rangle = \mathrm{e}^{-\mathrm{i}\theta}\,|\theta\rangle\ , \tag{106.95}$$

with $\theta \in [0, 2\pi)$ a superselection parameter: no local operator connects different θ [1573, 1582].

Rests on Proposition 106.81.

Derivation. *Derives Proposition 106.83.*

Gauge transformations that tend to the identity at infinity are generated by the Gauss constraint and act trivially on physical states. Those that tend to a non-trivial element — the *large* transformations, classified by Proposition 106.81 — are symmetries of the theory but are not required to act trivially, exactly as a translation by a lattice vector in a crystal is a symmetry that acts non-trivially on Bloch states. T is unitary and commutes with H, so H and T may be diagonalized together; the eigenvalues of a unitary operator with $T\,|n\rangle = |n+1\rangle$ are phases $\mathrm{e}^{-\mathrm{i}\theta}$, and the corresponding eigenvector is Equation (106.95). Because a local operator changes n by a finite amount, its matrix elements between $|\theta\rangle$ and $|\theta'\rangle$ are proportional to $\delta(\theta-\theta')$: the θ sectors are superselected and θ is a parameter of the theory, not a state to be chosen. □

Corollary 106.84 (The theta term)**.** *Working in the θ vacuum is equivalent to adding to the Lagrangian density*

$$\mathcal{L}_\theta = \theta\hbar\, q(x) = \frac{\theta\hbar c}{32\pi^2}\,\epsilon^{\mu\nu\rho\sigma}\ \mathrm{tr}(\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma})\ , \tag{106.96}$$

which is Equation (105.110), and which contributes the phase $\mathrm{e}^{\mathrm{i}\theta\nu}$ to the weight of a configuration of winding number ν.

Rests on Equation (106.95) and Definition 106.79.

Derivation. *Derives Corollary 106.84.*

Summing over sectors with the weights of Equation (106.95) inserts $\mathrm{e}^{\mathrm{i}n\theta}$ into the path integral for each topological class n. By Definition 106.79 that class is labelled by $\nu = \int \mathrm{d}t\,\mathrm{d}^3x\ q$, so the insertion is $\exp(\mathrm{i}\theta\int \mathrm{d}t\,\mathrm{d}^3x\,q) = \exp(\frac{\mathrm{i}}{\hbar}\cdot\frac{1}{c}\int \mathrm{d}^4x\ \theta\hbar q)$, which is the addition of Equation (106.96) to $\mathcal{L}$. That $\mathcal{L}_\theta$ has the dimension of an energy density follows from $[q] = 1/(\mathrm{m}^3\,\mathrm{s})$ and $[\hbar] = \mathrm{J\,s}$. □

Three consequences follow, and each is taken up elsewhere in this part rather than repeated here.

Baryon number is not conserved. The baryon and lepton currents of the Standard Model are anomalous in the sense of Section 106.7.1, with the topological density of Equation (106.91) of the $\mathrm{SU}(2)_L$ field on the right-hand side. Integrating gives $\Delta B = \Delta L = n_f\nu$ with $n_f = 3$ generations, which is Equation (105.103); $B-L$ is conserved. At zero temperature the transition rate carries the factor Equation (106.93) with α_W in place of α_s and is utterly negligible, but above the electroweak scale the barrier — the sphaleron of Equation (105.104) — can be crossed thermally and the rate is unsuppressed [1569, 1758]. This is how the Standard Model satisfies the first of Sakharov's conditions, Theorem 105.41.

The theta term violates P and CP. That Equation (106.96) is P-odd and T-odd is Proposition 105.44; that only the combination $\bar\theta = \theta + \arg\det M_q$ is physical, because a chiral rotation of the quark fields shifts θ through the non-invariance of the measure, is Equation (105.111) — and the mechanism of that shift is precisely Section 106.7.3. The experimental bound from the neutron electric dipole moment, $\left|\bar\theta\right| \lesssim 10^{-10}$, is Equation (105.113) [2090, 2346]. The strong CP problem is the observation that a parameter which could have been anything is measured to be this small, and it is recorded as an open question in Section 105.7. The best-known proposed resolution promotes $\bar\theta$ to a dynamical field [1609,

1630]; the particle it predicts has not been observed, and this book records it as a proposal, not as physics.

The θ dependence is invisible in perturbation theory. q is a total derivative, so Equation (106.96) contributes nothing to any Feynman diagram; its effects exist only because the boundary term is non-zero on configurations of non-trivial topology. A parameter that is invisible perturbatively and physical non-perturbatively is the worst possible combination for anyone hoping to argue it away, and that is the whole difficulty.

106.7 Anomalies

106.7.1 The Adler–Bell–Jackiw anomaly

A classical conservation law

Proposition 106.85 (Classical conservation of the axial current)**.** *For a Dirac field of mass m coupled to an external gauge field, the axial current*

$$j_5^\mu = c\,\bar\psi\gamma^\mu\gamma^5\psi\,, \qquad [j_5^\mu] = 1/(\mathrm{m}^2\,\mathrm{s})\,, \tag{106.97}$$

satisfies, by the classical field equations,

$$\partial_\mu j_5^\mu = \frac{2\mathrm{i}mc^2}{\hbar}\,\bar\psi\gamma^5\psi\,, \tag{106.98}$$

which vanishes identically for $m = 0$: the axial charge of a massless Dirac field is conserved.
Rests on Equation (100.5)*.*

Derivation. *Derives Proposition 106.85.*

The Dirac equation in an external field is $(\mathrm{i}\hbar\gamma^\mu D_\mu - mc)\psi = 0$, and its conjugate reads $\mathrm{i}\hbar\,(D_\mu\bar\psi)\gamma^\mu + mc\,\bar\psi = 0$, the derivative acting on $\bar\psi$. Then

$$\partial_\mu(\bar\psi\gamma^\mu\gamma^5\psi) = (D_\mu\bar\psi)\gamma^\mu\gamma^5\psi + \bar\psi\gamma^\mu\gamma^5(D_\mu\psi) = \frac{\mathrm{i}mc}{\hbar}\bar\psi\gamma^5\psi + \frac{\mathrm{i}mc}{\hbar}\bar\psi\gamma^5\psi\,,$$

using $\{\gamma^\mu,\gamma^5\} = 0$ to move γ^5 past γ^μ in the second term, which flips the sign of the mass contribution and makes the two add rather than cancel. Multiplying by c gives Equation (106.98). The gauge field drops out because the covariant derivatives combine into an ordinary one in a neutral bilinear. □

By Noether's theorem [456] this conservation law is the statement that the massless action is invariant under the global chiral rotation

$$\psi \longmapsto \mathrm{e}^{\mathrm{i}\alpha\gamma^5}\psi\,, \qquad \bar\psi \longmapsto \bar\psi\,\mathrm{e}^{\mathrm{i}\alpha\gamma^5}\,, \tag{106.99}$$

the second transformation carrying $\mathrm{e}^{+\mathrm{i}\alpha\gamma^5}$ rather than its inverse because γ^5 anticommutes with the γ^0 hidden in $\bar\psi$. Everything above is classical. What Adler [1388] and Bell and Jackiw [1391] found is that Equation (106.98) is false in the quantum theory even at $m = 0$.

Where the failure comes from The one-loop amplitude with one axial and two vector vertices — the triangle — is linearly divergent, and a linearly divergent integral is not invariant under a shift of its integration variable.

Lemma 106.86 (A shift of a divergent integral leaves a surface term)**.** *For a smooth $f:\mathbb{R}^4\to\mathbb{C}$ and constant a,*

$$\int \mathrm{d}^4\ell\,\big[f(\ell+a) - f(\ell)\big] = \lim_{R\to\infty}\oint_{|\ell|=R} a_\mu\, f(\ell)\,\mathrm{d}S^\mu\,, \tag{106.100}$$

which vanishes when f falls faster than $|\ell|^{-3}$ and is a finite non-zero constant, linear in a, when f falls exactly as $|\ell|^{-3}$ — that is, when the integral is linearly divergent.
Rests on Theorem 7.101.

Derivation. *Derives Lemma 106.86.*

Expand $f(\ell + a) - f(\ell) = a_\mu \partial^\mu f + O(a^2)$ — the higher terms give integrals of higher divergences of f and are handled the same way — and apply the divergence theorem to the ball $|\ell| \le R$. The surface element grows as R^3, so the limit is zero, finite, or infinite according as f falls faster than, exactly as, or slower than R^{-3}. □

Theorem 106.87 (The axial anomaly)**.** *In the quantum theory of a massless Dirac field of charge Q in an external electromagnetic field, the axial current is not conserved:*

$$\partial_\mu j_5^\mu = \frac{Q^2 c}{16\pi^2 \hbar^2}\, \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma} = \frac{\alpha}{4\pi \mu_0 \hbar}\, \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}\,, \tag{106.101}$$

the second form for $Q = e$, with $\epsilon^{0123} = +1$. Both sides carry $1/(\mathrm{m}^3\,\mathrm{s})$. The vector current $j^\mu = Qc\bar\psi\gamma^\mu\psi$ of Equation (100.6) remains exactly conserved.

Rests on Proposition 106.85 and Equation (106.99).

The coefficient is derived in Section 106.7.3, where the computation is short and its topological character is manifest. What the triangle diagram contributes is the *reason*: the anomaly is not a choice but an obstruction.

Proposition 106.88 (The obstruction)**.** *The triangle amplitude $T^{\mu\nu\rho}$ with one axial and two vector vertices depends on how the loop momentum is routed, by Lemma 106.86. Fixing the routing so that the two vector currents are conserved, $k_{1\nu} T^{\mu\nu\rho} = k_{2\rho} T^{\mu\nu\rho} = 0$, forces $(k_1 + k_2)_\mu T^{\mu\nu\rho} \neq 0$, and conversely. No regulator preserves both.*

Rests on Lemma 106.86 and Theorem 100.17.

Derivation. *Derives Proposition 106.88.*

The integrand of the triangle falls as $|\ell|^{-3}$ at large loop momentum, since it is a product of three fermion propagators (one power of ℓ each in the denominator, one in the numerator from each $\gamma \cdot \ell$) — the superficial degree of divergence is $D = +1$ by the counting of Theorem 100.17 applied to three external boson lines and a closed fermion loop. By Lemma 106.86 a shift of the routing therefore changes the amplitude by a finite, non-zero, momentum-dependent constant. The three Ward identities — one per vertex — are each linear conditions on that constant, and the constant has fewer free parameters than there are conditions: their sum is fixed independently of the routing and is non-zero. The routing can distribute the failure among the three vertices but cannot remove it. Since the vector current is coupled to the photon and its non-conservation would destroy gauge invariance and unitarity (Section 106.7.4), the failure is assigned entirely to the axial vertex.

The same statement in the language of regulators: Pauli–Villars requires a heavy fermion of mass M, and a Dirac mass term $M\bar\psi\psi$ is not chirally invariant, so the regulator breaks the axial symmetry by construction and the breaking survives $M \to \infty$ by Equation (106.98). Dimensional regularization requires γ^5 in $d \neq 4$ dimensions, where a totally antisymmetric product of four gamma matrices is not available. A lattice regulator is defeated by Theorem 106.75. Every route fails in a different way, which is itself the evidence that the obstruction is physical rather than technical. □

Theorem 106.89 (Adler–Bardeen)**.** *The one-loop result Equation (106.101) is exact: the coefficient of the anomaly receives no corrections at any higher order in the coupling [1389].*

Rests on Equation (106.101).

The reason is visible in Section 106.7.3 and not in the diagrams: the integrated anomaly is an integer — the index of the Dirac operator — and an integer cannot depend continuously on a coupling constant. This is the second time in this chapter that a topological argument makes a statement that a perturbative one can only verify order by order, the first being Proposition 106.81.

Proposition 106.90 (Wess–Zumino consistency)**.** *Let $G_a(x)$ generate gauge transformations, satisfying the algebra $[G_a(x), G_b(y)] = \mathrm{i} f_{abc}\, \delta^4(x-y)\, G_c(x)$, and let $\mathsf{A}_a(x) := G_a(x)\, W$ be the anomalous variation of the effective action. Then*

$$G_a(x)\, \mathsf{A}_b(y) - G_b(y)\, \mathsf{A}_a(x) = \mathrm{i} f_{abc}\, \delta^4(x-y)\, \mathsf{A}_c(x)\,, \tag{106.102}$$

a strong constraint on the possible form of an anomaly [1459].

Rests on Equations (106.37) *and* (106.67)*.*

Derivation. *Derives Proposition 106.90.*

Apply the commutator of two gauge generators to the single functional W and use the algebra: $[G_a(x), G_b(y)]\, W = \mathrm{i} f_{abc} \delta^4(x-y) G_c(x) W$. Writing out the left-hand side as $G_a(x)(G_b(y)W) - G_b(y)(G_a(x)W)$ and substituting the definition of A gives Equation (106.102). The content is that the anomaly is a cocycle of the gauge group: it is not an arbitrary functional but one constrained by the group structure, which is why the possible anomalies in four dimensions form a one-parameter family and the coefficient is the only thing left to compute. □

106.7.2 Neutral pion decay as the measurement

The anomaly is not a formal curiosity. It fixes, with no free parameter beyond one measured decay constant, the rate of a decay that has been measured to about one and a half percent — and the answer depends on the number of colours.

Phenomenon 106.91 (The neutral pion decays to two photons at the anomaly rate)**.** The two-photon width of the neutral pion is fixed by the axial anomaly to be

$$\Gamma(\pi^0 \to \gamma\gamma) = \left(\frac{N_c}{3}\right)^2 \frac{\alpha^2\, (m_\pi c^2)^3}{64\pi^3 F_\pi^2}\,, \qquad \frac{1}{\tau_{\gamma\gamma}} = \frac{\Gamma(\pi^0 \to \gamma\gamma)}{\hbar}\,, \tag{106.103}$$

with F_π the pion decay constant. The first quantity is an energy — the width as the Particle Data Group quotes it — and $\hbar$ enters only in the second, which converts it to a rate; the right-hand side of the first carries $(\text{energy})^3/(\text{energy})^2$ and no $\hbar$ at all. Using $m_{\pi^0} c^2 = (134.9768 \pm 0.0005)\,\text{MeV}$ [2427], $F_\pi = f_\pi/\sqrt{2} = 92.07\,\text{MeV}$ from $f_\pi = (130.2 \pm 1.2)\,\text{MeV}$ [2427], and $\alpha = 7.297\,352\,564\,3 \times 10^{-3}$ [2431], the prediction for $N_c = 3$ is

$$\Gamma = (7.79 \pm 0.14)\,\text{eV}\,, \qquad \frac{1}{\tau_{\gamma\gamma}} = 1.18 \times 10^{16}/\text{s}\,, \tag{106.104}$$

the quoted uncertainty being that of f_π alone, which enters squared and so contributes twice its own 0.9 %. Against this stands the PrimEx-II measurement

$$\Gamma_{\text{exp}} = (7.802 \pm 0.117)\,\text{eV} \tag{106.105}$$

[2361]: the two agree to 0.2 %, which is 0.09 of the combined uncertainty — and the prediction is now the less precise of the two, its error being dominated by the measured decay constant rather than by anything in the anomaly. Were there one colour instead of three, the prediction would be nine times smaller.

Rests on Equation (106.101) *and Theorem 106.89.*

Derivation. *Derives Phenomenon 106.91.*

The anomaly Equation (106.101), applied to the third component of the axial isospin current of the light quarks and combined with the partial conservation of that current, produces an effective interaction between the neutral pion field and two photons,

$$\mathcal{L}_{\pi\gamma\gamma} = -\frac{g_{\pi\gamma\gamma}}{4}\, \pi^0\, F_{\mu\nu} \widetilde{F}^{\mu\nu}\,, \qquad g_{\pi\gamma\gamma} = \frac{N_c}{3} \cdot \frac{\alpha}{\pi F_\pi}\,, \tag{106.106}$$

with $\widetilde{F}^{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}$ and $g_{\pi\gamma\gamma}$ of dimension $(\text{energy})^{-1}$ once the fields are normalized as in Notation 106.23. The colour factor is $N_c(e_u^2 - e_d^2) = N_c(\frac{4}{9} - \frac{1}{9}) = \frac{N_c}{3}$: each quark flavour runs around the triangle once for each colour, weighted by the square of its electric charge, and the two light flavours enter with opposite sign because the current is the third isospin component. That is where the sensitivity to N_c comes from, and it is the only place in this book where a decay rate counts colours directly.

Given Equation (106.106), the width follows from kinematics. The amplitude for $\pi^0(p) \to \gamma(k_1,\varepsilon_1)\gamma(k_2,\varepsilon_2)$ is $\mathcal{M} = g_{\pi\gamma\gamma}\,\epsilon^{\mu\nu\rho\sigma}k_{1\mu}\varepsilon^*_{1\nu}k_{2\rho}\varepsilon^*_{2\sigma}$. Sum over photon polarizations with $\sum \varepsilon^*_\mu\varepsilon_\nu \to -\eta_{\mu\nu}$ — legitimate because $\mathcal{M}$ vanishes when either ε is replaced by its momentum. The two metric factors enter with $(-1)^2 = +1$, and the two Levi-Civita symbols contract by

$$\epsilon^{\mu\nu\rho\sigma}\,\epsilon^{\alpha}{}_{\nu}{}^{\gamma}{}_{\sigma} = -2(\eta^{\mu\alpha}\eta^{\rho\gamma} - \eta^{\mu\gamma}\eta^{\rho\alpha})$$

in the signature $\mathrm{diag}(+1,-1,-1,-1)$ with $\epsilon^{0123} = +1$, so that

$$\sum_{\text{pol}} |\mathcal{M}|^2 = -2g_{\pi\gamma\gamma}^2\left[k_1^2k_2^2 - (k_1\cdot k_2)^2\right] = 2g_{\pi\gamma\gamma}^2\,(k_1\cdot k_2)^2\,,$$

the first term vanishing because both photons are massless. The coefficient is 2, not 8: the same number comes out of summing $|\mathcal{M}|^2$ over the two physical transverse polarizations of each photon directly, without the covariant substitution. On the mass shell $2k_1\cdot k_2 = p^2 = m_\pi^2c^2$. Measuring every momentum of this kinematic step as an energy, $k \mapsto ck$, that reads $k_1\cdot k_2 = (m_\pi c^2)^2/2$ and makes $g_{\pi\gamma\gamma}$ an inverse energy throughout, whence $\sum|\mathcal{M}|^2 = \frac{1}{2}g_{\pi\gamma\gamma}^2(m_\pi c^2)^4$. The two-body massless phase-space volume is $1/8\pi$, the flux factor for a decay at rest is $1/(2m_\pi c^2)$, and the two photons are identical so the result is halved:

$$\frac{1}{\tau_{\gamma\gamma}} = \frac{1}{2}\cdot\frac{1}{2m_\pi c^2}\cdot\frac{1}{8\pi}\cdot\frac{g_{\pi\gamma\gamma}^2(m_\pi c^2)^4}{2\hbar} = \frac{g_{\pi\gamma\gamma}^2(m_\pi c^2)^3}{64\pi\hbar}\,,$$

a rate, since $g_{\pi\gamma\gamma}^2(m_\pi c^2)^3$ is an energy and $\hbar$ divides it. The width is $\hbar$ times that rate, $\Gamma = g_{\pi\gamma\gamma}^2(m_\pi c^2)^3/64\pi$, and substituting $g_{\pi\gamma\gamma}$ from Equation (106.106) gives Equation (106.103). That is the only place $\hbar$ enters, and it is why the displayed width carries none.

Arithmetic, in MeV: $\alpha^2 = 5.325\,14\times10^{-5}$; $(m_\pi c^2)^3 = 2.4591\times10^6\,\text{MeV}^3$, the cube of $134.9768\,\text{MeV}$; $64\pi^3 = 1984.40$; and $F_\pi^2 = 8476.0\,\text{MeV}^2$, the square of $130.2\,\text{MeV}/\sqrt{2}$. Then

$$\Gamma = \frac{5.325\,14\times10^{-5}\times2.4591\times10^6}{1984.40\times8476.0}\,\text{MeV} = 7.786\times10^{-6}\,\text{MeV} = 7.79\,\text{eV}\,,$$

which is Equation (106.104), and $\Gamma/\hbar = 7.79\,\text{eV}/6.582\,119\,569\times10^{-16}\,\text{eV s} = 1.18\times10^{16}/\text{s}$. The prediction and the measurement differ by 0.2 % — well inside either uncertainty separately, and 0.09 of the two combined in quadrature. □

Remark 106.92 (Two lifetimes that are both right). The shipped Particle Data Group compilation gives the *total* width $\Gamma_{\text{tot}} = (7.81\pm0.12)\,\text{eV}$ [2427], whence a mean life

$$\tau = \frac{\hbar}{\Gamma_{\text{tot}}} = \frac{1.054\,571\,817\times10^{-34}\,\text{J s}}{7.81\,\text{eV}\times1.602\,176\,634\times10^{-19}\,\text{J/eV}} = 8.43\times10^{-17}\,\text{s}\,.$$

The PrimEx-II paper quotes $\tau = 8.34\times10^{-17}\,\text{s}$ [2361], which is a different number and not a discrepancy: what PrimEx-II measures is the two-photon partial width Equation (106.105), and converting it to a lifetime requires dividing by the branching fraction $B(\pi^0\to\gamma\gamma) = 0.988\,23$, giving $\Gamma_{\text{tot}} = 7.895\,\text{eV}$ and $\tau = \hbar/\Gamma_{\text{tot}} = 8.34\times10^{-17}\,\text{s}$. The two lifetimes differ by about one percent because the PrimEx-II partial width is about one percent above the world average it is now the dominant input to. Quoting either without saying which is which is how a one-percent inconsistency gets into a book.

This is the cleanest existing evidence that the number of colours is three, and it is independent of the other route — the ratio R of hadronic to muonic annihilation cross-sections at an electron–positron collider, Equation (102.14), which counts colours through a sum over quark charges rather than through an anomaly. The two are worth having both, because they fail in different ways: R requires the perturbative treatment of the final state and carries QCD corrections of order α_s/π, while Equation (106.103) is protected from corrections by Theorem 106.89 but requires the chiral treatment of the pion.

Derivation pending #167

The chiral matching for the pion two-photon coupling: the phase space, the polarization sum and the colour counting of the neutral-pion width are derived above, but the step from the anomalous divergence of the axial isospin current to the effective coupling $g_{\pi\gamma\gamma}$ — the partial conservation of the axial current, the pion pole dominance and the normalization by the decay constant — is quoted rather than derived. It belongs in Appendix A, alongside the chiral material of the QCD chapter of this part.

106.7.3 Fujikawa's derivation from the measure

Every derivation so far has located the anomaly in a divergent loop integral. Fujikawa showed that it is in the *measure* [1638]: the classical action of a massless fermion is chirally invariant, and so is the classical field equation, but $\mathcal{D}\bar\psi\,\mathcal{D}\psi$ is not.

Theorem 106.93 (Fujikawa)**.** *Under the local chiral rotation Equation (106.99) with $\alpha=\alpha(x)$, the Euclidean fermion measure transforms with the Jacobian*

$$\mathcal{D}\bar\psi'\,\mathcal{D}\psi' = \mathcal{D}\bar\psi\,\mathcal{D}\psi\;\exp\!\left[-\frac{\mathrm{i}}{16\pi^2}\int \mathrm{d}^4x\;\alpha(x)\,\epsilon_{\mu\nu\rho\sigma}\,\mathrm{tr}(\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma})\right], \tag{106.107}$$

which for constant α is $\mathrm{e}^{-2\mathrm{i}\alpha\nu}$ with ν the topological charge of Equation (106.91). The anomaly Equation (106.101) follows.

Rests on Equations (106.91) and (106.99) and Corollary 106.36.

Derivation. *Derives Theorem 106.93.*

Expand the fields in eigenfunctions of the Hermitian Euclidean Dirac operator $\mathcal{D}=\gamma^\mu D_\mu$, $\mathcal{D}\varphi_n=\lambda_n\varphi_n$, with the φ_n orthonormal: $\psi(x)=\sum_n a_n\varphi_n(x)$, $\bar\psi(x)=\sum_n \bar b_n\varphi_n^\dagger(x)$, the coefficients $a_n,\bar b_n$ being Grassmann. The measure is $\prod_n \mathrm{d}a_n\,\mathrm{d}\bar b_n$.

Under Equation (106.99) the coefficients transform linearly, $a'_m=\sum_n C_{mn}a_n$ with

$$C_{mn}=\int \mathrm{d}^4x\;\varphi_m^\dagger(x)\,\mathrm{e}^{\mathrm{i}\alpha(x)\gamma^5}\varphi_n(x)=\delta_{mn}+\mathrm{i}\int \mathrm{d}^4x\;\alpha(x)\,\varphi_m^\dagger\gamma^5\varphi_n+O(\alpha^2),$$

and $\bar b$ transforms with the same matrix, because Equation (106.99) carries the same sign for $\bar\psi$. By Corollary 106.36 a Grassmann measure transforms with the *inverse* determinant, so

$$\prod_n \mathrm{d}a'_n\,\mathrm{d}\bar b'_n=(\det C)^{-2}\prod_n \mathrm{d}a_n\,\mathrm{d}\bar b_n\,,\qquad (\det C)^{-2}=\exp\!\left[-2\mathrm{i}\int \mathrm{d}^4x\;\alpha(x)\,\mathcal{J}(x)\right],$$

using $\det=\exp\mathrm{tr}\ln$ to first order in α, with $\mathcal{J}(x)=\sum_n\varphi_n^\dagger(x)\gamma^5\varphi_n(x)$.

The sum $\mathcal{J}$ is formally $\mathrm{tr}\,\gamma^5$ times a delta function — zero times infinity — and must be regularized. The regulator that respects gauge invariance is the operator's own spectrum:

$$\mathcal{J}(x)=\lim_{M\to\infty}\sum_n \varphi_n^\dagger(x)\gamma^5\mathrm{e}^{-\lambda_n^2/M^2}\varphi_n(x)=\lim_{M\to\infty}\mathrm{tr}\,\langle x|\,\gamma^5\mathrm{e}^{-\mathcal{D}^2/M^2}\,|x\rangle\,,$$

where the trace is over Dirac and gauge indices. Insert plane waves, $\langle x|\cdots|x\rangle = \int \mathrm{d}^4k\,(2\pi)^{-4}\,\mathrm{e}^{-\mathrm{i}k\cdot x}(\cdots)\mathrm{e}^{\mathrm{i}k\cdot x}$, and use

$$\mathcal{D}^2 = (\gamma^\mu D_\mu)^2 = D^2 + \frac{1}{2}\gamma^\mu\gamma^\nu\,[D_\mu, D_\nu] = D^2 + \frac{\mathrm{i}}{2}\gamma^\mu\gamma^\nu\mathcal{F}_{\mu\nu}\,,$$

by Equation (106.64). Expanding the exponential, the Dirac trace with γ^5 vanishes unless at least four gamma matrices are present, so the first surviving term is the second order in $\mathcal{F}$:

$$\mathcal{J} = \lim_{M\to\infty}\int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\mathrm{e}^{-k^2/M^2}\,\frac{1}{2!}\,\frac{1}{M^4}\left(\frac{\mathrm{i}}{2}\right)^2 \mathrm{tr}\Big(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\Big)\,\mathrm{tr}(\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma})\,.$$

Terms with fewer than four gammas vanish on the Dirac trace; terms with more carry additional inverse powers of M and vanish in the limit. Now $\int \mathrm{d}^4k\,(2\pi)^{-4}\mathrm{e}^{-k^2/M^2} = M^4/(16\pi^2)$ by Lemma 106.2, which cancels the M^{-4} exactly — so the limit is finite and independent of the regulator scale — and $\mathrm{tr}(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4\epsilon^{\mu\nu\rho\sigma}$. Collecting the numbers, $\frac{1}{2}\times(-\frac{1}{4})\times(-4)\times\frac{1}{16\pi^2} = \frac{1}{32\pi^2}$, so

$$\mathcal{J}(x) = \frac{1}{32\pi^2}\,\epsilon_{\mu\nu\rho\sigma}\,\mathrm{tr}(\mathcal{F}_{\mu\nu}\mathcal{F}_{\rho\sigma})\,, \tag{106.108}$$

which is Equation (106.107). Comparison with Equation (106.91) gives $\int \mathrm{d}^4x\,\mathcal{J} = \nu$, so for constant α the Jacobian is $\mathrm{e}^{-2\mathrm{i}\alpha\nu}$.

Finally, the anomalous divergence. Invariance of Z under a change of integration variables requires that the variation of the action cancel the Jacobian. The action's variation under a local rotation produces $\int \alpha\,\partial_\mu j_5^\mu$ after integrating by parts, so $\partial_\mu j_5^\mu = 2c\,\mathcal{J}$ for a massless field, i.e. $\partial_\mu j_5^\mu = 2q(x)$ with the topological charge density q of Definition 106.79 — not to be confused with the electric charge, which is why the latter is written Q throughout this chapter. For the abelian case, $\mathcal{F}_{\mu\nu} = QF_{\mu\nu}/\hbar$ with no trace factor, and $2c/(32\pi^2)\times Q^2/\hbar^2 = Q^2c/(16\pi^2\hbar^2)$, which is Equation (106.101). □

Three things about this derivation are worth separating out.

It uses the Grassmann Jacobian, and only the Grassmann Jacobian. Corollary 106.36 — that a fermionic measure transforms with $(\det)^{-1}$ where a bosonic one transforms with $\det$ — was derived in Section 106.3.3 from Berezin's rules, which were themselves derived from translation invariance. That chain is the whole content of the anomaly: a symmetry of the action that fails to be a symmetry of the measure.

It is manifestly topological. By Equation (106.108) and Proposition 106.81, $\int \mathcal{J}$ is an integer. The Atiyah–Singer index theorem identifies it further: the eigenvalue sum $\sum_n \varphi_n^\dagger\gamma^5\varphi_n$ receives contributions only from zero modes, because $\mathcal{D}$ maps the $\gamma^5 = +1$ and $\gamma^5 = -1$ subspaces into each other and therefore pairs every non-zero eigenvalue with a partner of opposite chirality, whose contributions cancel. Hence

$$\nu = n_+ - n_-\,, \tag{106.109}$$

the difference between the numbers of right- and left-handed zero modes of the Dirac operator. A decay rate — the measured $(7.802 \pm 0.117)\,\mathrm{eV}$ of Equation (106.105) — is thereby tied to an index. It is also the reason for Theorem 106.89: a quantity that equals an integer cannot vary continuously with a coupling constant.

It explains the third failure. The chiral rotation that would remove the phase of the quark mass matrix does not remove it: it shifts θ by the Jacobian, which is why only $\bar\theta = \theta + \arg\det M_q$ is observable (Equation (105.111)). The mechanism promised there is Equation (106.107), exactly.

106.7.4 Anomaly cancellation

An anomaly in a *global* symmetry is a prediction, and Section 106.7.2 measured one. An anomaly in a *gauge* symmetry is fatal.

Theorem 106.94 (A gauge anomaly destroys the theory)**.** *If the currents coupled to gauge fields are anomalous, the Slavnov–Taylor identities Equation* (106.76) *fail. Then the unphysical polarizations no longer decouple (Proposition 106.60), the S-matrix is not unitary on $\mathcal{H}_{\text{phys}}$, and the divergences no longer organize into a renormalization of finitely many parameters [1475].*

Rests on Theorem 106.62, Proposition 106.60, and Equation (106.107)*.*

Derivation. *Derives Theorem 106.94.*

Theorem 106.62 derived Equation (106.76) from the invariance of the action *and of the measure* under BRST. An anomaly is precisely the statement that the measure is not invariant: by Equation (106.107) the Jacobian contributes an extra term to every identity, so $\langle sX\rangle = \langle X\,\mathsf{A}\rangle \neq 0$. The chain of consequences then runs backwards through Section 106.4.2: the decoupling of the quartet in Proposition 106.60 used $\langle\Phi|Q_B\Lambda\rangle = 0$, which requires Q_B to be conserved, and gauge-parameter independence Theorem 106.61 used $\langle sX\rangle = 0$ directly. Losing them means that a gauge-dependent quantity appears in a physical answer and that states of negative norm contribute to the optical theorem, which is a loss of probability, not a technical inconvenience. □

Theorem 106.95 (The cancellation condition)**.** *For chiral fermions in a representation with generators T^a, the gauge anomaly is proportional to*

$$\mathsf{A}^{abc} = \operatorname{tr}\Big(\big\{T^a,T^b\big\}\,T^c\Big)_L - \operatorname{tr}\Big(\big\{T^a,T^b\big\}\,T^c\Big)_R\,, \tag{106.110}$$

the traces running over the left- and right-handed multiplets separately, and the theory is consistent if and only if $\mathsf{A}^{abc}=0$ for every triple [1467].

Rests on Propositions 106.88 and 106.90.

Derivation. *Derives Theorem 106.95.*

The triangle of Proposition 106.88 now carries a group generator at each of its three vertices, and the two orientations of the fermion loop contribute the two orderings, so the group factor is the symmetrized trace $\operatorname{tr}(T^aT^bT^c + T^aT^cT^b) = \operatorname{tr}(\big\{T^b,T^c\big\}\,T^a)$. A right-handed fermion contributes with the opposite sign, because γ^5 has the opposite eigenvalue and the anomalous piece of the triangle is the one proportional to γ^5. Summing over all fermions in the theory gives Equation (106.110), and by Proposition 106.90 nothing else can appear. □

Proposition 106.96 (The Standard Model cancels, and only with three colours)**.** *Write each generation as left-handed Weyl fields with hypercharges Y normalized by $Q = T^3 + Y$: $Q_L = (3,2)_{1/6}$, $u_L^c = (\bar3,1)_{-2/3}$, $d_L^c = (\bar3,1)_{1/3}$, $L_L = (1,2)_{-1/2}$, $e_L^c = (1,1)_{1}$. Then every anomaly coefficient of $\mathrm{SU}(3)\times\mathrm{SU}(2)\times\mathrm{U}(1)$ vanishes, and two of them vanish only because the number of colours equals three.*

Rests on Theorem 106.95 and Equation (106.110)*.*

Derivation. *Derives Proposition 106.96.*

There are four independent conditions, since $\mathrm{SU}(3)^3$ vanishes identically (the quarks appear in a vector-like pair of triplet and antitriplet with respect to colour, once left and right are combined) and $\mathrm{SU}(2)^3$ vanishes because the symmetrized trace of three SU(2) generators is zero for any representation, SU(2) having only real representations.

(i) $\mathrm{SU}(3)^2\,\mathrm{U}(1)$. Sum Y over the colour-triplet Weyl fields, weighted by the number of SU(2) components:

$$2\times\tfrac{1}{6} + 1\times\left(-\tfrac{2}{3}\right) + 1\times\tfrac{1}{3} = \tfrac{1}{3} - \tfrac{2}{3} + \tfrac{1}{3} = 0\,.$$

(ii) $\mathrm{SU}(2)^2\,\mathrm{U}(1)$. Sum Y over the SU(2) doublets, weighted by their colour multiplicity:

$$N_c \times \tfrac{1}{6} + 1 \times \left(-\tfrac{1}{2}\right) = \frac{N_c}{6} - \frac{1}{2}\,,$$

which vanishes if and only if $N_c = 3$.

(iii) $\mathrm{U}(1)^3$. Sum Y^3 over all Weyl fields with their multiplicities $6, 3, 3, 2, 1$:

$$6\left(\tfrac{1}{6}\right)^3 + 3\left(-\tfrac{2}{3}\right)^3 + 3\left(\tfrac{1}{3}\right)^3 + 2\left(-\tfrac{1}{2}\right)^3 + 1\cdot 1^3 = \tfrac{1}{36} - \tfrac{32}{36} + \tfrac{4}{36} - \tfrac{9}{36} + \tfrac{36}{36} = 0\,.$$

Carrying N_c instead of 3 through the quark multiplicities gives $N_c\left[\frac{1}{108} - \frac{8}{27} + \frac{1}{27}\right] + \frac{3}{4} = \frac{3-N_c}{4}$, so this condition too holds only for $N_c = 3$.

(iv) Mixed gauge–gravitational. The same triangle with two insertions of the energy–momentum tensor requires $\sum Y = 0$:

$$6\left(\tfrac{1}{6}\right) + 3\left(-\tfrac{2}{3}\right) + 3\left(\tfrac{1}{3}\right) + 2\left(-\tfrac{1}{2}\right) + 1 = 1 - 2 + 1 - 1 + 1 = 0\,.$$

This one is a statement about the Standard Model in a fixed classical background metric — a one-loop consistency condition on the gauge currents, not a theory of quantum gravity.

In every case the quarks alone and the leptons alone fail; only the complete generation cancels, and only with three colours. This is the theoretical counterpart of the measurement in Section 106.7.2, and the reason Chapter 104 requires complete generations: a fourth lepton doublet without its quark partners would make the theory inconsistent, so the discovery of a new charged lepton is a prediction that its quarks exist. □

Remark 106.97 (The surviving non-perturbative constraint). Theorem 106.95 is a perturbative condition, derived from a triangle diagram. Witten found a further one that no diagram sees [1707]: because $\pi_4(\mathrm{SU}(2)) = \mathbb{Z}_2$, there are gauge transformations on S^4 not continuously connected to the identity, and the fermion determinant changes sign under them unless the number of SU(2) doublets is even. The functional integral then vanishes identically — the theory has no non-vanishing amplitudes at all, which is a more complete failure than a broken Ward identity.

The Standard Model passes. Each generation contributes $N_c = 3$ quark doublets and one lepton doublet, four in all, and three generations give twelve: even. Had the leptons been counted without the quarks, or the colours been two, the count would have been odd and the theory empty. That two independent consistency conditions — one perturbative and one topological — and one measurement, Equation (106.105), all point at the same integer is the kind of redundancy that makes the Standard Model believable.

Chapter 107

Nuclear Forces and Nuclear Structure

The nucleus is the one place in this book where a residual force does the work. Quantum chromodynamics (Chapter 102) confines quarks into colour-neutral hadrons, and what leaks out between those hadrons binds protons and neutrons into nuclei — the analogue of the van der Waals force between neutral atoms, and about as hard to derive from first principles. The chapter therefore begins where the evidence began: Rutherford's inference of a small massive nucleus from large-angle alpha scattering [379], Chadwick's neutron [693], and Heisenberg's two-nucleon picture of nuclear matter [699]. From there it develops the Yukawa exchange mechanism [765], the pion that confirmed it [902], and the two complementary models — the liquid drop [763, 768, 830] and the shell model [933, 940] — whose reconciliation is the collective model of Bohr and Mottelson [1015].

The chapter sits after the field theory of Chapters 64 and 102 because that is where its force comes from, and before the astrophysical applications of Chapter 52, where nuclear binding energies set the energy budget of every star. Its data are unusually good and unusually well tabulated: masses to sub-keV precision [2393], charge radii from electron scattering [1088, 2209], and gamma-ray resonances so narrow that Mössbauer's recoil-free absorption [1154] measured a gravitational redshift over 22.5 m [1189]. Every quantitative claim below is anchored to such a measurement.

Notation 107.1 (Units and constants used throughout). Units are SI, with the electronvolt admitted as in Section 100.1.1, and $\hbar$ and c are written out in every formula. Three combinations recur so often that they are fixed here once, from the CODATA 2022 adjustment [2431]:

$$\hbar c = 1.973\,269\,8 \times 10^{-7}\ \text{eV m} = 197.326\,98\ \text{MeV fm}\,, \tag{107.1}$$

$$\frac{e^2}{4\pi\varepsilon_0} = \alpha\,\hbar c = 1.439\,964\,5\ \text{MeV fm}\,, \tag{107.2}$$

$$u\,c^2 = 931.494\ \text{MeV}\,, \tag{107.3}$$

with $\alpha = e^2/(4\pi\varepsilon_0\hbar c) = 7.297\,352\,6 \times 10^{-3}$ the dimensionless fine-structure constant and u the unified atomic mass unit. One femtometre, 1×10^{-15} m, is the natural length here; one MeV the natural energy. A nucleus is written ${}^{A}_{Z}\mathrm{X}_{N}$ with Z protons, N neutrons and $A = Z + N$ nucleons; Z is redundant given the chemical symbol and N is redundant given A, so the short form ${}^{A}\mathrm{X}$ is used except where the neutron number is the point. Nuclides sharing Z are *isotopes*, sharing N *isotones*, sharing A *isobars*; a long-lived excited state of one nuclide is an *isomer*, marked ${}^{Am}\mathrm{X}$.

Two masses anchor everything that follows. From the 2024 Particle Data Group compilation [2427],

$$m_p c^2 = 938.272\,09\ \text{MeV}\,, \qquad m_n c^2 = 939.565\,42\ \text{MeV}\,, \tag{107.4}$$

equivalently $m_p = 1.672\,621\,93 \times 10^{-27}\,\mathrm{kg}$ and $m_n = 1.674\,927\,50 \times 10^{-27}\,\mathrm{kg}$ [2431]. Their difference,

$$(m_n - m_p)\,c^2 = 1.293\,33\,\mathrm{MeV}\,, \tag{107.5}$$

is larger than the electron rest energy 0.511 00 MeV and smaller than the binding energy per nucleon of any bound nucleus, and those two inequalities between them decide which nuclei are stable, which decay, and in which direction — a point taken up in Section 107.3.2.

107.1 Discovery of the nucleus

107.1.1 Radioactivity

Becquerel found in 1896 that uranium salts fog a photographic plate through opaque wrapping, and — decisively — that the effect does not require prior exposure to sunlight, so it is not phosphorescence [271]. The radiation is emitted continuously, at a rate independent of temperature, pressure and chemical combination, and it discharges an electroscope, which made it measurable rather than merely visible. Two years later the Curies, following the ionization current rather than the photographic plate, isolated from pitchblende two new elements far more active than uranium: polonium [278] and radium [279]; radium's activity per unit mass exceeds uranium's by more than six orders of magnitude [279], which is what made the subsequent experiments possible at all.

Rutherford separated the radiation by absorption [287]. One component is stopped by a few hundredths of a millimetre of aluminium and one requires some millimetres; he named them α and β. A third, far more penetrating and undeflected by a magnetic field, was identified later and named γ. The identifications that followed are: α is a helium nucleus, β an electron (or, after 1934, a positron [737]), γ a photon.

Phenomenon 107.2 (Radioactive decay is exponential and spontaneous)**.** A sample of N identical nuclei of one species disintegrates at a rate proportional to N alone,

$$\frac{\mathrm{d}N}{\mathrm{d}t} = -\lambda N\,, \qquad N(t) = N(0)\,\mathrm{e}^{-\lambda t}\,, \tag{107.6}$$

with a decay constant λ of dimension 1/s that is a property of the species and of nothing else. It is unaffected by temperature over the range from liquid helium to a flame, by pressure, by the chemical state of the atom and by the presence of other nuclei — an insensitivity of many orders of magnitude, and the first evidence that the process happens inside a system decoupled from the chemistry. Rutherford and Soddy drew the conclusion that in a decay one element is transmuted into another [312].

Derivation. *Derives Phenomenon 107.2.*

Suppose only that each nucleus has, in any short interval $\mathrm{d}t$, the same probability $\lambda\,\mathrm{d}t$ of decaying, independently of its age and of what the other nuclei do. This is a statement about a collection of identical, memoryless, independent systems, and it is the whole physical input; everything else is arithmetic. The number of decays expected in $\mathrm{d}t$ is then $\lambda N\,\mathrm{d}t$, which is Equation (107.6), and the solution follows by separation of variables. The *half-life* is the time for N to halve,

$$T_{1/2} = \frac{\ln 2}{\lambda}\,, \tag{107.7}$$

and the *mean life* is $\tau = 1/\lambda = T_{1/2}/\ln 2$.

Two properties of this law are worth stating exactly, because both are routinely misread. First, memorylessness is not an extra assumption but a consequence: the probability that a nucleus surviving to time t survives a further s is $\mathrm{e}^{-\lambda s}$, independent of t, so a nucleus does not age. The exponential is the unique distribution with that property. Second, λ is a

statement about an ensemble and says nothing whatever about when a given nucleus will decay. The number $\mathcal{N}$ counted in a fixed interval is a Poisson variable of mean $\mu = \lambda N\,\Delta t$ and variance μ, so the fractional uncertainty on a measured activity is $\mathcal{N}^{-1/2}$; this is the statistics of Chapter 11, and it is why a counting experiment quotes $\sqrt{\mathcal{N}}$ as its error bar.

The *activity* $\mathcal{A} = \lambda N$ is measured in becquerels, $\mathrm{Bq} = 1/\mathrm{s}$, one disintegration per second. The older unit, the curie, was defined as the activity of one gram of ^{226}Ra, and the definition can be checked: with $T_{1/2} = 1600\,\mathrm{yr} = 5.05 \times 10^{10}\,\mathrm{s}$ [2382] and $N = N_A/226$ atoms per gram,

$$\mathcal{A} = \frac{\ln 2}{5.05 \times 10^{10}\,\mathrm{s}} \cdot \frac{6.022\,140\,76 \times 10^{23}/\mathrm{mol}}{226\,\mathrm{g/mol}} \times 1\,\mathrm{g} = 3.66 \times 10^{10}\,\mathrm{Bq}\,, \tag{107.8}$$

against the defined $3.7 \times 10^{10}\,\mathrm{Bq}$; the small discrepancy is the improvement in the measured half-life since 1910. □

Proposition 107.3 (Secular equilibrium in a decay chain)**.** *Let a parent of decay constant λ_1 feed a daughter of decay constant λ_2. Then*

$$N_2(t) = \frac{\lambda_1 N_1(0)}{\lambda_2 - \lambda_1}\left(\mathrm{e}^{-\lambda_1 t} - \mathrm{e}^{-\lambda_2 t}\right) + N_2(0)\,\mathrm{e}^{-\lambda_2 t}\,, \tag{107.9}$$

and if the parent is much the longer lived, $\lambda_1 \ll \lambda_2$, the daughter's activity approaches the parent's, $\lambda_2 N_2 \to \lambda_1 N_1$, after a time of order $1/\lambda_2$.

Rests on Phenomenon 107.2 and Equation (107.6).

Proof. *Derives Proposition 107.3.*

The daughter is created at the rate at which the parent decays and destroyed at its own rate, $\mathrm{d}N_2/\mathrm{d}t = \lambda_1 N_1 - \lambda_2 N_2$, a linear first-order equation whose integrating factor is $\mathrm{e}^{\lambda_2 t}$. With $N_1 = N_1(0)\mathrm{e}^{-\lambda_1 t}$,

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(N_2 \mathrm{e}^{\lambda_2 t}\right) = \lambda_1 N_1(0)\,\mathrm{e}^{(\lambda_2 - \lambda_1)t}\,,$$

which integrates to Equation (107.9). When $\lambda_1 \ll \lambda_2$ the second exponential dies first and $N_2 \to \lambda_1 N_1/\lambda_2$, so the two activities are equal. This is why a sealed uranium ore assays as though every member of the chain were a separate element of fixed abundance, and why the Curies could isolate radium at all: its abundance in pitchblende is set by Equation (107.9) at $\lambda_1/\lambda_2 \approx 3.6 \times 10^{-7}$ of the uranium by number, which is about one gram of radium in three tonnes of uranium. □

Remark 107.4 (What "spontaneous" does and does not mean). Nothing in Phenomenon 107.2 says a decay is uncaused; it says the cause is not in the laboratory. The insensitivity to chemistry follows because a chemical energy is of order 1 eV and a nuclear one of order 1 MeV: a perturbation six orders of magnitude below the scale of the states involved cannot shift a rate. The exceptions prove the rule and are measurable. Electron capture (Section 107.5.2) proceeds through the electron density at the nucleus, so the half-life of ^{7}Be differs by a fraction of a per cent between chemical compounds; and a fully ionized nucleus in a storage ring cannot capture at all.

107.1.2 Rutherford scattering

Geiger and Marsden, at Rutherford's suggestion, looked for alpha particles scattered backwards from a thin metal foil, and found them [354]. The Thomson atom, a diffuse positive charge with electrons embedded in it, cannot produce them: a single encounter can deflect an alpha particle by at most a small angle, so a large deflection requires many small ones to conspire, and the probability of that falls off exponentially. What was observed instead falls off as a power.

Phenomenon 107.5 (Alpha particles are occasionally turned back)**.** A beam of α particles crossing a thin metal foil is overwhelmingly transmitted with small deflection, but a small and countable fraction is scattered through more than a right angle [354]. The number counted per unit solid angle varies with the scattering angle as

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \left(\frac{Z_1 Z_2 e^2}{16\pi\varepsilon_0 E}\right)^2 \frac{1}{\sin^4(\theta/2)}\,, \tag{107.10}$$

with E the kinetic energy of the incident particle [379]. The charge and the mass of the atom are therefore concentrated in a volume small compared with the atom, and the energy at which the formula begins to fail is the first bound ever placed on the size of that volume.

Derivation. *Derives Phenomenon 107.5.*

The interaction is the repulsive Coulomb potential $V(r) = Z_1 Z_2 e^2/4\pi\varepsilon_0 r$. It is central, so the orbit is a hyperbola and the deflection of a particle incident with impact parameter b and kinetic energy E is fixed by

$$\tan\frac{\theta}{2} = \frac{Z_1 Z_2 e^2}{8\pi\varepsilon_0 E b} \tag{107.11}$$

[1585, 2027], the hyperbolic-orbit relation of the classical repulsive Kepler problem. Write $\kappa = Z_1 Z_2 e^2/8\pi\varepsilon_0 E$, so that $b = \kappa\cot(\theta/2)$. The deflection decreases monotonically with b, so the particles arriving in the annulus between b and $b + \mathrm{d}b$ are exactly those leaving between θ and $\theta - \mathrm{d}\theta$, and the cross-section is the ratio of the two areas,

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{b}{\sin\theta}\left|\frac{\mathrm{d}b}{\mathrm{d}\theta}\right|\,. \tag{107.12}$$

From $b = \kappa\cot(\theta/2)$ one has $|\mathrm{d}b/\mathrm{d}\theta| = \frac{1}{2}\kappa/\sin^2(\theta/2)$, and with $\sin\theta = 2\sin(\theta/2)\cos(\theta/2)$,

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{\kappa\cos(\theta/2)/\sin(\theta/2)}{2\sin(\theta/2)\cos(\theta/2)}\cdot\frac{\kappa}{2\sin^2(\theta/2)} = \frac{\kappa^2}{4\sin^4(\theta/2)}\,,$$

which is Equation (107.10). Two features carry the physics. The distribution diverges as $\theta \to 0$ because the Coulomb force has infinite range, so no total cross-section exists and only a differential rate is meaningful. And it falls only as $\sin^{-4}(\theta/2)$: backscattering is rare but not exponentially rare, which is precisely what distinguishes a single point charge from a charge spread over the whole atom, for which small deflections compound at random and large ones are suppressed exponentially. □

Corollary 107.6 (First bound on the size of the nucleus)**.** *An α particle of kinetic energy E fired head-on at a nucleus of charge $Z_2 e$ stops at the distance d where all its kinetic energy has become potential energy,*

$$d = \frac{Z_1 Z_2 e^2}{4\pi\varepsilon_0 E}\,. \tag{107.13}$$

So long as Equation (107.10) is obeyed at angle $\theta = \pi$, the nucleus is smaller than d.
Rests on Equations (107.2) and (107.10).

Proof. *Derives Corollary 107.6.*

Energy conservation in the head-on collision gives $E = Z_1 Z_2 e^2/4\pi\varepsilon_0 d$, which is Equation (107.13); and Equation (107.10) was derived assuming a pure Coulomb field down to the turning point, so its persistence at $\theta = \pi$ certifies that nothing else was met. For the 7.7 MeV α particles from ^{214}Po incident on gold, $Z_2 = 79$, and Equation (107.2) gives

$$d = \frac{2 \times 79 \times 1.4400\,\mathrm{MeV\,fm}}{7.7\,\mathrm{MeV}} = 30\,\mathrm{fm}\,,$$

about 2×10^{-4} of the atomic radius. The volume ratio is 10^{-11}: essentially all of the atom is empty, and that is the content of the experiment. Geiger and Marsden went on to verify every separate dependence of Equation (107.10) — on angle, on foil thickness, on the kinetic energy and on Z_2^2 — which is what converted a suggestive anomaly into a measurement [404]. □

Remark 107.7 (Why the classical formula is right). Equation (107.10) was obtained from Newtonian orbits, and there is no reason in advance for a classical calculation to describe the scattering of a quantum particle. It does, exactly: the first Born approximation gives the same formula, and so does the exact solution of the Schrödinger equation in parabolic coordinates. The coincidence is special to the inverse-square law, and its discussion belongs to Chapter 86; the exact treatment differs from the classical one only in a logarithmic distortion of the phase, which no rate measurement sees. At energies high enough for the projectile's spin and the target's finite size to matter, the formula is replaced by Mott's [633] and then by a form factor, and the departure from Equation (107.10) becomes the measurement of the charge distribution treated in Section 107.3.3.

107.1.3 The neutron and the constitution of nuclei

Beryllium bombarded by α particles emits a radiation of extraordinary penetrating power that carries no charge. Curie and Joliot found that it ejects fast protons from paraffin. Chadwick measured the recoils and showed that no photon can account for them [693].

Phenomenon 107.8 (A neutral particle of nucleonic mass)**.** The radiation from α-bombarded beryllium is uncharged, is not absorbed like a photon, and ejects from hydrogen protons of maximum speed $3.3 \times 10^7\,\mathrm{m/s}$ and from nitrogen recoils of maximum speed $4.7 \times 10^6\,\mathrm{m/s}$ [693]. Elastic collisions of a single neutral particle account for both numbers with one mass, close to the proton's; a photon interpretation requires two different and impossibly large energies.

Derivation. *Derives Phenomenon 107.8.*

Take a neutral particle of mass m and speed v striking a nucleus of mass M at rest. In a head-on elastic collision, non-relativistic kinematics gives the target the maximum speed

$$V = \frac{2m}{m+M}\,v\,, \tag{107.14}$$

so the ratio of the maximum recoil speeds of hydrogen and nitrogen is

$$\frac{V_{\mathrm{H}}}{V_{\mathrm{N}}} = \frac{m + M_{\mathrm{N}}}{m + M_{\mathrm{H}}}\,, \tag{107.15}$$

in which the unknown v has cancelled. Measured, the left-hand side is $3.3 \times 10^7\,\mathrm{m/s}/4.7 \times 10^6\,\mathrm{m/s} = 7.0$; with $M_{\mathrm{H}} = m_p$ and $M_{\mathrm{N}} \approx 14 m_p$,

$$\frac{m/m_p + 14}{m/m_p + 1} = 7.0 \quad\Longrightarrow\quad m \approx 1.2\,m_p\,,$$

a mass within the experimental error of the proton's. The modern value is $m_n c^2 = 939.565\,42\,\mathrm{MeV}$ [2427], larger than the proton's by Equation (107.5).

The alternative had to be excluded quantitatively. A photon of energy E_γ scattering elastically from a mass M at rest imparts at most

$$T_{\max} = \frac{2E_\gamma^2}{Mc^2 + 2E_\gamma}\,, \tag{107.16}$$

the Compton kinematics of Chapter 69. The observed proton speed corresponds to $T = 5.7\,\mathrm{MeV}$, which by Equation (107.16) needs $E_\gamma \approx 55\,\mathrm{MeV}$; the observed nitrogen recoil corresponds to $T = 1.6\,\mathrm{MeV}$ and needs $E_\gamma \approx 1.0 \times 10^2\,\mathrm{MeV}$. One radiation cannot have two energies, and neither energy is available: the reaction $^9\mathrm{Be} + \alpha$ releases about 10 MeV in total. The photon hypothesis fails by an order of magnitude and by an internal inconsistency, and the neutral-particle hypothesis fails by neither. □

Proposition 107.9 (No electrons in the nucleus)**.** *A nucleus cannot be built of protons and electrons.*

Rests on Phenomenon 107.8 and Equation (107.1)*.*

Proof. *Derives Proposition 107.9.*

Three independent arguments close the question, and each is quantitative.

Localization. Confining an electron to a region of size $\Delta x \approx 5\,\mathrm{fm}$ requires, by the uncertainty relation, a momentum spread $\Delta p \gtrsim \hbar/2\Delta x$, that is

$$\Delta p\, c \gtrsim \frac{197.3\,\mathrm{MeV\,fm}}{2 \times 5\,\mathrm{fm}} = 20\,\mathrm{MeV}\,,$$

so the electron would be ultrarelativistic with an energy of order 20 MeV. Nothing in the nucleus binds at that scale — the total binding energy per nucleon is 8 MeV — and the electrons actually observed emerging in β decay carry about 1 MeV. The same estimate for a nucleon, heavier by $m_p/m_e \approx 1836$, gives a non-relativistic kinetic energy $(\Delta p)^2/2m_p \approx 0.2\,\mathrm{MeV}$, comfortably below the binding: a nucleon fits in a nucleus and an electron does not.

Spin and statistics. The proton–electron model assigns $^{14}\mathrm{N}$ fourteen protons and seven electrons, twenty-one spin-$\frac{1}{2}$ particles, hence half-integer total spin and Fermi–Dirac statistics for the molecule $^{14}\mathrm{N}_2$. Band spectra show integer spin 1 and Bose–Einstein statistics. The proton–neutron model assigns seven protons and seven neutrons, fourteen fermions, integer spin: correct. The argument is decisive because the alternation of intensities in a band spectrum measures the statistics directly and admits of no adjustment; the general theory of identical particles belongs to Chapter 83.

Magnetic moment. A nuclear magnetic moment is measured in units of the nuclear magneton $\mu_N = e\hbar/2m_p = 5.050\,783\,7 \times 10^{-27}\,\mathrm{J/T}$ [2431], some 1836 times smaller than the Bohr magneton. An electron inside the nucleus would contribute of order a Bohr magneton. No nuclear moment of that size exists [652]. □

Heisenberg took the neutron as a constituent immediately, and with it introduced the formal device that has organized nuclear physics ever since [699].

Definition 107.10 (Isospin)**.** Treat the proton and the neutron as two states of one particle, the *nucleon*, distinguished by the eigenvalue of a formal spin-$\frac{1}{2}$ operator $\boldsymbol{T}$ acting in an internal two-dimensional space:

$$|p\rangle = \left|T = \tfrac{1}{2},\, T_3 = +\tfrac{1}{2}\right\rangle\,, \qquad |n\rangle = \left|T = \tfrac{1}{2},\, T_3 = -\tfrac{1}{2}\right\rangle\,. \tag{107.17}$$

For a nucleus, $T_3 = (Z - N)/2$. The algebra is that of SU(2) (Chapter 14), and $\boldsymbol{T}$ is dimensionless: it is not an angular momentum and carries no factor of $\hbar$.

Remark 107.11 (What isospin asserts, and how well)*.* The claim is that the nuclear force is invariant under rotations in this space, so that states differing only in T_3 have the same energy. It is a good approximate symmetry and not an exact one, and the two sources of breaking are known and separately measurable: the electromagnetic interaction, which sees Z and not A, and the up–down quark mass difference of Chapter 102. The evidence is collected in Section 107.2.4; the anticipation is that the SU(2) here is a subgroup of the flavour symmetry of the light quarks, so that the approximate symmetry of nuclear physics is inherited from an approximate degeneracy in the quark masses.

Phenomenon 107.12 (The free neutron lifetime is disputed)**.** A neutron bound in a stable nucleus lives forever; a free neutron decays, $n \to p + e^- + \bar{\nu}_e$, with mean life

$$\tau_n = (878.4 \pm 0.5)\,\mathrm{s} \tag{107.18}$$

[2427]. Two classes of experiment measure it. Bottle experiments store ultracold neutrons and count the survivors; beam experiments pass a neutron beam through a trap and count the protons produced. The bottle result, $(877.75 \pm 0.36)\,\mathrm{s}$ [2380], and the beam result, near 888 s, differ by about 10 s, some four standard deviations. The discrepancy is unresolved.

Rests on Phenomenon 107.8 and Equation (107.5).

Remark 107.13 (How to report an unresolved discrepancy)*.* The two methods do not measure quite the same thing. A bottle counts neutrons that disappear by any route; a beam counts protons that appear by one route. If some small branch of neutron decay produced no proton, the beam lifetime would exceed the bottle lifetime by exactly the observed sense — which is why searches for such a branch have been made, and have found nothing. The honest statement is that either one experiment has an unaccounted systematic effect or the neutron has an unobserved decay channel at the 10^{-2} level, and that as of the 2024 compilation neither has been established [2427]. What is not honest is to average the two and quote the result, which is what an uncritical combination does. The number in Equation (107.18) is the Particle Data Group's average over the bottle measurements, with the beam results excluded on exactly these grounds; the derivation of the lifetime from the weak coupling belongs to Chapter 101.

107.2 The nucleon–nucleon interaction

107.2.1 Yukawa's exchange mechanism

Two facts about the nuclear force were established before anyone knew what carried it. It is enormously stronger than the electrostatic repulsion it overcomes, and it has a range: nucleons a few femtometres apart do not feel it at all, or nuclear matter would not saturate (Section 107.3.1). Electromagnetism has no range because the photon is massless. Yukawa's proposal was that the nuclear force is carried by a quantum that is not [765].

Theorem 107.14 (The Yukawa potential)**.** *A neutral scalar field of mass m coupled to static point sources produces between two of them the potential energy*

$$V(r) = -\frac{g^2}{4\pi}\,\frac{\hbar c}{r}\,\mathrm{e}^{-r/\lambda}\,, \qquad \lambda = \frac{\hbar}{mc}\,, \tag{107.19}$$

where λ is the reduced Compton wavelength of the quantum, in m*, and g is dimensionless. Equivalently, in terms of the momentum $\boldsymbol{q}$ transferred between the sources,*

$$\tilde{V}(\boldsymbol{q}) = \int \mathrm{d}^3 r\; \mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}/\hbar}\, V(r) = -\frac{g^2\hbar^3 c}{\boldsymbol{q}^2 + m^2c^2}\,, \tag{107.20}$$

of SI dimension $\mathrm{J\,m^3}$*: the exchanged quantum's propagator, evaluated at zero energy transfer.*

Rests on Equation (107.1) and Notation 100.1.

Derivation. *Derives Theorem 107.14.*

Let ϕ obey the Klein–Gordon equation of Chapter 92 with a source,

$$\left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2} - \nabla^2 + \frac{1}{\lambda^2}\right)\phi = \rho\,, \qquad \frac{1}{\lambda} = \frac{mc}{\hbar}\,, \tag{107.21}$$

in which $1/\lambda$ has dimension $1/\mathrm{m}$, as it must: it is the only combination of m, c and $\hbar$ with that dimension, and its appearance is the whole of Yukawa's idea. For a static source the time derivative drops and

$$\left(\nabla^2 - \frac{1}{\lambda^2}\right)\phi = -g\,\delta^3(\boldsymbol{r})\,, \tag{107.22}$$

with a strength g whose dimension is fixed below. Away from the origin the solution is spherically symmetric, and the substitution $\phi = u(r)/r$ turns $\nabla^2\phi$ into u''/r, so that $u'' = u/\lambda^2$ and $u \propto \mathrm{e}^{\pm r/\lambda}$. Only the decaying sign is admissible. The coefficient is fixed by integrating Equation (107.22) over a small ball: the $1/\lambda^2$ term contributes nothing as the radius shrinks, and the divergence theorem gives $\oint \nabla\phi \cdot \mathrm{d}\boldsymbol{S} = -g$, which for $\phi = C\mathrm{e}^{-r/\lambda}/r$ is $-4\pi C$. Hence $C = g/4\pi$ and

$$\phi(r) = \frac{g}{4\pi}\,\frac{\mathrm{e}^{-r/\lambda}}{r}\,. \tag{107.23}$$

As $\lambda \to \infty$ this is the Coulomb field, which is the check that the algebra is right.

A second source at distance r has energy $-g'\phi(r)$ in this field, and for two identical nucleons $g' = g$. Writing the product g^2 so that the result carries the dimension of energy fixes the normalization: with g dimensionless the natural coefficient is $g^2\hbar c/4\pi$, since $\hbar c$ has dimension $\mathrm{J\,m}$ by Equation (107.1) and dividing by r gives an energy. That is Equation (107.19). The convention is deliberately the electromagnetic one: comparing with $V_{\mathrm{Coulomb}} = e^2/4\pi\varepsilon_0 r = \alpha\hbar c/r$ shows that $g^2/4\pi$ is the exact analogue of the fine-structure constant, dimensionless and directly comparable with $\alpha = 7.3 \times 10^{-3}$.

For Equation (107.20), do the angular integral,

$$\int \mathrm{d}^3 r\; \mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}/\hbar}\frac{\mathrm{e}^{-r/\lambda}}{r} = \frac{4\pi\hbar}{|\boldsymbol{q}|}\int_0^\infty \mathrm{d}r\;\sin\!\left(\frac{|\boldsymbol{q}|\,r}{\hbar}\right)\mathrm{e}^{-r/\lambda} = \frac{4\pi\hbar^2}{\boldsymbol{q}^2 + \hbar^2/\lambda^2}\,,$$

the last step by elementary integration (or by closing a contour, as in Chapter 8). Multiplying by $-g^2\hbar c/4\pi$ and using $\hbar/\lambda = mc$ gives Equation (107.20). The denominator $\boldsymbol{q}^2 + m^2c^2$ is a squared momentum, in $\mathrm{kg^2\,m^2/s^2}$, exactly as the mass-shell condition of Notation 100.1 requires; it is the propagator denominator $p^2 - m^2c^2$ continued to a purely spacelike momentum transfer, which is what a static force is. □

Corollary 107.15 (Range fixes mass)**.** *A force of observed range λ requires a quantum of mass $m = \hbar/\lambda c$. For $\lambda = 1.4\,\mathrm{fm}$,*

$$mc^2 = \frac{\hbar c}{\lambda} = \frac{197.33\,\mathrm{MeV\,fm}}{1.4\,\mathrm{fm}} = 141\,\mathrm{MeV}\,, \tag{107.24}$$

that is $m = 141\,\mathrm{MeV}/c^2$, some 270 electron masses and about a seventh of a nucleon mass.
Rests on Theorem 107.14 and Equation (107.1).

Proof. *Derives Corollary 107.15.*

Immediate from $\lambda = \hbar/mc$ and Equation (107.1). The inference runs both ways, and Yukawa ran it in this direction: the range was known from the size of light nuclei — the deuteron is bound and the diproton is not, which places the range within a factor of two of a femtometre — and the mass was the prediction. It is one of the few predictions in physics of a new particle's mass, made in 1935 and confirmed in 1947 [902] with the observed $m_{\pi^\pm}c^2 = 139.570\,39\,\mathrm{MeV}$ [2427]. The equivalent range is

$$\lambda_\pi = \frac{\hbar}{m_\pi c} = \frac{197.326\,98\,\mathrm{MeV\,fm}}{139.570\,39\,\mathrm{MeV}} = 1.4138\,\mathrm{fm}\,. \tag{107.25}$$

□

Remark 107.16 (The exchange picture and its limits). Proposition 101.65 makes the same statement for the weak interaction, where the exchanged quantum weighs $80.37\,\mathrm{GeV}/c^2$ [2427] and the range is $2.5\times10^{-3}\,\mathrm{fm}$ — so short that the interaction looks pointlike at every energy at which it was first studied. The two cases differ in one respect that decides how far each may be pushed. The electroweak and electromagnetic couplings are small, so a single exchange is the leading term of a controlled expansion. Here $g^2/4\pi$ is not small: with the pion–nucleon coupling $g_{\pi N}=13.05$ from the Nijmegen partial-wave analysis of the nucleon–nucleon scattering data [1874],

$$\frac{g_{\pi N}^2}{4\pi}=13.6\,, \tag{107.26}$$

against $\alpha=1/137$, a ratio of nearly 2000. A one-quantum exchange is therefore not the first term of a convergent series, and Equation (107.19) cannot be trusted at short distance, where two-pion and heavier exchanges enter with comparable weight. What survives is the *tail*: at r well beyond λ_π the single-pion term dominates because every other exchange is more heavily damped, and it is there that Equation (107.19) is a theorem rather than a model. This is the observation that Section 107.2.4 turns into a systematic expansion.

Remark 107.17 (The quantum is pseudoscalar, and the potential changes). Theorem 107.14 assumed a *scalar* field, which is the simplest case and gives the range correctly. The pion is pseudoscalar (Section 107.2.2), so it couples to the nucleon through γ^5, and the derivative structure of that vertex replaces the plain e^{-x}/x by a spin- and isospin-dependent form. The change is not cosmetic. The effective coupling that appears is not $g_{\pi N}$ but

$$f=\frac{m_\pi c}{2m_N c}\,g_{\pi N}\,,\qquad \frac{f^2}{4\pi}=\frac{g_{\pi N}^2}{4\pi}\left(\frac{m_\pi}{2m_N}\right)^2=0.075\,, \tag{107.27}$$

smaller by the square of the mass ratio, and the strength of the long-range potential is set by $(f^2/4\pi)\,m_\pi c^2/3=3.5\,\mathrm{MeV}$ rather than by $13.6\,\hbar c/r$. Evaluated at $r=2\,\mathrm{fm}$ the one-pion-exchange tail is of order 0.6 MeV, which is the right size for the outer part of a force that binds the deuteron by 2.2 MeV. The apparent paradox of Equation (107.26) — a coupling of 13.6 producing a potential of a fraction of a MeV — is entirely accounted for by Equation (107.27), and noticing that is the difference between a numerical estimate and a number pulled from the air.

107.2.2 The pion

Yukawa's quantum was looked for in cosmic rays and, in 1937, apparently found: a penetrating charged particle of roughly the right mass. It was the wrong particle, and the experiment that showed so is a model of how to kill an identification.

Phenomenon 107.18 (The cosmic-ray mesotron is not strongly interacting)**.** Negative mesotrons brought to rest in carbon decay rather than being absorbed by a nucleus [899]. A negatively charged particle stopped in matter cascades into a Bohr orbit about a nucleus; if it felt the nuclear force it would be absorbed from that orbit in a time of order the nuclear transit time. The observed absorption rate is smaller than that estimate by some thirteen orders of magnitude.

Derivation. *Derives Phenomenon 107.18.*

The mesonic Bohr radius scales as $a_0 m_e/m$, so a particle of mass $\approx 200\,m_e$ orbits carbon at $a\approx a_0 m_e/(200\times6)=4.4\times10^{-14}\,\mathrm{m}$, which is still large compared with the nucleus but small enough that the overlap of the orbital wave function with the nuclear volume is $|\psi(0)|^2\,V_{\mathrm{nuc}}\sim(R/a)^3\approx2\times10^{-4}$. A strong interaction absorbs on contact, in a time $R/c\approx1\times10^{-23}\,\mathrm{s}$, so the expected lifetime against nuclear capture is $\sim5\times10^{-20}\,\mathrm{s}$ — against

a measured decay time $2.2 \times 10^{-6}\,\mathrm{s}$ [2427] that is unchanged by the presence of the nucleus. Thirteen orders of magnitude is not a discrepancy to be argued about. The particle is the muon; its lifetime and its couplings belong to Chapter 101.

The resolution came from photographic emulsions exposed at altitude, where Lattes, Muirhead, Occhialini and Powell found tracks in which one particle comes to rest and a second, of definite and shorter range, sets off from the end point [902]: the chain $\pi \to \mu \to e$. Two particles of similar mass had been conflated; the heavier one is Yukawa's, is produced strongly and is absorbed strongly, and therefore never reaches sea level, while the lighter is the weakly interacting decay product that does. □

Table 107.1: The pion triplet, from the 2024 Particle Data Group compilation [2427]. The mean life is computed from the listed width as $\tau = \hbar/\Gamma$, and the range from $\lambda = \hbar/mc$. The neutral pion decays electromagnetically to two photons, which is why it is shorter lived by nine orders of magnitude than its charged partners, whose only open channel is weak.

	mc^2 (MeV)	λ (fm)	τ	principal decay
$\pi^{\pm}$	139.57039(18)	1.4138	$2.603 \times 10^{-8}\,\mathrm{s}$	$\mu^{\pm}\nu$
π^{0}	134.9768(5)	1.4619	$8.43 \times 10^{-17}\,\mathrm{s}$	$\gamma\gamma$

Proposition 107.19 (The pion has odd intrinsic parity)**.** *The reaction $\pi^- + d \to n + n$, observed to proceed from a captured s state [985], requires the intrinsic parity of the pion to be -1.*

Rests on Phenomena 83.1 and 105.5.

Proof. *Derives Proposition 107.19.*

A π^- stopped in deuterium cascades to the $1s$ level of pionic deuterium and is captured from there, so the initial orbital angular momentum is $\ell = 0$. The deuteron has spin 1 and the pion spin 0 (Section 107.2.3 and the observed decay to two spin-zero particles), so the initial total angular momentum is $J = 1$ and the initial parity is $P_\pi P_d (-1)^\ell = P_\pi$, the deuteron being even.

The final state is two identical fermions, whose total wave function must be antisymmetric. Enumerate the two-neutron states with $J = 1$: ${}^1P_1$ has $S = 0$ (antisymmetric spin) and $L = 1$ (antisymmetric space), hence a symmetric total — forbidden; ${}^3S_1$ and ${}^3D_1$ have $S = 1$ (symmetric) and even L (symmetric) — also forbidden. Only ${}^3P_1$, with $S = 1$ and $L = 1$, is antisymmetric, and its parity is $(-1)^L = -1$. Parity is conserved by the strong interaction (Chapter 105), so $P_\pi = -1$.

The pion is therefore a *pseudoscalar*: spin 0, parity -1, written $J^P = 0^-$. Nothing in the argument is model dependent; it uses only the Pauli principle, the observed spins, and the fact that the capture is from an s state — which is itself measured, from the intensity of the X-rays emitted in the atomic cascade. □

Remark 107.20 (Why the pion is light, and why that is not a coincidence)*.* A pion weighs a seventh of a nucleon although both are made of the same light quarks, and the whole shape of nuclear physics — saturation at $0.17/\mathrm{fm}^3$, a binding energy per nucleon of 8 MeV, a force of range 1.4 fm — follows from that one number. The explanation is that the pion is not an ordinary bound state but the almost-Goldstone boson of a chiral symmetry of the light quarks that is spontaneously broken, so that its mass vanishes in the limit of massless quarks and is small because the quark masses are small. That account is the business of Chapter 102, and the relation between the pion decay constant, the pion–nucleon coupling and the axial coupling of the nucleon is already derived in Proposition 101.42, where it is verified to 0.6 per cent. What belongs here is only the consequence: the range of the nuclear

force is a low-energy relic of a symmetry of the quark Lagrangian, and not an independent parameter of nuclear physics.

107.2.3 The deuteron

The one bound state of two nucleons is the hydrogen atom of nuclear physics: simple enough to solve and rich enough to constrain the force. Urey, Brickwedde and Murphy found it spectroscopically, as a faint set of lines displaced from the Balmer series by the isotope shift [708]; Chadwick and Goldhaber measured its binding directly, by breaking it with the 2.62 MeV gamma ray of thorium C″ and detecting the proton [734] — the first nuclear photodisintegration, and the first direct measurement of a nuclear binding energy. The modern value from the atomic-mass evaluation is

$$B_d = (m_p + m_n - m_d)\,c^2 = 2.2246\,\mathrm{MeV} \tag{107.28}$$

[2393].

Phenomenon 107.21 (The deuteron is not spherical)**.** The only bound state of two nucleons has spin 1, a binding energy of 2.2246 MeV [2393], no excited state, and — decisively — a small but non-vanishing electric quadrupole moment, measured by molecular-beam magnetic resonance [840]. There is moreover no bound state of two protons and none of two neutrons.

Derivation. *Derives Phenomenon 107.21.*

A state of orbital angular momentum $L = 0$ has a spherically symmetric spatial distribution and therefore exactly zero quadrupole moment, so the observed moment proves that the deuteron ground state is not a pure S wave. But a central potential $V(r)$ commutes with $\boldsymbol{L}$, so L would then be a good quantum number and no admixture of $L = 2$ into an $L = 0$ ground state would be possible. The nucleon–nucleon interaction therefore contains a non-central piece. Which piece is fixed by what is available: the interaction must be a scalar built from the separation $\hat{\boldsymbol{r}}$ and the two spins, and the only non-central such scalar that is even under parity, even under time reversal and independent of velocity is the tensor operator

$$S_{12} = 3\,(\boldsymbol{\sigma}_1 \cdot \hat{\boldsymbol{r}})\,(\boldsymbol{\sigma}_2 \cdot \hat{\boldsymbol{r}}) - \boldsymbol{\sigma}_1 \cdot \boldsymbol{\sigma}_2\,. \tag{107.29}$$

This conserves the total angular momentum J but not L, and since $L = 0$ and $L = 2$ have the same parity it mixes exactly the ${}^3S_1$ and ${}^3D_1$ states that share $J = 1$. The measured quadrupole moment is thus a direct measurement of the D-state admixture. The two null results complete the picture: that no diproton and no dineutron binds, while the deuteron does, says the force is spin dependent, since the ${}^1S_0$ configuration is the only one open to two identical nucleons at low energy and it is very nearly, but not quite, binding. □

Proposition 107.22 (The deuteron is barely bound)**.** *Model the ${}^3S_1$ interaction as a square well of depth V_0 and radius R. The bound state at energy $-B_d$ requires*

$$k \cot kR = -\kappa\,, \qquad k = \frac{\sqrt{2\mu\,(V_0 - B_d)}}{\hbar}\,, \qquad \kappa = \frac{\sqrt{2\mu B_d}}{\hbar}\,, \tag{107.30}$$

with $\mu = m_N/2$ the reduced mass. For $R = 2.0\,\mathrm{fm}$ this gives $V_0 = 36.6\,\mathrm{MeV}$, against a minimum depth of 25.6 MeV needed to bind at all and 2.3×10^2 MeV needed to bind a second s state.

Rests on Equations (107.1) and (107.28).

Proof. *Derives Proposition 107.22.*

Inside the well the regular s-wave radial function is $u \propto \sin kr$; outside it is $u \propto \mathrm{e}^{-\kappa r}$, since a bound state must decay. Continuity of u'/u at $r = R$ is Equation (107.30). Numerically,

$$\kappa = \frac{\sqrt{2 \times 469.46\,\mathrm{MeV} \times 2.2246\,\mathrm{MeV}}}{197.327\,\mathrm{MeV\,fm}} = 0.2316/\mathrm{fm}\,, \tag{107.31}$$

so $1/\kappa = 4.32\,\mathrm{fm}$. Solving Equation (107.30) at $R = 2.0\,\mathrm{fm}$ gives $k = 0.910/\mathrm{fm}$ and $V_0 = B_d + (\hbar c k)^2/2\mu c^2 = 36.6\,\mathrm{MeV}$. The threshold for binding is $kR = \pi/2$ with $\kappa \to 0$, that is $V_0 = \pi^2\hbar^2/8\mu R^2 = 25.6\,\mathrm{MeV}$; the second level needs $kR = 3\pi/2$, nine times as much.

Three conclusions follow, and each is a statement about the force rather than about the model. First, $B_d/V_0 = 0.06$: the well is only about forty per cent deeper than the minimum that binds anything at all, so the deuteron sits just below threshold and its properties are correspondingly sensitive to the force — which is what makes it a good measuring instrument. Second, there is no excited state because there is no room for one, and none is observed. Third, and most striking, $1/\kappa = 4.3\,\mathrm{fm}$ exceeds the range of the force by a factor of two or three: most of the deuteron's probability lies *outside* the region where the two nucleons interact. A bound state that spends most of its time out of range of the force that binds it is the signature of a system barely bound, and it is the reason the low-energy properties of the two-nucleon system can be described without knowing the force in detail — the subject of the next proposition. □

Proposition 107.23 (The deuteron and the triplet scattering length)**.** *The effective-range expansion, whose systematic derivation belongs to Section 86.3.3,*

$$k\cot\delta_0 = -\frac{1}{a} + \frac{1}{2}r_e k^2 + \cdots , \tag{107.32}$$

relates the triplet scattering length a_t to the deuteron binding through $1/a_t = \kappa - \frac{1}{2}r_t\kappa^2$. With $B_d = 2.2246\,\mathrm{MeV}$ and the measured triplet effective range $r_t = 1.75\,\mathrm{fm}$, this predicts $a_t = 5.42\,\mathrm{fm}$, the measured value.

Rests on Equation (107.31) and Phenomenon 86.1.

Proof. *Derives Proposition 107.23.*

A bound state is a pole of the s-wave scattering amplitude at $k = \mathrm{i}\kappa$, where $\cot\delta_0 = \mathrm{i}$; substituting $k = \mathrm{i}\kappa$ in Equation (107.32) gives $-\kappa = -1/a_t - \frac{1}{2}r_t\kappa^2$, that is $1/a_t = \kappa - \frac{1}{2}r_t\kappa^2$. With Equation (107.31),

$$\frac{1}{a_t} = 0.2316/\mathrm{fm} - \tfrac{1}{2}\times 1.75\,\mathrm{fm}\times(0.2316/\mathrm{fm})^2 = 0.1847/\mathrm{fm}\,,$$

so $a_t = 5.42\,\mathrm{fm}$, which is what neutron–proton scattering measures. Two quantities from unrelated experiments — a photodisintegration threshold and a scattering cross-section — are tied by two parameters, and the tie holds. Note that the deuteron enters nowhere in the derivation as a model: only the position of the pole. This is the content of Phenomenon 86.1, that low-energy scattering sees one length and does not care what produced it. □

Derivation pending #168

The effective-range expansion itself: the proof that $k\cot\delta_0$ is an even analytic function of the wave number at low energy, with the scattering length and the effective range as its first two coefficients. It is the premise of the proposition above; its derivation belongs to the low-energy section of the scattering-theory chapter, where it is not yet written.

Phenomenon 107.24 (The neutron–proton cross-section depends violently on spin)**.** The total cross-section for thermal neutrons on hydrogen is $20.5\times10^{-28}\,\mathrm{m}^2$, five and a half times what the triplet interaction alone would give. The singlet scattering length is large and *negative*, $a_s = -23.7\,\mathrm{fm}$, against $a_t = 5.42\,\mathrm{fm}$: the two spin channels of the same pair of particles behave completely differently.

Rests on Phenomenon 86.1 and Equation (107.32).

Derivation. *Derives Phenomenon 107.24.*

Of the four spin states of a neutron and a proton, three are triplet and one singlet, and an unpolarized beam populates them in that ratio. Since $\sigma = 4\pi a^2$ at zero energy (Phenomenon 86.1),

$$\sigma = 4\pi\left(\frac{3}{4}a_t^2 + \frac{1}{4}a_s^2\right) = 4\pi\left[\frac{3}{4}\,(5.42\,\mathrm{fm})^2 + \frac{1}{4}\,(23.7\,\mathrm{fm})^2\right] = 20.4\times10^{-28}\,\mathrm{m}^2\,, \tag{107.33}$$

against the measured $20.5\times10^{-28}\,\mathrm{m}^2$. Had the force been spin independent, $a_s = a_t$ would give $4\pi a_t^2 = 3.7\times10^{-28}\,\mathrm{m}^2$, less by a factor of five and a half. The cross-section was measured long before it was understood, and it is the singlet channel that supplies almost all of it.

The negative sign is the further information. By Equation (107.32) with $r_s = 2.73\,\mathrm{fm}$, solving $1/a_s = \kappa_s - \frac{1}{2}r_s\kappa_s^2$ gives $\kappa_s = -0.0400/\mathrm{fm}$ — the root of the wrong sign, so the pole lies on the unphysical sheet and the state is *virtual*, not bound. Its energy is

$$E_s = \frac{(\hbar c\kappa_s)^2}{2\mu c^2} = 66\,\mathrm{keV}\,, \tag{107.34}$$

just *above* threshold, where the triplet state lies 2.2 MeV below it. Fitting the square well of Proposition 107.22 to a_s at the same radius $R = 2.0\,\mathrm{fm}$ gives a singlet depth of 23.9 MeV against the 25.6 MeV that would just bind: the singlet channel fails by six per cent in the depth of the well, and by 66 keV in the energy. That near-miss is why there is no dineutron and no diproton: two identical nucleons at low energy are confined by the Pauli principle — whose general theory belongs to Chapter 83 — to ${}^1S_0$, which is precisely the channel that just fails to bind. Six per cent more attraction and the universe would contain bound dineutrons, and hydrogen burning in stars would proceed by a strong reaction rather than a weak one — in which case the Sun would have exhausted its fuel long before the Earth formed. □

Proposition 107.25 (The D-state admixture from the magnetic moment)**.** *If the deuteron ground state is* $|d\rangle = \sqrt{1-P_D}\,|{}^3S_1\rangle + \sqrt{P_D}\,|{}^3D_1\rangle$*, then*

$$\mu_d = \mu_p + \mu_n - \frac{3}{2}\left(\mu_p + \mu_n - \frac{1}{2}\mu_N\right)P_D\,, \tag{107.35}$$

and the measured moments give $P_D \approx 0.04$.

Rests on Equation (107.29) and Phenomenon 107.21.

Proof. *Derives Proposition 107.25.*

In a pure ${}^3S_1$ state the orbital motion contributes nothing and the moment is the sum of the intrinsic moments, $\mu_p + \mu_n = (2.79285 - 1.91304)\,\mu_N = 0.87981\,\mu_N$.

In a ${}^3D_1$ state the spins and the orbital motion are coupled to $J = 1$ with $L = 2$ and $S = 1$, and the moment must be projected. Within a manifold of fixed J only the component of a vector operator along $\boldsymbol{J}$ survives — the projection theorem, whose proof belongs to Chapter 79 — so with $\boldsymbol{\mu} = \mu_N\hbar^{-1}\,(g_L\boldsymbol{L} + g_S\boldsymbol{S})$ and

$$\langle\boldsymbol{L}\cdot\boldsymbol{J}\rangle = \tfrac{1}{2}\,[J(J+1) + L(L+1) - S(S+1)]\,\hbar^2 = 3\hbar^2\,,$$
$$\langle\boldsymbol{S}\cdot\boldsymbol{J}\rangle = \tfrac{1}{2}\,[J(J+1) + S(S+1) - L(L+1)]\,\hbar^2 = -\hbar^2\,,$$

the projections in the state of maximal J_z are $\langle L_z\rangle = \frac{3}{2}\hbar$ and $\langle S_z\rangle = -\frac{1}{2}\hbar$, since $J(J+1) = 2$. Two g factors are then needed. The orbital one is $g_L = \frac{1}{2}$, because only the proton carries charge and in the centre-of-mass frame it carries half of the relative orbital angular momentum. The spin one is fixed by the triplet coupling: with $\boldsymbol{\mu}_{\mathrm{spin}} = \mu_N\hbar^{-1}(g_p\boldsymbol{s}_p + g_n\boldsymbol{s}_n)$ and

$g_p = 2\mu_p/\mu_N$, $g_n = 2\mu_n/\mu_N$, projecting on $\boldsymbol{S} = \boldsymbol{s}_p + \boldsymbol{s}_n$ gives $g_S = \tfrac{1}{2}(g_p + g_n) = (\mu_p + \mu_n)/\mu_N$. Hence

$$\mu\left({}^3D_1\right) = \tfrac{1}{2}\cdot\tfrac{3}{2}\mu_N + \frac{\mu_p + \mu_n}{\mu_N}\left(-\tfrac{1}{2}\right)\mu_N = \tfrac{3}{4}\mu_N - \tfrac{1}{2}\left(\mu_p + \mu_n\right) = 0.310\,\mu_N\,,$$

markedly smaller than the S-state value, which is why a few per cent of D state suffices to explain the discrepancy. Weighting the two by $1 - P_D$ and P_D yields Equation (107.35). With $\mu_d = 0.85744\,\mu_N$,

$$P_D = \frac{0.87981 - 0.85744}{\tfrac{3}{2}\,(0.87981 - 0.5)} = 0.039\,,$$

some four per cent. The quadrupole moment, $Q_d = +2.86 \times 10^{-31}\,\mathrm{m}^2$ in units of the elementary charge, gives a compatible figure of four to six per cent depending on the assumed radial functions — and gives it with a sign, the positive value saying the deuteron is prolate, stretched along its spin axis, which is the shape the tensor force Equation (107.29) produces when the spins are aligned along the separation. Two independent static moments, measured by molecular-beam resonance [840], therefore agree on the size of a component of the wave function that no experiment observes directly. The interpretation is not free of assumptions — P_D is not an observable, because it depends on the off-shell convention for the potential — but the tensor force it diagnoses is. □

107.2.4 Phenomenological and effective-field-theory potentials

Phenomenon 107.26 (Charge symmetry and charge independence)**.** After the electromagnetic interaction has been removed, the ${}^1S_0$ scattering lengths of the three nucleon pairs are

$$a_{pp} = -17.3\,\mathrm{fm}\,, \qquad a_{nn} = -18.9\,\mathrm{fm}\,, \qquad a_{np} = -23.7\,\mathrm{fm}\,. \tag{107.36}$$

The first two agree to within one part in ten (*charge symmetry*: the nn force equals the pp force); all three agree to within about a quarter (*charge independence*: the force does not depend on the nucleons' identity at all). Neither is exact.

Rests on Definition 107.10 and Proposition 107.23.

Derivation. *Derives Phenomenon 107.26.*

Charge independence is precisely the statement that the interaction commutes with the isospin operators of Definition 107.10, so that the three $T = 1$ states pp, nn and the symmetric combination of np share one interaction. Charge symmetry is the weaker statement that it commutes with the single rotation by π about the 2-axis in isospin space, which exchanges p and n.

The apparent size of the violation is deceptive, and this is where Proposition 107.23 earns its keep. A scattering length close to a pole is not a linear measure of the force: with the ${}^1S_0$ state a mere 66 keV from threshold, a change of one per cent in the well depth moves a by tens of per cent. Converting Equation (107.36) back into an equivalent well depth through Equation (107.30) shows the underlying interactions differing by about 1 per cent between np and pp, and by a few tenths of a per cent between nn and pp. Two sources of that residual are known and are not adjustable: the electromagnetic interaction beyond the Coulomb term already removed, and the up–down quark mass difference of Chapter 102, which makes $\pi^{\pm}$ and π^0 differ in mass by 4.59 MeV [2427] and therefore in exchange range by 0.048 fm. □

The empirical picture that the scattering data enforce has four ingredients, and every one of them is required by a measurement already quoted.

Definition 107.27 (The phenomenological nucleon–nucleon potential)**.** The static two-nucleon interaction is written

$$V = V_C(r) + V_\sigma(r)\,\boldsymbol{\sigma}_1\cdot\boldsymbol{\sigma}_2 + V_T(r)\,S_{12} + V_{LS}(r)\,\boldsymbol{L}\cdot\boldsymbol{S} + \cdots , \tag{107.37}$$

each radial function carrying a further dependence on $\boldsymbol{\tau}_1\cdot\boldsymbol{\tau}_2$, and each of dimension J. The operators are the complete list of scalars that can be built from $\hat{\boldsymbol{r}}$, $\boldsymbol{\sigma}_1$, $\boldsymbol{\sigma}_2$ and $\boldsymbol{L}$ subject to invariance under rotations, parity and time reversal, up to terms quadratic in $\boldsymbol{L}$.

Remark 107.28 (What each term is doing). V_C is strongly repulsive inside about 0.5 fm — a *hard core*, without which nuclear matter would collapse rather than saturate, since an attraction alone gives an energy growing as A^2 and not as A (Section 107.3.1); the evidence is that the $^1S_0$ phase shift, positive at low energy, changes sign near 250 MeV of laboratory energy, which is what a repulsive core at short distance does. V_σ is demanded by Phenomenon 107.24. V_T is demanded by Phenomenon 107.21. V_{LS} is demanded by the polarization of nucleons scattered from nuclei, and independently by the shell structure of Section 107.4.2, whose magic numbers cannot be reproduced without it. Fitted to the several thousand measured phase shifts below 350 MeV, this form with about forty parameters — the Argonne v_{18} potential [1913] — reproduces the world scattering data with χ^2 per datum near unity. That is an excellent fit and a poor theory: forty parameters are forty things not understood, and the potential has no systematic error estimate because it has no expansion parameter.

Theorem 107.29 (Chiral power counting for the nuclear force)**.** *Let Q denote a momentum of order the pion mass or a nucleon momentum inside a nucleus, and $\Lambda \approx 1\,\mathrm{GeV}/c$ the scale at which the pionic description fails. Then a connected diagram with A nucleons, L loops, C separately connected pieces and vertices of type i carrying d_i derivatives and n_i nucleon fields contributes to the potential at order $(Q/\Lambda)^\nu$ with*

$$\nu = 2\,(L - C + 1) + \sum_i \left(d_i + \frac{n_i}{2} - 2 \right) , \tag{107.38}$$

a sum of non-negative terms [1840]. Consequently many-body forces are suppressed: the leading two-nucleon force enters at $\nu = 0$, the leading three-nucleon force at $\nu = 3$, and the leading four-nucleon force at $\nu = 4$.

Rests on Proposition 102.67 and Theorem 102.70.

Remark 107.30 (What the chiral power counting buys). The counting of Theorem 107.29 is effective-field-theory power counting — a subject that belongs to Chapter 108 — applied to the effective theory whose fields are nucleons and pions and whose symmetry is the spontaneously broken chiral symmetry of Chapter 102. Three things follow that no fit can supply. The long-range part of the force is *predicted*, since at leading order it is exactly the one-pion exchange of Remark 107.17 with the coupling already measured in πN scattering. The short-range part is parametrized by contact terms whose number at each order is finite and known in advance, so the theory has a controlled expansion rather than a free-form fit. And the hierarchy of many-body forces is derived rather than assumed: the three-nucleon force is down by $(Q/\Lambda)^3$, which is the order of a per cent in the amplitude, and this is why two-body forces alone describe light nuclei to a few hundred keV per nucleon and no better. Modern implementations carried to fourth and fifth order fit the same phase shifts as [1913] with comparable quality and, unlike it, with an error band [2177].

The three-nucleon force is not optional. Two-body forces fitted to scattering underbind ^{3}H by about 0.8 MeV out of 8.48 MeV and misplace the saturation point of nuclear matter badly; adding the leading chiral three-body terms, whose two parameters are fixed once from light nuclei, repairs both. A force between three particles that is not the sum of pairwise

forces is unfamiliar from electromagnetism, where it is absent to leading order, and it is unavoidable here for a plain reason: the nucleon is composite, and eliminating its internal degrees of freedom in favour of a potential leaves behind exactly such terms.

Derivation pending #169

Chiral power counting: the derivation of the counting formula for the exponent, by assembling the powers of Q from each propagator, each loop integration and each vertex of the effective Lagrangian, and the demonstration that every bracket in the sum is non-negative for a Lagrangian consistent with chiral symmetry. It belongs in Appendix A, since it needs the full vertex enumeration and runs to several pages; the statement and its consequences are used above without it.

107.3 Nuclear masses and binding

107.3.1 The binding-energy curve

Definition 107.31 (Binding energy and mass defect)**.** The binding energy of a nuclide with Z protons and N neutrons is the energy needed to take it apart into free nucleons at rest,

$$B(Z,N) = \left[Z m_p + N m_n - M(Z,N)\right] c^2 \,, \tag{107.39}$$

in J, with $M(Z,N)$ the mass of the bound nucleus. A bound system weighs less than its parts by B/c^2, the *mass defect*, which is the only place in this book where the relativistic mass–energy relation is used as a routine measuring instrument rather than tested: nuclear masses are measured to keV by Penning traps and mass spectrometry [2393], and the binding energy is read off.

Phenomenon 107.32 (Nuclear matter saturates, and iron is the most tightly bound)**.** The binding energy per nucleon, $B/A = \left[Z m_p + N m_n - M(Z,N)\right] c^2/A$, is nearly constant across the chart of nuclides at about 8 MeV, rising to a maximum near 8.79 MeV in the neighbourhood of ^{56}Fe and falling away on both sides [2393]. Charge radii measured by electron scattering follow $R \approx r_0 A^{1/3}$ with $r_0 \approx 1.2\,\mathrm{fm}$, so the density of nuclear matter is the same in a light nucleus as in a heavy one [1088, 2209]. Both regularities say the same thing — a nucleon binds only to its neighbours, not to every other nucleon — and because the curve has an interior maximum, energy is released both by fusing light nuclei and by splitting heavy ones.

Rests on Definition 107.31.

Derivation. *Derives Phenomenon 107.32.*

Suppose first that every nucleon attracted every other with the same strength. There are $A(A-1)/2$ pairs, so B would grow as A^2 and B/A as A; the binding energy per nucleon of uranium would be sixty times that of carbon. It is not: the two agree within fifteen per cent. The interaction must therefore *saturate*, each nucleon binding to a fixed number of neighbours regardless of how many nucleons the nucleus contains. Two independent facts follow at once and both are observed. The energy is proportional to the number of nucleons, $B \approx a_V A$, and the volume is proportional to the number of nucleons, so the density is constant and $R = r_0 A^{1/3}$.

Saturation is not automatic. A purely attractive short-range force does not saturate: nucleons would simply pile into the same region until the density diverged. Two mechanisms prevent that, and both are established independently. The Pauli principle keeps identical nucleons apart, since at fixed volume the kinetic energy rises as $\rho^{2/3}$ (the Fermi gas of

Proposition 107.36 below); and the short-range repulsive core of Remark 107.28 forbids close packing outright. The observed saturation density is

$$\rho_0 \approx 0.17/\mathrm{fm}^3 = 1.7 \times 10^{44}/\mathrm{m}^3 \,, \tag{107.40}$$

which in mass terms is $2.8 \times 10^{17}\,\mathrm{kg/m^3}$, some fourteen orders of magnitude above the density of water and the same density that supports a neutron star (Chapter 49).

That B/A has an interior maximum then follows from two competing corrections to $B = a_V A$, both of which reduce it. Nucleons near the surface have fewer neighbours, which costs an energy proportional to the surface area, $A^{2/3}$; being a smaller fraction of the whole in a large nucleus, this correction favours large A. The protons repel each other electrostatically, which costs $Z^2/A^{1/3} \sim A^{5/3}$; per nucleon this grows as $A^{2/3}$ and so disfavours large A. One term decreasing and one increasing with A produce a maximum in between, and Proposition 107.41 locates it at $A \approx 61$.

That the maximum exists is the whole energy economy of the chart. Combining two nuclei below it, or dividing one above it, moves nucleons to a more tightly bound configuration and releases the difference. The measured curve is tabulated in Table 107.2; the most tightly bound nuclide is in fact ^{62}Ni at 8.7945 MeV per nucleon, with ^{58}Fe at 8.7923 MeV and ^{56}Fe at 8.7903 MeV [2393] — a spread of two parts in a thousand, so the customary phrase "iron is the most tightly bound nucleus" is very nearly right and exactly wrong. It is ^{56}Fe that dominates the cosmic abundance peak, for reasons of nuclear statistical equilibrium and of the decay of ^{56}Ni that belong to Chapter 52, not because it is the minimum of the mass curve. □

Table 107.2: Binding energy per nucleon, measured [2393] and from the semi-empirical mass formula Equation (107.41) with the coefficients of Equation (107.43). The formula is not intended below $A \approx 20$, where the surface term removes more than the volume term supplies, and ^{2}H is included only to show how badly it fails there. Above $A \approx 20$ the residuals are below one per cent.

nuclide	A	B/A measured (MeV)	B/A formula (MeV)	difference (MeV)
^{2}H	2	1.112	−2.331	−3.443
^{4}He	4	7.074	5.710	−1.364
^{12}C	12	7.680	7.468	−0.212
^{16}O	16	7.976	7.873	−0.103
^{40}Ca	40	8.551	8.614	+0.063
^{56}Fe	56	8.790	8.846	+0.056
^{62}Ni	62	8.794	8.863	+0.069
^{90}Zr	90	8.710	8.749	+0.039
^{120}Sn	120	8.504	8.548	+0.044
^{208}Pb	208	7.867	7.857	−0.010
^{235}U	235	7.591	7.645	+0.054
^{238}U	238	7.570	7.625	+0.055

107.3.2 The semi-empirical mass formula

Von Weizsäcker wrote the nuclear mass as a sum of terms with the A and Z dependences that the liquid-drop picture and the Pauli principle between them dictate [763]; Bethe and Bacher systematized it and published the first fitted coefficients [768]. What follows derives

each term's dependence from the physics that produces it. Only the five coefficients are fitted.

Definition 107.33 (The semi-empirical mass formula)**.**

$$B(Z,N) = a_V A - a_S A^{2/3} - a_C \frac{Z(Z-1)}{A^{1/3}} - a_A \frac{(N-Z)^2}{A} + \delta(Z,N)\,, \tag{107.41}$$

with

$$\delta(Z,N) = \begin{cases} +a_P A^{-1/2} & Z,N \text{ both even}\,, \\ 0 & A \text{ odd}\,, \\ -a_P A^{-1/2} & Z,N \text{ both odd}\,, \end{cases} \tag{107.42}$$

and the coefficients, in MeV,

$$a_V = 15.75\,, \quad a_S = 17.8\,, \quad a_C = 0.711\,, \quad a_A = 23.7\,, \quad a_P = 11.18\,. \tag{107.43}$$

Proposition 107.34 (Origin of the volume and surface terms)**.** *Saturation gives $B = a_V A$; the deficit of neighbours within one force range of the surface gives a correction $-a_S A^{2/3}$ with*

$$a_S = 4\pi r_0^2 \sigma\,, \tag{107.44}$$

σ being a surface energy per unit area. The fitted value corresponds to $\sigma = 0.98\,\mathrm{MeV/fm^2} = 1.58 \times 10^{17}\,\mathrm{J/m^2}$.

Rests on Phenomenon 107.32 and Equation (107.41).

Proof. *Derives Proposition 107.34.*

If each nucleon binds to n neighbours with average energy ε, the total is $\frac{1}{2}nA\varepsilon$, linear in A; that is the volume term, and a_V is not predicted by the argument, only its A dependence. A nucleon within a distance of order the force range λ of the surface has fewer neighbours, and the number of such nucleons is $\rho_0 \times 4\pi R^2 \lambda \propto A^{2/3}$. Writing the deficit as an energy per unit area gives Equation (107.44) with $R = r_0 A^{1/3}$; from $a_S = 17.8\,\mathrm{MeV}$ and $r_0 = 1.2\,\mathrm{fm}$,

$$\sigma = \frac{17.8\,\mathrm{MeV}}{4\pi\,(1.2\,\mathrm{fm})^2} = 0.98\,\mathrm{MeV/fm^2}\,,$$

which converts to $1.58 \times 10^{17}\,\mathrm{J/m^2}$ — eighteen orders of magnitude above the $0.072\,\mathrm{J/m^2}$ of water, and the reason the liquid-drop analogy is quantitative rather than merely pictorial: the same two competing energies, surface tension and Coulomb repulsion, govern a charged raindrop and a fissioning nucleus (Section 107.6.1). □

Proposition 107.35 (The Coulomb term)**.** *The electrostatic energy of Z protons spread uniformly through a sphere of radius $R = r_0 A^{1/3}$ is*

$$E_C = \frac{3}{5}\frac{Z(Z-1)e^2}{4\pi\varepsilon_0 R} = a_C \frac{Z(Z-1)}{A^{1/3}}\,, \qquad a_C = \frac{3}{5}\frac{e^2}{4\pi\varepsilon_0 r_0}\,, \tag{107.45}$$

which for $r_0 = 1.2\,\mathrm{fm}$ evaluates to $0.720\,\mathrm{MeV}$, against the fitted $0.711\,\mathrm{MeV}$.

Rests on Equations (107.2) and (107.41).

Proof. *Derives Proposition 107.35.*

Assemble the sphere by bringing in successive shells from infinity. When the charge assembled is q and the radius is s, with uniform density $q = Q(s/R)^3$, the work to add $\mathrm{d}q$ at radius s is $q\,\mathrm{d}q/4\pi\varepsilon_0 s$. Writing $\mathrm{d}q = 3Qs^2\mathrm{d}s/R^3$,

$$E_C = \frac{1}{4\pi\varepsilon_0}\int_0^R \frac{Qs^3/R^3}{s}\,\frac{3Qs^2}{R^3}\,\mathrm{d}s = \frac{3Q^2}{4\pi\varepsilon_0 R^6}\int_0^R s^4\,\mathrm{d}s = \frac{3}{5}\frac{Q^2}{4\pi\varepsilon_0 R}\,.$$

Setting $Q = Ze$ counts each proton as repelling itself, which is wrong; the correction replaces Z^2 by $Z(Z-1)$, the number of distinct pairs counted twice. Numerically, using Equation (107.2),

$$a_C = \frac{3}{5} \times \frac{1.4400\,\text{MeV fm}}{1.2\,\text{fm}} = 0.720\,\text{MeV}\,,$$

within one and a half per cent of the fitted value. This is the one coefficient of Equation (107.41) that is genuinely *calculated*: it involves no nuclear physics at all, only electrostatics and the measured radius, and its agreement with the fit is a check that the radius entering the mass formula is the radius that electron scattering measures. □

Proposition 107.36 (The Fermi gas and the asymmetry term)**.** *Treat the nucleons as two independent Fermi gases, Z protons and N neutrons, filling a volume $V = A/\rho_0$. Then the Fermi momentum and energy of symmetric nuclear matter are*

$$k_F = \left(\frac{3\pi^2\rho_0}{2}\right)^{1/3} = 1.36/\text{fm}\,, \qquad E_F = \frac{(\hbar c k_F)^2}{2m_N c^2} = 38\,\text{MeV}\,, \tag{107.46}$$

and the excess kinetic energy of an asymmetric system is

$$\Delta E_{\text{kin}} = \frac{E_F}{3}\,\frac{(N-Z)^2}{A}\,, \qquad \frac{E_F}{3} = 12.8\,\text{MeV}\,. \tag{107.47}$$

Rests on Equations (107.1) and (107.40).

Proof. *Derives Proposition 107.36.*

Each species fills momentum states up to its own Fermi momentum. With two spin states per momentum state, the number of one species is $n = V k_{F,n}^3/3\pi^2$, so for symmetric matter $Z = N = A/2$ and $\rho_0 = A/V$ give $k_F = (3\pi^2\rho_0/2)^{1/3}$, which is Equation (107.46) for $\rho_0 = 0.17/\text{fm}^3$; the Fermi energy is $(\hbar k_F)^2/2m_N$, evaluated using Equation (107.1). The total kinetic energy of a filled Fermi sea is

$$E_{\text{kin}} = \frac{3}{5}\left(N\,\frac{\hbar^2 k_{F,n}^2}{2m_N} + Z\,\frac{\hbar^2 k_{F,p}^2}{2m_N}\right) = \frac{3}{5}\,\frac{C}{V^{2/3}}\left(N^{5/3} + Z^{5/3}\right)\,, \qquad C = \frac{\hbar^2}{2m_N}\left(3\pi^2\right)^{2/3}\,,$$

since $k_{F,i} \propto (n_i/V)^{1/3}$. Put $N = \frac{A}{2}(1+x)$ and $Z = \frac{A}{2}(1-x)$ with $x = (N-Z)/A$ and expand: $(1+x)^{5/3} + (1-x)^{5/3} = 2 + \frac{10}{9}x^2 + O(x^4)$. The constant part is the symmetric kinetic energy; the x^2 part is

$$\frac{3}{5}\cdot\frac{C}{V^{2/3}}\left(\frac{A}{2}\right)^{5/3}\cdot\frac{10}{9}x^2 = \frac{2}{3}\cdot\frac{A}{2}\cdot C\left(\frac{A}{2V}\right)^{2/3}x^2 = \frac{A}{3}E_F x^2\,,$$

using $E_F = C(\rho_0/2)^{2/3}$, which is Equation (107.47).

Comparison with the fitted $a_A = 23.7\,\text{MeV}$ is the point of the calculation. The Pauli principle alone accounts for 12.8 MeV, a little more than half, and the remainder must come from the interaction — specifically from the fact, already visible in Phenomenon 107.24, that the isospin-singlet *np* interaction is stronger than the isospin-triplet one, so that a nucleus does better with equal numbers of the two species than the counting of levels alone would suggest. Both halves of the asymmetry term are therefore consequences of the exclusion principle and of isospin, and neither has anything to do with the liquid drop, whose name the term is often filed under. □

Remark 107.37 (The depth of the nuclear well). Equation (107.46) fixes a number used repeatedly in Section 107.4.2. The most weakly bound nucleon sits at the top of the Fermi sea and its separation energy is about 8 MeV, so the single-particle well must have depth

$$V_0 \approx E_F + S_n \approx 38\,\text{MeV} + 8\,\text{MeV} \approx 46\,\text{MeV}\,, \tag{107.48}$$

which is where the conventional 50 MeV of the shell model comes from. Note what has and has not been derived: the *shape* of the asymmetry and the depth of the well follow from Proposition 107.36, but a_V does not. A Fermi gas has positive energy; binding requires the interaction, and the average potential energy per nucleon needed to produce $B/A = 15.75\,\mathrm{MeV}$ against a kinetic $\frac{3}{5}E_F = 23\,\mathrm{MeV}$ is about $-39\,\mathrm{MeV}$. That number is an output of the fit, not of the model.

Remark 107.38 (The pairing term is measured, not derived). δ in Equation (107.42) is the one term with no derivation offered here. Its existence is a direct observation: of the roughly 250 stable nuclides, some 150 have both Z and N even and only four have both odd (^{2}H, ^{6}Li, ^{10}B, ^{14}N). Its origin is that two identical nucleons in the same orbital, coupled to $J = 0$, have maximal spatial overlap and so gain the most from a short-range attraction — the same mechanism, and the same mathematics, as the formation of Cooper pairs in a superconductor, a subject that belongs to Chapter 130. The consequences recur throughout this chapter: it is why even-even nuclei all have $J^P = 0^+$ ground states, why the moment of inertia of a deformed nucleus falls below the rigid-body value (Section 107.4.3), and why ^{235}U fissions with thermal neutrons and ^{238}U does not (Section 107.6.1).

Proposition 107.39 (The valley of beta stability). *At fixed A, the mass Equation (107.41) is minimized at*

$$Z^*(A) = \frac{4a_A + (m_n - m_p)\,c^2 + a_C A^{-1/3}}{8a_A/A + 2a_C A^{-1/3}}\,, \tag{107.49}$$

which for small A tends to $A/2$ and for large A falls well below it.

Rests on Equations (107.5) and (107.41).

Proof. *Derives Proposition 107.39.*

Write $M(Z,A)c^2 = Zm_pc^2 + (A-Z)m_nc^2 - B$ and differentiate at fixed A, using $\partial B/\partial Z = -a_C(2Z-1)A^{-1/3} + 4a_A(A-2Z)/A$ from Equation (107.41) (the pairing term is not differentiable in Z and is treated by comparing the three parities separately). Setting $\partial M/\partial Z = 0$,

$$(m_p - m_n)\,c^2 + a_C\frac{2Z-1}{A^{1/3}} - \frac{4a_A(A-2Z)}{A} = 0\,,$$

which rearranges to Equation (107.49). For small A the $8a_A/A$ term dominates the denominator and $Z^* \to A/2$: the asymmetry term wants equal numbers, and light stable nuclei have them (^{4}He, ^{12}C, ^{16}O, ^{40}Ca). As A grows, the Coulomb term in the denominator takes over and Z^*/A falls: at $A = 56$, $Z^* = 25.6$, so the stable isobar is ^{56}Fe with $Z = 26$; at $A = 120$, $Z^* = 51.5$ against the observed ^{120}Sn with $Z = 50$; at $A = 208$, $Z^* = 83.6$ against ^{208}Pb with $Z = 82$. The systematic overshoot of one to one and a half units at large A is the formula's known weakness, and it is not a rounding accident: it is the absence of shell structure, since both ^{120}Sn ($Z = 50$) and ^{208}Pb ($Z = 82$) are closed-proton-shell nuclei bound more tightly than any smooth formula predicts. That the deviation appears exactly at the magic numbers is the first evidence for Section 107.4.2. □

Corollary 107.40 (Which decay a nuclide chooses). *A nuclide with $Z < Z^*$ has too many neutrons and reaches the valley by β^- decay, $n \to p + e^- + \bar{\nu}_e$; one with $Z > Z^*$ by β^+ decay or electron capture. For odd A the mass parabola is single and there is one stable isobar; for even A the pairing term splits it into two parabolas separated by $2a_PA^{-1/2}$, the even–even one lying lower, so that two or even three stable isobars can coexist and an odd–odd nuclide between them can be unstable in both directions at once.*

Rests on Proposition 107.39 and Equation (107.42).

Proof. *Derives Corollary 107.40.*

The direction follows from the sign of $\partial M/\partial Z$. For the parity structure, note that Equation (107.42) shifts the parabola by $\pm a_PA^{-1/2}$ according to whether Z and N are both

even or both odd, which for even A alternates with every unit step in Z. The even–even isobars therefore lie on a parabola below the odd–odd one by $2a_P A^{-1/2}$, which at $A = 100$ is 2.2 MeV. An odd–odd nuclide with even–even neighbours on both sides can then decay to either, which is exactly what ^{40}K does — β^- to ^{40}Ca in 89 per cent of decays and electron capture to ^{40}Ar in 11 per cent [2382] — and it is why $A = 40$ has two stable isobars while $A = 39$ has one. The four odd–odd stable nuclides of Remark 107.38 are the exceptions, all at $A \leq 14$ where the parabolas are too shallow for the argument to bite. □

Proposition 107.41 (Where the binding curve peaks)**.** *Along the valley Equation* (107.49)*, and dropping the pairing term, B/A from Equation* (107.41) *has its maximum at*

$$A_{\max} = 61\,, \qquad Z^* = 27.7\,, \qquad \left(\frac{B}{A}\right)_{\max} = 8.84\,\mathrm{MeV}\,, \tag{107.50}$$

against the measured maximum at ^{62}Ni, $A = 62$, $Z = 28$, $B/A = 8.7945$ MeV.

Rests on Equations (107.41) *and* (107.49)*.*

Proof. *Derives Proposition 107.41.*

Substitute $Z = Z^*(A)$ from Equation (107.49) into Equation (107.41), divide by A, and maximize numerically in A; the function is smooth and has a single interior maximum. The competition is transparent in the two dominant A-dependent terms per nucleon, $-a_S A^{-1/3}$, which rises towards zero as A grows, and $-a_C Z^{*2} A^{-4/3}$, which falls; the asymmetry term per nucleon, $-a_A(1 - 2Z^*/A)^2$, also falls with A because Z^*/A departs from $\frac{1}{2}$. The maximum is broad — B/A is within 0.01 MeV of its peak over the whole range $A = 54$ to $A = 69$ — which is why the identity of the most bound nuclide is decided by shell effects of a few tenths of a MeV that Equation (107.41) does not contain, and why it is ^{62}Ni, with $Z = 28$ magic, that wins. The formula gets the position of the peak right to one unit in A and its height right to half a per cent, which is all a five-parameter fit can be asked for. □

Remark 107.42 (Reading the residuals)*.* Table 107.2 shows the formula failing badly below $A \approx 20$ — for ^{2}H it predicts a negative binding energy, and ^{4}He is underbound by 5.5 MeV out of 28.3 MeV — and succeeding to better than one per cent above it. The failure at small A is not mysterious: the surface term is a correction of relative size $A^{-1/3}$, which at $A = 4$ is 0.63, so the expansion it belongs to has no small parameter there.

What matters is the structure of the residuals above $A = 20$. They are not noise. Plotted against N or Z they show sharp excursions at 2, 8, 20, 28, 50, 82 and 126, and the excursions have a consistent sign: nuclei at those numbers are bound more than the formula allows. That pattern was visible in the earliest fits, and it is the whole content of Phenomenon 107.51. Reading a regularity out of the residuals of a fit is how nuclear structure was found, and it is worth naming as a method: a formula that is right to one per cent is most useful for the one per cent it gets wrong.

107.3.3 Radii, form factors and the charge distribution

Everything above assumed $R = r_0 A^{1/3}$. That is a measurement, and the instrument is the electron: structureless, interacting only electromagnetically through a coupling small enough that one photon exchange suffices, and available at wavelengths short compared with a nucleus. Hofstadter turned it into a quantitative map of the nuclear charge density [1088].

Theorem 107.43 (Scattering measures the charge form factor)**.** *In the one-photon-exchange approximation, elastic scattering of electrons from a static charge distribution $\rho(\boldsymbol{r})$ normalized to $\int \rho\, \mathrm{d}^3 r = Ze$ gives*

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\text{point}} |F(\boldsymbol{q})|^2\,, \qquad F(\boldsymbol{q}) = \frac{1}{Ze}\int \mathrm{d}^3 r\; \mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}/\hbar}\rho(\boldsymbol{r})\,, \tag{107.51}$$

with $\boldsymbol{q}$ the momentum transferred, of dimension kg m/s. *For a spherical distribution*

$$F(q) = 1 - \frac{q^2 \langle r^2 \rangle}{6\hbar^2} + O(q^4)\,, \tag{107.52}$$

so the initial slope of the measured form factor is the mean square charge radius.
Rests on Equation (107.10).

Proof. *Derives Theorem 107.43.*

The Born amplitude for scattering off a potential V is proportional to its Fourier transform, and here $V(\boldsymbol{r}) = -e\phi(\boldsymbol{r})$ with ϕ the electrostatic potential of ρ. Since $\nabla^2\phi = -\rho/\varepsilon_0$, the transforms obey $\tilde{\phi}(\boldsymbol{q}) = \hbar^2\tilde{\rho}(\boldsymbol{q})/\varepsilon_0\boldsymbol{q}^2$, so the amplitude is the point-charge amplitude — which is what gives the Rutherford or Mott cross-section — times $\tilde{\rho}(\boldsymbol{q})/Ze$, and the cross-section is its modulus squared. That is Equation (107.51). For a spherical ρ, doing the angular integral,

$$F(q) = \frac{4\pi\hbar}{Zeq}\int_0^\infty r\rho(r)\sin\!\left(\frac{qr}{\hbar}\right)\mathrm{d}r\,,$$

and expanding $\sin u = u - u^3/6 + \cdots$ gives Equation (107.52) with $\langle r^2\rangle = \int r^2\rho\,\mathrm{d}^3r/Ze$. The Fourier inversion that recovers ρ from F is the transform pair of Chapter 17; in practice F is measured over a finite range of q, so the inversion is not unique and the data are fitted to a parametrized shape instead. □

Corollary 107.44 (Diffraction minima give the radius directly)**.** *For a uniformly charged sphere of radius R,*

$$F(q) = \frac{3}{x^3}\left(\sin x - x\cos x\right)\,, \qquad x = \frac{qR}{\hbar}\,, \tag{107.53}$$

whose first zero is at $x = 4.493$. A minimum in the measured angular distribution at momentum transfer q_1 therefore gives $R = 4.493\,\hbar/q_1$.
Rests on Theorem 107.43.

Proof. *Derives Corollary 107.44.*

Insert $\rho = 3Ze/4\pi R^3$ for $r < R$ in the radial integral above and integrate by parts twice. The zeros of $\sin x - x\cos x$, that is of $\tan x = x$, are at $x = 4.493, 7.725, \ldots$, and the diffraction pattern they produce is the same phenomenon as the Airy pattern of a circular aperture: a sharp-edged object has a form factor with zeros, a diffuse one has minima that do not reach zero. That the observed minima are filled in is the first evidence for a surface of finite thickness, quantified next. □

Definition 107.45 (The two-parameter Fermi distribution)**.**

$$\rho(r) = \frac{\rho_0}{1 + \exp\left[(r-c)/a\right]}\,, \tag{107.54}$$

with c the half-density radius and a the diffuseness. The *surface thickness*, the distance over which the density falls from 90 to 10 per cent of ρ_0, is $t = 4a\ln 3$.

Phenomenon 107.46 (Constant central density, constant surface)**.** Fits of Equation (107.54) to electron-scattering data across the chart give

$$c \approx 1.1\,\mathrm{fm} \times A^{1/3}\,, \qquad a \approx 0.54\,\mathrm{fm}\,, \qquad t \approx 2.4\,\mathrm{fm}\,, \tag{107.55}$$

with a central density ρ_0 near $0.17/\mathrm{fm}^3$ of nucleons that does not depend on A [1088]. The surface thickness is the same for carbon and for lead.
Rests on Equation (107.54) *and Theorem 107.43.*

Derivation. *Derives Phenomenon 107.46.*

Normalizing Equation (107.54) to A nucleons gives, to the accuracy of an expansion in a/c,

$$A = \rho_0 \frac{4\pi c^3}{3}\left[1 + \left(\frac{\pi a}{c}\right)^2\right],$$

so for ^{208}Pb, with $c = 6.52\,\text{fm}$ and $a = 0.54\,\text{fm}$, $\rho_0 = 0.168/\text{fm}^3$, which is Equation (107.40). The relation to the equivalent-uniform-sphere radius $R = r_0 A^{1/3}$ used in Equation (107.41) is the mean square radius: a uniform sphere has $\langle r^2\rangle = \frac{3}{5}R^2$, so

$$r_0 = \sqrt{\frac{5}{3}}\,\frac{\langle r^2\rangle^{1/2}}{A^{1/3}}, \tag{107.56}$$

and Table 107.3 evaluates it. That r_0 is 1.20 fm for lead but 1.39 fm for carbon is not an inconsistency: with a surface of fixed thickness 2.4 fm, a carbon nucleus of radius 2.5 fm is essentially all surface, and its equivalent uniform sphere is correspondingly larger than its half-density radius. The constant that is really constant is ρ_0, not r_0. □

Table 107.3: Root-mean-square charge radii from the compilation of [2209], with the equivalent-uniform-sphere parameter r_0 from Equation (107.56). The trend in r_0 is the effect of the finite surface thickness, not a failure of saturation.

nuclide	A	$\langle r^2\rangle^{1/2}$ (fm)	r_0 (fm)
^{12}C	12	2.4702	1.393
^{40}Ca	40	3.4776	1.313
^{56}Fe	56	3.7377	1.261
^{208}Pb	208	5.5012	1.199

Remark 107.47 (Two other rulers, and a discrepancy). Electron scattering is not the only measurement of a nuclear size. An atomic level is shifted by the finite size of the nucleus, by an amount proportional to $|\psi(0)|^2\,\langle r^2\rangle$, so optical isotope shifts measure *differences* of $\langle r^2\rangle$ along an isotopic chain with great precision. Replacing the electron by a muon multiplies $|\psi(0)|^2$ by $(m_\mu/m_e)^3 \approx 8.9\times10^6$ and turns the shift into the dominant term, which is what makes muonic-atom spectroscopy the most accurate absolute method.

Applied to the proton itself the two rulers disagreed. Muonic hydrogen gave a charge radius $(0.841\,84 \pm 0.000\,67)$ fm [2164, 2210], some five standard deviations below the then-accepted value near 0.8775 fm from ordinary hydrogen spectroscopy and electron scattering. The resolution was not new physics: later measurements of the ordinary-hydrogen Lamb shift [2331] and a re-analysis of low-q electron scattering [2344] both moved to the smaller value, and the CODATA 2022 recommendation is $(8.4075 \pm 0.0064)\times10^{-16}$ m [2431]. The episode is a worked case of systematic error rather than of discovery; its full experimental record belongs to Chapter 90.

107.4 Nuclear models

Two pictures of a nucleus are in flat contradiction, and both work. In one, the nucleons are so strongly coupled that no individual motion survives and the nucleus behaves as a drop of incompressible charged fluid; that is the picture behind Equation (107.41), and it accounts for masses, for fission and for the compound nucleus. In the other, each nucleon moves independently in an average field produced by all the others, with well-defined orbitals and

shell closures; that is what Phenomenon 107.51 demands. Reconciling them is the subject of Section 107.4.3, and the reconciliation turns on one point: the Pauli principle removes almost all of the collisions that the strong coupling would otherwise cause.

107.4.1 The liquid-drop model and the compound nucleus

The drop analogy is already quantitative in Proposition 107.34: an incompressible fluid of fixed density with a surface energy $4\pi R^2\sigma$ reproduces the first two terms of Equation (107.41) with a surface tension $1.58\times10^{17}\,\mathrm{J/m^2}$. What the analogy adds beyond the mass formula is dynamics — the drop can vibrate, deform and divide — and a picture of what happens when a projectile is absorbed.

Phenomenon 107.48 (Slow-neutron capture makes long-lived states)**.** A heavy nucleus absorbing a slow neutron shows, as a function of the neutron energy, a dense forest of sharp resonances: in ^{238}U the first lies at 6.67 eV, the spacing between neighbours is of order 20 eV, and the widths are of order 25 meV. A width that small corresponds to a lifetime of order $2.6\times10^{-14}\,\mathrm{s}$, some 10^8 times the time a nucleon takes to cross the nucleus. Moreover the products of the decay do not depend on how the compound system was made: the same excited nucleus reached by neutron capture and by a different reaction decays in the same proportions to the same channels [770].

Rests on Equation (107.46).

Derivation. *Derives Phenomenon 107.48.*

The two observations are one statement. A width Γ corresponds to a mean life $\tau=\hbar/\Gamma$; for $\Gamma=25\,\mathrm{meV}$,

$$\tau=\frac{6.582\times10^{-16}\,\mathrm{eV\,s}}{25\times10^{-3}\,\mathrm{eV}}=2.6\times10^{-14}\,\mathrm{s}\,,$$

whereas a nucleon moving at the Fermi velocity $v_F=\hbar k_F/m_N=0.29\,c$ from Equation (107.46) crosses a lead-sized nucleus in $2R/v_F=1.7\times10^{-22}\,\mathrm{s}$. The incident neutron therefore does not pass through: it is absorbed, its 6 MeV or so of binding energy is shared among all A nucleons, and the system wanders through an enormous number of configurations before, by a statistical fluctuation, enough energy is again concentrated on one nucleon for it to escape. That is Bohr's compound nucleus. Its signature consequence is factorization,

$$\sigma(a\to b)=\sigma_{\mathrm{form}}(a)\,\frac{\Gamma_b}{\Gamma}\,,\qquad \Gamma=\sum_c\Gamma_c\,, \tag{107.57}$$

the compound nucleus having forgotten how it was formed — which is exactly what the branching-ratio measurements show, and what the resonance formalism that belongs to Section 86.5.1 encodes as a pole whose residue splits into an entrance and an exit factor. □

Proposition 107.49 (The $1/v$ law for slow-neutron capture)**.** *Far below an isolated capture resonance, the cross-section for (n,γ) varies as the reciprocal of the neutron velocity.*

Rests on Phenomenon 107.48 and Equation (86.2).

Proof. *Derives Proposition 107.49.*

The Breit–Wigner cross-section for capture through a single resonance at E_0 is

$$\sigma_{n\gamma}(E)=\frac{\pi\hbar^2}{p^2}\,g\,\frac{\Gamma_n(E)\,\Gamma_\gamma}{(E-E_0)^2+\Gamma^2/4}\,, \tag{107.58}$$

with $p=\sqrt{2m_nE}$ the neutron momentum and g a statistical factor. Two energy dependences matter at small E. The prefactor $\pi\hbar^2/p^2$ goes as $1/E$. The neutron width is a transmission probability through the centrifugal and surface barriers and for s waves is proportional to the momentum, $\Gamma_n\propto p\propto\sqrt{E}$, which is the threshold law of Equation (86.2) in another

guise. The photon width Γ_γ and the denominator are both essentially constant for $E \ll E_0$. Hence

$$\sigma_{n\gamma} \propto \frac{1}{E} \cdot \sqrt{E} = \frac{1}{\sqrt{E}} \propto \frac{1}{v} .$$

The law holds over many decades below the first resonance and is what makes a moderated reactor work: slowing a neutron from 2 MeV to the thermal 0.025 eV raises its capture and fission cross-sections by a factor of $\sqrt{8 \times 10^7} \approx 9 \times 10^3$ (Section 107.6.1). It also means that a tabulated "thermal cross-section" is a convention, quoted at $v = 2200\,\mathrm{m/s}$, and not a property of the nucleus alone. □

Derivation pending #170

The Breit–Wigner formula: the derivation of the single-level resonance cross-section used above, with its partial widths and the statistical spin factor g, from the pole structure of the S matrix. It is taken here as a premise; its derivation belongs to the resonance section of the scattering-theory chapter, where it is not yet written.

Remark 107.50 (What the drop cannot do). The liquid drop has no single-particle levels, so it cannot produce a magic number, a ground-state spin, a magnetic moment or a low-lying excited state at a particular energy. It also predicts, through Equation (107.41), a smooth mass surface, and the residuals of Remark 107.42 show that the smooth surface is wrong by up to 10 MeV in total binding at the closed shells. The two pictures are not alternatives to be chosen between; they describe different degrees of freedom of the same object, and Section 107.4.3 couples them.

107.4.2 Magic numbers and the shell model

Phenomenon 107.51 (Certain nucleon numbers are anomalously stable)**.** At proton or neutron numbers $2, 8, 20, 28, 50, 82$ and 126 nuclei are more tightly bound than the smooth mass formula predicts, are more abundant in Nature [1098], have anomalously small neutron-capture cross-sections, carry their first excited state unusually high, and have vanishing electric quadrupole moments [933, 940]. The pattern is that of closed shells, as in the noble gases; but it is not the pattern of any simple one-body well, since a harmonic oscillator or a square well gives the first three numbers and then none of the rest.

Rests on Equations (107.41) *and* (107.48).

Derivation. *Derives Phenomenon 107.51.*

The derivation is in two steps: a mean field, which gets three of the seven numbers, and a spin–orbit term, which gets all seven.

Step one: the oscillator. Take the nucleons to move independently in a common potential. Its shape is bounded between two solvable cases — a harmonic oscillator, which is too soft at the edge, and an infinite square well, which is too hard — and the real Woods–Saxon well, of the shape Equation (107.54) with depth Equation (107.48), lies between them. For the isotropic oscillator the levels are

$$E_{\mathcal{N}} = \hbar\omega \left(\mathcal{N} + \frac{3}{2} \right) , \qquad \mathcal{N} = 2(n-1) + \ell \, , \tag{107.59}$$

so a given $\mathcal{N}$ collects $\ell = \mathcal{N}, \mathcal{N}-2, \ldots$, and, counting $2(2\ell+1)$ states per level for the two spin projections, has degeneracy $(\mathcal{N}+1)(\mathcal{N}+2)$. The cumulative occupancies are therefore

$$2,\ 8,\ 20,\ 40,\ 70,\ 112,\ 168\,, \tag{107.60}$$

which reproduces 2, 8 and 20 and then fails: the observed numbers are 28, 50, 82, 126. A square well gives $2, 8, 18, 20, 34, 40, \ldots$ and fails in a different way. No choice of radial shape repairs this, which is why the problem stood for fifteen years.

The oscillator constant itself follows from the size. Each nucleon species fills its own well, so for a symmetric nucleus filled up to shell $\mathcal{N}_F$ the cumulative degeneracy gives $A/2 \approx \mathcal{N}_F^3/3$, and the virial theorem gives $\langle r^2 \rangle = \frac{3}{4}\mathcal{N}_F\hbar/m_N\omega$; equating this to the $\frac{3}{5}r_0^2 A^{2/3}$ of a uniform sphere,

$$\hbar\omega = \frac{5}{4}\left(\frac{3}{2}\right)^{1/3} \frac{\hbar^2}{m_N r_0^2}\, A^{-1/3} \approx \frac{41\,\mathrm{MeV}}{A^{1/3}}\,, \tag{107.61}$$

the familiar empirical value, which for ^{208}Pb is 6.9 MeV and for ^{16}O is 16 MeV.

Step two: the spin–orbit term. Mayer [940] and, independently, Haxel, Jensen and Suess [933] added

$$V_{LS} = -C\,\boldsymbol{L}\cdot\boldsymbol{S}\,, \qquad C > 0\,, \tag{107.62}$$

with C carrying whatever dimension makes $C\hbar^2$ an energy, since $\boldsymbol{L}\cdot\boldsymbol{S}$ has dimension $\mathrm{J}^2\,\mathrm{s}^2$. Since $\boldsymbol{L}\cdot\boldsymbol{S} = \frac{1}{2}\left(\boldsymbol{J}^2 - \boldsymbol{L}^2 - \boldsymbol{S}^2\right)$,

$$\langle \boldsymbol{L}\cdot\boldsymbol{S}\rangle = \begin{cases} +\frac{1}{2}\ell\hbar^2\,, & j = \ell + \frac{1}{2}\,, \\ -\frac{1}{2}(\ell+1)\hbar^2\,, & j = \ell - \frac{1}{2}\,, \end{cases} \tag{107.63}$$

so the two members of a spin–orbit doublet are separated by

$$\Delta E_{LS} = \tfrac{1}{2}C\,(2\ell+1)\,\hbar^2\,, \tag{107.64}$$

with the level of *higher* j pushed *down*. Two features are essential and both are contrary to the atomic case: the sign, so that $j = \ell + \frac{1}{2}$ is the more bound, and the magnitude, which is comparable with $\hbar\omega$ rather than a fine-structure correction — a factor of order $(v/c)^{-2} \sim 10^4$ larger, because this spin–orbit force is a property of the strong interaction (Remark 107.28) and not a relativistic correction to an electromagnetic one.

Since Equation (107.64) grows with ℓ, the highest-ℓ level of each oscillator shell is depressed the most. For $\ell \geq 3$ the depression exceeds the shell gap $\hbar\omega$ and that level drops out of its shell into the gap below. Theorem 107.52 does the arithmetic. □

Theorem 107.52 (The magic numbers)**.** *Let the level of highest total angular momentum in oscillator shell $\mathcal{N}$, namely $j = \mathcal{N} + \frac{1}{2}$ with $\ell = \mathcal{N}$, be depressed below the shell gap. Then the closed-shell occupancies are*

$$M_{\mathcal{N}} = \frac{\mathcal{N}(\mathcal{N}+1)(\mathcal{N}+2)}{3} + 2\mathcal{N} + 2\,, \tag{107.65}$$

for $\mathcal{N} \geq 3$, and the unmodified oscillator closures $2, 8, 20$ for $\mathcal{N} \leq 2$. These are

$$2,\ 8,\ 20,\ 28,\ 50,\ 82,\ 126\,, \tag{107.66}$$

with 184 *predicted next.*

Rests on Equations (107.60) *and* (107.64).

Proof. *Derives Theorem 107.52.*

The first term of Equation (107.65) is the cumulative oscillator degeneracy through shell $\mathcal{N}-1$,

$$\sum_{k=0}^{\mathcal{N}-1} (k+1)(k+2) = \frac{\mathcal{N}(\mathcal{N}+1)(\mathcal{N}+2)}{3}\,,$$

verified by induction. The intruder from shell $\mathcal{N}$ carries $2j+1 = 2\mathcal{N}+2$ states, which is the second term. A gap opens above the intruder because the rest of shell $\mathcal{N}$ remains $\hbar\omega$ higher.

Evaluating: $\mathcal{N}=3$ gives $20+8=28$ (the intruder is $1f_{7/2}$); $\mathcal{N}=4$ gives $40+10=50$ ($1g_{9/2}$); $\mathcal{N}=5$ gives $70+12=82$ ($1h_{11/2}$); $\mathcal{N}=6$ gives $112+14=126$ ($1i_{13/2}$); $\mathcal{N}=7$ gives $168+16=184$ ($1j_{15/2}$). For $\mathcal{N}\le 2$ the formula would give 6 and 14; those are not observed, and correctly so, because Equation (107.64) for $\ell\le 2$ is smaller than $\hbar\omega$ and the intruder does not leave its shell. The threshold at $\ell=3$ is thus not fitted but forced: it is the condition $\tfrac{1}{2}C(2\ell+1)\hbar^2>\hbar\omega$ with the single constant C chosen once. Every observed magic number is then reproduced, and no unobserved one is produced. That is the whole argument, and it is why the two 1949 papers ended a fifteen-year impasse in three pages each. □

Table 107.4: The single-particle levels in order of increasing energy, grouped by the gaps that produce Equation (107.66). Each level $n\ell_j$ holds $2j+1$ nucleons. The intruder that closes each shell above 20 is the high-j level driven down from the oscillator shell above by Equation (107.62).

levels	states added	cumulative
$1s_{1/2}$	2	2
$1p_{3/2}$, $1p_{1/2}$	6	8
$1d_{5/2}$, $2s_{1/2}$, $1d_{3/2}$	12	20
$1f_{7/2}$	8	28
$2p_{3/2}$, $1f_{5/2}$, $2p_{1/2}$, $1g_{9/2}$	22	50
$1g_{7/2}$, $2d_{5/2}$, $2d_{3/2}$, $3s_{1/2}$, $1h_{11/2}$	32	82
$1h_{9/2}$, $2f_{7/2}$, $2f_{5/2}$, $3p_{3/2}$, $3p_{1/2}$, $1i_{13/2}$	44	126

Proposition 107.53 (Why independent-particle motion survives)**.** *A nucleon inside a nucleus has a mean free path against collision with its neighbours that is short compared with the nuclear radius if computed from the free nucleon–nucleon cross-section, and long compared with it once the Pauli principle is imposed.*

Rests on Equations (107.40) *and* (107.46).

Proof. *Derives Proposition 107.53.*

The free cross-section at a laboratory energy of a few tens of MeV is about $2\times10^{-29}\,\mathrm{m}^2$, so at the density Equation (107.40) the naive mean free path is

$$\ell=\frac{1}{\rho_0\sigma}=\frac{1}{1.7\times10^{44}/\mathrm{m}^3\times2\times10^{-29}\,\mathrm{m}^2}=2.9\times10^{-16}\,\mathrm{m}=0.29\,\mathrm{fm}\,,$$

a quarter of the internucleon spacing. On that estimate no orbital could survive for even one revolution and the shell model would be absurd — which is exactly the objection raised against it in 1949.

The estimate omits the exclusion principle. A collision must take both partners to unoccupied states, and below the Fermi surface there are none. Let a nucleon of energy E above E_F collide with one of the filled sea; energy conservation confines the two final energies to a shell of thickness E above E_F, and momentum conservation confines the initial partner similarly, so the fraction of collisions that is kinematically allowed is of order

$$\frac{\Gamma}{\Gamma_{\mathrm{free}}}\sim\left(\frac{E-E_F}{E_F}\right)^2\,, \tag{107.67}$$

the same phase-space counting that makes a Fermi liquid's quasiparticles long-lived, a subject that belongs to Chapter 126. For a nucleon near the top of the filled sea, $E-E_F$ is a few MeV against $E_F=38\,\mathrm{MeV}$, so the factor is of order 10^{-2} and the mean free path becomes tens of femtometres — larger than the nucleus. The paradox dissolves completely:

the nucleons that matter for the ground state are exactly those for which collisions are forbidden, and a strongly interacting system can nevertheless be an almost ideal gas of independent particles. Note that the argument fails for a highly excited nucleus, where $E - E_F$ is large; and there the compound-nucleus picture of Phenomenon 107.48, which assumes the opposite extreme, takes over. The two models describe the same nucleus at different excitation energies. □

Corollary 107.54 (Ground-state spins and parities)**.** *An even–even nucleus has $J^P = 0^+$; a nucleus with one nucleon outside closed shells, or one hole in them, has the j and the parity $(-1)^\ell$ of that level.*

Rests on Theorem 107.52 and Equation (107.42).

Proof. *Derives Corollary 107.54.*

Pairing (Remark 107.38) couples identical nucleons in the same level to $J = 0$ with even parity, so a filled or paired configuration contributes nothing, and every one of the several hundred known even–even ground states is 0^+ — a prediction with no exceptions. For an odd-A nucleus the unpaired nucleon carries the spin. Reading Table 107.4: ^{17}O has one neutron in $1d_{5/2}$, predicting $\frac{5}{2}^+$, observed $\frac{5}{2}^+$; ^{15}N has a proton hole in $1p_{1/2}$, predicting $\frac{1}{2}^-$, observed $\frac{1}{2}^-$; ^{41}Ca has a neutron in $1f_{7/2}$, predicting $\frac{7}{2}^-$, observed $\frac{7}{2}^-$; ^{207}Pb has a neutron hole in $3p_{1/2}$, predicting $\frac{1}{2}^-$, observed $\frac{1}{2}^-$; ^{209}Bi has a proton in $1h_{9/2}$, predicting $\frac{9}{2}^-$, observed $\frac{9}{2}^-$. The rule works best next to closed shells and degrades in mid-shell, where several nucleons are unpaired and the coupling is a genuine many-body problem. □

Proposition 107.55 (The Schmidt lines)**.** *For a single nucleon of orbital angular momentum ℓ and total j, with $g_\ell = 1$ for a proton and 0 for a neutron and $g_s = +5.586$ for a proton and -3.826 for a neutron, the magnetic moment is*

$$\frac{\mu}{\mu_N} = \begin{cases} \left(j - \tfrac{1}{2}\right) g_\ell + \tfrac{1}{2} g_s \,, & j = \ell + \tfrac{1}{2} \,, \\ \dfrac{j}{j+1}\left[\left(j + \tfrac{3}{2}\right) g_\ell - \tfrac{1}{2} g_s\right] \,, & j = \ell - \tfrac{1}{2} \,. \end{cases} \tag{107.68}$$

Measured moments of odd-A nuclei fall between *the two curves rather than on them.*

Rests on Proposition 107.25 and Corollary 107.54.

Proof. *Derives Proposition 107.55.*

Write $\boldsymbol{\mu} = \mu_N \hbar^{-1} (g_\ell \boldsymbol{L} + g_s \boldsymbol{S})$ and take the expectation in the state of maximal j_z. Since $\boldsymbol{L}$ and $\boldsymbol{S}$ are not separately conserved, project each on $\boldsymbol{J}$ by the same projection theorem used in Proposition 107.25, that within a manifold of fixed j only the component of a vector operator along $\boldsymbol{J}$ contributes: $\langle \boldsymbol{L} \rangle = \langle \boldsymbol{L} \cdot \boldsymbol{J} \rangle \, \boldsymbol{J} / j(j+1)\hbar^2$ and likewise for $\boldsymbol{S}$, with $\langle \boldsymbol{L} \cdot \boldsymbol{J} \rangle = \tfrac{1}{2}\left[j(j+1) + \ell(\ell+1) - s(s+1) \right] \hbar^2$. Substituting $\ell = j \mp \tfrac{1}{2}$ and simplifying gives Equation (107.68).

The two branches bracket the data, and the bracketing is itself the result. For a neutron with $j = \ell + \tfrac{1}{2}$ the prediction is $\tfrac{1}{2} g_s = -1.913$ regardless of ℓ; ^{17}O measures -1.894, within one per cent. But ^{209}Bi, a $1h_{9/2}$ proton with $j = \ell - \tfrac{1}{2}$, is predicted $+2.62$ and measures $+4.11$, which lies between that value and the $+6.79$ of the other branch. Schmidt's compilation [800] showed this pattern for every measured moment before the shell model existed. The interpretation is that the odd nucleon is not alone: its orbital is mixed with configurations in which the core is excited, and in addition the nucleons' intrinsic moments are modified inside nuclear matter by the exchange currents that the pion of Section 107.2.2 carries. The single-particle model is therefore right about the *spins* (Corollary 107.54) and only qualitatively right about the *moments*, and the difference between the two is a quantitative measure of how far the independent-particle approximation is from exact. □

107.4.3 The collective model

Phenomenon 107.56 (Deformed nuclei have rotational spectra)**.** Away from closed shells, even–even nuclei show a sequence of excited states with spins $0^+, 2^+, 4^+, 6^+, \ldots$ whose energies are proportional to $J(J+1)$. In ^{238}U the 2^+ lies at 44.9 keV and the 4^+ at 148.4 keV, a ratio of 3.30 against the rigid-rotor value $10/3 = 3.33$. Their electric quadrupole moments are one to two orders of magnitude larger than any single nucleon could produce, so many nucleons are moving together.

Derivation. *Derives Phenomenon 107.56.*

A rigid axially symmetric body has Hamiltonian $\mathcal{H} = \boldsymbol{J}^2/2\mathcal{I}$ about the axes perpendicular to its symmetry axis, so

$$E_J = \frac{\hbar^2}{2\mathcal{I}}\, J(J+1)\,, \tag{107.69}$$

in J, with $\mathcal{I}$ in $\mathrm{kg\,m^2}$. Only even J occurs, because a reflection through the plane perpendicular to the symmetry axis is a symmetry of the shape and the rotational wave function must be even under it, which kills the odd members. The ratio $E_4/E_2 = 20/6 = 3.33$ is then a parameter-free prediction, against the 2.0 that a harmonic surface vibration would give — so the single measured ratio distinguishes the two collective modes.

The moment of inertia is a measurement. From $E_2 = 44.9\,\mathrm{keV}$,

$$\frac{\hbar^2}{2\mathcal{I}} = \frac{E_2}{6} = 7.5\,\mathrm{keV}\,, \qquad \mathcal{I} = 4.6 \times 10^{-54}\,\mathrm{kg\,m^2}\,,$$

whereas a rigid sphere of mass $238\,u$ and radius $r_0 A^{1/3} = 7.4\,\mathrm{fm}$ has $\frac{2}{5}MR^2 = 8.7 \times 10^{-54}\,\mathrm{kg\,m^2}$. The observed moment is about half the rigid-body value — and, at the other extreme, several times the value for irrotational flow of a deformed drop, in which only the surface deformation and not the matter travels round. □

Remark 107.57 (Why the moment of inertia is between the two limits). That $\mathcal{I}$ falls between rigid and irrotational is the central quantitative fact of the collective model, and its explanation is pairing. A paired system has a gap: to change the motion of a single nucleon costs at least 2Δ, of order 1 MeV by Equation (107.42), so slow rotation cannot excite individual nucleons and part of the nuclear fluid simply does not rotate. This is the nuclear counterpart of the non-classical rotational inertia of a superfluid, and the same mathematics applies: the reduction factor is governed by the ratio of the rotational frequency to the pairing gap. Two independent consequences confirm it. The moment of inertia *increases* with angular momentum along a band and jumps sharply at a critical rotation — the pairing is being broken; and the odd-A neighbours of an even–even rotor have systematically larger moments, because the odd nucleon is already unpaired.

Remark 107.58 (Rainwater's argument and the unified model). Why should a nucleus be deformed at all, when a drop with surface tension is spherical? Rainwater's answer [967] is that the single-particle levels of Table 107.4 respond to deformation: a partly filled high-j level splits, and the nucleons occupy the lowered members, so the energy gained is linear in the deformation while the surface energy lost is quadratic. A linear gain always beats a quadratic cost for small enough deformation, so a nucleus with a partly filled shell is *always* deformed, and one with a closed shell — where there is nothing to lower — is not. That is exactly the observed pattern: quadrupole moments vanish at the magic numbers and are largest in mid-shell.

Bohr and Mottelson built this into a model in which the shape variables and the single-particle motion are dynamical partners [1015, 1396]: the nucleons move in a deformed well whose deformation is itself a degree of freedom, and the two are coupled. The quantitative test is the electric quadrupole transition strength $B(E2)$ between the members of a band,

which measures the square of the collective matrix element and comes out one to two orders of magnitude above the single-particle estimate of Equation (107.84) — the standard statement being that the transition is "a hundred Weisskopf units", which is a direct count of how many nucleons are moving coherently.

107.4.4 Where the models fail

Phenomenon 107.59 (Halo nuclei break the $A^{1/3}$ law)**.** The interaction cross-sections of light neutron-rich nuclei measured with radioactive beams give matter radii that follow $r_0 A^{1/3}$ for stable species and depart from it abruptly at the neutron drip line: ^{11}Li has a matter radius near 3.1 fm where the systematics predict 2.7 fm, comparable with that of ^{40}Ca although it has a quarter as many nucleons [1764].

Rests on Proposition 107.22 and Phenomenon 107.32.

Derivation. *Derives Phenomenon 107.59.*

The mechanism is the one already used for the deuteron in Proposition 107.22. A weakly bound s or p neutron has an exterior wave function $\mathrm{e}^{-\kappa r}$ with $\kappa = \sqrt{2\mu S_n}/\hbar$, so its spatial extent is $1/\kappa$; for ^{11}Li the two-neutron separation energy is only $S_{2n} = 0.37\,\mathrm{MeV}$, and with the reduced mass of a neutron pair against a ^{9}Li core,

$$\frac{1}{\kappa} = \frac{\hbar c}{\sqrt{2\mu c^2 S_{2n}}} = \frac{197.33\,\mathrm{MeV\,fm}}{\sqrt{2 \times 1536\,\mathrm{MeV} \times 0.37\,\mathrm{MeV}}} = 5.9\,\mathrm{fm}\,,$$

several times the radius of the core. The last neutrons therefore spend most of their time outside the nuclear surface, in a region where there is no nuclear matter at all, and the concept of a saturated drop with a well-defined surface no longer applies. That the phenomenon is confined to the drip line follows from the same formula: at a normal separation energy of 8 MeV, $1/\kappa = 1.6\,\mathrm{fm}$ and nothing unusual happens. The halo is not a new force; it is the same threshold physics that makes the deuteron large, applied to a system that is barely bound because it is at the edge of stability. □

Remark 107.60 (Magic numbers migrate)*.* Theorem 107.52 was derived for a well filled near the valley of Equation (107.49). Far from it the ordering of Table 107.4 changes, because the parts of the nucleon–nucleon interaction that depend on isospin — in particular the tensor term Equation (107.29) — shift proton and neutron levels differently when N/Z departs from its usual value. The consequences are measured. $N = 20$ and $N = 28$, magic near stability, are not magic in the neutron-rich magnesium and silicon isotopes; and a new closure appears at $N = 34$, established from the energy of the first 2^+ state of ^{54}Ca [2224]. A magic number is therefore not a property of the nuclear force but of a particular filling of a particular mean field, and the extrapolation of Equation (107.66) to the superheavy region (Section 107.6.3) has to be made with that in mind.

Remark 107.61 (What is and is not computable from the interaction)*.* The programme of Theorem 107.29 — solve the many-body Schrödinger equation with a two- and three-nucleon interaction derived from chiral effective field theory, with no further parameters — is complete for $A \lesssim 16$ and, with various controlled truncations, reaches the medium-mass region and the doubly magic ^{100}Sn and ^{132}Sn. Binding energies come out to a few tenths of a MeV per nucleon and spectra to a few hundred keV. What remains out of reach is the deformed mid-shell heavy nuclei — precisely the ones that Section 107.4.3 describes with two collective coordinates — because the number of configurations grows combinatorially and the collective correlations are exactly the ones that converge most slowly. The honest statement, as of the present writing, is that the light nuclei are computed, the heavy spherical ones are approached, and the heavy deformed ones are modelled.

107.5 Radioactive decay

107.5.1 Alpha decay

Phenomenon 107.62 (Alpha lifetimes span twenty orders of magnitude)**.** The half-lives of α emitters run from less than a microsecond to more than 10^{17} seconds, while the energies of the emitted α particles vary only between about 4 MeV and 9 MeV. Within a decay chain the logarithm of the decay constant is an almost exactly linear function of the reciprocal square root of that energy [372] — in the modern statement; Geiger and Nuttall's own relation was between $\log\lambda$ and the logarithm of the α particle's range in air, which is equivalent because the range grows as a power of the speed. A factor of two in energy therefore buys more than twenty orders of magnitude in lifetime — an extreme sensitivity of a rate to an energy, and one that no classical picture of escape over a barrier can produce.

Rests on Phenomenon 107.2.

The classical impossibility is worth stating precisely before the resolution. The α particle emerges with 4 MeV; the Coulomb barrier it must have crossed, evaluated at the nuclear surface $R = 9.3\,\mathrm{fm}$ of Equation (107.71), is

$$V(R) = \frac{2Z_d e^2}{4\pi\varepsilon_0 R} = \frac{2 \times 90 \times 1.4400\,\mathrm{MeV\,fm}}{9.3\,\mathrm{fm}} = 27.9\,\mathrm{MeV}\,, \tag{107.70}$$

nearly seven times higher. A classical particle inside the nucleus with 4 MeV can never be outside it, and one outside with 4 MeV can never get in — which is also why an α-particle beam of that energy shows pure Rutherford scattering. Gamow [600], and independently Gurney and Condon [603, 625], resolved it by tunnelling: the first application of quantum mechanics to the nucleus, made within two years of the Schrödinger equation.

Theorem 107.63 (Alpha decay rate)**.** *Let a nucleus of mass number A emit an α particle to a daughter of charge $Z_d e$ and mass number $A_d = A - 4$, with total energy release Q. Write μ for the reduced mass of the α–daughter pair,*

$$R = r_0\left(A_d^{1/3} + 4^{1/3}\right)\,, \qquad b = \frac{2Z_d e^2}{4\pi\varepsilon_0 Q}\,, \qquad \xi = \frac{R}{b}\,. \tag{107.71}$$

Then the decay constant is $\lambda = fT$ with T the barrier transmission of Theorem 9.76 and f an assault frequency, and the Gamow exponent is

$$2\gamma = \frac{2\sqrt{2\mu Q}\;b}{\hbar}\left[\arccos\sqrt{\xi} - \sqrt{\xi\,(1-\xi)}\right]\,. \tag{107.72}$$

Rests on Theorem 9.76 and Equation (9.93).

Derivation. Derives Theorem 107.63.

The mathematics is done, in SI, in Section 9.6.6: Theorem 9.76 gives the transmission through a barrier between turning points as $T \approx \mathrm{e}^{-2\gamma}$ with $\gamma = \hbar^{-1}\int\sqrt{2m(V-E)}\,\mathrm{d}x$, and Example 9.81 evaluates that integral for exactly this potential, obtaining Equation (9.93), which is Equation (107.72). Nothing needs to be rebuilt here; what needs to be supplied is the nuclear input, and there are three pieces of it.

The two-body reduction. The problem is not a particle in a fixed potential but two bodies, so the mass in the exponent is the reduced mass $\mu = m_\alpha M_d/(m_\alpha + M_d)$ and the energy is the total release Q, not the α particle's laboratory kinetic energy $E_\alpha = QM_d/(M_d + m_\alpha)$. These are consistent: $\sqrt{2\mu Q} = \sqrt{2m_\alpha E_\alpha}$, so the momentum in the exponent is the measured one either way, while the outer turning point $b = 2Z_d e^2/4\pi\varepsilon_0 Q$ must be computed from Q. For ^{238}U the difference between using Q and using E_α is two per cent in b and a factor of three in the half-life — which is the measure of how sensitive this calculation is.

The inner radius. Unlike the outer turning point, R is not determined by the energy: it is where the Coulomb potential is cut off by the nuclear surface, and the natural estimate is the sum of the two radii, Equation (107.71). At $r = R$ the potential is Equation (107.70), far above Q, so the momentum does not vanish there and no connection formula is applied at the inner edge; the single delicate matching is the one at b, which is what Theorem 9.76 performs.

The prefactor. The α particle must exist inside the nucleus and must present itself at the barrier. Writing $\lambda = fT$ with $f = v/2R$, $v = \sqrt{2Q/\mu}$ the relative speed, treats the α as rattling to and fro across the nuclear diameter. This is crude in two ways that pull in opposite directions: the speed inside the well is larger than v, because the well is 40 MeV deep, which raises f; and there is a *preformation* probability, the chance that four nucleons are found grouped as an α particle at the surface at all, which is of order 10^{-2} and lowers λ. Neither is supplied by the method — Remark 9.77 says as much for the mathematics, and it is doubly true here — and the calculation below simply omits both. What can be defended is the exponent. □

Table 107.5: Alpha decay computed from Equation (107.72) with $r_0 = 1.20\,\mathrm{fm}$ and $\lambda = (v/2R)\,\mathrm{e}^{-2\gamma}$, against the measured half-lives [2382]. The Q values are from the mass evaluation [2393]. All seven agree within a factor of five, over a range of 1.5×10^{24} in the half-life. No parameter is fitted: r_0 is the value measured independently by electron scattering (Table 107.3).

parent	Q (MeV)	2γ	T	$T_{1/2}$ calc. (s)	$T_{1/2}$ obs. (s)	ratio
^{238}U	4.270	88.0	6.1×10^{-39}	1.5×10^{17}	1.4×10^{17}	1.0
^{232}Th	4.082	89.1	2.0×10^{-39}	4.6×10^{17}	4.4×10^{17}	1.0
^{226}Ra	4.871	72.8	2.5×10^{-32}	3.3×10^{10}	5.0×10^{10}	0.66

^{218}Po	6.115	53.0	9.4×10^{-24}	7.8×10^{1}	1.9×10^{2}	0.42
^{214}Po	7.833	39.0	1.2×10^{-17}	5.5×10^{-5}	1.6×10^{-4}	0.34
^{212}Po	8.954	32.3	9.5×10^{-15}	6.3×10^{-8}	2.9×10^{-7}	0.21

Corollary 107.64 (The Geiger–Nuttall relation)**.** *For $\xi \ll 1$ the exponent Equation (107.72) reduces to*

$$2\gamma \to 2\pi\eta = \frac{2\pi}{\hbar}\,\frac{2Z_d e^2}{4\pi\varepsilon_0}\sqrt{\frac{\mu}{2Q}}\,, \tag{107.73}$$

so that

$$\log_{10}(\lambda\,\mathrm{s}) = a(Z_d) - \frac{b(Z_d)}{\sqrt{Q}}\,, \tag{107.74}$$

which is the empirical relation of [372], in the modern energy variable rather than their original logarithm of the range (Phenomenon 107.62).

Rests on Equation (107.72) and Phenomenon 107.62.

Proof. *Derives Corollary 107.64.*

Setting $\xi \to 0$ in Equation (107.72) replaces the bracket by $\arccos 0 = \pi/2$, and $\sqrt{2\mu Q}\,b = 2Z_d e^2\sqrt{2\mu/Q}/4\pi\varepsilon_0$ gives Equation (107.73). Taking the logarithm of $\lambda = f\mathrm{e}^{-2\gamma}$ and absorbing the slowly varying f into a gives Equation (107.74) with

$$b(Z_d) = \frac{2\pi}{\hbar \ln 10}\,\frac{2Z_d e^2}{4\pi\varepsilon_0}\sqrt{\frac{\mu}{2}} = 1.70\,Z_d\ \mathrm{MeV}^{1/2}\,,$$

using Equations (107.1) and (107.2) and $\mu c^2 = 3657\,\mathrm{MeV}$ for the heavy emitters.

The finite radius R cuts the barrier off at $\xi \approx 0.15$ to 0.35 and roughly halves the exponent — for ^{238}U, $2\pi\eta = 171$ against the exact $2\gamma = 88$ — but it barely touches the *slope*, and the reason is worth having. Expanding the bracket of Equation (107.72) for small ξ gives $2\gamma \approx 2\pi\eta\,[1 - (4/\pi)\sqrt{\xi} + \cdots]$, and since $2\pi\eta \propto Q^{-1/2}$ while $\sqrt{\xi} \propto Q^{1/2}$, the correction term is nearly independent of Q: it shifts the intercept $a(Z_d)$, not the coefficient of $Q^{-1/2}$. The exact exponents of Table 107.5 confirm both statements. Take the three polonium isotopes, for which $Z_d = 82$ is fixed: plotting 2γ against $Q^{-1/2}$ gives successive slopes 298 and 290 — linear to three per cent, and within ten per cent of the point-nucleus $b \ln 10 = 322$ — while the differences $2\pi\eta - 2\gamma$ are 77, 76 and 75: the predicted constant. In terms of the observable, $\log_{10}(\lambda\,\mathrm{s})$ against $Q^{-1/2}$ has predicted slope $-298/\ln 10 = -129$, and the measured half-lives give -129 and -119. That is the Geiger–Nuttall relation derived, with the right slope, from a barrier and a wave function. □

Remark 107.65 (What the agreement does and does not prove). Table 107.5 spans 1.5×10^{24} in half-life and holds within a factor of five, which is a striking result for a calculation with no fitted parameter. It should not be over-read. The exponent is so large that everything depends on it and almost nothing on the prefactor: changing r_0 from 1.20 fm to 1.30 fm shortens the computed half-life of ^{238}U by a factor of 22, and to 1.10 fm lengthens it by a factor of 26. What the table establishes is that a single value of r_0, the one independently measured by electron scattering, reproduces the whole range; it does not establish the prefactor, and the agreement of f with the truth to order unity is partly a cancellation between the two errors identified in Theorem 107.63. The preformation factor is the model's honest weak point, and it is where the α-decay rate stops being a barrier problem and becomes a nuclear-structure problem: it is smallest for odd-A emitters, whose unpaired nucleon must be broken out of its orbital, which is why they are systematically slower than Table 107.5 would predict by a further factor of 10 to 1000 — the phenomenon called hindrance.

Proposition 107.66 (Why alpha and not proton or deuteron emission)**.** *Among the light fragments a heavy nucleus might emit, only the α particle generally has $Q > 0$.*

Rests on Phenomenon 107.32 and Definition 107.31.

Proof. *Derives Proposition 107.66.*

The energy release for emitting a fragment X is $Q = B(X) + B(\text{daughter}) - B(\text{parent})$, and the term that decides it is $B(X)$. From Table 107.2, $B(^4\text{He}) = 28.30\,\text{MeV}$, against $B(^2\text{H}) = 2.22\,\text{MeV}$, $B(^3\text{H}) = 8.48\,\text{MeV}$ and, for a single nucleon, zero. The rest of the expression — the loss of binding by the parent — is of order A times the local slope of the binding curve and is much the same in each case, roughly 25 MeV for the removal of four nucleons from a heavy nucleus. Only the α particle brings enough binding of its own to pay for it, because it is doubly magic and exceptionally tightly bound for its size. That proton emission and ^{12}C emission do occur, the first beyond the proton drip line and the second as a rare branch called cluster decay with branching ratios near 10^{-11}, is the exception that measures the rule. □

107.5.2 Beta decay

The dynamics of β decay — Fermi's four-fermion interaction [738], the spectrum shape, the Kurie plot, parity violation and the $V - A$ structure — is derived in Chapter 101, and the detection of the antineutrino that closed the argument is [1085]. What belongs here is what the nucleus contributes: which decays are energetically open, which are fast and which are slow, and what the systematics measure.

Proposition 107.67 (Energy conditions for the three modes)**.** *Let* $M_{\mathrm{at}}(Z,A)$ *denote* atomic *masses, which is what mass spectrometry reports. Then*

$$Q_{\beta^-} = [M_{\mathrm{at}}(Z,A) - M_{\mathrm{at}}(Z+1,A)]\,c^2\,, \tag{107.75}$$

$$Q_{\beta^+} = [M_{\mathrm{at}}(Z,A) - M_{\mathrm{at}}(Z-1,A)]\,c^2 - 2m_e c^2\,, \tag{107.76}$$

$$Q_{\mathrm{EC}} = [M_{\mathrm{at}}(Z,A) - M_{\mathrm{at}}(Z-1,A)]\,c^2 - B_e\,, \tag{107.77}$$

with B_e *the binding energy of the captured atomic electron. Electron capture is therefore open in a window of* $2m_ec^2 = 1.022\,\mathrm{MeV}$ *in which* β^+ *emission is forbidden.*

Rests on Equation (107.5).

Proof. *Derives Proposition 107.67.*

Work with nuclear masses first and convert. For β^-, $M_{\mathrm{nuc}}(Z) \to M_{\mathrm{nuc}}(Z+1) + m_e$, so $Q = [M_{\mathrm{nuc}}(Z) - M_{\mathrm{nuc}}(Z+1) - m_e]\,c^2$; substituting $M_{\mathrm{nuc}} = M_{\mathrm{at}} - Zm_e$ (neglecting electron binding) the Z electrons on the left and the $Z+1$ on the right differ by exactly the emitted electron, and it cancels, giving Equation (107.75). For β^+ the same substitution leaves *two* electron masses uncancelled — the positron created, and the atomic electron the daughter no longer needs — and gives Equation (107.76). For electron capture the electron is taken from the atom rather than created, so no such term appears and only its binding energy is lost, giving Equation (107.77).

The window follows. Between $Q_{\mathrm{EC}} = 0$ and $Q_{\mathrm{EC}} = 1.022\,\mathrm{MeV}$ a nuclide can capture but not emit a positron, which is why ^{7}Be ($Q_{\mathrm{EC}} = 0.862\,\mathrm{MeV}$) decays only by capture. The free neutron sits at the other extreme with

$$Q_n = (m_n - m_p - m_e)\,c^2 = 939.565\,42\,\mathrm{MeV} - 938.272\,09\,\mathrm{MeV} - 0.511\,00\,\mathrm{MeV} = 0.782\,33\,\mathrm{MeV}\,, \tag{107.78}$$

which is the endpoint of the neutron β spectrum and the number that Equation (107.5) made available. □

Remark 107.68 (Why a bound neutron does not decay)*.* Equation (107.78) is positive, so a free neutron decays; yet a neutron in ^{4}He does not, and the reason is entirely nuclear. Converting a neutron into a proton in a stable nucleus moves it up the parabola of Proposition 107.39, and the cost — the asymmetry term plus the Coulomb term, several MeV — exceeds 0.78 MeV. Conversely, in a neutron-rich nucleus the gain exceeds it and the decay proceeds. The neutron's fate is decided by the mass formula, not by the weak interaction, which only fixes how fast.

Definition 107.69 (Comparative half-life and forbiddenness)**.** The ft value of Definition 101.16 divides out the phase-space factor $f(Z,E_0)$, leaving a number proportional to the inverse square of the nuclear matrix element. Transitions are classified by the orbital angular momentum L carried off by the lepton pair: $L=0$ is *allowed*, $L=1$ *first forbidden*, and so on.

Proposition 107.70 (The forbiddenness ladder)**.** *Each unit of forbiddenness suppresses the rate by a factor of order*

$$\left(\frac{p_e R}{\hbar}\right)^2 \approx 6 \times 10^{-4}\,, \tag{107.79}$$

for $p_ec = 1\,\mathrm{MeV}$ *and* $R = 5\,\mathrm{fm}$*, and so adds between three and four to* $\log_{10}(ft/\mathrm{s})$.

Rests on Definition 107.69 and Equation (107.1).

Proof. *Derives Proposition 107.70.*

The lepton wave functions are plane waves over the nuclear volume, and the Rayleigh plane-wave expansion $e^{i\mathbf{p}\cdot\mathbf{r}/\hbar} = \sum_L i^L(2L+1)j_L(pr/\hbar)P_L(\cos\theta)$ has $j_L(x) \sim x^L/(2L+1)!!$ for small x. With $x = p_eR/\hbar$ evaluated at $p_ec = 1\,\mathrm{MeV}$ and $R = 5\,\mathrm{fm}$,

$$x = \frac{1\,\mathrm{MeV} \times 5\,\mathrm{fm}}{197.33\,\mathrm{MeV\,fm}} = 0.0253\,,$$

so the amplitude for $L = 1$ is smaller than for $L = 0$ by x and the rate by $x^2 = 6.4 \times 10^{-4}$, which is Equation (107.79): three and a fifth in the logarithm. The parity of the nuclear state must also change with each unit of L, since the lepton pair carries parity $(-1)^L$, which is what makes the classification observable rather than merely formal — a transition between states of the same parity and $\Delta J = 2$ must be second forbidden and cannot be anything else.

Measured $\log_{10}(ft/\mathrm{s})$ values confirm the ladder: about 3.5 for superallowed, 5 to 6 for allowed, 6 to 9 for first forbidden, and up to 22 for the highest observed. The extremes are instructive. ^{6}He decays in 0.81 s with $\log_{10} ft = 2.9$; ^{40}K, a third-forbidden unique transition from 4^- to 0^+, lives 1.25×10^9 yr [2382] with $\log_{10} ft \approx 18$. That is fifteen orders of magnitude in ft from three units of forbiddenness, against the ten that Equation (107.79) predicts; the shortfall is the extra cost of a *unique* transition, in which the lepton pair must carry not only $L = 3$ but the maximum spin coupling as well, and it is why the classification distinguishes unique from non-unique cases at all. □

Derivation pending #171

The Rayleigh plane-wave expansion: the expansion of a plane wave in Legendre polynomials and spherical Bessel functions, with the small-argument behaviour $j_L(x) \sim x^L/(2L+1)!!$ used above. Both are premises of the forbiddenness ladder; the expansion belongs to the chapter on Fourier and integral transforms, where it is not yet derived.

Remark 107.71 (What the superallowed decays measure). The Fermi operator of Proposition 101.15 is the isospin raising operator, whose matrix element between members of an isospin multiplet is fixed by the SU(2) algebra of Definition 107.10 and not by the nuclear wave function at all. The $0^+ \to 0^+$ decays within an isospin triplet therefore carry no nuclear-structure uncertainty, and the constancy of their $\mathcal{F}t$ across some fourteen cases spanning a factor of 10^4 in phase space (Phenomenon 101.18 and Equation (101.19)) is simultaneously the proof that the vector coupling is not renormalized by the strong interaction and the most precise determination of $|V_{ud}|$. This is the one place where nuclear physics supplies a number to the Standard Model rather than the reverse, and it works precisely because the nuclear physics cancels.

Phenomenon 107.72 (Double beta decay)**.** A dozen even–even nuclides for which single β decay is energetically forbidden decay by emitting two electrons and two antineutrinos at once, with half-lives between 10^{18} and 10^{24} years — the slowest processes ever measured. The neutrinoless mode, in which the two electrons carry the whole energy release and no neutrinos are emitted, has not been observed; limits on its half-life exceed 10^{26} years.

Rests on Corollary 107.40.

Derivation. *Derives Phenomenon 107.72.*

That the mode exists at all is a consequence of Corollary 107.40. For even A the pairing term splits the mass parabola in two, and an even–even nuclide can find itself lower than *both* of its odd–odd neighbours while being higher than the even–even nuclide two steps away. Single β decay is then closed and double β decay is open. The classic case is ^{76}Ge, which cannot reach ^{76}As but can reach ^{76}Se; the same arithmetic selects ^{82}Se, ^{100}Mo, ^{130}Te and ^{136}Xe.

The rate is second order in the weak interaction, so it carries G_F^4 instead of G_F^2, and the four-body final state gives a phase-space factor scaling as Q^{11} rather than Q^5. Those two together are the twenty orders of magnitude between an allowed β decay and a double one. The neutrinoless mode is a different matter: it requires the neutrino emitted at one vertex to be absorbed at the other, which is possible only if the neutrino is its own antiparticle and has mass, so its observation would establish lepton-number violation and the Majorana nature

of the neutrino. It has not been observed, and this book records searches by what they have excluded. The status belongs to Chapter 103; what belongs here is that the experimental signature is entirely nuclear — a peak at the Q value of the two-electron spectrum, sitting on the continuum of the two-neutrino mode — and that the conversion of a half-life limit into a mass limit requires a nuclear matrix element which different many-body methods disagree about by a factor of two or three. □

107.5.3 Gamma decay and the Mössbauer effect

Proposition 107.73 (Multipole selection rules)**.** *A gamma transition between nuclear states of spins and parities $J_i^{\pi_i}$ and $J_f^{\pi_f}$ proceeds by multipoles L with*

$$|J_i - J_f| \le L \le J_i + J_f\,, \qquad L \ge 1\,, \tag{107.80}$$

and the parity change fixes the type: $\pi_i \pi_f = (-1)^L$ for an electric multipole EL and $(-1)^{L+1}$ for a magnetic one ML. A transition $0 \to 0$ cannot emit a photon at all.

Rests on Phenomenon 79.5.

Proof. *Derives Proposition 107.73.*

The photon carries away angular momentum $L\hbar$ and the total is conserved, which with the triangle rule for adding $\boldsymbol{J}_i = \boldsymbol{J}_f + \boldsymbol{L}$ (Chapter 79) gives the range in Equation (107.80). The lower bound $L \ge 1$ is the statement that a free photon has no monopole mode: its field is transverse, so the $L = 0$ component of the multipole expansion of a radiation field vanishes identically. The parity of an EL photon is $(-1)^L$ and of an ML photon $(-1)^{L+1}$, because the electric and magnetic multipole operators differ by one factor of the (axial) magnetic field; conservation of parity in the electromagnetic interaction then fixes which type may occur. For $J_i = J_f = 0$ the range in Equation (107.80) is empty and single-photon emission is strictly forbidden. Such transitions nevertheless occur, by internal conversion or, if the energy exceeds $2m_e c^2$, by internal pair creation — and the fact that these proceed while photon emission does not is direct evidence that they are not merely a photon reabsorbed. □

Theorem 107.74 (Single-particle transition rates)**.** *For an electric multipole of order L,*

$$\lambda(EL) = \frac{8\pi\,(L+1)}{L\,[(2L+1)!!]^2}\,\frac{1}{4\pi\varepsilon_0\hbar}\left(\frac{E_\gamma}{\hbar c}\right)^{2L+1} B(EL)\,, \tag{107.81}$$

with $B(EL)$ the reduced transition probability of dimension $\mathrm{C}^2\,\mathrm{m}^{2L}$. Estimating $B(EL)$ for a single proton moving in a uniform sphere of radius $R = r_0 A^{1/3}$,

$$B(EL)_W = \frac{e^2}{4\pi}\left(\frac{3}{L+3}\right)^2 R^{2L}\,, \tag{107.82}$$

gives, with $r_0 = 1.2\,\mathrm{fm}$ and E_γ in MeV*,*

$$\lambda(E1) = 1.0 \times 10^{14}\; A^{2/3} E_\gamma^3\;\mathrm{1/s}\,, \tag{107.83}$$

$$\lambda(E2) = 7.3 \times 10^{7}\; A^{4/3} E_\gamma^5\;\mathrm{1/s}\,, \tag{107.84}$$

$$\lambda(E3) = 34\; A^{2} E_\gamma^7\;\mathrm{1/s}\,, \tag{107.85}$$

$$\lambda(E4) = 1.1 \times 10^{-5}\; A^{8/3} E_\gamma^9\;\mathrm{1/s}\,. \tag{107.86}$$

Rests on Propositions 107.70 and 107.73.

Derivation. *Derives Theorem 107.74.*

Equation (107.81) is the multipole expansion of the radiation field applied to Fermi's golden rule; its structure is what matters here and it is fixed by dimensional analysis together

with the small parameter of the problem. The photon field at the nucleus varies as $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}$ with $k = E_\gamma/\hbar c$, and $kR \ll 1$ — for $E_\gamma = 1\,\mathrm{MeV}$ and $R = 6\,\mathrm{fm}$, $kR = 0.030$ — so each successive term of the expansion of Proposition 107.70 costs one power of kR in the amplitude. Two powers of kR per unit of L in the rate, and one factor of E_γ from the density of photon states, give the $(E_\gamma/\hbar c)^{2L+1}$; the numerical coefficient comes from the normalization of the vector spherical harmonics and is quoted.

Substituting Equation (107.82) and using $e^2/4\pi\varepsilon_0\hbar = \alpha c$ collapses the prefactor to a pure number times αc:

$$\lambda(EL) = \frac{8\pi(L+1)}{L\,[(2L+1)!!]^2}\cdot\frac{1}{4\pi}\left(\frac{3}{L+3}\right)^2\cdot\alpha c\,R^{2L}\left(\frac{E_\gamma}{\hbar c}\right)^{2L+1}.$$

For $L = 1$ the two numerical factors are $16\pi/9$ and $(1/4\pi)(3/4)^2$, whose product is exactly $\frac{1}{4}$, so

$$\lambda(E1) = \frac{\alpha c}{4}\,R^2\left(\frac{E_\gamma}{\hbar c}\right)^3,$$

and inserting $\alpha = 7.2974\times10^{-3}$, $c = 3.0\times10^{23}\,\mathrm{fm/s}$, $R^2 = 1.44A^{2/3}\,\mathrm{fm}^2$ and $\hbar c = 197.33\,\mathrm{MeV\,fm}$ gives Equation (107.83). The same substitution at $L = 2, 3, 4$ gives the rest. These are the *Weisskopf units*, and they are estimates of an order of magnitude, not predictions: a measured rate is quoted as a multiple of them, and the multiple is the physics.

Magnetic multipoles are suppressed relative to electric ones of the same order by roughly

$$\frac{\lambda(ML)}{\lambda(EL)} \sim \left(\frac{\hbar}{m_p c R}\right)^2 = \left(\frac{0.210\,\mathrm{fm}}{R}\right)^2, \tag{107.87}$$

about 2×10^{-3} for a medium-mass nucleus, since the magnetic moment of a nucleon carries the extra factor $\hbar/m_p c$ that a charge does not. □

Derivation pending #172

The multipole normalization: the coefficient $8\pi(L+1)/L[(2L+1)!!]^2$ of the electric multipole rate is quoted, not derived. Its derivation — the multipole expansion of the quantized radiation field, the normalization of the vector spherical harmonics and Fermi's golden rule — belongs in Appendix A; the power counting in kR and the dimensional structure are derived in the text.

Corollary 107.75 (Isomers)**.** *A transition requiring a high multipole is slow by many orders of magnitude, and a nuclear state whose only decay is such a transition is metastable.*
Rests on Theorems 107.52 and 107.74.

Proof. *Derives Corollary 107.75.*

From Equations (107.83) and (107.86), for $A = 125$ and $E_\gamma = 1\,\mathrm{MeV}$ the rates are 2.6×10^{15}, 4.6×10^{10}, 5.3×10^{5} and $4.2\,1/\mathrm{s}$ for $L = 1, 2, 3, 4$: a factor near 10^5 per unit of L, which is $(kR)^2$ combined with the falling numerical coefficient. A 4^+ state lying just above a 0^+ ground state therefore lives of order a second rather than a femtosecond. The islands of isomerism sit just below the magic numbers, where Table 107.4 places levels of very different j next to one another — $1g_{9/2}$ beside $2p_{1/2}$ below Z or $N = 50$, $1h_{11/2}$ beside $3s_{1/2}$ below 82 — so that the lowest available transition has $\Delta J = 4$ or 5. That the isomer islands are found exactly where the shell model puts high-j intruders is a further confirmation of Theorem 107.52 that uses no binding energies at all. □

Remark 107.76 (Internal conversion). A nucleus may also give its energy directly to an atomic electron, which leaves with kinetic energy $E_\gamma - B_e$ — a *line*, not a continuum, and historically the first clue that the continuous β spectrum was a genuine puzzle rather than an instrumental artefact, since the two were seen side by side. The conversion coefficient $\alpha_{\mathrm{IC}} = \lambda_e/\lambda_\gamma$ grows as Z^3, grows with L, and falls steeply with E_γ; measuring it is a standard way of determining the multipolarity of a transition whose spins are unknown. It is not internal photoelectric absorption of an emitted photon: it happens even when Proposition 107.73 forbids photon emission outright.

Phenomenon 107.77 (Recoil-free resonant absorption of gamma rays)**.** A nucleus bound in a crystal can emit a gamma ray, and another such nucleus absorb it, with no energy lost to recoil, so that the line keeps the natural width set by the lifetime of the state [1154]. For the 14.4 keV transition of ^{57}Fe that width is a fraction of about 3×10^{-13} of the transition energy, and by measuring displacements of a fraction of the line the method resolved the gravitational redshift over a vertical drop of 22.5 m, a shift of a few parts in 10^{15} [1189]. Free nuclei show no such resonance at all.

Derivation. *Derives Phenomenon 107.77.*

A free nucleus of mass M emitting a photon of energy E_γ recoils with momentum E_γ/c and so carries away

$$E_R = \frac{E_\gamma^2}{2Mc^2}\,, \tag{107.88}$$

to first order in E_R/E_γ. The emitted quantum is thus short of the transition energy by E_R, while an absorbing nucleus needs E_R more than the transition energy in order to recoil in turn: emission and absorption lines are displaced from one another by $2E_R$. Resonance survives only if that displacement is small against the line width Γ. For the 14.4 keV line of ^{57}Fe, $Mc^2 = 53.0\,\mathrm{GeV}$ gives $E_R = 1.96 \times 10^{-3}\,\mathrm{eV}$, whereas the mean life of 141 ns gives $\Gamma = \hbar/\tau = 4.67 \times 10^{-9}\,\mathrm{eV}$: the displacement exceeds the width by a factor of 8.4×10^5, and no resonance between free nuclei is possible. Bound in a lattice the nucleus cannot recoil by itself. A finite fraction of the transitions leave the crystal in its original vibrational state, and for those the mass appearing in Equation (107.88) is the mass of the whole crystal, which makes E_R utterly negligible. The line is then as narrow as the lifetime permits, and it is that narrowness, not any large signal, which gives the method its resolution:

$$\frac{\Gamma}{E_\gamma} = \frac{4.67 \times 10^{-9}\,\mathrm{eV}}{14.4 \times 10^{3}\,\mathrm{eV}} = 3.2 \times 10^{-13}\,. \tag{107.89}$$

□

Proposition 107.78 (The recoil-free fraction)**.** *In the Debye model of a lattice at zero temperature, the fraction of emissions that leave the crystal in its original vibrational state is*

$$f = \exp\left(-\frac{3E_R}{2k_B\Theta_D}\right)\,, \tag{107.90}$$

which for ^{57}Fe *in iron,* $\Theta_D = 470\,\mathrm{K}$*, is* $f = 0.93$*.*

Rests on Phenomenon 107.77 and Equation (107.88)*.*

Proof. *Derives Proposition 107.78.*

The probability of a zero-phonon transition is $f = \exp(-k^2\,\langle x^2\rangle)$ with $k = E_\gamma/\hbar c$ the photon wave number and $\langle x^2\rangle$ the mean square displacement of the emitting nucleus along the photon direction — the same Debye–Waller factor that governs the intensity of a Bragg peak, a subject that belongs to Chapter 125. Both formulas are used here as stated. In the Debye model at $T = 0$, $\langle x^2\rangle = 3\hbar^2/(4Mk_B\Theta_D)$, so $k^2\,\langle x^2\rangle = 3E_\gamma^2/(4Mc^2k_B\Theta_D) = 3E_R/2k_B\Theta_D$, which is Equation (107.90). With $k_B\Theta_D = 40.5\,\mathrm{meV}$ and $E_R = 1.96\,\mathrm{meV}$ the exponent

is 0.073 and $f = 0.93$. Two conditions for a usable Mössbauer isotope follow at once: a low transition energy, since $E_R \propto E_\gamma^2$, and a stiff lattice, since f falls with Θ_D. That ^{57}Fe satisfies both is why essentially all Mössbauer spectroscopy uses it. □

Derivation pending #173

The Debye–Waller factor: the derivation of the zero-phonon probability $f = \exp(-k^2 \langle x^2 \rangle)$ for a harmonic lattice, and of the Debye-model zero-temperature mean square displacement $\langle x^2 \rangle = 3\hbar^2/(4Mk_B\Theta_D)$. Both are premises of the proposition above; they belong to the chapter on phonons and lattices, where they are not yet derived.

Corollary 107.79 (The velocity scale, and the Pound–Rebka measurement)**.** *A source moved at speed v shifts the emitted line by $\Delta E/E = v/c$, so the velocity needed to shift by one natural width is*

$$v_\Gamma = c\,\frac{\Gamma}{E_\gamma} = 9.7 \times 10^{-5}\,\mathrm{m/s}\,, \tag{107.91}$$

about a tenth of a millimetre per second. The gravitational redshift over a height H is gH/c^2, which for $H = 22.5\,\mathrm{m}$ is 2.46×10^{-15}, or 7.6×10^{-3} of the natural width.

Rests on Phenomenon 107.77 and Equation (107.89).

Proof. *Derives Corollary 107.79.*

The first-order Doppler shift gives Equation (107.91) directly from Equation (107.89); the millimetre-per-second scale of a Mössbauer spectrometer's drive is therefore not a convenience but a consequence of the line width. For the redshift,

$$\frac{gH}{c^2} = \frac{9.806\,65\,\mathrm{m/s^2} \times 22.5\,\mathrm{m}}{(299\,792\,458\,\mathrm{m/s})^2} = 2.46 \times 10^{-15}\,,$$

so Pound and Rebka had to locate the centre of a line to better than one per cent of its width, which they did by modulating the source velocity and measuring the asymmetry of the counting rate [1189]. The experiment is a test of the equivalence principle and belongs equally to Chapter 42; what belongs here is that the instrument is a nuclear energy level, and that its precision comes from a lifetime. □

107.6 Fission and fusion

107.6.1 Fission

Hahn and Strassmann, following up Fermi's irradiation of uranium with neutrons, established by radiochemistry that one of the products is barium — an element of half the atomic number, which no known nuclear process could produce [837]. Meitner and Frisch identified the process as the division of the nucleus and estimated its energy release from the mass defect before any measurement of it existed [842].

Phenomenon 107.80 (Uranium divides, and the energy released is enormous)**.** Uranium irradiated with neutrons yields barium among its products [837]: the nucleus divides into two fragments of comparable mass. The energy released per division is of order 200 MeV [842] — some eight orders of magnitude more than the few eV released when the same number of atoms rearrange chemically — and the division is accompanied by two or three prompt neutrons, which is what allows the process to sustain itself.

Rests on Phenomenon 107.32.

Derivation. *Derives Phenomenon 107.80.*

The energy released is the increase in total binding energy, and it can be read straight off the curve of Phenomenon 107.32. At $A \approx 236$ the binding is about 7.6 MeV per nucleon; near the fragment masses, $A \approx 100$ to 140, it is about 8.5 MeV per nucleon [2393]. The gain is therefore

$$\Delta E \approx 236\,(8.5\,\mathrm{MeV} - 7.6\,\mathrm{MeV}) \approx 210\,\mathrm{MeV}\,, \tag{107.92}$$

the observed order of magnitude, and — since two numbers were read off a curve — as much precision as the argument is entitled to. The same estimate says why fission is confined to the heavy end of the chart: the gain is positive only where the curve is falling, and it is worth a substantial fraction of a nucleon's binding only where it has fallen far. It says nothing about the *rate*, which is governed by the barrier and not by the energy release, and that is why ^{235}U and ^{238}U behave so differently under slow neutrons although their release is nearly the same. □

Table 107.6: Where the energy of one thermal-neutron fission of ^{235}U goes [1809]. The antineutrinos leave the reactor entirely, so the recoverable total is about 190 MeV; they are also what makes a reactor the brightest artificial antineutrino source available, which is how [1085] detected the neutrino at all.

channel	energy (MeV)
kinetic energy of the fragments	168
prompt neutrons	5
prompt gamma rays	7
beta particles from fragment decay	7
delayed gamma rays	6
antineutrinos (not recoverable)	9
total	202

Theorem 107.81 (The fission barrier and the fissility parameter)**.** *Deform a nucleus at constant volume into the spheroid $R(\theta) = R_0\,[1 + \alpha_2 P_2(\cos\theta)]$. To second order in α_2 the surface and Coulomb terms of Equation (107.41) become*

$$E_S = a_S A^{2/3}\left(1 + \tfrac{2}{5}\alpha_2^2\right)\,, \tag{107.93}$$

$$E_C = a_C \frac{Z^2}{A^{1/3}}\left(1 - \tfrac{1}{5}\alpha_2^2\right)\,, \tag{107.94}$$

so the energy change on deformation is

$$\Delta E = \frac{\alpha_2^2}{5}\left(2a_S A^{2/3} - a_C \frac{Z^2}{A^{1/3}}\right)\,, \tag{107.95}$$

and the sphere is unstable against spontaneous fission when

$$\frac{Z^2}{A} > \left(\frac{Z^2}{A}\right)_{\mathrm{crit}} = \frac{2a_S}{a_C} = 50.1\,. \tag{107.96}$$

Rests on Equations (107.41) and (107.44).

Proof. *Derives Theorem 107.81.*

Volume conservation fixes R_0 in terms of the equivalent spherical radius R: expanding $V = \frac{4\pi}{3}R_0^3\left(1 + \frac{3}{5}\alpha_2^2\right)$ to second order gives $R_0 = R\left(1 - \frac{1}{5}\alpha_2^2\right)$. The surface area of the

deformed shape, expanded to the same order, is $4\pi R^2\left(1+\frac{2}{5}\alpha_2^2\right)$, which with $E_S = 4\pi R^2\sigma$ from Equation (107.44) gives Equation (107.93); the electrostatic energy of a uniformly charged spheroid, expanded likewise, gives Equation (107.94). The first coefficient is positive and the second negative because stretching increases the surface but moves charge apart. Subtracting the spherical values leaves Equation (107.95), and the sphere is stable if and only if the bracket is positive, which rearranges to Equation (107.96) with the coefficients Equation (107.43).

The parameter is customarily normalized as $x = (Z^2/A)/(Z^2/A)_{\text{crit}}$, and for the actinides: ^{232}Th has $x = 0.70$, ^{238}U $x = 0.71$, ^{239}Pu $x = 0.74$. All are stable against small deformations and all can fission, because a stable sphere is only a *local* minimum: the ultimate configuration, two separated fragments, lies 200 MeV lower (Equation (107.92)), and between them stands a barrier that Equation (107.95) describes only near $\alpha_2 = 0$. The full barrier requires the whole deformation energy surface, which is the calculation of Bohr and Wheeler [830]; its height for the actinides is 5 MeV to 6 MeV, small compared with the release and comparable with the neutron separation energy — which is the coincidence on which the whole subject turns. □

Derivation pending #174

The fission barrier: the deformation energy surface of the charged liquid drop beyond second order, through the saddle point to the scission configuration, giving the barrier height as a function of the fissility x and its collapse to zero as x approaches one. It belongs in Appendix A, since it requires the multipole expansion of the electrostatic energy of an arbitrary axially symmetric shape. The second-order result and the critical fissility are derived in the text.

Phenomenon 107.82 (Only one uranium isotope fissions with slow neutrons)**.** The fission cross-section of ^{235}U for neutrons at 0.025 eV is 5.9×10^{-25} m^2; that of ^{238}U is immeasurably small below a neutron energy of about 1 MeV. The two nuclides differ by three neutrons and their fission energy releases agree within a few MeV.

Rests on Equation (107.42) and Theorem 107.81.

Derivation. Derives Phenomenon 107.82.

Capture of a neutron leaves a compound nucleus excited by exactly the neutron separation energy of the product, and it is that number, not the fission Q value, which must be compared with the barrier. From the mass evaluation [2393],

$$S_n\left(^{236}\text{U}\right) = 6.5\,\text{MeV}\,, \qquad S_n\left(^{239}\text{U}\right) = 4.8\,\text{MeV}\,, \tag{107.97}$$

against barriers of about 5.7 MeV and 6.2 MeV respectively. In the first case the compound nucleus is created *above* its barrier and fissions promptly, with no help from the neutron's kinetic energy; in the second it is created more than a MeV below, and the neutron must supply the difference.

The 1.7 MeV between the two separation energies is pairing. ^{235}U has $N = 143$, odd, so the captured neutron completes a pair and the system gains the pairing energy of Equation (107.42); ^{238}U has $N = 146$, even, so the captured neutron is unpaired and gains nothing. The predicted difference is $2a_P A^{-1/2} = 2\times 11.18/\sqrt{237} = 1.45$ MeV, against the 1.7 MeV observed. A term worth 1 MeV in a formula whose leading term is 3700 MeV therefore decides which isotope of uranium is a fuel, which is as sharp an illustration as the subject affords of why the small terms of Equation (107.41) were worth deriving. □

Remark 107.83 (The chain reaction). Fission of ^{235}U emits on average $\nu = 2.4$ prompt neutrons at a mean energy near 2 MeV. Three facts then decide whether a chain can be

sustained. Those neutrons are born fast, where the fission cross-section is small; slowing them to thermal energy raises it by the $1/v$ law of Proposition 107.49 by some three orders of magnitude, which is what a moderator is for. But natural uranium is 99.3 per cent ^{238}U, which absorbs neutrons in its capture resonances on the way down without fissioning, so the moderator must slow them in as few collisions as possible and away from the fuel — hence lumps of fuel in a lattice of graphite or heavy water, and hence enrichment. The multiplication factor k is the number of fissions in one generation per fission in the preceding one, and criticality is $k = 1$ exactly.

That last condition would be uncontrollable were it not for a detail of nuclear structure. A small fraction $\beta \approx 0.0065$ of the fission neutrons is not prompt: it is emitted seconds later by excited fragment nuclei whose neutron separation energy lies below the β-decay Q value of their parents, so that a β decay leaves a state that immediately emits a neutron. The mean generation time of the prompt neutrons is of order $1 \times 10^{-4}\,\mathrm{s}$, while these *delayed* neutrons arrive with the half-lives of their precursors, of order 10 s. A reactor held just below prompt criticality — $k = 1$ including the delayed fraction, $k < 1$ without it — therefore has an effective response time set by the precursors and not by the prompt neutrons, longer by five orders of magnitude, which is what makes mechanical control possible at all. The margin is β, six-tenths of one per cent, and it is a nuclear-structure accident.

Example 107.84 (Energy density)**.** Taking 200 MeV per fission, complete fission of one kilogram of ^{235}U releases

$$\frac{200\,\mathrm{MeV} \times N_A}{0.235\,\mathrm{kg/mol}} = \frac{3.204 \times 10^{-11}\,\mathrm{J} \times 6.022\,140\,76 \times 10^{23}/\mathrm{mol}}{0.235\,\mathrm{kg/mol}} = 8.2 \times 10^{13}\,\mathrm{J/kg}\,, \quad (107.98)$$

against about $3 \times 10^7\,\mathrm{J/kg}$ for the combustion of coal: a factor of 2.7×10^6. The ratio is not accidental — it is the ratio of a nuclear binding energy to a chemical one, of 1 MeV to 1 eV — and it is the entire practical significance of this chapter.

107.6.2 Fusion

Fusion faces the same Coulomb barrier as α decay, from the other side. Two protons at 2 fm have electrostatic energy

$$\frac{e^2}{4\pi\varepsilon_0 r} = \frac{1.4400\,\mathrm{MeV\,fm}}{2\,\mathrm{fm}} = 720\,\mathrm{keV}\,, \quad (107.99)$$

whereas the centre of the Sun is at $T = 1.57 \times 10^7\,\mathrm{K}$, that is $k_B T = 1.35\,\mathrm{keV}$ — smaller by a factor of 530. No classical gas at that temperature fuses at any rate whatever, and the resolution is again tunnelling, combined with the fact that a Maxwell–Boltzmann distribution has an exponential tail.

Theorem 107.85 (The Gamow peak)**.** *Let two nuclei of charges $Z_1 e$, $Z_2 e$ and reduced mass μ react with cross-section*

$$\sigma(E) = \frac{S(E)}{E}\,\exp\left(-\sqrt{\frac{E_G}{E}}\right)\,, \qquad E_G = 2\mu c^2\,(\pi\alpha Z_1 Z_2)^2\,, \quad (107.100)$$

with $S(E)$ slowly varying. In a thermal gas at temperature T the reaction rate per pair is dominated by a narrow band of energies centred on

$$E_0 = \left(\frac{E_G\,(k_B T)^2}{4}\right)^{1/3}\,, \quad (107.101)$$

of full width at $1/\mathrm{e}$ *of the maximum*

$$\Delta E = 4\sqrt{\frac{E_0 k_B T}{3}}\,. \tag{107.102}$$

Rests on Equation (107.73).

Derivation. *Derives Theorem 107.85.*

The exponent in Equation (107.100) is the point-Coulomb Gamow factor Equation (107.73) rewritten: with $\eta = Z_1 Z_2 e^2/(4\pi\varepsilon_0\hbar v)$ and $v = \sqrt{2E/\mu}$,

$$2\pi\eta = \frac{2\pi Z_1 Z_2 e^2}{4\pi\varepsilon_0\hbar}\sqrt{\frac{\mu}{2E}} = \pi\alpha Z_1 Z_2\sqrt{\frac{2\mu c^2}{E}} = \sqrt{\frac{E_G}{E}}\,,$$

using $e^2/4\pi\varepsilon_0\hbar = \alpha c$; the factor $1/E$ outside is the geometric area $\pi(\hbar/p)^2 \propto 1/E$, and everything not exponential and not geometric is collected into the *astrophysical S factor* $S(E)$, which is what a laboratory measurement extrapolates to stellar energies. Here the point-Coulomb limit is the right one — unlike in Corollary 107.64, where the finite nuclear radius mattered — because the classical turning point $b = Z_1 Z_2 e^2/4\pi\varepsilon_0 E$ at $E = 6\,\mathrm{keV}$ is $240\,\mathrm{fm}$, so $\xi = R/b \approx 0.01$ and the correction is a per cent.

The rate is the cross-section averaged over the Maxwell–Boltzmann distribution — whose derivation belongs to Chapter 55 — which contributes e^{-E/k_BT} and a factor E that varies slowly. So

$$\langle\sigma v\rangle \propto \int_0^\infty S(E)\,\exp\left[-\frac{E}{k_B T} - \sqrt{\frac{E_G}{E}}\right]\mathrm{d}E\,. \tag{107.103}$$

The two exponents pull in opposite directions — one kills large E, the other kills small E — so the integrand is sharply peaked. Setting the derivative of the bracket to zero,

$$-\frac{1}{k_B T} + \frac{1}{2}\frac{\sqrt{E_G}}{E^{3/2}} = 0 \quad\Longrightarrow\quad E_0 = \left(\frac{\sqrt{E_G}\,k_B T}{2}\right)^{2/3},$$

which is Equation (107.101). Expanding the bracket about E_0 to second order gives a Gaussian of variance $1/|f''(E_0)|$ with $f'' = -\frac{3}{4}\sqrt{E_G}E_0^{-5/2} = -3/(2E_0 k_B T)$, whence Equation (107.102). The construction is an evaluation by steepest descent, carried out on the real axis. □

Example 107.86 (Hydrogen burning in the Sun)**.** For two protons, $\mu c^2 = m_p c^2/2 = 469.14\,\mathrm{MeV}$ and $Z_1 Z_2 = 1$, so

$$E_G = 2 \times 469.14\,\mathrm{MeV} \times \left(\pi \times 7.2974 \times 10^{-3}\right)^2 = 493\,\mathrm{keV}\,,$$

and at the solar central temperature $k_B T = 1.353\,\mathrm{keV}$,

$$E_0 = \left(\frac{493\,\mathrm{keV} \times (1.353\,\mathrm{keV})^2}{4}\right)^{1/3} = 6.1\,\mathrm{keV}\,, \qquad \Delta E = 6.6\,\mathrm{keV}\,.$$

Fusion in the Sun therefore happens almost entirely between protons whose relative energy is between about $3\,\mathrm{keV}$ and $9\,\mathrm{keV}$ — four and a half times the mean thermal energy, in a part of the tail containing a small fraction of the protons, and still more than a hundred times below the barrier Equation (107.99). Both exponentials are essential: a purely thermal argument gives no reactions and a purely quantum one gives no temperature dependence. It is also why stellar burning is so violently temperature sensitive — the rate goes as a high power of T, four for the *pp* chain and near twenty for the CNO cycle — which is what Chapter 52 turns into the stability of a star.

Phenomenon 107.87 (Stars burn hydrogen to helium)**.** The net reaction $4p \to {}^4\mathrm{He} + 2e^+ + 2\nu_e$ releases

$$Q = 26.73\,\mathrm{MeV} \tag{107.104}$$

per helium nucleus, of which the neutrinos carry away on average about 0.6 MeV. Bethe identified the two competing routes, the *pp* chain and the CNO cycle [828], and the neutrinos predicted by the first have been detected at the rate the Sun's luminosity requires (Chapter 114).

Rests on Phenomenon 107.24 and Proposition 107.23.

Derivation. *Derives Phenomenon 107.87.*

The energy release is the mass difference. Using atomic masses, so that the two positrons annihilate with two of the electrons already counted,

$$Q = \left[4M_{\mathrm{at}}\left({}^1\mathrm{H}\right) - M_{\mathrm{at}}\left({}^4\mathrm{He}\right)\right]c^2 = 0.028\,697\,u\,c^2 = 0.028\,697 \times 931.494\,\mathrm{MeV} = 26.73\,\mathrm{MeV}\,,$$

equivalently $4m_pc^2 - M_{\mathrm{nuc}}({}^4\mathrm{He})c^2 = 25.71\,\mathrm{MeV}$ of nuclear release plus $4m_ec^2 = 2.04\,\mathrm{MeV}$ from the two annihilations, minus the $2m_ec^2$ carried into existence as positrons — the two bookkeepings agreeing, as they must.

The rate-limiting step is the first, $p + p \to d + e^+ + \nu_e$, which is a *weak* process: two protons cannot form a bound diproton (Phenomenon 107.24), so one of them must convert to a neutron during the collision. Its cross-section has never been measured and cannot be, being some twenty orders of magnitude below anything a laboratory can reach; it is computed from the weak coupling of Chapter 101 and the two-nucleon wave function of Proposition 107.23. That a weak interaction gates the whole chain is why the Sun burns for 10^{10} years instead of exploding, and it is a rare case in which the slowness of a rate is the reason there is anybody to measure it.

The flux at the Earth follows from the luminosity alone, with no solar model. Each helium nucleus releases Q and two neutrinos, so

$$\Phi_\nu = \frac{2L_\odot}{4\pi d^2\,Q} = \frac{2 \times 3.828 \times 10^{26}\,\mathrm{W}}{4\pi\,(1.496 \times 10^{11}\,\mathrm{m})^2 \times 4.28 \times 10^{-12}\,\mathrm{J}} = 6.4 \times 10^{14}/(\mathrm{m^2\,s})\,, \tag{107.105}$$

some sixty billion neutrinos through every square centimetre of the reader every second. That this number is right, and that the number of *electron* neutrinos observed was for thirty years only a third of it, is the subject of Chapter 114. □

Remark 107.88 (Carbon, and the resonance predicted from its existence)*.* Beyond helium the chart has a gap: there is no stable nuclide at $A = 5$ or $A = 8$. ${}^8\mathrm{Be}$ is unbound against two α particles by 92 keV and has a half-life of $8.2 \times 10^{-17}\,\mathrm{s}$. Carbon must therefore be assembled from three α particles, and a genuine three-body collision at stellar densities is far too rare. The route is two-step: the tiny equilibrium population of ${}^8\mathrm{Be}$ maintained by $\alpha + \alpha \rightleftharpoons {}^8\mathrm{Be}$ captures a third α, with total release

$$Q = B\left({}^{12}\mathrm{C}\right) - 3B\left({}^4\mathrm{He}\right) = 92.16\,\mathrm{MeV} - 84.89\,\mathrm{MeV} = 7.27\,\mathrm{MeV}\,.$$

Even so the rate is far too small unless the capture is resonant. Hoyle argued that since carbon exists in quantity, ${}^{12}\mathrm{C}$ must have a 0^+ state a few hundred keV above the three-α threshold [1044]; the state was then looked for and found, at an excitation energy of 7.65 MeV, that is 0.38 MeV above threshold. It remains the clearest case in physics of a nuclear level predicted from an astronomical abundance, and the systematic account of how the rest of the chart is built — the *s* and *r* neutron-capture processes, the α ladder, the iron peak — is [1105, 1106], developed in Chapter 52.

Example 107.89 (Deuterium–tritium fusion)**.** The reaction easiest to arrange on Earth is $d + t \to {}^4\mathrm{He} + n$, with

$$Q = B\left({}^4\mathrm{He}\right) - B\left({}^2\mathrm{H}\right) - B\left({}^3\mathrm{H}\right) = 28.30\,\mathrm{MeV} - 2.22\,\mathrm{MeV} - 8.48\,\mathrm{MeV} = 17.59\,\mathrm{MeV}\,,$$

shared by momentum conservation in the inverse ratio of the masses: 3.5 MeV to the α particle and 14.1 MeV to the neutron. Per unit mass of a one-to-one d–t mixture the release is 3.4×10^{14} J/kg, four times the fission value Equation (107.98). It is favoured not for that but for its S factor, which is enhanced by a broad resonance in ${}^5\mathrm{He}$ just above threshold, and the practical operating point is near $T = 1.5 \times 10^8$ K, where Equation (107.101) with $\mu c^2 = 1125$ MeV gives $E_G = 1.18$ MeV and a Gamow peak at $E_0 = 37$ keV. That the α particle is charged and the neutron is not divides the engineering in two: the first can be confined magnetically and heats the plasma (Chapter 66), the second cannot and must be absorbed in a blanket, where it also breeds the tritium.

107.6.3 The heaviest nuclei

Proposition 107.90 (The liquid-drop limit)**.** *Equation* (107.96) *places the end of the chart at* $Z^2/A = 50.1$. *Along the observed neutron-to-proton ratio of the heaviest nuclides,* $A \approx 2.5Z$, *this is* $Z \approx 125$*; but the barrier falls to below* 1 MeV *— comparable with the zero-point energy of the deformation mode itself — already near* $Z = 106$.

Rests on Equations (107.95) *and* (107.96).

Proof. *Derives Proposition 107.90.*

Setting $A = 2.5Z$ in Equation (107.96) gives $Z/2.5 = 50.1$, that is $Z = 125$: beyond that, a nucleus is unstable against an infinitesimal deformation and cannot exist even momentarily. Below it the barrier does not vanish but shrinks rapidly, since Equation (107.95) is the leading term of a surface that flattens as $x \to 1$; the height falls from 6 MeV at $x = 0.7$ (uranium) to a fraction of a MeV at $x \approx 0.9$ ($Z \approx 106$ at the same neutron-to-proton ratio). A barrier that low is transparent, and the liquid drop therefore predicts that no nuclide beyond about $Z = 106$ survives long enough to have a chemical identity. □

Phenomenon 107.91 (Elements exist that the liquid drop forbids)**.** Nuclides up to $Z = 118$ have been synthesized and identified, with half-lives from milliseconds to minutes — many orders of magnitude longer than Proposition 107.90 allows. Their existence is due entirely to shell corrections: the single-particle level density of Table 107.4 is low near a closed shell, which adds several MeV of extra binding to the spherical shape and so restores a barrier where the drop has none.

Rests on Proposition 107.90.

Derivation pending #175

The shell correction: the derivation that a low single-particle level density near a closed shell adds several MeV *of binding relative to the smooth liquid-drop average and so restores a fission barrier — the Strutinsky shell-correction method. It belongs in Appendix A; the phenomenon above uses the statement without it.*

Remark 107.92 (The island, and how far it has been approached). Extrapolating Equation (107.65) past 126 gives 184 as the next neutron closure, and various mean fields put the next proton closure at 114, 120 or 126 — the spread being itself a measure of how far the extrapolation is being pushed, and a reminder of Remark 107.60, that a magic number is a property of a filling and not of the force. Around such a doubly closed configuration the shell correction should be largest and the half-lives longest: the predicted *island of stability*.

The synthesis route is fusion of a heavy target with a beam, followed by evaporation of a few neutrons; the $Z = 117$ case [2162] used a ^{48}Ca beam on a ^{249}Bk target, and is the standard worked example of the identification chain. A recoil separator removes the beam and the transfer products; a surviving recoil is implanted in a position-sensitive silicon detector; and the claim rests on observing, at the same position, a time-correlated sequence of α decays with the right energies terminating in a known nuclide or in spontaneous fission. The identification is thus of a decay *chain*, not of an atom, and the statistics are correspondingly harsh — a handful of chains from weeks of irradiation.

The honest statement is that the island has not been reached. The most neutron-rich nuclides made carry $N = 177$, seven short of 184, and their half-lives are tens of milliseconds; every heavier isotope would require a neutron-rich projectile that no accelerator currently delivers. What has been established is that shell corrections are real and large — without them none of these nuclides would exist for a microsecond — and what has not is the size of the effect at the predicted centre. The standard textbook account of everything in this chapter is [1809].

Chapter 108

The Renormalization Group

A coupling constant is not constant. What the renormalization of Chapter 100 treats as a technical device for removing infinities is, read correctly, a statement about nature: the strength of an interaction depends on the scale at which it is probed, and the dependence is measurable. The idea began as an invariance of the subtraction procedure [1028, 1038], was put in differential form by Callan [1415] and Symanzik [1435], and was then transformed by Kadanoff [1334] and Wilson [1461, 1462] into something far more general — a flow in the space of all theories, generated by integrating out short-distance degrees of freedom.

That reformulation is why this chapter sits at the end of Part XI and faces in two directions. Towards particle physics it gives asymptotic freedom [1501, 1511], the running of α_s measured over more than two decades of energy (Chapter 102), and the effective-field-theory logic [1538, 1647] by which a low-energy theory can be predictive while remaining ignorant of what lies above it. Towards condensed matter it gives universality: the critical exponents of a fluid and of a uniaxial magnet agree because both flow to the same fixed point (Chapter 123), a prediction confirmed to better than a percent [2054]. The chapter also states the technical apparatus honestly — dimensional regularization [1463, 1465], the minimal subtraction schemes [1492, 1613] — and the limits that follow from it, including the triviality of the scalar sector [1662, 2371] that bears on Chapter 104. Standard treatments are [1536, 1918, 2042].

108.1 Conventions carried into this chapter

Everything below is written in SI, as the front matter requires and as Section 100.1.1 sets out in detail for this part. Four points of bookkeeping are used so often that they are collected here.

Notation 108.1 (The renormalization scale, and what it is). The subtraction scale introduced by dimensional continuation in Definition 100.30 is written $\bar{\mu}$ and carries the SI dimension of a *momentum*, $\mathrm{kg\,m/s}$; the corresponding energy is $\bar{\mu}c$, and the corresponding length is $\hbar/\bar{\mu}$. The literature calls both the momentum and the energy μ and does not distinguish them, for the reason recorded in Remark 108.5. Nothing in this chapter depends on the choice, since

$$\mathrm{d}\ln\bar{\mu} = \mathrm{d}\ln(\bar{\mu}c) = -\mathrm{d}\ln(\hbar/\bar{\mu})\ , \tag{108.1}$$

$\hbar$ and c being constants: a derivative with respect to the logarithm of the scale is the same operator whether the scale is measured as a momentum, as an energy or as an inverse length. Where an energy is wanted the symbol E is used, with $E = \bar{\mu}c$. The quantity Q always denotes a momentum transfer, $Q^2 = -q^2 \geq 0$ for a spacelike exchange in the metric of Notation 100.1, so that Qc is the energy scale a scattering experiment resolves and $\hbar c/(Qc) = \hbar/Q$ the length.

Notation 108.2 (Reduced fields and the dimension of an operator). Power counting requires every field to be a pure power of an inverse length, which in SI two of the three are already and the third is not. The Dirac field carries $1/\mathrm{m}^{3/2}$ by Definition 100.2; the geometric gauge field $\mathcal{A}_\mu = (g_s/\hbar)A^a_\mu T_a$ of Equation (102.18) carries $1/\mathrm{m}$; but the scalar field of Equation (106.33) carries $\mathrm{J}^{1/2}/\mathrm{m}^{1/2}$. Define therefore the *reduced* scalar

$$\hat{\phi} := \frac{\phi}{\sqrt{\hbar c}}\,, \qquad \left[\hat{\phi}\right] = 1/\mathrm{m}\,, \tag{108.2}$$

since $\hbar c = 3.161\,527 \times 10^{-26}\,\mathrm{J\,m}$. With this one substitution every field of the Standard Model is a power of an inverse length: $\hat{\phi} \sim \ell^{-1}$, $\psi \sim \ell^{-3/2}$, $\mathcal{A}_\mu \sim \ell^{-1}$, $\partial_\mu \sim \ell^{-1}$. A local operator O built from n_ϕ reduced scalars, n_ψ Dirac fields, n_A geometric gauge fields and n_∂ derivatives therefore carries

$$[O] = 1/\mathrm{m}^D\,, \qquad D = n_\phi + \frac{3}{2}n_\psi + n_A + n_\partial\,, \tag{108.3}$$

and D — an integer or half-integer, and a pure number — is what this chapter means by *the dimension of the operator*. It is the same integer the natural-units literature calls the mass dimension, obtained here without setting anything to one.

Proposition 108.3 (The SI dimension of a coupling)**.** *If the Lagrangian density contains a term $c_O O$ with O of dimension D in the sense of Equation (108.3), then*

$$[c_O] = \mathrm{J}/\mathrm{m}^3 \times \mathrm{m}^D = [\hbar c] \times \mathrm{m}^{D-4}\,, \tag{108.4}$$

so that c_O may always be written

$$c_O = \hat{c}_O\,\hbar c\,\ell_\star^{D-4} = \hat{c}_O\,\hbar c\left(\frac{\hbar c}{E_\star}\right)^{D-4} \tag{108.5}$$

with $\hat{c}_O$ a pure number, $\ell_\star$ a reference length and $E_\star = \hbar c/\ell_\star$ the corresponding energy. The dimensionless strength with which O acts on a process of energy E is

$$\hat{c}_O(E) = \hat{c}_O\left(\frac{E}{E_\star}\right)^{D-4}. \tag{108.6}$$

Rests on Equations (100.2) and (108.3).

Proof. *Derives Proposition 108.3.*

A Lagrangian density is an energy density, J/m^3, by Equation (100.2), and $[O] = 1/\mathrm{m}^D$, which gives the first equality in Equation (108.4). Since $[\hbar c] = \mathrm{J\,m}$, dividing by it leaves m^{D-4}, which is the second. Writing that residual length dependence as a power of a chosen $\ell_\star$ defines $\hat{c}_O$, and Equation (108.6) follows because the only length a process of energy E supplies is $\hbar c/E$, so the matrix element of $c_O O$ carries $c_O(E/\hbar c)^D$ divided by the energy density scale $E^4/(\hbar c)^3$ that any term of the Lagrangian is measured against. □

Example 108.4 (Three couplings of the Standard Model, checked)**.** Take $\ell_\star = \hbar c/E_\star$ with $E_\star$ whatever the context supplies.

- The scalar self-coupling. $\hat{\phi}^4$ has $D = 4$, so $[c_O] = [\hbar c]$ exactly, and $\phi^4 = (\hbar c)^2\,\hat{\phi}^4$ by Equation (108.2), so $-\frac{g}{4!}\phi^4 = -\frac{g\hbar c}{4!}\,\hbar c\,\hat{\phi}^4$, which gives $\hat{c}_O = g\hbar c = \hat{g}$ as Equation (106.34) defines it, the residual $\hbar c/4!$ belonging to the operator's normalization. A marginal coupling is a pure number and does not run with E at tree level.
- The Dirac mass term. $\bar{\psi}\psi$ has $D = 3$, so $[c_O] = [\hbar c] \times 1/\mathrm{m} = \mathrm{J\,m} \cdot 1/\mathrm{m}$, that is an energy; and indeed the term is $-mc^2\bar{\psi}\psi$. Its dimensionless strength at energy E is mc^2/E, which *falls* as E rises: a mass is a relevant coupling and matters at low energy.

- The Fermi interaction. $(\bar\psi\Gamma\psi)^2$ has $D=6$, so $[c_O]=\mathrm{J\,m^3}$, which is Equation (101.7) exactly. Its dimensionless strength is $G_F E^2/(\hbar c)^3$, which *grows* as E rises. That is the whole of Section 101.7.1 read off from one integer.

The length $\ell_F=[G_F/(\hbar c)]^{1/2}=6.7392\times10^{-19}\,\mathrm{m}$ built from Fermi's constant of Equation (101.8) corresponds to the energy $\hbar c/\ell_F=292.8\,\mathrm{GeV}$ of Equation (101.9): the four-fermion description carries in its own dimension the energy at which it must be replaced, and it was.

Remark 108.5 (Reading this chapter against the natural-units literature). Every reference cited below sets $\hbar=c=1$. The dictionary is the one given once in Remark 100.4; three entries are used so heavily here that they are repeated. A scalar field maps to its reduced form Equation (108.2); a coupling of a dimension-D operator maps to the hatted number of Equation (108.5), which is what those texts write with no hat; and the "mass dimension" of an operator is the integer D of Equation (108.3), which in this book is a power of metres. To go the other way, restore an $\hbar c$ for every unit by which the operator's dimension exceeds four. No derivation in this chapter is carried out with $\hbar$ or c set to one; this remark exists so that a reader can check the chapter against its sources, which is a different thing.

108.2 Origins in field theory

108.2.1 The arbitrariness of the subtraction point

Renormalization as Chapter 100 presents it is a procedure with a free choice in it. The divergent parts of the counterterms are forced; their finite parts are not, and Definition 100.54 fixes them by a convention — a mass shell, a subtraction momentum, a minimal pole. Stueckelberg and Petermann observed that the freedom is not a defect but a structure: the transformations relating one admissible choice of finite parts to another compose, are invertible, and therefore form a group, which they named the *groupe de normalisation* [1028]. Gell-Mann and Low turned the observation into a calculation by writing a functional equation for the electromagnetic coupling measured at short distance [1038], and Bogoliubov and Shirkov gave the first systematic account of the resulting apparatus [1166].

The physical content is best seen before any diagram is drawn.

Definition 108.6 (The effective coupling)**.** Let a scattering process be governed at momentum transfer Q by a single dimensionless coupling. Define the *effective coupling* $\bar\alpha(Q)$ to be the number that, inserted in the tree-level formula, reproduces the measured rate at that Q. It is by construction an observable: it is a rate, re-expressed. Its SI dimension is that of a pure number, and Q is a momentum.

Theorem 108.7 (The Gell-Mann–Low functional equation)**.** *There is no scale in a massless theory other than the one the experimenter brings, so $\bar\alpha(Q)$ cannot depend on Q alone. Fixing a reference momentum κ and writing $\alpha_\kappa:=\bar\alpha(\kappa)$, there is a function F of two pure numbers with*

$$\bar\alpha(Q)=F\!\left(\frac{Q}{\kappa},\alpha_\kappa\right),\qquad F(1,x)=x\,, \tag{108.7}$$

and F satisfies the group law

$$F\!\left(\frac{Q}{\kappa_1},\alpha_{\kappa_1}\right)=F\!\left(\frac{Q}{\kappa_2},F\!\left(\frac{\kappa_2}{\kappa_1},\alpha_{\kappa_1}\right)\right) \tag{108.8}$$

for every pair of reference momenta [1038]. Equivalently, in differential form,

$$\frac{\mathrm{d}\bar\alpha}{\mathrm{d}\ln Q}=\beta(\bar\alpha)\,,\qquad \beta(x):=\left.\frac{\partial F(t,x)}{\partial\ln t}\right|_{t=1}, \tag{108.9}$$

a first-order ordinary differential equation whose right-hand side does not contain Q.
Rests on Definition 108.6 and Notation 108.1.

Proof. *Derives Theorem 108.7.*

$\bar{\alpha}$ is a pure number and the only quantities available are Q, κ and α_κ; since $\hbar$ and c are constants they build no further independent dimensionless combination, and Q and κ can enter only through their ratio. That is Equation (108.7), and $F(1,x)=x$ is the definition of α_κ.

For Equation (108.8): the left side computes $\bar{\alpha}(Q)$ using κ_1 as reference. The right side computes it using κ_2, whose own effective coupling is $\alpha_{\kappa_2}=F(\kappa_2/\kappa_1,\alpha_{\kappa_1})$ by Equation (108.7) applied at $Q=\kappa_2$. Both are the same measured number, so they are equal. The reference momentum is a bookkeeping device, and Equation (108.8) is the statement that the answer does not remember which one was used. The transformations $T_\lambda : x \mapsto F(\lambda,x)$ therefore satisfy $T_{\lambda\lambda'}=T_\lambda\circ T_{\lambda'}$ and $T_1=\mathrm{id}$: a one-parameter group, which is what [1028] named.

For Equation (108.9), put $\kappa_2=\kappa_1(1+\epsilon)$ in Equation (108.8) and expand to first order in ϵ. Write $t=Q/\kappa_1$ and $x=\alpha_{\kappa_1}$. The left side is $F(t,x)$, independent of ϵ. On the right, $Q/\kappa_2=t(1-\epsilon)$ and $F(1+\epsilon,x)=x+\epsilon\beta(x)$ by the definition of β in Equation (108.9), so the right side is

$$F(t(1-\epsilon),x+\epsilon\beta(x))=F(t,x)-\epsilon\,\frac{\partial F}{\partial \ln t}+\epsilon\,\beta(x)\frac{\partial F}{\partial x}\,.$$

Equality for all ϵ forces $\partial F/\partial\ln t=\beta(x)\,\partial F/\partial x$. Now use the group law a second time, in the form $F(t,x)=F(t/t',F(t',x))$, differentiated with respect to $\ln t$ at $t=t'$: it gives $\partial F(t,x)/\partial\ln t=\beta(F(t,x))$, which is Equation (108.9) with $\bar{\alpha}=F(t,x)$. □

Corollary 108.8 (The flow is integrable in closed form)**.** *Wherever β does not vanish,*

$$\ln\frac{Q}{\kappa}=\int_{\alpha_\kappa}^{\bar{\alpha}(Q)}\frac{\mathrm{d}x}{\beta(x)}\,. \tag{108.10}$$

Rests on Theorem 108.7 and Equation (108.9).

Proof. *Derives Corollary 108.8.*

Separate the variables in Equation (108.9) and integrate from $Q=\kappa$, where $\bar{\alpha}=\alpha_\kappa$. □

Remark 108.9 (What has and has not been assumed). Theorem 108.7 uses no perturbation theory and no regulator. It uses one physical assumption — that the theory contains no mass with which Q could be compared — and one piece of dimensional analysis. Everything specific to a theory sits in the one function β, and computing β is what perturbation theory is for. Two consequences are worth stating at once, because they are the skeleton of the whole chapter.

First, a *zero* of β is a scale-invariant theory: by Equation (108.9) the coupling then does not move, and by Equation (108.10) the integral diverges as $\bar{\alpha}$ approaches the zero, so the zero is reached only as $\ln Q\to\pm\infty$. Such a point is a *fixed point* (Section 108.4.3).

Second, if β has no zero between α_κ and some value, Equation (108.10) converts a statement about a dimensionless coupling into a statement about an *energy*. Where the integral converges at the upper limit the theory acquires a finite scale out of nothing: this is dimensional transmutation, and it is why Λ_{QCD} exists (Definition 102.38) and why the one-loop Landau pole of Proposition 100.64 has a location at all.

108.2.2 The Callan–Symanzik equation

Theorem 108.7 is about an observable. The equation Callan [1415] and Symanzik [1435] obtained independently is about the Green functions of the theory, which are not observables, and it is more useful precisely because it says how the unobservable parts move too.

Definition 108.10 (Bare and renormalized Green functions)**.** Following Definition 100.45, let ϕ_0 be the bare field of a theory regulated as in Definition 100.30, and let

$$\phi_0 = Z_\phi^{1/2}(\bar{\mu})\,\phi\,, \tag{108.11}$$

define the renormalized field, Z_ϕ being a pure number depending on $\bar{\mu}$, on the regulator and on the dimensionless coupling $\hat{g}$. The bare and renormalized connected n-point functions

$$G_0^{(n)}(x_1,\dots,x_n) := \langle T\,\phi_0(x_1)\cdots\phi_0(x_n)\rangle\,, \qquad G^{(n)} = Z_\phi^{-n/2} G_0^{(n)}\,, \tag{108.12}$$

carry the SI dimension $[\phi]^n$ and are otherwise pure functions of the separations.

Theorem 108.11 (The Callan–Symanzik equation)**.** *The renormalized n-point functions of a theory with one dimensionless coupling $\hat{g}$ and one mass m satisfy*

$$\left[\frac{\partial}{\partial \ln\bar{\mu}} + \beta(\hat{g})\,\frac{\partial}{\partial \hat{g}} + \gamma_m(\hat{g})\,m\frac{\partial}{\partial m} + n\gamma_\phi(\hat{g})\right] G^{(n)} = 0\,, \tag{108.13}$$

where, at fixed bare parameters and fixed regulator,

$$\beta := \frac{\partial \hat{g}}{\partial \ln\bar{\mu}}\,, \qquad \gamma_\phi := \frac{1}{2}\frac{\partial \ln Z_\phi}{\partial \ln\bar{\mu}}\,, \qquad \gamma_m := \frac{\partial \ln m}{\partial \ln\bar{\mu}}\,. \tag{108.14}$$

All three are pure numbers, functions of $\hat{g}$ alone in a mass-independent scheme (Theorem 108.18) [1415, 1435].

Rests on Definition 108.10 and Equation (108.12).

Proof. *Derives Theorem 108.11.*

The bare field ϕ_0, the bare coupling and the bare mass are defined by the regulated Lagrangian; the scale $\bar{\mu}$ enters only through the *choice* of what to call renormalized, that is through Z_ϕ and through the finite parts of the counterterms. Hence

$$\left.\frac{\partial G_0^{(n)}}{\partial \ln\bar{\mu}}\right|_0 = 0\,, \tag{108.15}$$

the subscript recording that the bare quantities are held fixed. This is the whole physical input, and it is the exact counterpart of Equation (108.8): the arbitrary reference must drop out.

Substituting $G_0^{(n)} = Z_\phi^{n/2} G^{(n)}$ into Equation (108.15) and using the chain rule — $G^{(n)}$ depends on $\bar{\mu}$ explicitly, through $\hat{g}(\bar{\mu})$ and through $m(\bar{\mu})$ —

$$0 = \frac{\partial}{\partial \ln\bar{\mu}}\left[Z_\phi^{n/2} G^{(n)}\right] = Z_\phi^{n/2}\left[\frac{n}{2}\frac{\partial \ln Z_\phi}{\partial \ln\bar{\mu}} + \frac{\partial}{\partial \ln\bar{\mu}} + \frac{\partial \hat{g}}{\partial \ln\bar{\mu}}\frac{\partial}{\partial \hat{g}} + \frac{\partial m}{\partial \ln\bar{\mu}}\frac{\partial}{\partial m}\right] G^{(n)}\,.$$

Dividing by $Z_\phi^{n/2}$, which is non-zero, and inserting the definitions Equation (108.14) — with $\partial m/\partial \ln\bar{\mu} = \gamma_m m$ — gives Equation (108.13).

The three coefficients are pure numbers: $\bar{\mu}$ appears only inside a logarithm, so $\partial/\partial\ln\bar{\mu}$ is dimensionless; $\hat{g}$ and Z_ϕ are pure numbers by construction; and $m\,\partial/\partial m$ is dimensionless whatever the SI dimension of m. The equation is therefore a statement among pure numbers acting on a quantity of dimension $[\phi]^n$, and every term of it has that same dimension, as it must. □

Definition 108.12 (Beta function and anomalous dimensions)**.** β is the *beta function* of the coupling. γ_ϕ is the *anomalous dimension* of the field and γ_m that of the mass. The names are earned in Corollary 108.14: at a zero of β the two-point function scales with a power that differs from the one dimensional analysis alone would give, and the difference is $2\gamma_\phi$.

The equation is solved by the method of characteristics, which is the statement that moving the scale and changing the coupling are the same motion seen twice.

Proposition 108.13 (Solution by characteristics)**.** *Let $\Gamma^{(n)}(p_1,\dots,p_n;\hat g,m,\bar\mu)$ be the one-particle-irreducible n-point function in momentum space, whose SI dimension after the overall momentum-conserving factor is removed is an inverse length raised to some power d_n, that is $(1/\mathrm{m})^{d_n}$; and suppose all n momenta are scaled together, $p_i \mapsto \sigma p_i$ with σ a pure number. Then*

$$\Gamma^{(n)}(\sigma p_i;\hat g,m,\bar\mu) = \sigma^{d_n}\,\Gamma^{(n)}(p_i;\bar g(\sigma),\bar m(\sigma),\bar\mu)\exp\!\left[-n\int_1^\sigma \gamma_\phi(\bar g(s))\,\mathrm{d}\ln s\right], \tag{108.16}$$

where the running *coupling and mass solve*

$$\frac{\mathrm{d}\bar g}{\mathrm{d}\ln\sigma} = \beta(\bar g)\,, \qquad \frac{\mathrm{d}\ln\bar m}{\mathrm{d}\ln\sigma} = \gamma_m(\bar g) - 1\,, \tag{108.17}$$

with $\bar g(1)=\hat g$ and $\bar m(1)=m$.

Rests on Theorem 108.11 and Equation (108.12).

Proof. *Derives Proposition 108.13.*

Two facts are combined. The first is Equation (108.13), applied to $\Gamma^{(n)}$, for which the sign of the field term is reversed. The one-particle-irreducible function is obtained by amputating the external propagators, which inverts the field normalization: where Equation (108.12) has $G_0^{(n)} = Z_\phi^{n/2} G^{(n)}$, the corresponding relation is $\Gamma_0^{(n)} = Z_\phi^{-n/2}\Gamma^{(n)}$, as the case $n=2$ makes plain since $\Gamma^{(2)}$ is the reciprocal of $G^{(2)}$. Repeating the argument of Theorem 108.11 with that substitution gives

$$\left[\frac{\partial}{\partial\ln\bar\mu} + \beta\frac{\partial}{\partial\hat g} + \gamma_m m\frac{\partial}{\partial m} - n\gamma_\phi\right]\Gamma^{(n)} = 0\,. \tag{108.18}$$

The second is ordinary dimensional analysis. $\Gamma^{(n)}$ is a function of the momenta, of m, of $\bar\mu$ and of the pure number $\hat g$, and its SI dimension is fixed. Euler's theorem for a homogeneous function — every one of p_i, mc and $\bar\mu$ being a momentum — gives

$$\left[\sum_i p_i\cdot\frac{\partial}{\partial p_i} + m\frac{\partial}{\partial m} + \frac{\partial}{\partial\ln\bar\mu} - d_n\right]\Gamma^{(n)} = 0\,. \tag{108.19}$$

This is not an extra assumption: it says that multiplying every momentum, the mass and the subtraction scale by a common number multiplies $\Gamma^{(n)}$ by that number to the power d_n, which is what having an SI dimension means.

Subtracting Equation (108.19) from Equation (108.18) eliminates $\partial/\partial\ln\bar\mu$ and leaves

$$\left[\sum_i p_i\cdot\frac{\partial}{\partial p_i} - \beta\frac{\partial}{\partial\hat g} + (1-\gamma_m)\,m\frac{\partial}{\partial m} + n\gamma_\phi - d_n\right]\Gamma^{(n)} = 0\,. \tag{108.20}$$

For momenta scaled by σ the first operator is $\partial/\partial\ln\sigma$, and Equation (108.20) becomes a linear first-order partial differential equation in $(\ln\sigma,\hat g,\ln m)$. Its characteristics are exactly Equation (108.17), and along them the equation reduces to $\mathrm{d}\ln\Gamma^{(n)}/\mathrm{d}\ln\sigma = d_n - n\gamma_\phi$, which integrates to Equation (108.16). □

Corollary 108.14 (Anomalous scaling at a fixed point)**.** *Let $\hat{g}_\star$ be a zero of β and set $m = 0$. Then $\bar{g}(\sigma) \equiv \hat{g}_\star$, the exponential in Equation (108.16) becomes a power, and*

$$\Gamma^{(n)}(\sigma p_i) = \sigma^{\,d_n - n\gamma_\phi(\hat{g}_\star)}\,\Gamma^{(n)}(p_i)\ . \tag{108.21}$$

For $n = 2$ this says that the inverse propagator behaves as $p^2\,(p/\bar{\mu})^{-2\gamma_\phi}$ rather than as p^2, so that the field's correlation function in position space falls as $r^{-2}\,(\hbar/\bar{\mu}r)^{2\gamma_\phi}$ rather than as r^{-2}. The reference scale is written explicitly because a non-integer power of a dimensionful quantity is not defined without one: $p/\bar{\mu}$ and $\bar{\mu}r/\hbar$ are pure numbers by Notation 108.1, and the literature's $p^{2-2\gamma_\phi}$ and $r^{-2-2\gamma_\phi}$ are these expressions with $\bar{\mu}$ suppressed. The exponent is shifted from its classical value by $2\gamma_\phi$: hence the name.

Rests on Equation (108.16) and Notation 108.1.

Proof. *Derives Corollary 108.14.*

Immediate from Equation (108.16) with β vanishing, so that $\gamma_\phi(\bar{g}(s))$ is constant and the integral is $\ln\sigma$. The position-space statement follows by Fourier transform in $3+1$ dimensions (Chapter 17), a power p^{-a} in four dimensions transforming to r^{a-4} up to a constant. □

Remark 108.15 (The relation to the observable flow). Theorem 108.7 and Theorem 108.11 are the same statement addressed to different objects. Equation (108.9) governs a measured effective coupling and contains only β; Equation (108.13) governs Green functions, which depend on the arbitrary Z_ϕ, and pays for that generality with the extra term $n\gamma_\phi$. In a scheme where the renormalized coupling is *defined* as the effective coupling at $Q = \bar{\mu}$ the two beta functions coincide, which is how Proposition 100.63 was obtained in Chapter 100 without writing Equation (108.13) at all.

Example 108.16 (The one-loop running of the electromagnetic coupling)**.** For quantum electrodynamics Proposition 100.63 gives

$$\frac{\mathrm{d}\alpha}{\mathrm{d}\ln\bar{\mu}} = \frac{2\alpha^2}{3\pi}\sum_f N_c^{(f)}\left(\frac{q_f}{e}\right)^2 + O\!\left(\alpha^3\right)\ , \tag{108.22}$$

with $\alpha = e^2/(4\pi\varepsilon_0\hbar c)$ the dimensionless combination of Equation (100.3). Inserting this in Equation (108.10) with $\beta(x) = Bx^2$, $B := (2/3\pi)\sum_f N_c^{(f)}(q_f/e)^2$, gives

$$\frac{1}{\alpha(\bar{\mu})} = \frac{1}{\alpha(\kappa)} - B\ln\frac{\bar{\mu}}{\kappa}\,, \tag{108.23}$$

the closed form behind the measured six-per-cent growth of α between zero momentum transfer and the Z pole (Phenomenon 100.62). The sign is positive, so $1/\alpha$ decreases with $\bar{\mu}$ and the coupling grows: the vacuum screens (Remark 100.34). The measurement itself belongs to Chapter 112, where the value at zero momentum transfer is extracted from the electron anomaly.

108.2.3 Renormalization schemes and their arbitrariness

A renormalized coupling is not a measurement. It is a measurement processed through a convention, and the convention has to be quoted with it.

Definition 108.17 (Four schemes)**.** The prescriptions in use fix the finite parts of the counterterms in one of four ways.

- *On shell.* The parameters are defined by physical quantities at physical kinematics: the pole of the propagator is the mass, the residue is one, the coupling is the value at zero momentum transfer. This is Definition 100.46, and it is why $\alpha^{-1} = 137.035999177(21)$ [2431] is a number with no scale attached.

- *Momentum subtraction.* A Green function is required to take its tree-level value at a chosen spacelike point $Q^2 = \bar{\mu}^2$. This keeps the mass dependence of the counterterms and hence produces a beta function that depends on $m/\bar{\mu}$; it is the scheme in which decoupling is automatic (Theorem 108.64).

- *Minimal subtraction* MS. The counterterms remove the poles $1/\varepsilon$ of Definition 100.30 and nothing else [1492].

- *Modified minimal subtraction* $\overline{\text{MS}}$. The counterterms remove the whole recurring combination Equation (100.75), $\varepsilon^{-1} - \gamma_{\text{E}} + \ln 4\pi$, which by Lemma 100.28 accompanies every pole [1613]. This is the default in which α_s and the quark masses are quoted, including in Table 102.1 and in Equation (102.47).

The first two are *mass-dependent*, the last two *mass-independent*, in the sense made precise next.

Theorem 108.18 ('t Hooft's mass-independence)**.** *In minimal subtraction the beta function and the anomalous dimensions of Equation* (108.14) *are functions of the dimensionless couplings alone. No mass, and no ratio $m/\bar{\mu}$, appears in them [1492].*

Rests on Equation (108.14) *and Theorem 100.52.*

Derivation. *Derives Theorem 108.18.*

Two properties of the counterterms do the work, and both were established in Chapter 100. First, by Remark 100.53 a counterterm is a *polynomial* in the masses and external momenta, of degree the superficial divergence of the graph it cancels: the subtraction operator of Theorem 100.52 is a Taylor expansion, so nothing non-analytic in m can appear in it. Second, in minimal subtraction the counterterm is by definition a pure pole $a_k(\hat{g})/\varepsilon^k$ with no finite part attached.

Now count dimensions. The coefficient a_k multiplies an operator already present in the Lagrangian, so it is a pure number; a polynomial in the masses that is also a pure number and carries no $\bar{\mu}$ can only be a constant, because the only dimensionless combination available is $mc/\bar{\mu}$ and that is not polynomial in m unless it is absent. Hence $a_k = a_k(\hat{g})$. Since β and the γ's are computed from the a_k by differentiating with respect to $\ln\bar{\mu}$ at fixed bare coupling, they inherit the property.

The price is stated in Section 108.6.1: a heavy particle does not disappear from a mass-independent beta function when the scale drops below its mass, and must be removed by hand. □

Theorem 108.19 (The first two beta coefficients are scheme independent)**.** *Write the beta function of a dimensionless coupling a as*

$$\frac{\mathrm{d}a}{\mathrm{d}\ln\bar{\mu}} = -\beta_0 a^2 - \beta_1 a^3 - \beta_2 a^4 - \cdots . \tag{108.24}$$

Under any redefinition $a \mapsto a' = a + c_1 a^2 + c_2 a^3 + \cdots$ with finite c_i — which is what a change of scheme is, by Proposition 100.55 — the coefficients β_0 and β_1 are unchanged. Every coefficient from β_2 on is changed.

Rests on Proposition 100.55.

Proof. *Derives Theorem 108.19.*

Differentiate the redefinition:

$$\frac{\mathrm{d}a'}{\mathrm{d}\ln\bar{\mu}} = \left(1 + 2c_1 a + 3c_2 a^2 + \cdots\right)\left(-\beta_0 a^2 - \beta_1 a^3 - \beta_2 a^4\right) = -\beta_0 a^2 - (\beta_1 + 2c_1\beta_0)\, a^3 + O\left(a^4\right) .$$

Now express the right-hand side in a'. Inverting the redefinition, $a = a' - c_1 a'^2 + O(a'^3)$, so $a^2 = a'^2 - 2c_1 a'^3 + O(a'^4)$ and $a^3 = a'^3 + O(a'^4)$. Substituting,

$$\frac{\mathrm{d}a'}{\mathrm{d}\ln\bar{\mu}} = -\beta_0 a'^2 + 2c_1\beta_0 a'^3 - (\beta_1 + 2c_1\beta_0)\,a'^3 + O\Big(a'^4\Big) = -\beta_0 a'^2 - \beta_1 a'^3 + O\Big(a'^4\Big)\,.$$

The c_1 terms cancel identically. Carrying the same computation one order further — keeping c_2 in the derivative, inverting the redefinition to $a = a' - c_1 a'^2 + (2c_1^2 - c_2)a'^3 + O(a'^4)$ and collecting the coefficient of a'^4 — leaves

$$\beta_2' = \beta_2 - c_1^2\beta_0 + c_2\beta_0 - c_1\beta_1\,, \tag{108.25}$$

which depends on c_1 and c_2 and so is not invariant. □

Corollary 108.20 (What is physical in a beta function)**.** *The statement "$b_0 = 11 - \frac{2}{3}n_f$" of Theorem 102.35 is a property of* SU(3) *with n_f flavours and of nothing else; so is the two-loop coefficient. From three loops on, a quoted coefficient is a property of the theory* and *of the scheme, and the two cannot be separated. Correspondingly, a quoted* value *of a coupling is meaningless without both its scheme and its scale: $\alpha_s = 0.118$ is a statement about* $\overline{\text{MS}}$ *at $E = m_Z c^2 = (91.1880 \pm 0.0020)\,\text{GeV}$ [2427] and about nothing else, and the same holds for the top mass and for the three different weak mixing angles listed in Remark 104.34, whose values differ by about one per cent — hundreds of times the experimental errors.*

Rests on Theorems 102.35 and 108.19 and Equation (108.24)*.*

Proof. *Derives Corollary 108.20.*

The invariance of β_0 and β_1 is Theorem 108.19, and the non-invariance of β_2 is the last line of its proof. That a *value* of the coupling is scheme dependent follows from the redefinition $a \mapsto a + c_1 a^2 + \cdots$ itself, which changes the number at order a^2, and its scale dependence is Equation (108.24) with a non-vanishing right-hand side. □

Remark 108.21 (Why $\overline{\text{MS}}$ won). Minimal subtraction is not more physical than any other scheme; it is more *convenient*, for three reasons that are worth separating from any claim of naturalness. It is mass-independent, so the beta function is a polynomial in the couplings and multi-loop calculations are tractable. It respects gauge invariance, because dimensional regularization does (Section 108.3.1), so Ward–Takahashi identities hold order by order without extra counterterms. And the modification of [1613] — removing $-\gamma_{\text{E}} + \ln 4\pi$ along with the pole — removes a combination that would otherwise appear at every order in every process, so that residual coefficients are of order one rather than of order ten. That third point is bookkeeping and is the reason the modified scheme, not the minimal one, is the default for every number quoted in Chapter 102.

108.3 Regularization

108.3.1 Dimensional regularization

The machinery of dimensional continuation — the master integral, the measure, the poles — is Lemma 100.28 and Definition 100.30, and is not repeated. What belongs here is the reason the method *generates a scale*, since that is where the whole renormalization group comes from, and it is a purely dimensional argument that can be given in SI once and for all.

Proposition 108.22 (A coupling's dimension away from four)**.** *In d spacetime dimensions — one time and $d-1$ space, with $x^0 = ct$ so that $\mathrm{d}^d x$ carries m^d — a reduced scalar field carries*

$$\left[\hat{\phi}\right] = 1/\mathrm{m}^{(d-2)/2}\,, \tag{108.26}$$

and the coefficient of $\hat{\phi}^4$ carries

$$[c_4] = [\hbar c] \times \mathrm{m}^{d-4}\,. \tag{108.27}$$

The same is true of the squared gauge coupling. At $d = 4$ both are pure multiples of $\hbar c$; at $d = 4 - 2\varepsilon$ they are not, and a length must be supplied to restore a dimensionless coupling.
Rests on Equations (100.2) *and* (102.18).

Proof. *Derives Proposition 108.22.*

The exponent $S/\hbar$ of Chapter 106 is a pure number and $S = c^{-1}\int \mathrm{d}^d x\,\mathcal{L}$ by Equation (100.2), so $[\mathcal{L}] = [\hbar c] \times 1/\mathrm{m}^d$: in four dimensions that is $\mathrm{J\,m} \times 1/\mathrm{m}^4 = \mathrm{J/m}^3$, as it should be. The kinetic term is $\partial_\mu\hat{\phi}\,\partial^\mu\hat{\phi}$ up to a factor of $\hbar c$, carrying $1/\mathrm{m}^2[\hat{\phi}]^2$, and equating exponents gives Equation (108.26). Then $[\hat{\phi}^4] = 1/\mathrm{m}^{2(d-2)}$ and $[c_4] = [\hbar c]1/\mathrm{m}^d\mathrm{m}^{2(d-2)} = [\hbar c]\mathrm{m}^{d-4}$, which is Equation (108.27). For a gauge theory the geometric field $\mathcal{A}_\mu$ of Equation (102.18) must keep $1/\mathrm{m}$ in every dimension, since it appears added to ∂_μ; the Yang–Mills action then forces the squared coupling to carry the same m^{d-4}. □

Corollary 108.23 (Where $\bar{\mu}$ comes from, and why it must be arbitrary)**.** *Writing the length of Equation* (108.27) *as $\hbar/\bar{\mu}$ with $\bar{\mu}$ a momentum,*

$$c_4 = \hat{g}\,\hbar c \left(\frac{\bar{\mu}}{\hbar}\right)^{2\varepsilon}, \qquad d = 4 - 2\varepsilon\,, \tag{108.28}$$

with $\hat{g}$ a pure number; the factor is exactly the $(\bar{\mu}/\hbar)^{4-d}$ that Equation (100.48) *attaches to the loop measure. Nothing selects $\bar{\mu}$. The theory was specified by c_4, which is $\bar{\mu}$-independent; the split into a number $\hat{g}$ and a scale is a choice, and physical quantities cannot know about it. That is Equation* (108.15)*, and therefore Theorem 108.11: the running of couplings is the shadow of an arbitrary choice made when the regulator was installed.*
Rests on Equations (100.48) *and* (108.27).

Proof. *Derives Corollary 108.23.*

Equation (108.28) is Equation (108.27) with the residual length written as $\hbar/\bar{\mu}$ and $d - 4 = -2\varepsilon$, and the independence of c_4 from $\bar{\mu}$ is the statement that c_4 was fixed before the split was made. □

Remark 108.24 (Why this regulator and not another). Dimensional regularization was introduced independently by 't Hooft and Veltman [1463] and by Bollini and Giambiagi [1465], and it is the only regulator in common use that preserves gauge invariance and Lorentz invariance simultaneously. The reason is narrow and worth naming: it never introduces a preferred momentum into the integrand, so the shift $\ell \mapsto \ell + k$ of a loop momentum remains legitimate, and every Ward–Takahashi identity of Chapter 100 — each of which is proved by exactly such a shift — survives order by order. A momentum cutoff does introduce a preferred momentum, the shift is then illegal by a surface term, and the surface term is precisely a photon mass counterterm forbidden by gauge invariance. This is not an aesthetic preference. It is what made 't Hooft's proof that the spontaneously broken gauge theory of Chapter 104 is renormalizable possible at all, and the same point is recorded there in the discussion preceding Remark 104.50.

Remark 108.25 (The one defect, and the standing of d). Two honest qualifications.

The first is technical and specific to chiral theories: there is no definition of γ^5 away from four dimensions that both anticommutes with every γ^μ and keeps $\mathrm{tr}\,(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma)$ non-zero, because the two requirements are contradictory once the number of dimensions is not four. Every consistent prescription therefore breaks one of them and needs compensating finite counterterms; the point is taken up where it bites, in Remark 104.50. That the difficulty is unavoidable rather than a failure of ingenuity is the same fact that makes the

Adler–Bell–Jackiw anomaly of Theorem 106.87 real: a symmetry of the classical Lagrangian that no regulator can preserve is not a symmetry of the quantum theory.

The second is a matter of standing. The physical world of this book has three space dimensions and one of time, and every instantiated result below is at $d = 4$. The continuation in d is a device for defining an integral, exactly as the continuation of a factorial to the gamma function is a device for defining a product; the limit $\varepsilon \to 0$ is taken before any number is quoted. The same caution applies to the ε expansion of Section 108.4.4, where the continuation is in the number of *space* dimensions and the physical case is always the observed three.

108.3.2 Other regulators and the counterterm expansion

Every regulator breaks something. Knowing what each breaks is how one chooses, and it is also how one recognizes a spurious result.

- *Pauli–Villars.* Subtract from each propagator the same propagator with a large mass M, so that the difference falls two powers faster and the loop converges [945]. It preserves Lorentz invariance and abelian gauge invariance — a massive photon regulator does not spoil U(1) — and it fails for non-abelian theories, where a mass term for the gauge field is not gauge invariant and no set of regulator masses restores the symmetry.

- *Momentum cutoff.* Restrict $|\boldsymbol{\ell}| < \Lambda$. This is the regulator with the clearest physical meaning, and it is the one Wilson's construction uses (Section 108.4.2); it breaks both Lorentz invariance, by singling out a frame, and gauge invariance, by forbidding the shift of Remark 108.24.

- *The lattice.* Replace continuous space and Euclidean time by a hypercubic array of spacing a, as in Theorem 106.68. Gauge invariance is preserved *exactly*, at finite a, because the variables are group elements on links rather than algebra elements; rotational and Lorentz invariance are broken to a discrete subgroup and recovered only in the limit $a \to 0$. The lattice is the only regulator in this list that is non-perturbative, which is why it is the one that can address confinement (Section 102.7). Its own obstruction is exact and unavoidable: a lattice Dirac operator that is local, hermitian and chirally symmetric necessarily describes an equal number of left- and right-handed species, so the naive discretization of a single Weyl fermion produces sixteen [1673]. Like the γ^5 problem above, this is the anomaly asserting itself through whatever regulator is chosen.

The classification of theories by their divergences follows from Equation (108.3) alone.

Theorem 108.26 (Power counting in $3+1$)**.** *Consider a theory in four spacetime dimensions whose interaction vertices are local operators of dimensions D_i in the sense of Equation (108.3). A connected amputated diagram with E_B external boson lines, E_F external fermion lines and V_i vertices of type i has superficial degree of divergence*

$$D = 4 - E_B - \frac{3}{2} E_F + \sum_i V_i \left(D_i - 4 \right) , \tag{108.29}$$

meaning that the loop integrand behaves as $\ell^D \, \mathrm{d}^{4L}\ell / \ell^{4L}$ at large loop momentum.
Rests on Equations (100.1) and (108.3).

Proof. *Derives Theorem 108.26.*

Count powers of momentum. Each of the L loop integrations contributes $+4$; each internal boson propagator, going as $1/(\ell^2 - m^2 c^2)$ by Equation (100.1), contributes -2; each

internal fermion propagator, going as $1/(\gamma^\mu \ell_\mu - mc)$, contributes -1; and a vertex carrying $n_\partial^{(i)}$ derivatives contributes $+n_\partial^{(i)}$. Writing I_B, I_F for the numbers of internal lines,

$$D = 4L - 2I_B - I_F + \sum_i V_i n_\partial^{(i)} . \tag{108.30}$$

Three topological identities relate these. The number of loops is $L = I_B + I_F - V + 1$ with $V = \sum_i V_i$, since each internal line carries an integration and each vertex a delta function, one of which is the overall momentum conservation. Counting line ends at the vertices, with b_i and f_i the numbers of boson and fermion fields at a vertex of type i,

$$2I_B + E_B = \sum_i V_i b_i , \qquad 2I_F + E_F = \sum_i V_i f_i . \tag{108.31}$$

Substituting L into Equation (108.30),

$$D = 2I_B + 3I_F - 4V + 4 + \sum_i V_i n_\partial^{(i)} ,$$

and then eliminating I_B and I_F with Equation (108.31),

$$D = 4 - E_B - \frac{3}{2} E_F + \sum_i V_i \left(b_i + \frac{3}{2} f_i + n_\partial^{(i)} - 4 \right) .$$

The bracket is $D_i - 4$ by Equation (108.3), which is Equation (108.29). □

Corollary 108.27 (The three classes)**.** *The sign of $D_i - 4$ in Equation (108.29) sorts every theory into one of three kinds.*

- *If every $D_i < 4$ the theory is* super-renormalizable*: D decreases with the order, so only finitely many diagrams in the whole perturbation series diverge.*
- *If every $D_i = 4$ the theory is* renormalizable*: D is independent of the order, so the divergent amplitudes are those with few enough external legs — a finite list — and finitely many counterterms suffice at every order. Quantum electrodynamics is the case $D_i = 4$ for the single vertex $\bar\psi \gamma^\mu \psi \mathcal{A}_\mu$, and Equation (108.29) then reduces to Equation (100.26).*
- *If some $D_i > 4$ the theory is* non-renormalizable*: D grows without bound with the number of such vertices, so every amplitude diverges at sufficiently high order and no finite set of counterterms suffices. Fermi's theory has $D_i = 6$ and, with four external fermions, $D = 2V - 2$: this is Proposition 101.7 read as a statement about diagrams.*

Rests on Theorem 108.26 and Equation (108.29).

Proof. *Derives Corollary 108.27.*

Each case reads off the sign of the last term of Equation (108.29), which is the only place the order of perturbation theory enters. For the Fermi instance, put $E_B = 0$, $E_F = 4$ and $D_i = 6$ in Equation (108.29): $D = 4 - 6 + 2V = 2V - 2$. □

Remark 108.28 (Non-renormalizable is not the same as useless). It was regarded so for thirty years, and the reversal of that judgement is the single most consequential thing the renormalization group did to particle physics. Corollary 108.27 says that a theory with $D_i > 4$ cannot be extended to arbitrarily high energy with a finite number of parameters. It does not say the theory is wrong, and it does not say it is unpredictive: at energies below the scale $E_\star$ set by Equation (108.5), the operator's contribution is suppressed by $(E/E_\star)^{D-4}$, so a calculation to a stated accuracy needs only finitely many operators. Fermi's theory predicted the muon lifetime to a few per cent for forty years without knowing that the W existed, and that was not luck. The systematic version of the argument is Section 108.6.

Remark 108.29 (Superficial is not actual: what BPHZ adds). Theorem 108.26 controls the *overall* divergence of a diagram; a graph whose D is negative may still contain a divergent subgraph, and at two loops the electron self-energy already contains two vertex subgraphs that overlap (Definition 100.51). That the recursive subtraction terminates, that the forest formula solves it in closed form, and that the counterterms so generated are exactly those of the local Lagrangian, is the theorem of Bogoliubov and Parasiuk [1103], Hepp [1331] and Zimmermann [1411], stated as Theorem 100.52. It is what licenses every statement in this chapter about "the" beta function of a renormalizable theory: without it, a beta function would be an order-by-order accident rather than a property.

108.4 The Wilsonian picture

Everything above treats renormalization as a way of removing infinities and reads the group structure off the residual arbitrariness. Kadanoff [1334] and Wilson [1461, 1462] reversed the logic. The cutoff is kept, and taken seriously as a statement that the description is incomplete above some momentum; the transformation of interest is the one that *lowers* the cutoff by integrating out what lies between the old one and the new; and the object that flows is not a coupling but the whole Hamiltonian.

Notation 108.30 (Units in the statistical sections). The four subsections of Section 108.4 that follow this one treat classical statistical mechanics in three space dimensions, where the Boltzmann weight is e^{-H/k_BT} with H an energy in J, $k_B = 1.380\,649 \times 10^{-23}\,\mathrm{J/K}$ exact by the 2019 SI, and lengths in m. No $\hbar$ appears in a classical partition function and none is written; that is the correct SI statement, not an omission. The reduced temperature $t := (T - T_c)/T_c$ and the dimensionless field h conjugate to the order parameter are pure numbers, as is the block factor $b > 1$. Where the same equations are used for a field theory the correspondence is the Euclidean dictionary of Table 106.1, whose second row is the entry used here: k_BT takes the place of $\hbar$, the continuation to imaginary time itself being Definition 106.12.

108.4.1 Block spins and Kadanoff scaling

Definition 108.31 (The block transformation)**.** Let spins $s_{\boldsymbol{n}}$ sit on a cubic lattice of spacing a in d space dimensions, with $d = 3$ in the physical case, and let the Hamiltonian near the critical point be characterized by the reduced temperature t and the field h. Partition the lattice into cells of side ba containing b^d spins each, and assign to each cell a single block variable — the sign of the cell's total spin, or its normalized sum. Summing over the configurations of the original spins consistent with each block value defines a new Hamiltonian for the block variables, on a lattice of spacing ba [1334].

Theorem 108.32 (Kadanoff scaling and the exponent relations)**.** *Suppose that, sufficiently near the critical point and for b small compared with the correlation length measured in lattice units, the blocked Hamiltonian has the same form as the original with new parameters, and that these depend on the old ones through pure powers*

$$t' = b^{y_t}\, t\,, \qquad h' = b^{y_h}\, h\,, \tag{108.32}$$

for two numbers $y_t, y_h > 0$. Then the singular part of the free energy per site satisfies

$$f_s(t,h) = b^{-d} f_s(b^{y_t} t, b^{y_h} h)\ , \tag{108.33}$$

the correlation length satisfies $\xi(t) = b\,\xi(b^{y_t}t)$, and consequently

$$\nu = \frac{1}{y_t}\,, \quad \alpha = 2 - \frac{d}{y_t}\,, \quad \beta = \frac{d - y_h}{y_t}\,, \quad \gamma = \frac{2y_h - d}{y_t}\,, \quad \delta = \frac{y_h}{d - y_h}\,, \quad \eta = d + 2 - 2y_h\,. \tag{108.34}$$

Every exponent is determined by the two numbers y_t and y_h; the Rushbrooke and Griffiths inequalities of Phenomenon 123.4 hold as equalities; and in addition

$$2 - \alpha = d\nu \tag{108.35}$$

— hyperscaling*, which involves the dimension of space and which the thermodynamic arguments cannot produce.*

Rests on Definition 108.31, Phenomenon 123.4, and Equation (123.6).

Derivation. *Derives Theorem 108.32.*

The block transformation is a partial sum over configurations, so the partition function is unchanged; the total free energy is therefore unchanged, and only the number of sites has altered, from N to N/b^d. Hence $N f_s(t,h) = \left(N/b^d\right) f_s(t',h')$, which with Equation (108.32) is Equation (108.33). The correlation length is a physical distance, so it is the same before and after; measured in units of the new lattice spacing it is b times smaller, which is $\xi(t) = b\,\xi(t')$.

Now set $h = 0$ and choose $b = |t|^{-1/y_t}$, which sends $t' \to \pm 1$ and so removes all t dependence from the arguments. The correlation-length relation becomes $\xi(t) = |t|^{-1/y_t}\,\xi(\pm 1)$, and comparison with the definition $\xi \sim |t|^{-\nu}$ gives $\nu = 1/y_t$. The free-energy relation becomes

$$f_s(t,h) = |t|^{d/y_t}\;\Phi\!\left(\frac{h}{|t|^{y_h/y_t}}\right), \qquad \Phi(z) := f_s(\pm 1, z)\,, \tag{108.36}$$

which is exactly Widom's homogeneity assumption Equation (123.6) [1323] with

$$2 - \alpha = \frac{d}{y_t} = d\nu\,, \qquad \beta\delta = \frac{y_h}{y_t}\,. \tag{108.37}$$

The first of these is Equation (108.35) and the third entry of Equation (108.34). The remaining exponents follow by differentiating Equation (108.36), exactly as in the derivation accompanying Phenomenon 123.4: $m = -\partial f_s/\partial h \sim |t|^{(d-y_h)/y_t}$ gives β; $\chi = -\partial^2 f_s/\partial h^2 \sim |t|^{(d-2y_h)/y_t}$ gives γ; and setting $t = 0$ in Equation (108.33) with $b = h^{-1/y_h}$ gives $m \sim h^{(d-y_h)/y_h}$, that is $\delta = y_h/(d-y_h)$. For η, apply the same argument to the pair correlation function, which carries 2 powers of the field and so scales with $b^{-2(d-y_h)}$ at separations rescaled by b; matching to $G(r) \sim r^{-(d-2+\eta)}$ gives $\eta = d + 2 - 2y_h$.

The two classical relations are now identities. Rushbrooke:

$$\alpha + 2\beta + \gamma = 2 - \frac{d}{y_t} + \frac{2d - 2y_h}{y_t} + \frac{2y_h - d}{y_t} = 2\,.$$

Griffiths: $\beta(\delta - 1) = \frac{d-y_h}{y_t} \cdot \frac{y_h - (d-y_h)}{d-y_h} = \frac{2y_h - d}{y_t} = \gamma$. And Fisher's relation $\gamma = \nu(2-\eta)$ follows from $\nu(2-\eta) = (2 - d - 2 + 2y_h)/y_t = \gamma$. □

Remark 108.33 (What Kadanoff assumed, and what Wilson supplied). Theorem 108.32 derives every exponent relation from Equation (108.32), and derives nothing at all about the two numbers y_t and y_h. Worse, the assumption that the blocked Hamiltonian has *the same form* as the original is false as stated: blocking a nearest-neighbour Ising model generates couplings between next-nearest neighbours, four-spin couplings, and infinitely many others. Kadanoff's argument therefore explains why the exponents satisfy relations and why the same relations hold for a fluid and a magnet, but it cannot compute a single exponent and it rests on a premise known to be wrong.

Wilson's contribution was to accept the proliferation of couplings and to work in the infinite-dimensional space of Hamiltonians, where Equation (108.32) is not an assumption but the linearization of a flow about a fixed point, and where y_t and y_h are its eigenvalues, computable. That is Section 108.4.2 and Section 108.4.3. The three-dimensional critical exponents themselves, and the experimental verdict, are Section 108.4.4; the phenomenology they explain is collected in Section 123.5.

108.4.2 Integrating out momentum shells

Definition 108.34 (The Wilsonian transformation)**.** Let the theory be defined by an effective Hamiltonian $H_\Lambda[\phi]$ for field modes $\tilde{\phi}(\boldsymbol{k})$ with $|\boldsymbol{k}| < \Lambda$, Λ an inverse length. Split $\phi = \phi_< + \phi_>$, where $\phi_<$ contains the modes with $|\boldsymbol{k}| < \Lambda/b$ and $\phi_>$ those in the shell $\Lambda/b < |\boldsymbol{k}| < \Lambda$. Define the new Hamiltonian by

$$\exp\!\left(-\frac{H_{\Lambda/b}\left[\phi_<\right]}{k_B T}\right) := \int \mathcal{D}\phi_> \, \exp\!\left(-\frac{H_\Lambda\left[\phi_< + \phi_>\right]}{k_B T}\right), \tag{108.38}$$

and then restore the original cutoff by rescaling $\boldsymbol{k} \mapsto b\boldsymbol{k}$, equivalently $\boldsymbol{x} \mapsto \boldsymbol{x}/b$, together with a rescaling of the field chosen to keep the coefficient of the gradient term fixed. The composite operation $\mathcal{R}_b$ maps Hamiltonians to Hamiltonians on the same space and satisfies $\mathcal{R}_b \mathcal{R}_{b'} = \mathcal{R}_{bb'}$ [1461, 1462, 1536].

Remark 108.35 (Why it is a semigroup and not a group). Equation (108.38) integrates degrees of freedom *out*. Information is discarded and cannot be recovered: $\mathcal{R}_b$ has no inverse, and the "group" of the name is in fact a semigroup, $b \geq 1$ only. The name is historical, from [1028] where the transformations really did form a group because nothing was being discarded — only relabelled. The distinction is not pedantic: it is the reason the flow has a direction, which is the subject of Section 108.7.2.

The transformation acts on the infinite-dimensional space of local Hamiltonians. Its first, and purely dimensional, effect is already decisive.

Proposition 108.36 (Tree-level scaling of the couplings)**.** *Write the Hamiltonian in d space dimensions as*

$$\frac{H\left[\phi\right]}{k_B T} = \int \mathrm{d}^d x \left[\frac{1}{2}\left(\nabla\phi\right)^2 + \frac{1}{2} r \phi^2 + \frac{u}{4!}\phi^4 + \cdots\right], \tag{108.39}$$

the exponent being a pure number, so that $[\phi] = \mathrm{m}^{(2-d)/2}$, $[r] = 1/\mathrm{m}^2$ and

$$[u] = \mathrm{m}^{d-4}. \tag{108.40}$$

Under the rescaling step of Definition 108.34, and ignoring the shell integration itself, the couplings transform as

$$r \mapsto b^2 r, \qquad u \mapsto b^{4-d} u, \qquad u_6 \mapsto b^{6-2d} u_6, \tag{108.41}$$

u_6 being the coefficient of $\phi^6/6!$.

Rests on Definition 108.34.

Proof. *Derives Proposition 108.36.*

The exponent of a Boltzmann weight is dimensionless, so $\int \mathrm{d}^d x (\nabla\phi)^2$ is a pure number: $\mathrm{m}^d \times 1/\mathrm{m}^2 \times [\phi]^2 = 1$ gives $[\phi] = \mathrm{m}^{(2-d)/2}$. Then $\mathrm{m}^d [r][\phi]^2 = 1$ gives $[r] = 1/\mathrm{m}^2$, and $\mathrm{m}^d [u][\phi]^4 = 1$ gives $[u] = \mathrm{m}^{2d-4-d} = \mathrm{m}^{d-4}$, which is Equation (108.40). A coupling of dimension $1/\mathrm{m}^y$ measured against a length shrunk by b becomes b^y times itself, which gives Equation (108.41) with $y_r = 2$, $y_u = 4 - d$, $y_6 = 6 - 2d$. □

Corollary 108.37 (The upper critical dimension is four)**.** *u has SI dimension m^{d-4}, so it is dimensionless exactly at $d = 4$ and grows under coarse graining for $d < 4$. In the observed three space dimensions $[u] = 1/\mathrm{m}$, the quartic coupling is relevant, and mean-field theory — which is Equation (108.39) with the fluctuations dropped — must fail. For $d > 4$ it is irrelevant and mean-field exponents are exact. The sextic coupling has $y_6 = 6 - 2d$, which is negative for every $d > 3$ and* vanishes *at $d = 3$: in the observed three dimensions the sextic term is marginal at the Gaussian fixed point rather than relevant, so it opens no new relevant direction, and Equation (108.39) may be truncated at fourth order.*

Rests on Equations (108.39) to (108.41).

Proof. *Derives Corollary 108.37.*

Set $d = 4$ in Equation (108.40) to get m^0, and $d = 3$ to get $1/\mathrm{m}$; the eigenvalues are Equation (108.41), and $4 - d > 0$ for $d < 4$ while $6 - 2d \le 0$ for $d \ge 3$, with equality exactly at $d = 3$. That $d = 3$ is the borderline dimension for ϕ^6 in precisely the way $d = 4$ is for ϕ^4 is Equation (108.50) read at $n = 3$; the truncation is justified because a marginal coupling generates no new relevant scaling field, not because y_6 is negative there. Mean-field theory is Equation (108.39) evaluated at its saddle point, with the fluctuations that the shell integration would supply dropped; that same approximation, in its statistical-mechanics setting, belongs to Section 123.4. □

Remark 108.38 (This is the Ginzburg criterion, seen from above). The Ginzburg criterion [1181] compares the fluctuation of the order parameter within a correlation volume to its mean, and yields a computable window of reduced temperature inside which mean-field theory fails for $d < 4$; that estimate belongs to Section 123.4.4. Corollary 108.37 reaches the same conclusion from the SI dimension of one coupling and no estimate at all. The two are the same statement: a coupling with a positive length dimension is one whose dimensionless strength grows as the probe scale grows, and the correlation length near T_c is the probe scale that diverges.

The shell integration itself supplies the corrections to Equation (108.41), and one loop is enough to see the whole structure.

Theorem 108.39 (The one-loop flow of the quartic coupling)**.** *For the $O(N)$-symmetric version of Equation (108.39), with ϕ an N-component field and the quartic term $(u/4!)(\phi\cdot\phi)^2$, integrating an infinitesimal shell $b = 1 + \delta l$ and rescaling gives, near four dimensions with $\varepsilon = 4 - d$,*

$$\frac{\mathrm{d}u}{\mathrm{d}l} = \varepsilon u - \frac{N+8}{48\pi^2}\,u^2 + O\!\left(u^3\right) , \tag{108.42}$$

$$\frac{\mathrm{d}r}{\mathrm{d}l} = 2r + \frac{N+2}{48\pi^2}\,u\Lambda^2 - \frac{N+2}{48\pi^2}\,ur + O\!\left(u^2\right) , \tag{108.43}$$

where $l = \ln b$ increases towards the infrared [1489].

Rests on Equations (108.38), (108.39) and (108.41).

Derivation. *Derives Theorem 108.39.*

Write $\phi = \phi_< + \phi_>$ in Equation (108.38) and expand the quartic term. The Gaussian average over the shell modes has propagator $G(\boldsymbol{k}) = 1/(k^2 + r)$, supported only on $\Lambda/b < k < \Lambda$, and the cumulant expansion gives

$$\frac{H_{\Lambda/b}}{k_B T} = \frac{H_\Lambda\left[\phi_<\right]}{k_B T} + \langle \Delta H \rangle_> - \frac{1}{2}\left(\left\langle \Delta H^2 \right\rangle_> - \langle \Delta H \rangle_>^2\right) + \cdots , \tag{108.44}$$

ΔH collecting the terms containing $\phi_>$.

First order. The piece of $(\phi\cdot\phi)^2$ with two $\phi_<$ and two $\phi_>$ is, after averaging and using $\langle \phi_{>a}\phi_{>b}\rangle = \delta_{ab}\int_{\text{shell}} \mathrm{d}^d k\, G(k)/(2\pi)^d$, proportional to $\phi_<\cdot\phi_<$ and so renormalizes r. The combinatorial factor for $O(N)$ is $(N+2)/3$ relative to $u/4!$ times the 6 ways of choosing which two of four fields are hard, giving

$$\delta r = \frac{N+2}{6}\,u\int_{\text{shell}} \frac{\mathrm{d}^d k}{(2\pi)^d}\,\frac{1}{k^2 + r} . \tag{108.45}$$

For $N = 1$ the factor is $1/2$, which is the elementary count: of the $\binom{4}{2} = 6$ pairings, all contribute, and $6/4! = 1/4$, doubled by matching to $\frac{1}{2}\delta r\phi^2$.

Second order. The connected part of $\langle \Delta H^2 \rangle$ with four $\phi_<$ and two internal shell propagators renormalizes u. The same combinatorics with the $O(N)$ index contractions

gives the factor $(N+8)/6$, and the sign is negative because the term enters Equation (108.44) with $-1/2$:

$$\delta u = -\frac{N+8}{6}\,u^2 \int_{\text{shell}} \frac{\mathrm{d}^d k}{(2\pi)^d}\,\frac{1}{(k^2+r)^2}\,. \tag{108.46}$$

The shell integrals. At $d=4$, with $S_d = 2\pi^{d/2}/\Gamma(d/2)$ so that $S_4 = 2\pi^2$,

$$\int_{\text{shell}} \frac{\mathrm{d}^4 k}{(2\pi)^4} f(k) = \frac{2\pi^2}{16\pi^4}\int_{\Lambda(1-\delta l)}^{\Lambda} k^3 f(k)\,\mathrm{d}k = \frac{\Lambda^4 f(\Lambda)}{8\pi^2}\,\delta l\,, \tag{108.47}$$

for an infinitesimal shell. Hence $\int_{\text{shell}} G = \Lambda^2 \delta l/8\pi^2$ at $r=0$, with the correction $-r/\Lambda^2$ from expanding $1/(\Lambda^2+r)$, and $\int_{\text{shell}} G^2 = \delta l/8\pi^2$.

Assembling. Adding Equations (108.45) and (108.46) to the tree-level rescalings Equation (108.41), with $b^2 = 1+2\delta l$ and $b^\varepsilon = 1+\varepsilon\delta l$,

$$\frac{\mathrm{d}u}{\mathrm{d}l} = \varepsilon u - \frac{N+8}{6}\cdot\frac{u^2}{8\pi^2}\,, \qquad \frac{\mathrm{d}r}{\mathrm{d}l} = 2r + \frac{N+2}{6}\cdot\frac{u\,(\Lambda^2 - r)}{8\pi^2}\,,$$

which are Equations (108.42) and (108.43) since $6\times 8\pi^2 = 48\pi^2$. What is carried out in full above is the single-component count; the $O(N)$ index contractions giving $(N+2)/6$ in Equation (108.45) and $(N+8)/6$ in Equation (108.46) are quoted from [1489], and at $N=1$ they return $\frac{1}{2}$ and $\frac{3}{2}$, the first of which is the elementary count carried out above. □

Derivation pending #176

The $O(N)$ combinatorial factors of the one-loop shell integration: the explicit index contractions of $(\phi\cdot\phi)^2$ that produce $(N+2)/6$ in the mass renormalization and $(N+8)/6$ in the vertex renormalization, for general N. The $N=1$ case is counted in the derivation above and both general factors reduce to it; the general count belongs in Appendix A.

Remark 108.40 (Sign conventions, and translating to the scale). $l = \ln b$ increases towards *longer* distances, so $\mathrm{d}/\mathrm{d}l = -\mathrm{d}/\mathrm{d}\ln\bar{\mu}$. Translating Equation (108.42) accordingly, and using the dimensionless $\hat{g}$ of Equation (106.34) in place of u, the field-theoretic beta function of a single real scalar ($N=1$, $\varepsilon=0$) is

$$\frac{\mathrm{d}\hat{g}}{\mathrm{d}\ln\bar{\mu}} = \frac{3\hat{g}^2}{16\pi^2} + O\big(\hat{g}^3\big)\,, \tag{108.48}$$

positive, so a scalar self-coupling grows with energy exactly as the electromagnetic coupling does. That is the sign that will produce Section 108.5.3. A reader comparing with the sources should note that many of them write $\mathrm{d}/\mathrm{d}l$ and many others $\mathrm{d}/\mathrm{d}\ln\bar{\mu}$, with no warning, so an apparent sign disagreement between two texts is usually this.

Remark 108.41 (Exact formulations, and the method as a computational tool). Equation (108.38) can be written as an exact differential equation for the cutoff dependence of the effective Hamiltonian rather than as a perturbative expansion. Polchinski's form [1743] follows the flow of the Wilsonian action with a smooth cutoff and is the version usually used to *prove* things, including renormalizability; Wetterich's form [1876] flows the effective action of Definition 106.41 instead, with an added infrared regulator, and is the version usually used to *compute* in strongly coupled regimes, since truncating it does not require a small coupling. Both are exact statements about a functional and both require truncation to be evaluated; neither is free of that approximation, and the systematic error of a truncation is the honest weak point of the method.

That the Wilsonian construction computes rather than merely interprets was established by Wilson's numerical renormalization group, which solved the Kondo problem — a magnetic impurity in a metal, whose perturbation series diverges logarithmically at low temperature — by discretizing the conduction band logarithmically and diagonalizing shell by shell [1567]. It produced the impurity susceptibility and the Wilson ratio to a few per cent, in a regime where no expansion in the coupling exists at all.

108.4.3 Fixed points, relevant and irrelevant operators

Definition 108.42 (Fixed point and linearized flow)**.** Let $\{K_\alpha\}$ be coordinates on the space of Hamiltonians and $\mathrm{d}K_\alpha/\mathrm{d}l = \mathcal{B}_\alpha(K)$ the flow generated by Definition 108.34. A *fixed point* $K^\star$ is a zero of every $\mathcal{B}_\alpha$. Writing $K = K^\star + \delta K$ and linearizing,

$$\frac{\mathrm{d}\delta K_\alpha}{\mathrm{d}l} = \sum_\beta M_{\alpha\beta}\,\delta K_\beta\,, \qquad M_{\alpha\beta} := \left.\frac{\partial \mathcal{B}_\alpha}{\partial K_\beta}\right|_{K^\star}. \tag{108.49}$$

Let y_i be the eigenvalues of M and g_i the corresponding eigen-coordinates, the *scaling fields*. Then $g_i(l) = \mathrm{e}^{y_i l} g_i(0)$, and g_i is called *relevant* if $y_i > 0$, *irrelevant* if $y_i < 0$ and *marginal* if $y_i = 0$.

Theorem 108.43 (Criticality needs one tuning per relevant field)**.** *A Hamiltonian flows into the fixed point under repeated coarse graining if and only if every relevant scaling field vanishes. Hence the set of critical Hamiltonians is a surface of codimension n_r, n_r being the number of positive eigenvalues, and reaching criticality requires tuning exactly n_r parameters.*

Rests on Definition 108.42 and Equation (108.49)*.*

Proof. *Derives Theorem 108.43.*

By Equation (108.49) an irrelevant field decays as $\mathrm{e}^{-|y|l}$ and is forgotten; a relevant field grows as e^{yl} and eventually carries the system away from the fixed point, however small it was to begin with. The initial Hamiltonian therefore approaches $K^\star$ if and only if its relevant components vanish, which is n_r conditions on the parameters. The critical surface is the stable manifold of $K^\star$. □

Corollary 108.44 (Universality)**.** *Two microscopic Hamiltonians on the same critical surface flow to the same fixed point and therefore have the same singular behaviour, with exponents given by Equation* (108.34) *in terms of the eigenvalues of M at that fixed point. The exponents are properties of the fixed point; the microscopic Hamiltonians differ only in irrelevant directions, which decay.*

Rests on Theorems 108.32 and 108.43 and Equation (108.34)*.*

Proof. *Derives Corollary 108.44.*

Immediate from Theorem 108.43 and from Theorem 108.32, whose assumed relations Equation (108.32) are now *derived*: t and h are the two relevant scaling fields, and y_t, y_h their eigenvalues, since a scale change by b multiplies g_i by b^{y_i}. □

Example 108.45 (The Gaussian fixed point in three dimensions)**.** The free theory $r = u = 0$ is a fixed point of Equations (108.42) and (108.43). Its eigenvalues are read off from Equation (108.41): $y_r = 2$, $y_u = 4 - d$, $y_6 = 6 - 2d$, and in general the operator ϕ^{2n} carries

$$y_{2n} = d - n\,(d-2)\,. \tag{108.50}$$

In the observed $d = 3$ this gives $y_2 = +2$ (relevant, the temperature), $y_4 = +1$ (relevant, the quartic coupling), $y_6 = 0$ (marginal), $y_8 = -1$, and everything beyond irrelevant. The Gaussian fixed point therefore has two relevant directions in $d = 3$ and only one for $d > 4$, which is Corollary 108.37 again: above four dimensions u is irrelevant, the Gaussian fixed

point is the critical one, and the mean-field exponents $\nu = 1/y_2 = 1/2$, $\eta = 0$ and $\alpha = 0$ are exact. The last of these is *not* $2-d\nu = 2-d/2$, which is what hyperscaling Equation (108.35) would give: hyperscaling is exactly what fails above the upper critical dimension, for the reason recorded in Remark 108.51, and applying it at $d = 5$ would return $\alpha = -1/2$ for a theory whose specific heat has a finite jump, that is $\alpha = 0$. For $d < 4$ the second relevant direction means the Gaussian fixed point is unstable and cannot govern criticality: something else must, and Section 108.4.4 finds it.

Derivation of the Gaussian eigenvalues. *Derives Example 108.45.*

By Proposition 108.36, $[\phi] = \mathrm{m}^{(2-d)/2}$, so the coefficient of ϕ^{2n} in Equation (108.39) carries $1/\mathrm{m}^d \times \mathrm{m}^{n(d-2)}$, and a coupling of dimension $1/\mathrm{m}^y$ has eigenvalue y. Hence $y_{2n} = d - n(d-2)$. □

Remark 108.46 (Why an exponent is an eigenvalue, and what that explains). Three facts that had no explanation before Wilson follow at once, and Fisher's review sets them out in the order in which they were understood [1526]. That only two exponents are independent is Theorem 108.43 with $n_r = 2$. That a fluid and a uniaxial magnet share exponents is Corollary 108.44, the two Hamiltonians lying on the same critical surface because they have the same space dimension and the same order-parameter symmetry and differ only in irrelevant couplings. And that the exponents are not simple rational numbers is because an eigenvalue of a linearized flow on an infinite-dimensional space has no reason to be: the mean-field values $\frac{1}{2}$, 1, 3 are rational precisely because they come from naive dimensional counting at a Gaussian fixed point, and the true values do not.

108.4.4 Universality

Theorem 108.47 (The Wilson–Fisher fixed point)**.** *For $0 < \varepsilon = 4 - d$ small, Equation (108.42) has, besides the Gaussian fixed point $u = 0$, a second zero at*

$$u^\star = \frac{48\pi^2}{N+8}\,\varepsilon + O\!\left(\varepsilon^2\right), \tag{108.51}$$

which is stable in the u direction. Linearizing Equation (108.43) about it gives the thermal eigenvalue

$$y_t = 2 - \frac{N+2}{N+8}\,\varepsilon + O\!\left(\varepsilon^2\right), \qquad \nu = \frac{1}{y_t} = \frac{1}{2} + \frac{N+2}{4\,(N+8)}\,\varepsilon + O\!\left(\varepsilon^2\right), \tag{108.52}$$

and $\eta = O(\varepsilon^2)$, there being no field renormalization at one loop [1489].

Rests on Equations (108.42) and (108.43).

Proof. *Derives Theorem 108.47.*

Setting $\mathrm{d}u/\mathrm{d}l = 0$ in Equation (108.42) gives $u = 0$ or $u = 48\pi^2\varepsilon/(N+8)$, which is Equation (108.51). Its stability follows from $\mathrm{d}(\mathrm{d}u/\mathrm{d}l)/\mathrm{d}u = \varepsilon - 2(N+8)u^\star/48\pi^2 = -\varepsilon < 0$: the quartic direction, marginal at $d = 4$ and relevant at the Gaussian fixed point for $d < 4$, has become irrelevant here with eigenvalue $-\varepsilon$.

For the thermal eigenvalue, the term in Equation (108.43) proportional to Λ^2 is a constant shift of r, which relocates the critical temperature and is not universal; absorbing it into r and linearizing the remainder,

$$\frac{\mathrm{d}\delta r}{\mathrm{d}l} = \left(2 - \frac{N+2}{48\pi^2}u^\star\right)\delta r = \left(2 - \frac{N+2}{48\pi^2}\cdot\frac{48\pi^2\varepsilon}{N+8}\right)\delta r\,,$$

which is Equation (108.52). Expanding $1/(2-x) = \frac{1}{2}(1 + x/2) + O(x^2)$ gives the stated ν.

That η vanishes at this order is because γ_ϕ requires a correction to the coefficient of $(\nabla\phi)^2$, and the one-loop diagrams computed above carry no external momentum dependence: the tadpole Equation (108.45) is momentum independent and the vertex correction Equation (108.46) contributes to u, not to the gradient term. The first contribution to η is the two-loop sunset graph, of order $u^2 \sim \varepsilon^2$. □

Remark 108.48 (The ε expansion is a device). Theorem 108.47 is an expansion in a parameter that Nature does not supply. Its purpose is to give a controlled approximation scheme in which the fixed point is close to the Gaussian one and therefore calculable; the physical case is $\varepsilon = 1$, where the expansion parameter is not small and the series is in fact asymptotic rather than convergent. Setting $\varepsilon = 1$ in Equation (108.52) gives, for the Ising class $N = 1$, $y_t = 5/3$ and $\nu = 0.600$ against the true 0.6300, and for the XY class $N = 2$, $y_t = 8/5$ and $\nu = 0.625$ against the true 0.6717: the leading term captures roughly two thirds of the departure from the mean-field $\frac{1}{2}$ and no more. This is honest arithmetic about a one-loop truncation and not a defect of the framework; resummation of the series to high order, or methods that do not use the continuation at all, do far better, as Table 108.1 shows.

Table 108.1: Critical exponents of the three-dimensional Ising universality class ($N = 1$, $d = 3$), by three routes. The first column is Equation (108.52) at $\varepsilon = 1$; the second is the resummed field-theoretic calculation directly in three dimensions [1600]; the third is the conformal-bootstrap determination [2239], from which the remaining exponents are computed here through Equation (108.34) with $y_t = 1/\nu$ and $y_h = (d + 2 - \eta)/2$. The last row is a check, not a result: Rushbrooke must give exactly 2. In the first and third columns γ is $\nu(2 - \eta)$; the middle column is instead reproduced entry by entry as published, so its γ is [1600]'s own quoted value and not the 1.2402 that $\nu(2 - \eta)$ would give from the ν and η of the same column. The difference sits inside the quoted uncertainties, and it is a reminder that a resummed calculation determines each exponent separately rather than deriving one from another.

	one loop, $\varepsilon = 1$	resummed	bootstrap
ν	0.600	0.6300(15)	0.629971(4)
η	0	0.0315(35)	0.0362978(20)
$\alpha = 2 - 3\nu$	0.200	0.110(5)	0.110087
β	—	0.3250(15)	0.326419
γ	1.200	1.2410(20)	1.237075
δ	—	—	4.78984
$\alpha + 2\beta + \gamma$	—	—	2.000000

Phenomenon 108.49 (A critical exponent, and a disagreement)**.** The specific heat of liquid helium-4 at the superfluid transition can be followed to within nanokelvin of T_c only in free fall, because on the ground the hydrostatic pressure head across a sample of usable height smears the transition temperature over more than the resolution sought. Measured aboard an orbiting laboratory over more than five decades in reduced temperature, the singular specific heat gives

$$\alpha = -0.0127 \pm 0.0003 \tag{108.53}$$

[2054]: small, and *negative*, so that the specific heat approaches a finite cusp rather than diverging. Through hyperscaling Equation (108.35) in $d = 3$ this is

$$\nu = \frac{2 - \alpha}{3} = 0.670900 \pm 0.000100\,. \tag{108.54}$$

The best theoretical determination of the same exponent for the three-dimensional XY universality class is $\nu = 0.67155 \pm 0.00027$ [2035], that is $\alpha = -0.01465 \pm 0.00081$. The two do not agree: the difference is 0.00195 against a combined uncertainty of 0.00086, about two and a quarter standard deviations, and later and more precise theoretical determinations have moved away from the measurement rather than towards it. This is the most precisely measured critical exponent in physics, it is a quantitative test of a calculated number, and the test is currently not passed. This is the same measurement recorded as Phenomenon 123.6, not a second one; the analysis of it — the universality class, the hyperscaling step and the disagreement — is carried out here.

Rests on Corollary 108.44, Equation (108.35), and Phenomenon 123.6.

Derivation of what is being compared. *Derives Phenomenon 108.49.*

Helium-4's order parameter is a complex condensate wavefunction — the object whose theory belongs to Chapter 130 — which has two real components and a U(1) symmetry, so by Corollary 108.44 the transition belongs to the $N = 2$ class in $d = 3$: the same class as a planar magnet, and a different one from the Ising class of Table 108.1. The theoretical input is therefore ν for $N = 2$, and the measured input is α; the two are compared through Equation (108.35), $\alpha = 2 - 3\nu$, which is a consequence of Theorem 108.32 and holds below the upper critical dimension. Propagating the uncertainty, $\delta\alpha = 3\delta\nu = 0.00081$, and the discrepancy quoted follows by subtraction. Note what is *not* in doubt: the sign of α, the smallness of its magnitude, and the fact that both theory and experiment place it within two per cent of zero while mean-field theory predicts $\alpha = 0$ exactly and the Ising class gives $+0.110$. The framework is confirmed; the fourth decimal place is not. □

Remark 108.50 (Where the discrepancy might live). Three candidates are on the table and none has been eliminated. The measurement may carry an unmodelled systematic, most plausibly from the finite size of the sample cell, which cuts off the divergence of ξ at a few centimetres and enters the fit as a correction whose form must be assumed. The theory may be misestimating its own truncation error, the resummations involved being asymptotic. Or the comparison may be incomplete: corrections to scaling enter the measured specific heat with an exponent $\omega \approx 0.79$ and an amplitude that is not universal, and the two analyses do not treat them identically. The honest summary is that a two-standard-deviation disagreement between the sharpest measurement and the sharpest calculation in critical phenomena has stood for over twenty years without being resolved or explained, and that it is recorded here rather than smoothed over.

Remark 108.51 (What universality does and does not claim). It claims that the *exponents* and certain amplitude *ratios* depend only on the space dimension, the number of order-parameter components and the range of the interaction. It does not claim that T_c is universal — that is Equation (108.43)'s non-universal Λ^2 term, which depends on every microscopic detail — nor that amplitudes themselves are. And it fails where its premises do: for long-range interactions, for which the gradient term of Equation (108.39) is not the leading one; at a transition governed by a different fixed point, such as the Berezinskii–Kosterlitz–Thouless transition, which belongs to Section 123.6.2, where the singularity is essential rather than a power and the exponent language does not apply at all; and above the upper critical dimension, where hyperscaling Equation (108.35) breaks because the dangerous irrelevant variable u cannot be set to zero in the free energy.

108.5 Running couplings in the Standard Model

The preceding sections built an apparatus. This one is why the apparatus is believed: the flow it predicts is measured, over more than two decades of energy, in half a dozen unrelated processes.

108.5.1 Asymptotic freedom

The derivation of the negative beta function of $\mathrm{SU}(3)_c$ is Theorem 102.35, carried out in Chapter 102 by computing the magnetic permeability of the gauge vacuum, and it is not repeated here. What belongs here is what the result means for the flow, why the case is special, and what it generates.

Proposition 108.52 (Asymptotic freedom as a property of the flow)**.** *Let $\beta(a) = -\beta_0 a^2 + O(a^3)$ as in Equation (108.24). If $\beta_0 > 0$ then Equation (108.10) gives*

$$\frac{1}{a(\bar{\mu})} = \frac{1}{a(\kappa)} + \beta_0 \ln \frac{\bar{\mu}}{\kappa}\,, \tag{108.55}$$

so that $a(\bar{\mu}) \to 0$ as $\bar{\mu} \to \infty$, logarithmically, and the ultraviolet limit of the theory is the free theory: the Gaussian fixed point is reached from above, in infinite renormalization-group time. If $\beta_0 < 0$ the same formula sends a to infinity at a finite scale

$$\bar{\mu}_{\mathrm{L}} = \kappa \exp\!\left[\frac{1}{|\beta_0|\, a(\kappa)}\right], \tag{108.56}$$

and the perturbative description destroys itself there.

Rests on Equation (108.24) and Corollary 108.8.

Proof. *Derives Proposition 108.52.*

Separate variables in $\mathrm{d}a/\mathrm{d}\ln\bar{\mu} = -\beta_0 a^2$: $-\mathrm{d}(1/a) = -\beta_0 \mathrm{d}\ln\bar{\mu}$, which integrates to Equation (108.55). For $\beta_0 > 0$ the right-hand side grows without bound, so $a \to 0$; for $\beta_0 < 0$ it reaches zero at the scale Equation (108.56). The logarithmic approach is what makes the ultraviolet limit *asymptotically* free rather than free: at any finite energy the coupling is non-zero, and the corrections it produces fall only as $1/\ln$. □

Corollary 108.53 (The condition on the number of flavours)**.** *For $\mathrm{SU}(3)_c$, $\beta_0 = b_0/2\pi$ with $b_0 = 11 - \frac{2}{3}n_f$ by Equation (102.42), so asymptotic freedom requires $n_f < 33/2$, that is $n_f \le 16$. Nature supplies six. The eleven is $12 - 1$, the excess of the gluon's paramagnetic moment over its diamagnetic orbital response (Remark 102.36); the $-\frac{2}{3}n_f$ is the ordinary screening of a fermion loop, the same sign as in Proposition 100.63 and reproduced from the same master formula by Corollary 102.34.*

Rests on Proposition 108.52 and Equations (102.42) and (108.24).

Proof. *Derives Corollary 108.53.*

Comparing $\mathrm{d}\alpha_s/\mathrm{d}\ln E = -(b_0/2\pi)\alpha_s^2$ of Equation (102.42) with $-\beta_0\alpha_s^2$ of Equation (108.24) gives $\beta_0 = b_0/2\pi$, so $\beta_0 > 0$ is $b_0 > 0$, that is $11 > \frac{2}{3}n_f$ and $n_f < 33/2$. Since n_f is an integer this is $n_f \le 16$. □

Remark 108.54 (Non-abelian gauge theory is the only case). Among renormalizable theories in the observed $3+1$ dimensions — that is, among theories whose vertices all have $D_i = 4$ in the sense of Corollary 108.27 — a negative one-loop beta function requires a non-abelian gauge field. Scalar self-couplings contribute with the sign of Equation (108.48), Yukawa couplings and abelian gauge couplings with the sign of Equation (108.22), and only the gluon self-interaction contributes the other way, by Lemma 102.31. Adding matter can only reduce b_0, never increase it, which is Corollary 108.53. The theorem to this effect was proved by Coleman and Gross in the same year as [1501, 1511]; the treatise's bibliography does not carry that paper, and the statement is recorded here without a citation rather than attached to a source that does not contain it.

Remark 108.55 (Dimensional transmutation, and what it costs). Equation (108.55) can be read backwards. The pair $(a(\kappa), \kappa)$ — a pure number and an energy — can be traded for the single energy at which the right-hand side would vanish, which is Equation (102.45):

$$\Lambda_{\mathrm{QCD}} = E_0 \exp\!\left[-\frac{2\pi}{b_0 \alpha_s(E_0)}\right] ,$$

and Λ_{QCD} does not depend on which E_0 was used, as Definition 102.38 verifies by differentiation. A theory whose Lagrangian contains no dimensionful parameter at all has acquired one — Phenomenon 102.39 — and it is of the observed size, a few hundred MeV, corresponding to a hadronic length of about $1 \times 10^{-15}\,\mathrm{m}$.

What this costs is worth stating plainly, because it is easy to present dimensional transmutation as though a scale had been created from nothing. It has not. The number of free parameters is unchanged: one dimensionless coupling quoted at one energy has been re-expressed as one energy. What is genuinely explained is why that energy is far below any scale appearing in the Lagrangian, since the exponential in Equation (102.45) converts a modest coupling into an enormous ratio, and hence why 99 % of the proton's mass has no counterpart among the quark masses (Remark 102.40).

108.5.2 The measured running

Phenomenon 108.56 (The strong coupling runs as predicted)**.** The dimensionless coupling α_s of Equation (102.19), extracted independently from hadronic τ decays at $E = 1.777\,\mathrm{GeV}$, from the scaling violations of deep inelastic structure functions, from event shapes and jet rates in electron–positron annihilation, from heavy-quarkonium level spacings, from short-distance lattice quantities, and from the hadronic width of the Z at $E = (91.1880 \pm 0.0020)\,\mathrm{GeV}$, falls with energy along one curve whose shape contains no adjustable parameter [2142, 2427]. The curve is Equation (108.55) with β_0 fixed by Equation (102.42) from the gauge group and the particle content alone. The world average is

$$\alpha_s\!\left(m_Z c^2\right) = 0.1180 \pm 0.0009 \tag{108.57}$$

[2427], the 2009 compilation having given 0.1184 ± 0.0007 [2142]. The two determinations whose scales are quoted above differ by a factor of 51; the full set compiled in [2427] spans more than two decades in energy, which is the span Phenomenon 102.41 also reports. The agreement of all of them, after evolution by a formula with no free coefficient, is the measurement.

Rests on Equations (102.19) *and* (102.42) *and Proposition 108.52.*

Derivation of the predicted curve. *Derives Phenomenon 108.56.*

Integrate Equation (108.24) keeping two terms,

$$\frac{\mathrm{d}\alpha_s}{\mathrm{d}\ln E} = -\frac{b_0}{2\pi}\alpha_s^2 - \frac{b_1}{8\pi^2}\alpha_s^3 + O\!\left(\alpha_s^4\right) , \qquad b_0 = 11 - \frac{2}{3}n_f , \quad b_1 = 102 - \frac{38}{3}n_f , \tag{108.58}$$

the first coefficient being Equation (102.42) and the second the two-loop coefficient, quoted in the Particle Data Group's review of quantum chromodynamics [2427]. Both are scheme independent by Theorem 108.19, which is what makes the comparison below a test rather than a fit; the third coefficient is not, and is not needed at this accuracy.

Both b_0 and b_1 depend on the number of quark flavours light enough to circulate in a loop at the scale considered. The theory is therefore integrated piecewise: between thresholds n_f is constant, and at $E = m_Q c^2$ the coupling is matched continuously as the flavour is added or removed, the discontinuity in the matching being of order α_s^2 and negligible here. The slope of the reciprocal coupling in the one-loop approximation is $\mathrm{d}\,(1/\alpha_s)\,/\mathrm{d}\ln E = b_0/2\pi$, which takes the values 1.4324, 1.3263, 1.2202 and 1.1141 for $n_f = 3, 4, 5, 6$: the curve of

$1/\alpha_s$ against $\ln E$ is a polygon whose slope decreases by about 0.106 at each threshold, and the kinks are a prediction as sharp as the slopes.

Starting from Equation (108.57) at $E = m_Z c^2 = 91.1880\,\text{GeV}$ with $n_f = 5$, and integrating Equation (108.58) numerically with thresholds at the quark masses of Table 102.1, gives Table 108.2. Of the two coefficients, b_0 is derived in Chapter 102; b_1 is quoted, and every entry of the two-loop column depends on it. □

Derivation pending #177

The two-loop coefficient $b_1 = 102 - \frac{38}{3}n_f$ of the SU(3) beta function: the two-loop vacuum-polarization, vertex and self-energy graphs, their renormalization, and the cancellation that leaves a scheme-independent result. It is quoted from the Particle Data Group here and it fixes the whole two-loop column of the table above, so it is a number the book uses and does not yet derive; the derivation belongs in Appendix A.

Table 108.2: The strong coupling evolved from Equation (108.57) by Equation (108.58), with n_f changing at the quark masses of Table 102.1. The one-loop column reproduces Table 102.2, whose caption records honestly that the truncation drifts about ten per cent low at the τ mass. The second column shows where that drift goes: adding the single scheme-independent coefficient b_1 moves the prediction at $E = m_\tau c^2$ from 0.279 to 0.313, against a measured value of about 0.31 [2427]. The last column is the distance $\hbar c/E$ that energy resolves.

E	n_f	one loop	two loop	$\hbar c/E$
1.777 GeV $(m_\tau c^2)$	4	0.279	0.313	1.11×10^{-16} m
4.183 GeV $(m_b c^2)$	5	0.212	0.224	4.72×10^{-17} m
10 GeV	5	0.173	0.178	1.97×10^{-17} m
91.188 GeV $(m_Z c^2)$	5	0.1180	0.1180	2.16×10^{-18} m
1 TeV	6	0.089	0.088	1.97×10^{-19} m

Remark 108.57 (What the two-loop improvement demonstrates). The one-loop curve of Table 102.2 misses the τ-mass point by about ten per cent, and a reader is entitled to ask whether that is a failure of the theory or of the truncation. Table 108.2 answers it without any new input: the next term in a series whose coefficient is fixed by Equation (108.58) and is not adjustable moves the prediction by almost exactly the discrepancy, in the right direction, at the scale where the expansion parameter is largest and nowhere else. The correction at $m_Z c^2$ is nil by construction and at 1 TeV is one part in a hundred. That pattern — a truncation error that grows as the coupling grows and vanishes where it is small — is what an asymptotic series behaving properly looks like, and it is a stronger statement than agreement at any single point.

Remark 108.58 (The electromagnetic coupling, for contrast). The same apparatus applied to Equation (108.22) runs α the other way: from $\alpha^{-1} = 137.035999177(21)$ at zero momentum transfer [2431] to $\alpha^{-1} \approx 128.94$ at $E = m_Z c^2$ [2427], a rise of about six per cent in the coupling, of which roughly half is leptonic and computable from Equation (100.83) and roughly half hadronic and extracted from measured annihilation cross-sections through a dispersion relation. The derivation is Phenomenon 100.62. Two couplings of the same theory therefore run in opposite directions, by the same mechanism and with the same machinery, and both runs are measured. If the renormalization group were bookkeeping, that could not happen. The measurement at zero momentum transfer belongs to Chapter 112; the scaling

violations that measure α_s by a slope rather than a rate belong to Section 102.5.2 and to the experiment chapter Chapter 116.

108.5.3 Landau poles and triviality

A positive β_0 in Equation (108.24) is a promise about the ultraviolet; a negative one is a warning. This subsection states what the warning does and does not establish, for the two Standard Model sectors that carry it.

Proposition 108.59 (The hypercharge coupling and its pole)**.** *For the hypercharge group* $\mathrm{U}(1)_Y$ *with the Standard Model content of Table 104.1 — three generations of chiral fermions and one complex scalar doublet — the one-loop beta function of* $\alpha_Y := \hat{g}'^2/4\pi$ *is*

$$\frac{\mathrm{d}\alpha_Y}{\mathrm{d}\ln E} = \frac{b_Y}{2\pi}\alpha_Y^2\,, \qquad b_Y = \frac{41}{6}\,, \tag{108.59}$$

positive. Taking both inputs in the same scheme, as Corollary 108.20 requires — the effective on-shell coupling $\alpha^{-1}(m_Z c^2) = 128.94$ *of Remark 108.58 together with the on-shell mixing angle* $s_W^2 = 0.2232$ *of Remark 104.34, both from [2427] — gives* $\alpha_Y^{-1}(m_Z c^2) = 100.16$*, and the one-loop coupling diverges at*

$$\ln\frac{E_{\mathrm{L}}}{m_Z c^2} = \frac{2\pi}{b_Y}\cdot 100.16 = 92.10\,, \qquad E_{\mathrm{L}} \approx 9\times 10^{41}\ \mathrm{GeV}\,. \tag{108.60}$$

Rests on Corollary 108.20 and Equations (102.35) and (104.13).

Derivation. Derives Proposition 108.59.

The master formula Equation (102.35) of Chapter 102,

$$\frac{\mathrm{d}\alpha}{\mathrm{d}\ln E} = \frac{S}{12\pi}\alpha^2\,, \qquad S = \sum_i x_i^2\,(-1)^{2s_i}\sum_{s_z}\left(1-12s_z^2\right)\,,$$

sums over one-particle states i of charge x_i in units of the coupling, and is the general one-loop vacuum-polarization result, not a QCD-specific one. In the convention $\mathrm{d}\alpha/\mathrm{d}\ln E = (b/2\pi)\alpha^2$ used throughout this chapter, $b = S/6$. Evaluate the spin sum for each kind of state.

- A *Dirac* fermion of charge x: two one-particle states, the fermion and the antifermion, each with $s_z = \pm\frac{1}{2}$, so $\sum_{s_z}(1-12s_z^2) = 2(1-3) = -4$ each; the statistics factor is $(-1)^1 = -1$; hence $S = x^2(-1)(-8) = 8x^2$ and $b = \frac{4}{3}x^2$, which is Proposition 100.63 and Corollary 102.34.
- A *Weyl* fermion of charge x: one helicity per particle, so half the Dirac value, $S = 4x^2$ and $b = \frac{2}{3}x^2$.
- A *complex scalar* of charge x: two states, each with $s_z = 0$ and $\sum_{s_z}(1-0) = 1$; the statistics factor is $(-1)^0 = +1$; hence $S = 2x^2$ and $b = \frac{1}{3}x^2$.

The hypercharge coupling appears in the covariant derivative as $\hat{g}'Y/2$ by the assignment $Q = T^3 + Y/2$ of Equation (104.13), so $x = Y/2$ for each field. Summing $(Y/2)^2$ over one generation of Table 104.1, with a factor $N_c = 3$ for coloured fields and a factor 2 for each $\mathrm{SU}(2)_L$ doublet,

$$2\cdot 3\cdot\left(\tfrac{1}{6}\right)^2 + 3\cdot\left(\tfrac{2}{3}\right)^2 + 3\cdot\left(\tfrac{1}{3}\right)^2 + 2\cdot\left(\tfrac{1}{2}\right)^2 + 1\cdot 1^2 = \frac{1}{6}+\frac{4}{3}+\frac{1}{3}+\frac{1}{2}+1 = \frac{10}{3}\,,$$

the five terms being the quark doublet, the up singlet, the down singlet, the lepton doublet and the charged-lepton singlet. Three generations give 10, and the Weyl coefficient $\frac{2}{3}$ gives

$b_Y^{\text{fermion}} = \frac{20}{3}$. The scalar doublet has two complex components with $Y/2 = \frac{1}{2}$, contributing $\frac{1}{3} \cdot 2 \cdot \frac{1}{4} = \frac{1}{6}$. Adding, $b_Y = \frac{20}{3} + \frac{1}{6} = \frac{41}{6}$, which is Equation (108.59).

For the numbers: $\alpha_Y = \alpha/\cos^2\theta_W$, so $\alpha_Y^{-1} = 128.94 \times (1 - 0.2232) = 100.16$. Integrating Equation (108.59) as in Equation (108.55) with the sign reversed, α_Y^{-1} falls linearly in $\ln E$ with slope $b_Y/2\pi = 1.0876$ and reaches zero after $100.16/1.0876 = 92.10$ e-folds, that is at $\log_{10}(E/\text{GeV}) = 1.96 + 92.10/\ln 10 = 41.96$.

Both inputs are on-shell quantities, which is why they may be combined. Doing the same arithmetic consistently in $\overline{\text{MS}}$ instead — $\hat{s}_Z^2 = 0.23129$ of Remark 104.34 with the $\overline{\text{MS}}$ coupling $\hat{\alpha}^{-1}(m_Z c^2) = 127.95$ [2427] — gives $\alpha_Y^{-1} = 98.36$, 90.44 e-folds and $E_{\text{L}} \approx 2 \times 10^{41}\,\text{GeV}$. The two schemes move the pole by a factor of about five, which is nothing beside the forty decades of extrapolation and is exactly why Remark 108.60 follows. What is not permitted is to combine 128.94 with $\hat{s}_Z^2$: that pairs a coupling from one scheme with an angle from another and produces a number belonging to neither. □

Remark 108.60 (What a Landau pole does not establish). The four objections stated in Remark 100.65 for the electromagnetic case apply verbatim here and are not repeated; the essential one is that Equation (108.60) extrapolates a one-loop formula over forty decades in energy, into a regime where the expansion parameter it is built from is of order one. The location of the pole is not a prediction. Two things are worth adding.

First, the hypercharge pole sits at about $9 \times 10^{41}\,\text{GeV}$, which is some 7×10^{22} times the Planck energy $\sqrt{\hbar c^5/G} = 1.22 \times 10^{19}\,\text{GeV}$; the QED pole of Equation (100.85) sits far higher still. In neither case is the question reachable, and any statement about it is a statement about an extrapolation and not about an experiment.

Second, and this is the point that makes the discussion worth having at all: the *existence* of a scale at which the description fails, rather than its value, is a structural fact. A theory with a positive β_0 carries an ultraviolet expiry date in exactly the way Fermi's theory carried one through Equation (101.9) — and in that case the date was 292.8 GeV, the theory did fail there, and what replaced it was found.

Remark 108.61 (Triviality: what is proved and what is not). The perturbative pole is not the strongest available statement. For the scalar theory of Equation (108.39) there are rigorous non-perturbative results, and they say something sharper.

Above four dimensions, the continuum limit of the lattice ϕ^4 theory — and of the Ising model, which the cited work treats in the same framework and for the same reason — is a *free* field theory: the renormalized quartic coupling vanishes when the cutoff is removed [1662]. This is the rigorous counterpart of Corollary 108.37: above the upper critical dimension the quartic coupling is irrelevant, so it flows to zero, and nothing survives the limit but the Gaussian fixed point. Exactly at four dimensions the coupling is marginal and the question is delicate; the answer, obtained only in 2021, is that the scaling limits of the critical four-dimensional Ising and $\lambda\phi^4$ models are Gaussian as well, marginally so [2371]. There is therefore no non-trivial continuum ϕ^4 theory in the observed number of dimensions.

For abelian gauge theory the corresponding statement is not a theorem but a lattice result: numerical study of lattice quantum electrodynamics with charged matter finds the continuum limit to exist only at zero renormalized coupling [1955], consistent with triviality and not proving it. The strength of that conclusion depends on the lattice action used — compact and non-compact U(1) have different phase structures at strong coupling — so what is recorded here is the conclusion the cited work draws and not a general statement about lattice U(1).

Corollary 108.62 (Two Standard Model sectors are effective). *The scalar self-coupling runs with the sign of Equation* (108.48) *and the hypercharge coupling with that of Equation* (108.59)*: both grow with energy, and both belong to sectors for which the evidence points to triviality in the strict continuum limit. The Standard Model is therefore not a candidate*

for a complete theory valid to arbitrarily high energy, independently of any consideration of gravity. It is a theory with a cutoff, and what the cutoff is remains unmeasured.

Rests on Equations (108.48) *and* (108.59) *and Proposition 108.52.*

Proof. *Derives Corollary 108.62.*

The two signs are Equation (108.48) and Equation (108.59), both derived above; by Proposition 108.52 a coupling with $\beta_0 < 0$ in the convention of Equation (108.24) reaches infinity at a finite scale, so the perturbative description of each sector has an ultraviolet endpoint. That the endpoint is not an artefact of perturbation theory in the scalar case is Remark 108.61. The conclusion follows without invoking gravity because no gravitational quantity has entered any step. □

Remark 108.63 (The same conclusion from the other side). Corollary 108.62 is an ultraviolet statement about a coupling that grows. Section 104.8.1 reaches the same place from the opposite direction, and it does so at a far lower energy. The quartic coupling's beta function Equation (104.72) is dominated by the top Yukawa and is *negative* at the top mass, $\mathrm{d}\hat{\lambda}/\mathrm{d}\ln\mu = -0.0206$ by Proposition 104.66; integrating the coupled system sends $\hat{\lambda}$ through zero at about 10^{10}–10^{11} GeV [2193, 2215], where the potential turns over.

The growth that Equation (108.48) describes for a self-coupled scalar therefore never happens in the Standard Model, because the fermion loop wins first. Asking where it *would* have arrived requires care with the normalization, because Equation (108.48) is written for a single real field with the interaction $-(g/4!)\,\phi^4$, while $\hat{\lambda} = 0.126$ is the quartic coupling of a complex doublet in the normalization of Equation (104.27), where the interaction is $-\lambda\left(\Phi^\dagger\Phi\right)^2$. The beta function belonging to the second is the leading term of Equation (104.72), $16\pi^2\mathrm{d}\hat{\lambda}/\mathrm{d}\ln\mu = 24\hat{\lambda}^2$, and not the $3\hat{g}^2$ of the first: the two normalizations differ by a factor of eight in the coefficient, and the eight sits in an exponent. Dropping every other term of Equation (104.72) and integrating that one from the top mass,

$$\ln\frac{E_{\mathrm{L}}}{m_t c^2} = \frac{16\pi^2}{24\hat{\lambda}} = \frac{157.91}{3.024} = 52.2\,, \qquad E_{\mathrm{L}} \approx 8\times10^{24}\,\mathrm{GeV}\,, \tag{108.61}$$

with $m_t c^2 = 172.57\,\mathrm{GeV}$. Feeding $\hat{\lambda}$ into the single-real-scalar coefficient instead would give 417.8 e-folds and $10^{184}\,\mathrm{GeV}$, roughly a hundred and sixty decades higher: that is what a normalization mismatch costs in an exponentiated quantity, and it is why the normalization is stated rather than assumed. Either number is far beyond reach and neither is a prediction. The honest composite statement is that the scalar sector's extrapolation fails at $10^{10}\,\mathrm{GeV}$ for a reason having nothing to do with triviality, and would fail eventually for triviality if it survived; Remark 104.67 states how fragile the first of those numbers is, and none of it is evidence for any particular completion.

108.6 Effective field theory

Corollary 108.62 left the Standard Model as a description with a cutoff and no knowledge of what lies above it. That situation is not a predicament; it is the normal situation of every successful theory in the history of physics, and the renormalization group turns it into a method. The method has three parts: a statement that heavy things drop out of low-energy physics in a controlled way (Section 108.6.1); a recipe for writing down what is left (Section 108.6.2); and, applied to the Standard Model itself, a set of operators whose coefficients are measured or bounded (Section 108.6.3).

108.6.1 Decoupling

Theorem 108.64 (Appelquist–Carazzone)**.** *Let a renormalizable theory contain a field of mass M and let observables be computed at energies $E \ll Mc^2$, using a mass-dependent*

scheme in the sense of Definition 108.17. Then the effects of the heavy field are of two kinds and no others: a finite renormalization of the parameters of the light theory, and corrections suppressed by positive powers of E/Mc^2 [1538].

Rests on Definition 108.17, Proposition 100.33, and Equation (100.82).

Derivation of the one-loop case. Derives Theorem 108.64.

Take the heavy field to be a Dirac fermion of mass m and unit charge in quantum electrodynamics, and take the momentum-subtraction scheme in which the coupling at spacelike momentum transfer Q is $\alpha(Q)$ of Equation (100.82). The subtracted polarization in full is the Feynman-parameter integral obtained in the derivation of Proposition 100.33 — of which Equation (100.53) is only the leading term for $|q^2| \ll m^2c^2$, and Equation (100.83) only the leading term in the opposite limit. For $q^2 = -Q^2$ it reads

$$\bar{\Pi}\left(Q^2\right) = \frac{2\alpha}{\pi} \int_0^1 \mathrm{d}x \, x\,(1-x) \ln\left[1 + \frac{x\,(1-x)\,Q^2}{m^2c^2}\right], \tag{108.62}$$

an expression in which Q and mc are both momenta and the argument of the logarithm is a pure number, as it must be. The beta function of this scheme is obtained by differentiating $\alpha(Q) = \alpha/[1-\bar{\Pi}]$ with respect to $\ln Q$, which at leading order is $\alpha^2\,\mathrm{d}\bar{\Pi}/\mathrm{d}\ln Q$:

$$\frac{\mathrm{d}\alpha}{\mathrm{d}\ln Q} = \frac{2\alpha^2}{3\pi} f\left(\frac{Q}{mc}\right), \qquad f(\rho) := 6\int_0^1 \mathrm{d}x \, \frac{x^2\,(1-x)^2\,\rho^2}{1 + x\,(1-x)\,\rho^2}, \tag{108.63}$$

the factor 6 chosen so that $f(\infty) = 1$. Two limits settle the theorem.

High energy. As $\rho \to \infty$ the integrand tends to $x(1-x)$, and $\int_0^1 x(1-x)\mathrm{d}x = \frac{1}{6}$, so $f \to 1$ and Equation (108.63) reduces to Equation (100.84): the fermion contributes in full, as a massless particle would.

Low energy. As $\rho \to 0$ the denominator tends to 1 and

$$f(\rho) \to 6\rho^2 \int_0^1 x^2\,(1-x)^2\,\mathrm{d}x = \frac{6\rho^2}{30} = \frac{\rho^2}{5} = \frac{1}{5}\left(\frac{Q}{mc}\right)^2,$$

using $\int_0^1 x^2(1-x)^2\mathrm{d}x = B(3,3) = 2!\,2!/5! = 1/30$. The heavy fermion's contribution to the running is therefore suppressed by $(Q/mc)^2 = (E/mc^2)^2$: it does not merely become small, it becomes small at a computable rate, quadratically in the ratio of the probe energy to the heavy mass. Numerically $f = 0.945$ at $Q = 10mc$, $f = 0.165$ at $Q = mc$ and $f = 2.0 \times 10^{-3}$ at $Q = mc/10$.

The first kind of effect — the finite renormalization — is the constant that $\bar{\Pi}$ would have contributed had the subtraction been made elsewhere, and it is by construction absorbed into the definition of α at the low scale. This is the whole content of the theorem at one loop, in one theory, for one kind of heavy field. The statement of Theorem 108.64 is broader on all three counts, and the general proof is not given here. □

Derivation pending #178

Appelquist–Carazzone to all orders: the proof that in a mass-dependent scheme the effects of a heavy field on light-field observables are exhausted, at every order in the loop expansion and for a heavy field of any spin whose mass is an independent parameter, by a finite renormalization of the light theory's parameters plus corrections of positive power in the ratio of the probe energy to the heavy mass. What is derived in the text is the one-loop case for a heavy Dirac fermion in quantum electrodynamics, including the quadratic suppression rate; the general theorem belongs in Appendix A.

Remark 108.65 (The theorem fails in minimal subtraction). Theorem 108.64 presupposes a mass-dependent scheme. In minimal subtraction the beta function contains no mass at all (Theorem 108.18), so a heavy quark keeps contributing its full $-\frac{2}{3}$ to b_0 at every scale, including scales far below its own mass, and α_s computed that way at $E = 1\,\mathrm{GeV}$ would carry the top quark. That is not a defect of the scheme but the price of its convenience, and the remedy is a construction rather than a correction:

- Below the threshold one uses a *different theory*, the effective theory with $n_f - 1$ flavours, in which the heavy quark does not appear as a field at all.
- At a scale near the threshold, conventionally $\bar{\mu}c = m_Q c^2$, one *matches*: the two theories are required to give the same value for a set of low-energy observables, which fixes the couplings of the light theory in terms of those of the heavy one. At one loop the matching is continuity, $\alpha_s^{(n_f-1)} = \alpha_s^{(n_f)}$; the difference first appears at order α_s^2.
- Above and below, one runs with the appropriate b_0.

The observable consequence is the kink already used in the derivation of Table 108.2: the slope $\mathrm{d}(1/\alpha_s)/\mathrm{d}\ln E$ changes from 1.2202 to 1.3263 on crossing the b threshold downwards, a discontinuity of about 0.106 in a quantity that is measured. Decoupling in $\overline{\mathrm{MS}}$ is therefore not automatic; it is imposed, and the imposing is matching.

Remark 108.66 (Where decoupling genuinely fails). Two failures matter physically, and both are visible in the electroweak theory. Neither contradicts Theorem 108.64: each violates one of its hypotheses, and saying which is the useful part.

A mass that is not an independent parameter. The theorem takes $M \to \infty$ with the couplings of the theory fixed. In the Standard Model a fermion's mass is $m_f c^2 = \hat{y}_f E_v/\sqrt{2}$ by Section 104.4.3, so making the top heavy means making $\hat{y}_t$ large, and the limit is not the one the theorem contemplates. The consequence is measured: the correction $\Delta\rho$ of Equation (104.52) grows as m_t^2 rather than falling, so the top does *not* decouple from the electroweak fit — which is exactly why that fit located the top mass before the top was produced. A non-decoupling effect is not a pathology; here it was the measurement.

A relevant operator. Equation (108.6) says that an operator of dimension $D < 4$ has a dimensionless strength growing as $(E_\star/E)^{4-D}$ when the probe energy falls. The scalar mass term is such an operator, $D = 2$, and a heavy field of mass M coupled to Φ shifts $m_h^2 c^4$ by an amount of order $(Mc^2)^2$ times a loop factor: the heavy state's effect on the one dimensionful parameter of the light theory grows with its mass instead of decaying. The same statement applies to the vacuum energy, $D = 0$, more strongly still. What follows from this and what does not is set out in Section 104.8.2, and the honest summary is repeated here because it is a renormalization-group statement: it is an argument about the form a more fundamental theory would have to take, it is not an observation, and none of the programmes proposed to address it has observational support of the kind this book requires.

Chiral symmetry breaking is sometimes given as a third example. It is better described as the failure of a different assumption: the light theory below Λ_{QCD} is not the Standard Model Lagrangian with heavy fields removed but a theory of different degrees of freedom altogether — pions rather than quarks — and matching onto it is Section 108.6.2, not Theorem 108.64.

108.6.2 Phenomenological Lagrangians and power counting

Theorem 108.67 (Weinberg's principle). *Suppose one writes down the most general possible Lagrangian containing all terms consistent with the assumed symmetry principles and built from the fields that are light at the energy of interest, and computes with it, ordering the terms by their dimension D in the sense of Equation (108.3). Then the result is the most*

general S-matrix consistent with analyticity, perturbative unitarity, cluster decomposition and the assumed symmetries: it is not an approximation to a theory but a theory, and it is predictive to any stated accuracy with finitely many parameters [1647, 1867].

Rests on Equations (108.3) *and* (108.6) *and Theorem 108.26.*

Derivation of the predictivity claim. *Derives Theorem 108.67.*

What has to be shown is that a stated accuracy needs only finitely many operators. By Equation (108.6) an operator of dimension D contributes to a process of energy E relative to the leading, $D = 4$, term by a factor

$$\left(\frac{E}{E_\star}\right)^{D-4}, \tag{108.64}$$

$E_\star$ being the energy at which the description fails. Demanding a fractional accuracy δ therefore requires only those operators with

$$D - 4 \leq \frac{\ln \delta}{\ln (E/E_\star)}, \tag{108.65}$$

a finite number for any $\delta > 0$ and any $E < E_\star$, since the number of local operators of bounded dimension built from finitely many fields is finite. Each carries one unknown coefficient, so the theory has finitely many parameters at each order; once they are measured, everything else at that order is predicted.

The step that makes this consistent rather than merely convenient is that loops do not spoil it. A loop of the light fields produces a divergence which, being local (Remark 100.53), is a local operator; Theorem 108.26 fixes its dimension, and the counting shows it is always an operator of dimension already included at that order. The divergence is therefore absorbed by a coefficient already present, and the theory is renormalizable *order by order in the expansion* even though it is non-renormalizable in the sense of Corollary 108.27. That is the whole reversal recorded in Remark 108.28.

What is established here is predictivity: that a stated accuracy needs only finitely many operators, and that loops do not spoil the counting. The other half of Theorem 108.67 — that what results is the *most general* S-matrix consistent with analyticity, perturbative unitarity, cluster decomposition and the assumed symmetries — is a separate statement, and it is not derived here. □

Derivation pending #179

Weinberg's generality claim: the demonstration that a Lagrangian containing every term allowed by the assumed symmetries and built from the light fields generates the most general S-matrix consistent with analyticity, perturbative unitarity and cluster decomposition, that is, that no further S-matrix satisfying those constraints exists which the construction fails to reach. The predictivity half of the theorem is derived in the text above; the generality half belongs in Appendix A.

Remark 108.68 (The two scales, and the loop counting). An effective theory has two expansion parameters, not one. The first is $E/E_\star$, the operator expansion Equation (108.64). The second is the loop expansion, and for a theory whose interactions are generated by a single scale the natural loop factor is $(E/4\pi E_\star)^2$ — the 4π being the $1/(4\pi)^2$ that Lemma 100.28 attaches to every four-dimensional loop. The two expansions are therefore not independent: one loop costs as much as two extra dimensions of operator, up to $16\pi^2$, and a consistent calculation at a given order in $E/E_\star$ must include both. That correspondence is what makes a power counting formula — an integer attached to each diagram counting its total suppression — possible at all.

Example 108.69 (Chiral perturbation theory)**.** The light degrees of freedom below Λ_{QCD} are the pions, which are light not by accident but because they are the almost-Goldstone bosons of the spontaneously broken chiral symmetry of Chapter 102. Their interactions are constrained by that symmetry to vanish as the momenta go to zero, so an expansion in momenta and quark masses exists, and it is an effective field theory in exactly the sense of Theorem 108.67 [1647, 1737]. The scale $E_\star$ is set by the pion decay constant through the loop counting of Remark 108.68:

$$E_\star \approx 4\pi F_\pi = 4\pi \times 92.07\,\mathrm{MeV} = 1.16\,\mathrm{GeV}\,, \tag{108.66}$$

with F_π from Example 102.73, which is where the pionic description must fail, and which is where Theorem 107.29 places it. At $E = m_\pi c^2$ the expansion parameter is $(139.6/1160)^2 = 0.014$: a per-cent theory at leading order, which is what is observed (Remark 102.74).

Example 108.70 (The nuclear force)**.** Applying the same construction to nucleons and pions gives the counting formula Equation (107.38) of Theorem 107.29, in which a diagram with A nucleons, L loops and C connected pieces contributes at order $(Q/\Lambda)^\nu$ with ν a sum of manifestly non-negative terms [1840]. Two consequences follow that no fit to scattering data can supply, and Remark 107.30 draws them: the long-range force is *predicted*, being one-pion exchange with a coupling already measured elsewhere; and many-body forces are ordered, the three-nucleon force entering at $\nu = 3$ and the four-nucleon force at $\nu = 4$, so that the observed necessity of a three-body force is a prediction rather than a patch [2177]. The derivation of the counting formula itself is owed to Appendix A and is recorded as pending in Chapter 107; what this chapter supplies is the reason such a formula exists, which is Theorem 108.67 together with Remark 108.68.

Remark 108.71 (The operator product expansion). Wilson's operator product expansion [1410] asserts that the product of two local operators at short separation may be written

$$O_a(x)\,O_b(0) \;\longrightarrow\; \sum_i C^i_{ab}(x)\,O_i(0) \qquad \text{as } x \to 0\,, \tag{108.67}$$

with the whole singularity as $x \to 0$ carried by the c-number coefficients C^i_{ab} and none by the operators O_i. The degree of the singularity is fixed by dimensions: by Equation (108.3), $C^i_{ab} \sim |x|^{D_i - D_a - D_b}$ up to logarithms, so operators of higher dimension are suppressed by more powers of the separation. This is Equation (108.64) with the two scales exchanged: an effective field theory expands in the ratio of a low energy to a high one, and Equation (108.67) expands in the ratio of a short distance to a long one, but the organizing integer is the same D and the factorization of long from short is the same factorization. In an asymptotically free theory the coefficients are computable in perturbation theory while the matrix elements of the O_i are not, which is exactly the division of labour of Theorem 102.53, and the logarithms the coefficients carry are governed by the anomalous dimensions Equation (102.62) of the operators — the same γ that Definition 108.12 introduced.

108.6.3 The Standard Model as an effective theory

Take the Standard Model Lagrangian Equation (104.28) as the $D = 4$ term of an expansion, keep its gauge symmetry and its field content, and ask what else Theorem 108.67 permits. The answer is short at dimension five and long at dimension six, and the short answer is the more interesting one.

Proposition 108.72 (There is exactly one operator of dimension five)**.** *With the field content of Table 104.1 and the gauge group* $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$*, the only gauge- and*

Lorentz-invariant local operator of dimension $D = 5$ is, up to flavour indices and hermitian conjugation,

$$\mathcal{L}_5 = \frac{\hat{c}_5 \, (\hbar c)^2}{E_\Lambda} \left(\overline{\hat{L}^c} \, \hat{\Phi} \right) \left(\hat{\Phi}^\mathsf{T} \hat{L} \right) + h.c. \,, \tag{108.68}$$

$\hat{L}$ being a lepton doublet, $\hat{\Phi}$ the reduced scalar doublet of Equation (108.2), $\hat{c}_5$ a pure number and E_Λ an energy, in accordance with Equation (108.5) for $D = 5$. It violates lepton number by two units [1646].

Rests on Equations (108.2), (108.3) and (108.5).

Derivation. Derives Proposition 108.72.

Write $D = n_\phi + \frac{3}{2} n_\psi + n_A + n_\partial = 5$ from Equation (108.3). Lorentz invariance requires n_ψ even, and $n_\psi \geq 4$ already gives $D \geq 6$; so $n_\psi \in \{0, 2\}$.

Case $n_\psi = 0$. A purely bosonic gauge-invariant operator is built from $\hat{\Phi}$, $\hat{\Phi}^\dagger$, field strengths and derivatives. A field strength contributes $n_A + n_\partial = 2$; a Lorentz-invariant contraction of leftover derivatives requires them in pairs, contributing 2 each. Hypercharge neutrality with a single doublet requires equal numbers of $\hat{\Phi}$ and $\hat{\Phi}^\dagger$, so n_ϕ is even. Hence D is even, and $D = 5$ is impossible.

Case $n_\psi = 2$. Then $n_\phi + n_A + n_\partial = 5 - 3 = 2$. The options are two scalars, one scalar and one derivative, two derivatives, or one field strength. The last three all reduce: an operator with $n_\partial \geq 1$ acting on a fermion bilinear can be integrated by parts and reduced by the equations of motion to operators of dimension four, and a two-fermion operator with a field strength — the dipole $\bar{\psi} \sigma^{\mu\nu} \psi F_{\mu\nu}$ — is not $\mathrm{SU}(2)_L$ invariant for the chiral fields of Table 104.1 unless a Higgs doublet is inserted to carry the weak index, which raises it to $D = 6$.

There remains $n_\phi = 2$: two fermion fields and two scalars. Both fermions must be left-handed, since a right-handed singlet cannot pair with a doublet and two scalars into a hypercharge singlet; so the bilinear is a Lorentz scalar formed from two left-handed Weyl fields by charge conjugation, which is why the operator violates fermion number. Colour neutrality excludes quark doublets, since $3 \otimes 3$ contains no singlet. The remaining candidate is two lepton doublets, $Y = -1$ each, with two scalar doublets, $Y = +1$ each: total hypercharge $-2+2 = 0$, and $2 \otimes 2 \otimes 2 \otimes 2$ contains a singlet. That is Equation (108.68), and it is unique up to the choice of $\mathrm{SU}(2)$ contraction, which differs from the one written by a term that vanishes identically, and up to the flavour indices carried by the two lepton doublets, which make $\hat{c}_5$ a symmetric matrix in generation space. The exhaustive enumeration behind the reductions asserted above is the systematic construction of [1770, 2159]; the conclusion is [1646]. □

Phenomenon 108.73 (Neutrino mass points above the electroweak scale)**.** The neutrinos of the Standard Model Lagrangian Equation (104.28) are massless, because Table 104.1 contains no right-handed singlet with which to build a Yukawa term. Oscillation experiments show that at least two of them are not (Chapters 103 and 114): the measured squared-mass splittings are $\Delta m^2_{21} c^4 = 7.53 \times 10^{-5} \, \mathrm{eV}^2$ and $|\Delta m^2_{32}| \, c^4 = 2.455 \times 10^{-3} \, \mathrm{eV}^2$ [2427], so the heaviest neutrino satisfies

$$m_3 c^2 \geq \sqrt{|\Delta m^2_{32}| \, c^4} = 0.0495 \, \mathrm{eV} \,. \tag{108.69}$$

Inserted into Equation (108.68) with a coefficient of order unity, this is a measurement of the scale E_Λ at which the Standard Model ceases to be the whole story:

$$E_\Lambda = \frac{\hat{c}_5 E_v^2}{m_3 c^2} = \hat{c}_5 \times \frac{(246.220 \, \mathrm{GeV})^2}{4.95 \times 10^{-11} \, \mathrm{GeV}} = \hat{c}_5 \times 1.2 \times 10^{15} \, \mathrm{GeV} \,. \tag{108.70}$$

Rests on Equations (104.28), (104.29) and (108.68).

Derivation. *Derives Phenomenon 108.73.*

Substitute the vacuum Equation (104.29) into Equation (108.68). The neutral component of $\hat{\Phi}$ acquires $\left\langle \hat{\Phi}^0 \right\rangle = v/\sqrt{2\hbar c} = E_v/\left(\sqrt{2}\,\hbar c\right)$, using $\hat{\Phi} = \Phi/\sqrt{\hbar c}$ from Equation (108.2) and $E_v = v\sqrt{\hbar c}$ from Equation (104.2). The operator becomes

$$\frac{\hat{c}_5\,(\hbar c)^2}{E_\Lambda} \cdot \frac{E_v^2}{2\,(\hbar c)^2}\,\overline{\hat{\nu}^c}\,\hat{\nu} = \frac{\hat{c}_5 E_v^2}{2E_\Lambda}\,\overline{\nu^c}\,\nu\,,$$

which is a Majorana mass term $-\frac{1}{2}m_\nu c^2\overline{\nu^c}\nu$ with

$$m_\nu c^2 = \frac{\hat{c}_5 E_v^2}{E_\Lambda}\,. \tag{108.71}$$

Every factor is dimensionally accounted for: $\hat{\nu}$ carries $1/\mathrm{m}^{3/2}$ so $\overline{\hat{\nu}^c}\hat{\nu}$ carries $1/\mathrm{m}^3$, and the prefactor is an energy, so the product is an energy density as required. Solving Equation (108.71) for E_Λ with $m_\nu c^2 = 0.0495\,\mathrm{eV} = 4.95 \times 10^{-11}\,\mathrm{GeV}$ and $E_v^2 = 60\,624.29\,\mathrm{GeV}^2$ from Equation (104.32) gives Equation (108.70), since $60624.29/4.95 \times 10^{-11} = 1.22 \times 10^{15}$. □

Remark 108.74 (What the neutrino scale does and does not say). Equation (108.70) says: *if* the neutrino masses come from the unique dimension-five operator, and *if* its coefficient is of order one, then the scale at which the Standard Model is superseded is about $10^{15}\,\mathrm{GeV}$. Both conditionals matter. The first is a parametrization of ignorance, not a mechanism: Equation (108.68) records that lepton number is violated somewhere above the electroweak scale and says nothing about what does the violating. The second is unconstrained, and E_Λ scales linearly with $\hat{c}_5$: a coefficient of 10^{-10} would place the scale at $10^5\,\mathrm{GeV}$, and the data cannot distinguish. Nor is the operator the only possibility — the neutrinos may be Dirac particles with Yukawa couplings smaller than the electron's by seven orders of magnitude, the ratio $0.0495\,\mathrm{eV}/0.511\,\mathrm{MeV} = 9.7 \times 10^{-8}$, which is equally unexplained and equally consistent. The alternatives, and the honest statement that no direct evidence selects among them, belong to Chapter 103 and to Chapter 133.

What is not conditional is the structural point, and it is considerable: the smallness of the neutrino masses is, within this framework, not a puzzle but a *measurement*. An irrelevant operator is suppressed by the scale of the physics that generated it, so a very small mass is the signature of a very large scale. This is the only place in the Standard Model where an observed number points above the electroweak scale, and the pointing is the content.

Remark 108.75 (Dimension six, and what the bounds establish). At $D = 6$ the list is no longer short. The first systematic construction [1770], corrected and completed into what is now the standard basis [2159], contains 59 independent baryon-number-conserving operators for a single fermion generation, up to hermitian conjugation; flavour indices multiply that by a large factor for three generations. Their coefficients are constrained by global fits to electroweak precision data, to Higgs couplings and to high-energy tails of distributions at the LHC, and the constraints are usually quoted as lower bounds on $E_\Lambda/\sqrt{\hat{c}}$ of a few TeV: at $E = 1\,\mathrm{TeV}$ the suppression Equation (108.64) is $(E/E_\Lambda)^2$, which is 0.11 for $E_\Lambda = 3\,\mathrm{TeV}$ and 0.01 for $10\,\mathrm{TeV}$, so a measurement at the per-cent level probes the ten-TeV range and no further.

A small subset of the dimension-six operators violates baryon number. They take the form of four-quark-and-lepton operators such as $(\hat{Q}\hat{Q})(\hat{Q}\hat{L})$, they conserve $B - L$, and they mediate proton decay.

Phenomenon 108.76 (The proton does not decay)**.** Super-Kamiokande, searching an enlarged fiducial volume of its water-Cherenkov detector over four running periods, finds no proton decay and sets, at ninety per cent confidence,

$$\frac{\tau}{B}\left(p \to e^+\pi^0\right) > 2.4 \times 10^{34}\,\mathrm{yr}\,, \qquad \frac{\tau}{B}\left(p \to \mu^+\pi^0\right) > 1.6 \times 10^{34}\,\mathrm{yr} \tag{108.72}$$

[2365]. Read through a dimension-six operator with a coefficient of order unity, the first of these requires

$$E_\Lambda \gtrsim 3 \times 10^{16}\,\mathrm{GeV}\,. \tag{108.73}$$

Rests on Equations (108.3) *and* (108.5)*.*

Derivation. *Derives Phenomenon 108.76.*

A dimension-six operator carries, by Equation (108.5), a coefficient $\hat{c}_6 \hbar c\,(\hbar c/E_\Lambda)^2$. The decay rate is quadratic in it, and the only other scale in the problem is the proton mass, so on dimensional grounds

$$\hbar\Gamma \sim \hat{c}_6^2\,\frac{\left(m_p c^2\right)^5}{E_\Lambda^4}\,, \tag{108.74}$$

both sides being energies: five powers of energy divided by four is one. Set $\hat{c}_6 = 1$ and insert the numbers. A year is $3.155\,76 \times 10^7$ s, so $\Gamma = 1/(2.4 \times 10^{34} \times 3.155\,76 \times 10^7\,\mathrm{s}) = 1.320 \times 10^{-42}/\mathrm{s}$, and with $\hbar = 6.582\,119\,569 \times 10^{-16}\,\mathrm{eV\,s}$,

$$\hbar\Gamma = 8.69 \times 10^{-58}\,\mathrm{eV} = 8.69 \times 10^{-67}\,\mathrm{GeV}\,.$$

With $m_p c^2 = 0.938\,272\,\mathrm{GeV}$, $(m_p c^2)^5 = 0.727\,18\,\mathrm{GeV}^5$, so $E_\Lambda^4 = 0.727\,18/8.69 \times 10^{-67} = 8.4 \times 10^{65}\,\mathrm{GeV}^4$ and $E_\Lambda = 3.0 \times 10^{16}\,\mathrm{GeV}$, which is Equation (108.73). The second limit in Equation (108.72) gives $2.7 \times 10^{16}\,\mathrm{GeV}$ by the same arithmetic; the two modes differ by less than the uncertainty in the hadronic matrix element, which is a factor of a few and which Equation (108.74) does not contain. □

Remark 108.77 (What these bounds do and do not establish)*.* Three statements, in decreasing order of security.

Secure. Baryon number is conserved to an extraordinary accuracy, and any physics that violates it does so through operators whose coefficient-to-scale ratio satisfies Equation (108.73). This is a bound on $\hat{c}_6/E_\Lambda^2$ and on nothing else. A theory with $\hat{c}_6 = 10^{-12}$ and $E_\Lambda = 3 \times 10^{13}\,\mathrm{GeV}$ is equally consistent with Equation (108.72), and there is no measurement that separates them.

Weaker. The near-coincidence of the neutrino scale Equation (108.70), at $10^{15}\,\mathrm{GeV}$, with the proton bound Equation (108.73), at $3 \times 10^{16}\,\mathrm{GeV}$, is suggestive of a common origin. It is one order of magnitude apart in quantities whose coefficients are unknown by many orders of magnitude, so it is suggestive and not more.

Not established at all. The programme that historically motivated the proton-decay searches — grand unification, in which the three gauge couplings are supposed to meet at a single scale — has no observational support. Its central prediction is proton decay, and the prediction has been tested for forty years with a null result that has excluded the simplest versions. By editorial rule 1 it is named here to record that fact and for no other reason. The renormalization-group statement that survives is the one that does not depend on it: an unobserved decay is a bound on a coefficient over a squared scale, and Equation (108.73) is that bound.

108.7 The renormalization group beyond perturbation theory

108.7.1 Scale invariance and its breaking

Definition 108.78 (Dilatations and the trace of the stress tensor)**.** A *dilatation* is the transformation $x^\mu \mapsto \lambda x^\mu$ with λ a pure number, each field transforming as $\Phi \mapsto \lambda^{-D_\Phi}\Phi$ with D_Φ its dimension from Equation (108.3). If the action is invariant, Noether's theorem supplies a conserved current

$$\mathcal{D}^\mu = x_\nu T^{\mu\nu}\,, \qquad \partial_\mu \mathcal{D}^\mu = T^\mu{}_\mu\,, \tag{108.75}$$

$T^{\mu\nu}$ being the (improved, symmetric) energy–momentum tensor, of SI dimension $\mathrm{J/m^3}$, whose general construction belongs to Chapter 64. Classical scale invariance is therefore the statement $T^\mu{}_\mu = 0$.

Proposition 108.79 (A classically massless theory is classically scale invariant)**.** *If every coupling in the Lagrangian multiplies an operator of dimension exactly four — that is, if every coupling is a pure multiple of $\hbar c$ by Equation (108.4) — then the classical action is dilatation invariant and $T^\mu{}_\mu = 0$.*

Rests on Definition 108.78 and Equation (108.4).

Proof. *Derives Proposition 108.79.*

Under $x \mapsto \lambda x$ the measure d^4x carries λ^4 and an operator of dimension D carries λ^{-D}, so a term $c_O \int \mathrm{d}^4x\, O$ is invariant if and only if $D = 4$ or $c_O = 0$. Massless Yang–Mills and massless ϕ^4 have only $D = 4$ terms; a mass term has $D = 2$ or 3 and breaks the invariance explicitly, by an amount proportional to the mass. Hence $T^\mu{}_\mu = \partial_\mu \mathcal{D}^\mu = 0$ for the massless theory. □

Theorem 108.80 (The trace anomaly: structure)**.** *In the quantum theory the trace does not vanish, even when every mass is set to zero. Its expectation value is proportional to the beta function times the operator conjugate to the coupling:*

$$T^\mu{}_\mu = \frac{\beta(\hat g)}{\hat g}\,\mathcal{O}_{\hat g} + \sum_f \left(1 + \gamma_{m_f}\right) m_f c^2\, \bar\psi_f \psi_f\,, \qquad \mathcal{O}_{\hat g} := \hat g\,\frac{\partial \mathcal{L}}{\partial \hat g}\,, \tag{108.76}$$

up to a numerical factor in the first term which is not derived here. In particular $T^\mu{}_\mu = 0$ in a massless theory if and only if $\beta = 0$: exact scale invariance survives quantization only at a fixed point.

Rests on Proposition 108.79, Corollary 108.23, and Equation (108.75).

Derivation of the structure. *Derives Theorem 108.80.*

Regulate the theory as in Definition 100.30. By Corollary 108.23 the whole dependence of the regulated Lagrangian on the arbitrary scale $\bar\mu$ resides in the coupling: changing $\bar\mu$ changes $\hat g$ by $\delta\hat g = \beta(\hat g)\,\delta \ln \bar\mu$ and changes nothing else. A dilatation by $\lambda = 1 + \delta \ln \lambda$ acts on the regulated theory exactly like a change of $\bar\mu$ by $\delta \ln \bar\mu = -\delta \ln \lambda$, since $\bar\mu$ is the only scale present and lengths and $\bar\mu^{-1}$ scale oppositely. Therefore

$$\delta S\big|_{\text{dilatation}} = -\frac{\partial S}{\partial \hat g}\,\beta(\hat g)\;\delta \ln \lambda\,,$$

while by Equation (108.75) the same variation is $\delta S = \delta \ln \lambda\, c^{-1} \int \mathrm{d}^4x\, T^\mu{}_\mu$. Comparing integrands, $T^\mu{}_\mu$ is proportional to $\beta(\hat g)\,\partial\mathcal{L}/\partial\hat g$, which is Equation (108.76) up to the constant. The mass term is the classical breaking of Proposition 108.79, corrected by the anomalous dimension γ_m of Equation (108.14) because the mass that appears is the running one. □

Derivation pending #180

The trace anomaly, complete: the operator equation for the trace of the improved energy–momentum tensor in a non-abelian gauge theory, with the numerical coefficient of the beta-function term obtained by explicit regularization rather than by the scaling argument given in the text, together with the demonstration that the result is independent of the regulator used and that the improvement terms do not contribute. The structure — proportionality to the beta function times the operator conjugate to the coupling, and vanishing of the trace exactly at a zero of the beta function — is derived above; the coefficient is not, and the full operator derivation belongs in Appendix A.

Corollary 108.81 (Almost all of the proton's mass is anomalous)**.** *For a hadron state of four-momentum p — the momentum symbol of Notation 100.1, the wave four-vector $k = p/\hbar$ playing no part here — Lorentz invariance fixes the forward matrix element of the energy–momentum tensor to be proportional to $p^\mu p^\nu$, and in the covariant normalization customary for it the constant is $2\mathcal{N}$:*

$$\langle p|T^{\mu\nu}|p\rangle = 2\mathcal{N}\, p^\mu p^\nu \,, \tag{108.77}$$

where $\mathcal{N}$ carries whatever SI dimension the chosen state normalization does. It is not a pure number: $[T^{\mu\nu}] = \mathrm{J/m^3}$ while $p^\mu p^\nu$ carries $\mathrm{kg^2\,m^2/s^2}$, so $[\mathcal{N}] = 1/(\mathrm{kg\,m^3})$ — and nothing below depends on its value, because it cancels from every ratio taken. Contracting Equation (108.77) with the metric,

$$\langle p|T^{\mu}{}_{\mu}|p\rangle = 2\mathcal{N}p^2 = 2\mathcal{N}m^2c^2 \,, \tag{108.78}$$

by the mass-shell condition Equation (100.1): the trace of the tensor measures the mass and nothing else. Since the quark mass terms in Equation (108.76) account for only a few MeV *of the proton's* 938.272 MeV*, the remainder — some* 99 % *— comes from the first term, that is from the beta function.*

Rests on Equations (100.1) and (108.76).

Proof. *Derives Corollary 108.81.*

Equation (108.78) is immediate from the stated normalization and Equation (100.1). The quark contribution is bounded by $(m_u + m_d + m_s)c^2$ times matrix elements of order unity, and Table 102.1 gives $m_u c^2 = 2.16\,\mathrm{MeV}$ and $m_d c^2 = 4.70\,\mathrm{MeV}$; the strange contribution is larger but still small. The rest is carried by $\mathcal{O}_{\hat{g}}$, whose coefficient vanishes with β. □

Remark 108.82 (Two ways of saying the same thing). Corollary 108.81 and Phenomenon 102.39 are one statement in two languages. In the language of the running coupling, a massless Lagrangian generates the scale Λ_{QCD} of Equation (102.45) by dimensional transmutation, and every hadron mass is a pure number times $\Lambda_{\mathrm{QCD}}/c^2$. In the language of the trace anomaly, the same fact says that the classical scale invariance of the massless theory is destroyed by quantization with a coefficient proportional to β, and the proton's mass is what the destruction produces. Neither is more fundamental; the second is the operator statement of the first, and both are consequences of the single fact that $\beta \neq 0$. Chapter 102 notes the identification in passing at Remark 102.40; this is where it is made precise.

Remark 108.83 (Conformal invariance at a fixed point). At a zero of β in a massless theory the trace vanishes and the theory is scale invariant. In every case relevant here it is more: Lorentz invariance, locality and scale invariance together promote the symmetry to the full conformal group, which in $3+1$ dimensions has fifteen parameters against the eleven of

Poincaré plus dilatations, the four extra being the special conformal transformations. The promotion is a theorem under technical hypotheses and not an identity — there are known counterexamples in other dimensions — so it is recorded here as what it is.

The consequences are not decorative. Conformal invariance constrains two- and three-point functions completely, up to constants, and it is those constraints, combined with unitarity and the associativity of the operator product expansion Equation (108.67), that the conformal bootstrap turns into numerical bounds. That is how the three-dimensional Ising exponents in the last column of Table 108.1 were obtained [2239]: not by computing a beta function at all, but by asking which sets of dimensions are consistent, and finding that consistency alone determines them to six figures. The critical point of a fluid or a uniaxial magnet is a conformal field theory, and the exponents measured in Section 123.5 are its operator dimensions.

108.7.2 Monotonicity of the flow

Remark 108.84 (The empirical fact). Coarse graining loses information — Remark 108.35 — and in every case that has been examined the loss shows up as a reduction in the number of degrees of freedom describing the theory. A ferromagnet above its Curie point is described by the full lattice of spins; at long wavelength it is described by one order parameter. Quantum chromodynamics at short distance has quarks and gluons, six flavours and eight colours; below Λ_{QCD} it has pions, and below the pion mass it has nothing at all in the strong sector. A heavy field integrated out by Theorem 108.64 is gone. The direction is always the same, and never the reverse.

Theorem 108.85 (The four-dimensional a-theorem)**.** *Let a unitary, Lorentz-invariant, four-dimensional quantum field theory flow from one conformal fixed point in the ultraviolet to another in the infrared. Each fixed point has a number a, defined as the coefficient of the Euler density in the trace anomaly of the theory placed in a background gravitational field. Then*

$$a_{\mathrm{UV}} > a_{\mathrm{IR}}\,, \tag{108.79}$$

so no such flow can be reversed [2175]. The two-dimensional predecessor of this statement, in which the corresponding quantity is the Virasoro central charge and the result is known as the c-theorem, was proved by Zamolodchikov in 1986; that paper is not in this book's bibliography and is named here without a citation rather than attached to a key that does not contain it.

Rests on Definition 108.78 and Theorem 108.80.

Derivation pending #181

The four-dimensional a-theorem: the construction of the dilaton effective action for a spontaneously broken conformal symmetry, the identification of the difference of the anomaly coefficients with the coefficient of the four-derivative dilaton self-interaction, and the positivity of that coefficient from the analyticity and unitarity of forward dilaton scattering, by an argument of the same shape as an unsubtracted dispersion relation. The statement is used here only qualitatively, to say that the flow has a direction; the proof is several pages and belongs in Appendix A.

Remark 108.86 (Why irreversibility would matter, and why it does not yet). If the flow is a gradient flow of a monotone function, then the space of possible ultraviolet completions of a given low-energy theory is constrained: a candidate completion must have a larger a than the theory it completes, which is a necessary condition that can be checked. That is the reason the theorem is of interest here rather than only in mathematical physics.

Three qualifications must be attached, and the third is the one usually left out.

First, Theorem 108.85 is a statement about flows *between conformal fixed points*. The Standard Model is not such a flow. Its infrared is not a conformal theory: it contains a massless photon and nearly massless neutrinos alongside a gapped strong sector, and its ultraviolet is not a fixed point at all — by Corollary 108.62 the scalar and hypercharge couplings grow and the description fails. The theorem does not apply to the theory this book is about.

Second, the quantity a is not measurable. It is a coefficient in the response of a theory to a background curvature, and no experiment has measured one.

Third, and consequently, no classification of the possible ultraviolet completions of the observed $3 + 1$ Standard Model exists, and none is in prospect. What exists is a theorem about a class of theories to which the Standard Model does not belong, together with the empirical observation of Remark 108.84 that in every examined case the flow has run one way. That is worth recording and it is not worth more than that. It is recorded here rather than in Chapter 133, which lists the measured discrepancies and the one missing existence proof and does not carry the absence of a classification of ultraviolet completions as an entry — correctly, since nothing is measured that such a classification would explain.

Remark 108.87 (What this chapter has and has not established). The measured content is small, sharp and repeatedly confirmed. Two dimensionless couplings of the Standard Model have been watched to change with the energy at which they are measured, in opposite directions and by amounts predicted with no free coefficient (Phenomena 100.62 and 108.56). A critical exponent has been measured to four decimal places against a calculation of comparable precision, and the two do not quite agree (Phenomenon 108.49). The universality of critical behaviour across chemically unrelated systems is explained, not merely described (Corollary 108.44). And an observed number — the neutrino mass — points to a scale fifteen orders of magnitude above the electroweak one, conditionally but for a stated reason (Phenomenon 108.73).

The unmeasured content is larger and should not be confused with the above. The location of any Landau pole is an extrapolation over dozens of decades. The triviality of the scalar sector is a theorem about ϕ^4 in isolation, not about the Standard Model. The cutoff of the Standard Model is unmeasured, and every statement about what lies above it is a statement about a bound on a coefficient divided by a power of a scale. The renormalization group tells one how to be predictive without knowing what lies above; it does not tell one what lies above, and the two must not be traded for one another.

Chapter 109

Axiomatic Quantum Field Theory

Everything the preceding chapters of Part XI compute is perturbative: a formal power series in a coupling, defined by rules whose objects — an interaction picture, a Fock space of free quanta, a product of fields at the same point — do not survive mathematical scrutiny. Haag's theorem [1072] states the sharpest form of the difficulty: no unitary transformation connects a free field to an interacting one in the same Hilbert space, so the interaction picture that generates the whole perturbative apparatus does not exist. Axiomatic quantum field theory is the response. It asks what a relativistic quantum field theory *is*, independently of any Lagrangian or expansion, writes that down as a short list of assumptions — fields as operator-valued distributions on a Hilbert space carrying a positive-energy unitary representation of the Poincaré group, with a unique vacuum and local commutativity [1099, 1297] — and derives consequences.

The chapter earns its place because the consequences are theorems the rest of the book uses as if they were facts of Nature: the PCT theorem [1049, 1115], the spin–statistics connection [854, 1139, 1151] that Chapters 83 and 120 assume throughout, the Källén–Lehmann spectral representation [1003, 1048] that underlies every renormalized propagator in Chapters 100 and 108, the LSZ reduction [1073] that connects fields to the cross-sections of Chapter 86, and the operator product expansion [1410] on which the short-distance analysis of Chapters 102 and 116 rests. It closes honestly: no interacting quantum field theory in $3+1$ dimensions has ever been constructed satisfying these axioms. The constructive successes are in spacetimes of lower dimension [1371, 1500], and the existence of four-dimensional Yang–Mills theory with a mass gap is an open problem carrying a Clay Millennium Prize [2097]. Standing monographs are [1297, 1312, 1792, 1856].

Three analytic facts are used repeatedly below and are *imported*: the Paley–Wiener characterization of the Fourier transforms of functions with support in a cone, the edge-of-the-wedge theorem, and the Bargmann–Hall–Wightman extension theorem [1113]. None is proved in this book, and none is among the results of Chapter 17 or of Chapter 8, whose function theory stops at the residue theorem. Where one of them is used it is named at the point of use, and everything else in the chapter is derived. That bookkeeping is the whole point of an axiomatic chapter: the reader is entitled to know exactly which statements are assumptions, which are imports, and which are consequences.

109.1 Why axioms

109.1.1 Fields as operator-valued distributions

The first axiom is forced by a computation, not chosen for elegance. A quantum field cannot be an operator at a point, because the vector it would produce out of the vacuum has infinite length.

Proposition 109.1 (The field at a point is not an operator)**.** *Let ϕ be a Hermitian scalar field whose two-point function is that of a free field of mass m,*

$$\langle 0|\,\phi(x)\phi(y)\,|0\rangle = \hbar c^2 \int \frac{\mathrm{d}^3k}{(2\pi)^3\,2\omega_{\boldsymbol{k}}}\,\mathrm{e}^{-\mathrm{i}k\cdot(x-y)}\,, \qquad \omega_{\boldsymbol{k}} = c\sqrt{\boldsymbol{k}^2 + \frac{m^2c^2}{\hbar^2}}\,. \tag{109.1}$$

Then $\|\phi(x)\,|0\rangle\|^2 = +\infty$ for every x, while $\|\phi(f)\,|0\rangle\|^2$ is finite for every Schwartz test function f, where $\phi(f) = \int \mathrm{d}^4x\, f(x)\phi(x)$.

Rests on Notation 100.1 and Equation (105.101).

Derivation. Derives Proposition 109.1.

In Equation (109.1) the wave four-vector is $k^\mu = (\omega_{\boldsymbol{k}}/c, \boldsymbol{k})$, of dimension 1/m, so $k\cdot(x-y)$ is a pure number (Notation 100.1); the integral $\int \mathrm{d}^3k/(2\omega_{\boldsymbol{k}})$ carries $\mathrm{s/m^3}$ and the prefactor $\hbar c^2$ turns that into J/m, which is $[\phi]^2$ for a canonically normalized scalar in this book (Equation (105.101)). Setting $y = x$,

$$\|\phi(x)\,|0\rangle\|^2 = \hbar c^2 \int \frac{\mathrm{d}^3k}{(2\pi)^3\,2\omega_{\boldsymbol{k}}} = \frac{\hbar c^2}{(2\pi)^3}\,4\pi \int_0^\infty \frac{k^2\,\mathrm{d}k}{2\omega_k}\,, \tag{109.2}$$

and for $k \gg mc/\hbar$ the integrand is $k^2/(2ck) = k/(2c)$, so the integral diverges as Λ^2 with an ultraviolet cutoff Λ on $|\boldsymbol{k}|$. The divergence is quadratic and no subtraction of a constant removes it.

Smearing repairs it. With f real and $\tilde f(k) = \int \mathrm{d}^4x\, f(x)\mathrm{e}^{\mathrm{i}k\cdot x}$,

$$\|\phi(f)\,|0\rangle\|^2 = \hbar c^2 \int \frac{\mathrm{d}^3k}{(2\pi)^3\,2\omega_{\boldsymbol{k}}}\,\left|\tilde f(k)\right|^2\Big|_{k^0=\omega_{\boldsymbol{k}}/c}\,, \tag{109.3}$$

which converges because $\tilde f$ is Schwartz and therefore decays faster than any power. The physical content is that the divergence in Equation (109.2) is a statement about resolution: the number of modes available below a wavelength λ grows as λ^{-3}, each carries a zero-point amplitude, and a measurement confined to no region at all samples all of them. □

Definition 109.2 (Smeared field and test functions)**.** $\mathcal{S}(\mathbb{R}^4)$ is the Schwartz space of complex functions on Minkowski space, smooth and decaying with all derivatives faster than any power [971, 1276]; the treatment used here is Section 17.2.3. A test function $f \in \mathcal{S}$ is assigned the SI dimension $1/\mathrm{m}^4$, so that

$$\phi(f) := \int \mathrm{d}^4x\, f(x)\,\phi(x) \tag{109.4}$$

carries the dimension of the field itself. A *quantum field* is then a map $f \mapsto \phi(f)$ from $\mathcal{S}(\mathbb{R}^4)$ into (generally unbounded) operators on a Hilbert space, linear in f and continuous in the topology of $\mathcal{S}$: an operator-valued tempered distribution [1099, 1307].

The word *tempered* is not decoration either. A distribution is tempered exactly when its Fourier transform is a distribution of polynomial growth, and the spectrum condition of Axiom 109.10 will be a support statement about that Fourier transform. A field whose smeared correlation functions grew faster than polynomially in momentum would have no spectral condition to satisfy, and the entire analytic apparatus of Section 109.2.3 would be unavailable.

Bohr and Rosenfeld reached the same conclusion from the laboratory rather than from the mathematics [715]. A charged test body used to measure a field has finite extent and finite mass, so what it registers is an average of the field over the spacetime region it occupies during the exposure — exactly Equation (109.4) with f the indicator of that region — and the unavoidable uncertainties of such an apparatus turn out to be precisely those the commutators of the averaged fields demand, neither more nor less. That analysis is carried out for the electromagnetic field in Section 99.7.3; the point to carry forward is that the smearing is a physical prescription and not a mathematical convenience.

Remark 109.3 (What a common dense domain is for). An unbounded operator is not defined on all of a Hilbert space, and a product $\phi(f_1)\phi(f_2)$ makes no sense unless the range of the second lies in the domain of the first. The axioms therefore demand a single dense subspace $D \subset \mathcal{H}$, invariant under every $\phi(f)$ and containing the vacuum, on which all polynomials in the smeared fields are defined. Without it the Wightman functions of Section 109.2.2 would be symbols rather than numbers. The functional analysis of unbounded operators, domains and self-adjointness is standard [1481]; the chapter uses it and does not develop it.

109.1.2 Haag's theorem

Perturbation theory is built on the interaction picture, in which the interacting field at a fixed time is a unitary transform of a free field, so that both live in one Hilbert space and the dynamics is a unitary evolution of free-field states. Haag proved that this cannot happen [1072], and Hall and Wightman sharpened the hypotheses to the form used here [1113]. Theorem 99.53 states the result where it first bites; this is its derivation.

Theorem 109.4 (Haag)**.** *Let ϕ_1, π_1 and ϕ_2, π_2 be two irreducible sets of field and conjugate momentum at the common time $t = 0$, each acting on a Hilbert space carrying a continuous unitary representation of the Euclidean group of space — translations and rotations — with a unique invariant vacuum $|0_1\rangle$, $|0_2\rangle$. Suppose there is a unitary V with*

$$\phi_2(0,\boldsymbol{x}) = V\,\phi_1(0,\boldsymbol{x})\,V^{-1}\,, \qquad \pi_2(0,\boldsymbol{x}) = V\,\pi_1(0,\boldsymbol{x})\,V^{-1}\,, \tag{109.5}$$

intertwining the two representations of the Euclidean group. Then all equal-time vacuum expectation values of the two fields coincide. If in addition both theories are Poincaré covariant with spectrum in the forward cone and ϕ_1 is a free field of mass m, then ϕ_2 is a free field of the same mass.

Rests on Equation (109.1) and Theorems 109.21 and 109.26.

Derivation. *Derives Theorem 109.4.*

Step 1: the vacuum goes to the vacuum. Let E denote the Euclidean group of space and $U_i(R,\boldsymbol{a})$ its representation on $\mathcal{H}_i$. By hypothesis $VU_1V^{-1} = U_2$. Then $V\,|0_1\rangle$ is invariant under U_2, because $U_2V\,|0_1\rangle = VU_1\,|0_1\rangle = V\,|0_1\rangle$. Uniqueness of the invariant vector in theory 2 forces

$$V\,|0_1\rangle = \mathrm{e}^{\mathrm{i}\theta}\,|0_2\rangle\,, \qquad \theta \in \mathbb{R}\,. \tag{109.6}$$

Step 2: all equal-time correlators coincide. Let A_1 be any polynomial in the smeared $\phi_1(0,\cdot)$ and $\pi_1(0,\cdot)$, and A_2 the same polynomial in ϕ_2, π_2. Conjugating Equation (109.5) term by term gives $A_2 = VA_1V^{-1}$, and with Equation (109.6) the phases cancel between bra and ket:

$$\langle 0_2|\,A_2\,|0_2\rangle = \langle 0_1|\,V^{-1}VA_1V^{-1}V\,|0_1\rangle = \langle 0_1|\,A_1\,|0_1\rangle\,. \tag{109.7}$$

This holds to all orders and is the whole content of unitary equivalence: a unitary preserves every expectation value, so the two theories are indistinguishable by any equal-time measurement.

Step 3: the equal-time two-point function knows the mass. For a free field of mass m, set $x^0 = y^0$ in Equation (109.1):

$$\langle 0|\,\phi(0,\boldsymbol{x})\phi(0,\boldsymbol{y})\,|0\rangle = \hbar c^2 \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\frac{\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{y})}}{2c\sqrt{\boldsymbol{k}^2 + m^2c^2/\hbar^2}}\,. \tag{109.8}$$

The right-hand side is the Fourier transform of $\hbar c/(2\sqrt{\boldsymbol{k}^2 + m^2c^2/\hbar^2})$, and two different masses give two different functions of $\boldsymbol{k}$ — they already differ at $\boldsymbol{k} = 0$, where the value is $\hbar^2/(2m)$ — of dimension $\mathrm{J\,m^2}$, as it must be to produce J/m against the measure $\mathrm{d}^3k/(2\pi)^3$. Fourier inversion is injective, so Equation (109.8) determines m.

Step 4: from equal times to all times. By Step 2 the equal-time correlators of ϕ_2 are those of a free field of mass m, and by Step 3 that mass is m_1. A free field is Gaussian: all its correlators are sums of products of two-point functions, so *all* equal-time correlators of ϕ_2 agree with the free ones. The remaining step promotes this to all times. Poincaré covariance determines $\phi_2(x^0, \boldsymbol{x})$ from its restriction to $x^0 = 0$ together with π_2, because a boost mixes the time argument into the spatial ones and the Wightman functions are boundary values of functions analytic in the tube domain of Theorem 109.26, which are fixed by their values on a real neighbourhood. Hall and Wightman carried this out [1113]; the conclusion is that every W_n of theory 2 is the free one, and by the reconstruction theorem Theorem 109.21 the theory itself is free. □

Corollary 109.5 (The interaction picture does not exist)**.** *There is no unitary operator relating the fields of an interacting theory at a fixed time to those of a free theory in the same Hilbert space. Equivalently, the two representations of the canonical commutation relations are unitarily inequivalent, and the interacting vacuum is not a vector in the free theory's Fock space.*

Rests on Theorem 109.4.

Derivation. *Derives Corollary 109.5.*

Immediate from Theorem 109.4: if such a V existed the interacting theory would be free. The second sentence is the same statement in representation-theoretic language — Stone–von Neumann uniqueness holds for finitely many canonical pairs and fails for infinitely many, and quantum field theory has infinitely many. The mechanism is developed for the free field itself in Section 99.9.1, whose warning about the choice of Fock space this corollary makes precise. □

Remark 109.6 (What practitioners actually do, and what it costs)*.* Every one of Haag's hypotheses is violated in a real calculation, and each violation is the point of the corresponding device.

A momentum cutoff destroys Lorentz covariance and, with it, Step 4. *A finite volume* destroys translation invariance and with it Step 1, since a box has no unique translation-invariant state in the required sense. *Adiabatic switching*, in which the coupling is multiplied by a function $g(t)$ that vanishes as $t \to \pm\infty$, destroys time-translation invariance and hence the identification of an interacting vacuum at all. *Dimensional regularization* changes the dimension of spacetime, so the theorem as stated does not apply.

What is lost is the meaning of the limit. Each regularized theory is perfectly consistent and Haag's theorem says nothing about it; the difficulty is that the objects the regularization is supposed to approximate — an interacting field with a Poincaré-invariant vacuum in $3+1$ dimensions — are not known to exist. Perturbation theory is therefore an asymptotic construction: a recipe generating a formal power series whose terms are finite after renormalization (Chapter 100) and whose sum is believed to diverge [998]. That the first few terms of that series reproduce the electron's anomalous moment to about one part in 10^9 of a_e — the limit set by the independent determinations of α that the series must be fed, not by the measurement, as Chapter 112 is at pains to establish — is the strongest evidence available that the series is computing something real. It is not a proof that the something exists.

109.1.3 What axiomatization is for

An axiom system supports two quite different claims, and confusing them is the commonest error made about this subject.

The first is *conditional*: if a structure satisfying the axioms exists, then it has such and such properties. Every theorem of Section 109.3 is of this kind. *PCT* invariance,

spin–statistics, the Källén–Lehmann representation and the Reeh–Schlieder theorem are consequences of the axioms and therefore hold in *every* theory satisfying them, whatever its Lagrangian, whatever its particle content, to all orders and beyond all orders. That is a far stronger statement than any perturbative calculation can make, and it is why a measured violation of PCT would not be a discovery of a new particle but a refutation of locality, of Lorentz invariance, or of the positivity of the energy (Section 105.5.2).

The second is *existential*: a structure satisfying the axioms exists. Here axiomatic quantum field theory has almost nothing to offer in $3+1$ dimensions. No interacting example is known (Section 109.7), and for the simplest candidate — a single self-interacting scalar — the evidence points the other way (Section 109.7.2).

Remark 109.7 (The model-theoretic parallel, and its limits). The distinction is the one drawn in Section 3.8 between what a formal system proves and whether it has a model. A consistent first-order theory has a model, by completeness; but consistency itself is not provable from within (Theorem 3.88), and the existence question for a physical theory is harder still, because the Wightman axioms are not a first-order theory — they quantify over Hilbert spaces, operator domains and distributions, all of which are higher-order objects. Definition 3.82 does not apply to them, and no completeness theorem is available. The parallel is therefore an analogy about the *shape* of the two questions and not a transfer of results: nobody has shown that constructing a four-dimensional interacting field theory is undecidable, and nobody should say so.

The position taken in this book follows from the distinction. A theorem derived from the axioms is treated as a statement about all field theories and quoted as such throughout Part XI. A perturbative calculation is treated as a computation within a scheme, whose agreement with experiment is evidence for the scheme and not a proof of anything. And the fact that the Standard Model, the most accurately tested theory in physics, is not known to exist as a mathematical object is recorded in Section 109.7.4 as what it is: an open problem, not a technicality.

109.2 The Wightman axioms

109.2.1 Statement of the axioms

The axioms below are those of [1099], in the form given by Streater and Wightman [1297], with every dimensioned quantity carried in SI. They are stated for a single Hermitian scalar field; the extension to several fields and to fields carrying Lorentz indices is notational and is indicated in Remark 109.16.

Notation 109.8 (Conventions of this chapter). The metric, coordinates and momenta are those of Notation 100.1: $\eta_{\mu\nu}=\mathrm{diag}(+1,-1,-1,-1)$, $x^\mu=(ct,\boldsymbol{x})$ of dimension m, $p^\mu=(E/c,\boldsymbol{p})$ of dimension $\mathrm{kg\,m/s}$, and $k^\mu=p^\mu/\hbar$ of dimension $1/\mathrm{m}$. The closed forward cone in momentum space is

$$\overline{V}^{+}:=\left\{p\in\mathbb{R}^4:\ p\cdot p\geq 0 \text{ and } p^0\geq 0\right\}, \tag{109.9}$$

and V^+ is its interior. The corresponding cone in coordinate space, written $\overline{V}^{+}_{x}$, is the same set with m in place of $\mathrm{kg\,m/s}$. A scalar field is normalized so that $[\phi]^2=\mathrm{J/m}$, as in Chapter 99. $\mathcal{H}$ denotes the Hilbert space and $D\subset\mathcal{H}$ the common dense domain of Remark 109.3.

Axiom 109.9 (Relativistic states)**.** The states of the theory are the rays of a separable Hilbert space $\mathcal{H}$, on which there is a continuous unitary representation $U(a,\Lambda)$ of the universal covering group $\widetilde{\mathcal{P}}^{\uparrow}_{+}$ of the proper orthochronous Poincaré group (Definition 39.5), with a

a translation of dimension m. Translations are generated by four commuting self-adjoint operators P^μ of dimension kg m/s,

$$U(a,\mathbb{1}) = \exp\!\left(\frac{\mathrm{i}}{\hbar}\, a^\mu P_\mu\right) , \tag{109.10}$$

the exponent being dimensionless because $\hbar$ has the dimension of m × kg m/s.

Axiom 109.10 (Spectrum condition)**.** The joint spectrum of (P^0, P^1, P^2, P^3) is contained in $\overline{V}^+$. Physically: no state has negative energy in any inertial frame, and no state has spacelike four-momentum.

Axiom 109.11 (Unique vacuum)**.** There is a vector $|0\rangle \in D$, unique up to phase, invariant under every $U(a,\Lambda)$. It is the only eigenvector of P^μ with eigenvalue zero.

Axiom 109.12 (Fields)**.** There is a map $f \mapsto \phi(f)$ from $\mathcal{S}(\mathbb{R}^4)$ into operators defined on D, linear in f, with $\phi(f)D \subset D$ and $|0\rangle \in D$, such that $f \mapsto \langle\Psi|\,\phi(f)\,|\Psi'\rangle$ is a tempered distribution for every $\Psi, \Psi' \in D$, and $\phi(f)^\dagger \supset \phi(\bar f)$ on D.

Axiom 109.13 (Covariance)**.** For all (a,Λ) and all f,

$$U(a,\Lambda)\,\phi(f)\,U(a,\Lambda)^{-1} = \phi\Big(f_{(a,\Lambda)}\Big) , \qquad f_{(a,\Lambda)}(x) := f\Big(\Lambda^{-1}(x-a)\Big) , \tag{109.11}$$

which is the smeared form of $U\phi(x)U^{-1} = \phi(\Lambda x + a)$.

Axiom 109.14 (Local commutativity)**.** If the supports of f and g are spacelike separated — every point of one is at spacelike interval from every point of the other — then

$$[\phi(f), \phi(g)] = 0 \tag{109.12}$$

on D. For a field of half-integer spin the commutator is replaced by the anticommutator; that this replacement is forced and not chosen is Theorem 109.49.

Axiom 109.15 (Cyclicity of the vacuum)**.** The set of vectors $\phi(f_1)\cdots\phi(f_n)\,|0\rangle$, over all n and all test functions, spans a dense subspace of $\mathcal{H}$.

Remark 109.16 (Several fields, and fields with indices). For a finite collection ϕ_j carrying a finite-dimensional representation $S(\Lambda)$ of the covering group $\mathrm{SL}(2,\mathbb{C})$ of the Lorentz group, Equation (109.11) acquires the matrix $S(\Lambda)^{-1}_{jk}$ and Equation (109.12) is imposed on every pair, with the commutator for tensor fields and the anticommutator for spinor fields. Nothing else changes, and no theorem below depends on the number of fields. Two different pieces of representation theory are involved and it is worth keeping them apart. Chapter 94 classifies the *unitary* representations of the Poincaré group by Wigner's method — the Casimirs, the orbits, the little groups, massive spin and massless helicity — which is what labels the one-particle states; the general apparatus behind it is Chapters 5 and 14, and $\mathrm{SL}(2,\mathbb{C})$ appears there as the universal cover. What $S(\Lambda)$ carries is the other object: the *finite-dimensional*, necessarily non-unitary representations of $\mathrm{SL}(2,\mathbb{C})$, labelled by a pair of half-integers (A,B) and built as tensor products of the fundamental and its conjugate. That classification is not derived anywhere in this book; it is used below only through the index count of Theorem 109.49, where a field in the (A,B) representation carries $2A$ undotted and $2B$ dotted spinor indices.

Remark 109.17 (Reading this chapter against the literature). The monographs [1297, 1312, 1856] all work in units in which $\hbar$ and c are numerically one, and in that convention the exponent of Equation (109.10) is $\mathrm{i}a\cdot P$ and momenta, wave vectors and inverse lengths are the same quantity. The rule for reading their formulas here is the one already given in

Remark 100.4: a momentum p becomes $p/\hbar$ wherever it multiplies a coordinate, a mass m becomes mc wherever it stands beside a momentum and mc^2 wherever it stands beside an energy, and the spectral variable s of Section 109.3.3 is a squared momentum, $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$, rather than a squared mass. No derivation in this chapter is carried out in those units; this remark exists so that the reader can check the chapter against its sources.

Remark 109.18 (What is deliberately absent). Three things a physicist expects are not axioms. There is no Lagrangian, no equation of motion and no coupling constant: the axioms describe a theory, not a way of constructing one. There is no requirement that the theory have particles — the existence of one-particle states is an additional assumption, made in Section 109.3.4 and known to fail for the electron in quantum electrodynamics, where the charged states are infraparticles [1684]. And there is no assumption of *asymptotic completeness*, that the scattering states span the whole Hilbert space; it is an extra hypothesis, not a theorem, and it has never been verified in an interacting four-dimensional model.

109.2.2 Wightman functions and reconstruction

The axioms are about operators, which are hard to handle. Their entire content can be repackaged as a sequence of ordinary distributions, and this is what makes the subject tractable.

Definition 109.19 (Wightman functions)**.** The *Wightman functions* of the theory are the vacuum expectation values

$$W_n(x_1,\dots,x_n) := \langle 0|\,\phi(x_1)\cdots\phi(x_n)\,|0\rangle\ , \tag{109.13}$$

understood as tempered distributions: the number attached to test functions $f_1,\dots,f_n$ is $\langle 0|\,\phi(f_1)\cdots\phi(f_n)\,|0\rangle$, with $W_0 = 1$. Each W_n carries the SI dimension $(\mathrm{J/m})^{n/2}$, that is $[\phi]^n$.

Proposition 109.20 (Properties of the Wightman functions)**.** *The Wightman functions of a theory satisfying Axioms 109.9 to 109.15 satisfy:*

1. ***Temperedness.*** *Each W_n is a tempered distribution on $\mathbb{R}^{4n}$.*
2. ***Covariance.*** $W_n(\Lambda x_1 + a,\dots,\Lambda x_n + a) = W_n(x_1,\dots,x_n)$.
3. ***Spectral support.*** *W_n depends only on the differences $\xi_j = x_j - x_{j+1}$, and the Fourier transform of W_n in those differences is supported in $\overline{V}^+ \times\cdots\times \overline{V}^+$ ($n-1$ factors).*
4. ***Locality.*** *If x_j and x_{j+1} are spacelike separated, W_n is unchanged by exchanging them.*
5. ***Positivity.*** *For any finite sequence of test functions $f_0 \in \mathbb{C}$, $f_1 \in \mathcal{S}(\mathbb{R}^4)$, $f_2 \in \mathcal{S}(\mathbb{R}^8),\dots,$*

$$\sum_{m,n\geq 0} \int \mathrm{d}^{4m}x\ \mathrm{d}^{4n}y\ \overline{f_m(x_1,\dots,x_m)}\, W_{m+n}(x_m,\dots,x_1,y_1,\dots,y_n)\, f_n(y_1,\dots,y_n)\ \geq\ 0\,. \tag{109.14}$$

6. ***Hermiticity.*** $\overline{W_n(x_1,\dots,x_n)} = W_n(x_n,\dots,x_1)$.

Rests on Axioms 109.9 to 109.14.

Derivation. *Derives Proposition 109.20.*

(i) is Axiom 109.12 applied to the vector $\phi(f_2)\cdots\phi(f_n)\,|0\rangle$.

(ii) Insert $U^{-1}U$ between every pair of fields in Equation (109.13), use Equation (109.11) n times, and use $U\,|0\rangle = |0\rangle$ from Axiom 109.11.

(iii) Translation invariance is the $\Lambda = \mathbb{1}$ case of (ii) and gives the dependence on differences alone. For the support statement, write $\phi(x_j) = U(x_j)\phi(0)U(x_j)^{-1}$ with $U(a) = \exp(\mathrm{i}a\cdot P/\hbar)$ from Equation (109.10); then

$$W_n = \langle 0|\, \phi(0)\, \mathrm{e}^{-\mathrm{i}\xi_1\cdot P/\hbar}\, \phi(0) \cdots \mathrm{e}^{-\mathrm{i}\xi_{n-1}\cdot P/\hbar}\, \phi(0)\, |0\rangle \ , \tag{109.15}$$

using $P^\mu\,|0\rangle = 0$ at both ends. Each factor $\mathrm{e}^{-\mathrm{i}\xi\cdot P/\hbar}$ contributes, by the spectral theorem for the commuting family P^μ, a Fourier transform supported where the spectral measure lives, and Axiom 109.10 confines that to $\overline{V}^+$. Explicitly, with $\tilde{W}_n$ the transform in the variables ξ_j,

$$\tilde{W}_n(q_1, \dots, q_{n-1}) = 0 \quad \text{unless} \quad q_j \in \overline{V}^+ \ \forall j \, . \tag{109.16}$$

(iv) is Axiom 109.14 sandwiched between the vacuum and the remaining fields.

(v) The left-hand side of Equation (109.14) is $\|\Psi\|^2$ for $\Psi = \sum_n \int \mathrm{d}^{4n}y\, f_n(y)\phi(y_1)\cdots\phi(y_n)\,|0\rangle$, a vector in $\mathcal{H}$ by Axiom 109.12. A squared norm is non-negative; that is the whole derivation, and it is worth stressing that *positivity of the Wightman functions is the positivity of the Hilbert-space metric and nothing else.* The same statement reappears in Euclidean dress as reflection positivity in Section 109.5.1.

(vi) follows from $\phi(f)^\dagger \supset \phi(\bar{f})$ and $\overline{\langle 0|\, A\,|0\rangle} = \langle 0|\, A^\dagger\,|0\rangle$. □

The remarkable fact is that these six properties are not merely necessary but sufficient. Nothing is lost in passing from operators to distributions.

Theorem 109.21 (Wightman reconstruction)**.** *Let $\{W_n\}_{n\ge 0}$ be a family of tempered distributions satisfying (i)–(vi) of Proposition 109.20. Then there exist a separable Hilbert space $\mathcal{H}$, a continuous unitary representation $U(a,\Lambda)$ with spectrum in $\overline{V}^+$, a vector $|0\rangle$ and a field ϕ satisfying all the axioms, whose Wightman functions are the given W_n; and the construction is unique up to unitary equivalence [1099].*

Rests on Definition 109.19 and Proposition 109.20.

Derivation. *Derives Theorem 109.21.*

The construction is the same one that will reappear as the GNS construction in Section 109.4.2, and it is worth doing once by hand.

The algebra. Let $\mathfrak{B}$ be the set of terminating sequences $\mathsf{f} = (f_0, f_1, f_2, \dots)$ with $f_0 \in \mathbb{C}$ and $f_n \in \mathcal{S}(\mathbb{R}^{4n})$, made into an associative algebra by

$$(\mathsf{f}\,\mathsf{g})_n(x_1, \dots, x_n) = \sum_{j+k=n} f_j(x_1, \dots, x_j)\, g_k(x_{j+1}, \dots, x_n) \, , \tag{109.17}$$

with the involution $(\mathsf{f}^*)_n(x_1, \dots, x_n) = \overline{f_n(x_n, \dots, x_1)}$. This is the Borchers tensor algebra; the unit is $(1, 0, 0, \dots)$.

The linear functional. Define $w(\mathsf{f}) := \sum_n \int \mathrm{d}^{4n}x\, W_n(x) f_n(x)$, which converges because the sequence terminates. Property (vi) says $w(\mathsf{f}^*) = \overline{w(\mathsf{f})}$, and property (v) says exactly

$$w(\mathsf{f}^*\mathsf{f}) \ge 0 \qquad \text{for every } \mathsf{f} \in \mathfrak{B} \, . \tag{109.18}$$

The Hilbert space. Put $\langle \mathsf{f}, \mathsf{g}\rangle := w(\mathsf{f}^*\mathsf{g})$. This is a sesquilinear form, non-negative by Equation (109.18), hence obeying the Cauchy–Schwarz inequality $|\langle \mathsf{f}, \mathsf{g}\rangle|^2 \le \langle \mathsf{f}, \mathsf{f}\rangle\, \langle \mathsf{g}, \mathsf{g}\rangle$. Therefore $\mathfrak{N} := \{\mathsf{f} : w(\mathsf{f}^*\mathsf{f}) = 0\}$ is a linear subspace, and by Cauchy–Schwarz it is a left ideal:

product, and D the image of $\mathfrak{B}$, dense by construction.

The field. For $f \in \mathcal{S}(\mathbb{R}^4)$ let $\mathsf{f}^{(1)} = (0, f, 0, \dots)$ and define $\phi(f)[\mathsf{g}] := [\mathsf{f}^{(1)}\mathsf{g}]$. This is well defined because $\mathfrak{N}$ is a left ideal, maps D into D, is linear in f, and satisfies $\langle \mathsf{g}, \phi(f)\mathsf{h}\rangle = \big\langle \phi(\bar{f})\mathsf{g}, \mathsf{h}\big\rangle$ by the definition of the involution — which is Axiom 109.12. The

vacuum is $|0\rangle := [(1,0,\dots)]$, and cyclicity Axiom 109.15 holds because $\mathfrak{B}$ is generated by the $\mathsf{f}^{(1)}$.

The symmetry. Property (ii) says the form $\langle\cdot,\cdot\rangle$ is invariant under the action of (a,Λ) on test functions given by Equation (109.11). An invariant form induces an isometry of the quotient, and an isometry of a dense subspace extends to a unitary $U(a,\Lambda)$ on $\mathcal{H}$; the group law is inherited from the action on test functions. Continuity follows from continuity of that action in $\mathcal{S}$ together with temperedness (i), and Stone's theorem then supplies the self-adjoint generators P^μ of Equation (109.10). Property (iii) says the spectral measure of P^μ is supported in $\overline{V}^+$, which is Axiom 109.10; property (iv) gives Axiom 109.14.

Uniqueness. If two constructions $(\mathcal{H},\phi,|0\rangle)$ and $(\mathcal{H}',\phi',|0\rangle')$ have the same W_n, the map $\phi(f_1)\cdots\phi(f_n)\,|0\rangle \mapsto \phi'(f_1)\cdots\phi'(f_n)\,|0\rangle'$ preserves inner products by hypothesis, is defined on a dense set by cyclicity, and therefore extends to a unitary intertwining the two theories. □

Remark 109.22 (What the reconstruction theorem is worth)*.* It converts an existence problem about operators into an existence problem about distributions, which is the form every constructive attempt takes: build a family of W_n — or, in Section 109.5, a family of Euclidean S_n — verify six properties, and the theory follows. It also explains why Theorem 109.4 bites so hard: the Wightman functions are the theory, so two theories with the same correlators are the same theory, and no amount of reinterpretation can make one interacting and the other free.

Proposition 109.23 (Uniqueness of the vacuum equals clustering)**.** *Let the axioms hold except possibly Axiom 109.11, and let $|0\rangle$ be a translation-invariant unit vector. Then $|0\rangle$ is the* unique *such vector if and only if the Wightman functions cluster: for any spacelike a and any m,n,*

$$\lim_{\lambda\to\infty} W_{m+n}(x_1,\dots,x_m,y_1+\lambda a,\dots,y_n+\lambda a) = W_m(x_1,\dots,x_m)\,W_n(y_1,\dots,y_n)\,. \tag{109.19}$$

Rests on Axioms 109.9 and 109.10 and Theorem 109.26.

Derivation. *Derives Proposition 109.23.*

Write $A=\phi(x_1)\cdots\phi(x_m)$ and $B=\phi(y_1)\cdots\phi(y_n)$, so the left-hand side of Equation (109.19) is $\langle 0|\,A\,U(\lambda a)\,B\,|0\rangle$ with $U(\lambda a)=\exp(\mathrm{i}\lambda a\cdot P/\hbar)$. Let $E(\mathrm{d}^4p)$ be the joint spectral measure of P^μ and let E_0 be the projector onto the eigenvalue $p=0$. Then

$$\langle 0|\,A\,U(\lambda a)\,B\,|0\rangle = \langle 0|\,AE_0B\,|0\rangle + \int_{\overline{V}^+\setminus\{0\}} \mathrm{e}^{\mathrm{i}\lambda a\cdot p/\hbar}\;\langle 0|\,A\,E(\mathrm{d}^4p)\,B\,|0\rangle\;. \tag{109.20}$$

Two things must now be established: that the only atom of the spectral measure sits at $p=0$, and that the remaining integral vanishes in the limit. The first is a derivation and is where the physics is.

The only eigenvalue of P^μ is zero. Suppose $P^\mu|\chi\rangle = p^\mu|\chi\rangle$ with $p\neq 0$ and $p\in\overline{V}^+$. For every Λ in the proper orthochronous group the vector $U(0,\Lambda)\,|\chi\rangle$ is again an eigenvector, with eigenvalue Λp, and two eigenvectors of a self-adjoint family with different eigenvalues are orthogonal. The orbit $\{\Lambda p\}$ of a non-zero $p\in\overline{V}^+$ is an entire mass hyperboloid or half of the light cone — in either case an uncountable set — so $\mathcal{H}$ would contain an uncountable orthonormal family and could not be separable, contradicting Axiom 109.9. Hence the spectral measure has no atom away from the origin, and E_0 projects onto the translation-invariant vectors.

The oscillatory term vanishes. The remaining integral is the Fourier transform of a finite complex measure supported in $\overline{V}^+\setminus\{0\}$, evaluated along the spacelike ray λa. That it tends to zero is the content of the cluster theorem of [1297]: the measure has been shown to be non-atomic, so a Riemann–Lebesgue argument gives the vanishing of its transform in

the mean, and analyticity in the tube of Theorem 109.26 upgrades the mean convergence to a genuine limit, exponential with rate $\Delta/(\hbar c)$ when the spectrum has a gap Δ above the vacuum and power-law otherwise. That upgrade is the imported half of this proposition; the atom analysis above is the half that carries the physical content.

Granting it, if the vacuum is unique then $E_0 = |0\rangle\langle 0|$ and the surviving term is $W_m W_n$, which is Equation (109.19). Conversely, if Equation (109.19) holds then $\langle 0|\, A E_0 B\, |0\rangle = \langle 0|\, A\, |0\rangle\, \langle 0|\, B\, |0\rangle$ for all local A, B; since the vacuum is cyclic these exhaust a dense set, so $E_0 = |0\rangle\langle 0|$, which says precisely that the only translation-invariant vector is $|0\rangle$. □

Remark 109.24 (Why clustering is the physically meaningful form). Equation (109.19) says that two experiments performed far apart in space are statistically independent, which is a precondition for doing physics at all: a laboratory result must not depend on the contents of a distant galaxy. That this is *equivalent* to uniqueness of the vacuum is the reason a theory with several vacua — a spontaneously broken theory, Section 104.3 — must be decomposed into superselection sectors before it can be interpreted, each sector having one vacuum and clustering within itself. The algebraic version of that decomposition is Section 109.4.2. The convergence is not uniform in m and n and the rate depends on the mass gap: with a gap Δ the approach is exponential, with correlation length $\hbar c/\Delta$, and in a massless theory it is only power-law.

109.2.3 Analyticity and the Wightman–Hall domain

Everything sharp in this subject comes from one observation: the spectrum condition is a statement about the support of a Fourier transform, and a support condition makes a function analytic. This is where the theorems of Section 109.3 come from.

Lemma 109.25 (Positivity of the cone pairing). *If $q \in \overline{V}^+$ and $\eta \in V^+$, then $q \cdot \eta \geq 0$, with equality only for $q = 0$. The statement uses only the shape of the cones and not the scale of either vector, so it holds verbatim with q in the momentum cone and η in the coordinate cone V_x^+ of Notation 109.8 — which is how Theorem 109.26 applies it, the product $q \cdot \eta$ then carrying* $\mathrm{J}\,\mathrm{s} = [\hbar]$.

Rests on Notation 109.8.

Derivation. *Derives Lemma 109.25.*

Since $\eta \in V^+$ has $\eta \cdot \eta > 0$ and $\eta^0 > 0$, choose the frame in which $\boldsymbol{\eta} = 0$, so $\eta = (\eta^0, \mathbf{0})$ with $\eta^0 > 0$; this is possible by a proper orthochronous transformation, which preserves the pairing. Then $q \cdot \eta = q^0 \eta^0$, and $q \in \overline{V}^+$ gives $q^0 \geq |\boldsymbol{q}| \geq 0$. Hence $q \cdot \eta \geq 0$, and it vanishes only if $q^0 = 0$, which with $q^0 \geq |\boldsymbol{q}|$ forces $q = 0$. □

Theorem 109.26 (Analyticity in the forward tube). *Let W_n satisfy Equation (109.16). Define the* forward tube

$$\mathcal{T}_{n-1} := \left\{ (\zeta_1, \dots, \zeta_{n-1}) \in \mathbb{C}^{4(n-1)} :\ \zeta_j = \xi_j - \mathrm{i}\eta_j,\ \eta_j \in V_x^+ \right\}. \tag{109.21}$$

Then W_n is the boundary value, as $\eta_j \to 0$ from inside the cone, of a function $\mathcal{W}_n$ holomorphic in $\mathcal{T}_{n-1}$.

Rests on Equation (109.16) and Lemma 109.25.

Derivation. *Derives Theorem 109.26.*

Write the inverse transform of Equation (109.16),

$$\mathcal{W}_n(\zeta_1, \dots, \zeta_{n-1}) = \int \prod_j \frac{\mathrm{d}^4 q_j}{(2\pi\hbar)^4}\, \tilde{W}_n(q_1, \dots, q_{n-1}) \exp\left(-\frac{\mathrm{i}}{\hbar} \sum_j q_j \cdot \zeta_j \right). \tag{109.22}$$

With $\zeta_j = \xi_j - \mathrm{i}\eta_j$ the exponent is

$$-\frac{\mathrm{i}}{\hbar}\sum_j q_j \cdot \xi_j - \frac{1}{\hbar}\sum_j q_j \cdot \eta_j \,,$$

whose real part is $-\hbar^{-1}\sum_j q_j\cdot\eta_j$. By Lemma 109.25 each term is non-negative on the support of $\tilde{W}_n$ and grows linearly with $|q_j|$ when η_j is in the open cone, so the exponential decays exponentially in $|q_j|$. Since $\tilde{W}_n$ is a tempered distribution — of at most polynomial growth — the integral converges absolutely, and it converges together with all its ζ-derivatives; the integrand is holomorphic in each ζ_j in the region where the decay holds, so Equation (109.22) defines a holomorphic function there. Letting $\eta_j \to 0$ recovers W_n in the sense of distributions.

Two remarks on rigour. That a tempered distribution supported in a cone has a Fourier–Laplace transform holomorphic in the dual cone is the Paley–Wiener–Schwartz theorem, imported here and not proved; what Lemma 109.25 supplies is the identification of the dual cone, and that is the geometric content. The factors of $\hbar$ are forced: $q\cdot\zeta$ has dimension $\mathrm{kg\,m^2/s} = \mathrm{J\,s}$, so it is $q\cdot\zeta/\hbar$ that is a phase, and each four-dimensional momentum measure carries $(2\pi\hbar)^{-4}$ exactly as in the loop integrals of Chapter 100. □

The tube is a domain of holomorphy in the difference variables, but it contains no real points: setting $\eta_j = 0$ lands on the boundary. Lorentz covariance enlarges it until it does.

Definition 109.27 (The complex Lorentz group)**.** $L(\mathbb{C})$ is the set of complex 4×4 matrices Λ with $\Lambda^{\mathsf{T}}\eta\Lambda = \eta$, and $L_+(\mathbb{C})$ the subgroup with $\det\Lambda = +1$. The *extended tube* $\mathcal{T}'_{n-1}$ is the union of the images $\Lambda\mathcal{T}_{n-1}$ over $\Lambda \in L_+(\mathbb{C})$, acting simultaneously on all $n-1$ difference variables.

Theorem 109.28 (Bargmann–Hall–Wightman; imported)**.** *The holomorphic function $\mathcal{W}_n$ of Theorem 109.26 extends to a single-valued holomorphic function on the extended tube $\mathcal{T}'_{n-1}$, and satisfies there*

$$\mathcal{W}_n(\Lambda\zeta_1,\dots,\Lambda\zeta_{n-1}) = \mathcal{W}_n(\zeta_1,\dots,\zeta_{n-1})\,, \qquad \Lambda \in L_+(\mathbb{C})\,, \tag{109.23}$$

for a scalar field; for a field carrying a finite-dimensional representation S of $\mathrm{SL}(2,\mathbb{C})$ the right-hand side is multiplied by $S(\Lambda)$ analytically continued in the group parameters [1113].

Rests on Theorem 109.26, Definition 109.27, and Proposition 109.20.

Status. *Derives Theorem 109.28.*

Not proved here. The content is that real Lorentz covariance, Proposition 109.20(ii), plus holomorphy in the tube force covariance under the complexified group, and that the extension is single-valued — the delicate point, since $L_+(\mathbb{C})$ is not simply connected and the naive continuation could be multiple-valued. The proof is in [1113] and [1297, Ch. 2]. □

Derivation pending #182

The Bargmann–Hall–Wightman extension theorem: that the holomorphic Wightman function on the forward tube extends single-valuedly to the extended tube and is covariant under the complex Lorentz group; together with Jost's characterization of the real points of that extended tube as the totally spacelike configurations, stated below. These are the substantial analytic imports of the chapter and belong in Appendix A, together with the Paley–Wiener–Schwartz theorem and the edge-of-the-wedge theorem they use. Everything the chapter derives from them is derived explicitly in the text, and the non-emptiness of the set of real points is derived below.

The gain is that the extended tube contains real points, and they are exactly the totally spacelike ones.

Definition 109.29 (Jost points)**.** A real configuration $(\xi_1, \dots, \xi_{n-1})$ is a *Jost point* if every convex combination $\sum_j \lambda_j \xi_j$ with $\lambda_j \geq 0$ and $\sum_j \lambda_j > 0$ is spacelike, $\left(\sum_j \lambda_j \xi_j\right)^2 < 0$.

Theorem 109.30 (Jost; imported)**.** *The real points of the extended tube $\mathcal{T}'_{n-1}$ are exactly the Jost points [1115, 1297]. In particular the set of Jost points is open and non-empty.*

Rests on Definitions 109.27 and 109.29.

Proposition 109.31 (Jost points exist)**.** *For every $n \geq 2$ the set of Jost points in the difference variables is a non-empty open subset of $\mathbb{R}^{4(n-1)}$.*

Rests on Definition 109.29.

Derivation. *Derives Proposition 109.31.*

Take all ξ_j equal to a fixed purely spatial vector, $\xi_j = (0, \boldsymbol{d})$ with $\boldsymbol{d} \neq 0$. Then $\sum_j \lambda_j \xi_j = (0, (\sum \lambda_j)\boldsymbol{d})$ is spacelike whenever $\sum \lambda_j > 0$, so the configuration is a Jost point. Openness: the condition in Definition 109.29 need only be checked on the compact simplex $\sum \lambda_j = 1$, $\lambda_j \geq 0$, where $(\sum \lambda_j \xi_j)^2$ is a continuous function of (λ, ξ) attaining a strictly negative maximum; a small perturbation of ξ keeps it negative. □

Remark 109.32 (Why Jost points are the right real points). The Jost condition says more than that each ξ_j is spacelike: it says that the whole configuration is spacelike *simultaneously*, so that all n points $x_1, \dots, x_n$ lie at mutually spacelike separation and can be put on one spacelike hyperplane. That is exactly where Axiom 109.14 lets fields be permuted freely. Locality is thus an input *on the real boundary*, analyticity carries it into the complex domain, and the identity theorem carries the consequence back out to configurations that are not spacelike at all. Every theorem in Section 109.3 has this shape, and it is the reason a statement about the periodic table can rest on a statement about complex rotations.

109.2.4 The Reeh–Schlieder theorem

Cyclicity of the vacuum, Axiom 109.15, is stated for fields smeared over all of spacetime. The following theorem says that an arbitrarily small open region suffices, which is far from obvious and has consequences out of all proportion to the length of its proof.

Definition 109.33 (Local polynomial algebra)**.** For an open region $\mathcal{O} \subset \mathbb{R}^4$, let $\mathcal{P}(\mathcal{O})$ be the algebra of polynomials in the smeared fields $\phi(f)$ with $\operatorname{supp} f \subset \mathcal{O}$.

Theorem 109.34 (Reeh–Schlieder)**.** *Let $\mathcal{O}$ be any non-empty open region of spacetime. Then*

1. *$\mathcal{P}(\mathcal{O})\,|0\rangle$ is dense in $\mathcal{H}$: the vacuum is* cyclic *for every local algebra;*
2. *if $\mathcal{O}$ has a non-empty spacelike complement and $A \in \mathcal{P}(\mathcal{O})$ satisfies $A\,|0\rangle = 0$, then $A = 0$: the vacuum is* separating *[1218].*

Rests on Theorem 109.26 and Axioms 109.14 and 109.15.

Derivation. *Derives Theorem 109.34.*

(i) Choose an open $\mathcal{O}_0$ whose closure lies inside $\mathcal{O}$, and $\epsilon > 0$ so small that translating $\mathcal{O}_0$ by any a with $|a^\mu| < \epsilon$ keeps it inside $\mathcal{O}$. Suppose $\Psi \in \mathcal{H}$ is orthogonal to $\mathcal{P}(\mathcal{O})\,|0\rangle$. Fix n and test functions $f_1, \dots, f_n$ supported in $\mathcal{O}_0$ and consider

$$F(a_1, \dots, a_n) := \langle \Psi |\, \phi(f_1^{a_1}) \cdots \phi(f_n^{a_n})\, |0\rangle\,, \qquad f^a(x) := f(x - a)\,. \tag{109.24}$$

For all real a_j with $\left|a_j^\mu\right| < \epsilon$ every translated support is still in $\mathcal{O}$, so F vanishes on that open real neighbourhood of the origin by hypothesis.

Now repeat the argument of Theorem 109.26 on F. Writing $\phi(f^a) = U(a)\phi(f)U(a)^{-1}$ and using $P^\mu|0\rangle = 0$ at the right end, the exponentials collapse pairwise and Equation (109.24) becomes

$$F = \langle\Psi|\, U(a_1)\,\phi(f_1)\,\mathrm{e}^{-\mathrm{i}b_1\cdot P/\hbar}\,\phi(f_2)\cdots\mathrm{e}^{-\mathrm{i}b_{n-1}\cdot P/\hbar}\,\phi(f_n)\,|0\rangle\ ,$$

in the differences $b_j = a_j - a_{j+1}$. One step more is needed than in Equation (109.15), which used $P^\mu|0\rangle = 0$ at *both* ends: Ψ is not translation invariant, so a residual $U(a_1)$ survives on the left. Absorb it, holding a_1 fixed and replacing Ψ by $\Psi_{a_1} := U(a_1)^{-1}\Psi$, which is again orthogonal to $\mathcal{P}(\mathcal{O})|0\rangle$ for the correspondingly translated region and is a legitimate state. What remains is of exactly the form of Equation (109.15) with $\langle\Psi_{a_1}|$ in place of $\langle 0|$ at the left end. The spectrum condition applies unchanged to the right of each field, so for each fixed a_1, F is the boundary value of a function holomorphic in the forward tube in the variables b_j.

A function holomorphic in a tube whose distributional boundary value vanishes on a non-empty open set of the real boundary vanishes identically. (This is the edge-of-the-wedge theorem, imported; in the one-variable case it is the Schwarz reflection principle, and it is the statement that a real open set is a set of uniqueness for such functions.) Hence $F \equiv 0$ for all real a_j, so Ψ is orthogonal to $\phi(g_1)\cdots\phi(g_n)|0\rangle$ for all test functions g_j whatever — translates of a fixed f span a dense set of $\mathcal{S}$ in the relevant sense, and n was arbitrary. By Axiom 109.15, $\Psi = 0$.

(ii) Let $\mathcal{O}'$ be an open region spacelike to $\mathcal{O}$, and let $B \in \mathcal{P}(\mathcal{O}')$. Since $A \in \mathcal{P}(\mathcal{O})$ and B commute by Axiom 109.14,

$$A\,B\,|0\rangle = B\,A\,|0\rangle = 0\,.$$

By part (i) applied to $\mathcal{O}'$, the vectors $B|0\rangle$ are dense in $\mathcal{H}$; an operator vanishing on a dense subset of its domain is zero. □

Corollary 109.35 (No local operator annihilates the vacuum)**.** *There is no non-zero local operator A with $A|0\rangle = 0$. In particular there is no local number operator, no local projector onto the vacuum, and no local operator that creates "nothing".*

Rests on Theorem 109.34.

Derivation. *Derives Corollary 109.35.*

Part (ii) of Theorem 109.34 with $\mathcal{O}$ any bounded region, whose spacelike complement is never empty. A local projector E with $E|0\rangle = 0$ would violate it, and so would a number operator, since a number operator annihilates the vacuum by definition. □

Remark 109.36 (Vacuum entanglement, and what it does not permit). Part (i) has a startling reading. Acting on the vacuum with operators confined to a laboratory, one can approximate *any* state of the whole universe — a state containing a hundred protons on the far side of the Galaxy — to arbitrary accuracy in norm. The reason is that the vacuum is not a product state across any spatial division: it is entangled between every region and its complement, and part (i) is one expression of how strongly. The entanglement entropy of the vacuum restricted to a region is in fact ultraviolet divergent, growing with the area of the boundary; that is the field-theoretic case flagged in Chapter 84, and it is what Section 109.4.3 organizes.

It does *not* permit signalling. Let A act in $\mathcal{O}$ and let B be any observable in a spacelike-separated region $\mathcal{O}'$. An operation performed in $\mathcal{O}$ takes a state ρ to $\sum_k A_k \rho A_k^\dagger$ with $\sum_k A_k^\dagger A_k = \mathbb{1}$ and every $A_k \in \mathcal{P}(\mathcal{O})$. The expectation of B afterwards is

$$\sum_k \mathrm{tr}\Big(A_k \rho A_k^\dagger B\Big) = \sum_k \mathrm{tr}\Big(\rho A_k^\dagger B A_k\Big) = \mathrm{tr}\left(\rho\, B \sum_k A_k^\dagger A_k\right) = \mathrm{tr}(\rho B)\,,$$

the middle step being cyclicity of the trace and the next Axiom 109.14, which lets B move through $A_k^\dagger$ and A_k. Nothing measurable in $\mathcal{O}'$ changes. The approximation in part (i) is

achieved by operators of enormous norm acting with vanishing probability; it is a statement about the closure of a subspace, not about what an experimenter can bring about. The distinction is the field-theoretic form of Phenomenon 84.4, whose derivation from trace preservation is the same computation in a smaller setting.

109.2.5 Borchers classes

Which field a theory is written in terms of turns out not to be part of its physical content.

Definition 109.37 (Relative locality)**.** Two fields ϕ and ψ on the same Hilbert space are *relatively local* if $[\phi(f), \psi(g)] = 0$ (or the anticommutator vanishes, for two half-integer-spin fields) whenever the supports of f and g are spacelike separated. The *Borchers class* of ϕ is the set of all fields relatively local to it.

Theorem 109.38 (Borchers)**.** *Two relatively local fields, each satisfying the Wightman axioms with the same vacuum and the same representation of the Poincaré group, have the same S matrix [1177].*

Rests on Definition 109.37 and Theorem 109.59.

Status and mechanism. Derives Theorem 109.38.

The full proof requires the asymptotic construction of Section 109.3.4 and is not carried out here. The mechanism is that the asymptotic fields are built from a field only through its matrix elements between the vacuum and the one-particle states, together with its commutation properties; two relatively local fields have the same one-particle overlaps up to normalization and the same commutation properties, so they generate the same in and out states, and the S matrix is the map between those. □

Derivation pending #183

Borchers' theorem: that two relatively local Wightman fields generate the same asymptotic states and hence the same S matrix. The argument runs through the Haag–Ruelle construction and belongs in Appendix A next to it. The consequence used in this book, that a field redefinition leaves scattering amplitudes unchanged, is stated with its mechanism in the text.

Corollary 109.39 (Interpolating fields are conventions)**.** *A local field is not an observable of the theory. Any local operator with non-vanishing overlap with a one-particle state may be used to compute that particle's scattering amplitudes, and the result is independent of the choice.*

Rests on Theorem 109.38.

This is assumed without comment wherever a field redefinition is made: in the counterterm rearrangements of Chapter 100, where $\phi \to Z^{1/2}\phi$ is treated as harmless; in the scattering formalism of Chapter 86; and in Corollary 106.49, whose statement that lattice practitioners may create a proton with any convenient operator is Theorem 109.38 in another dress. The independence is not a convenience: it is the reason the S matrix is well defined at all, since the fields themselves are not measurable and only the asymptotic particle states are.

109.3 Theorems from the axioms

109.3.1 The PCT theorem

Chapter 105 proves the PCT theorem at the level of a Lagrangian, by counting Lorentz indices, and records the measurements that test it. That proof assumes a Lagrangian, a

field content and a perturbative expansion, and the theorem assumes none of them. This subsection supplies the theorem proper.

Definition 109.40 (The *PCT* condition)**.** A family of Wightman functions of a Hermitian scalar field satisfies the *PCT condition* if for every n

$$W_n(x_1,\dots,x_n) = W_n(-x_n,\dots,-x_1)\,. \tag{109.25}$$

For fields carrying Lorentz indices the right-hand side is multiplied by $(-1)^J$, J being the total number of undotted spinor indices plus the number of vector indices — the same index count that Lemma 105.35 performs on a Lagrangian monomial.

Definition 109.41 (Weak local commutativity)**.** The theory satisfies *weak local commutativity* (WLC) if for every n and every Jost point of the difference variables

$$W_n(x_1,\dots,x_n) = W_n(x_n,\dots,x_1)\,, \tag{109.26}$$

again with $(-1)^J$ for indexed fields.

WLC is strictly weaker than Axiom 109.14: locality lets *any* two spacelike-separated arguments be exchanged and hence implies Equation (109.26) by repeated transposition, while Equation (109.26) demands only that the total reversal be a symmetry, and only at totally spacelike configurations.

The decisive input is a fact about a group, and it can be verified by writing down a path.

Lemma 109.42 (Total inversion is a complex Lorentz transformation)**.** *$L_+(\mathbb{C})$ is connected and contains $-\mathbb{1}$, the total inversion $x \mapsto -x$. By contrast, over the reals $-\mathbb{1}$ lies in the component $L_+^{\downarrow}$ and is not connected to the identity.*

Rests on Definitions 39.5 and 109.27.

Derivation. *Derives Lemma 109.42.*

Consider the one-parameter family, written in the block form $(x^0,x^1)\oplus(x^2,x^3)$,

$$\Lambda(s) = \begin{pmatrix} \cos(\pi s) & \mathrm{i}\sin(\pi s) & 0 & 0 \\ \mathrm{i}\sin(\pi s) & \cos(\pi s) & 0 & 0 \\ 0 & 0 & \cos(\pi s) & -\sin(\pi s) \\ 0 & 0 & \sin(\pi s) & \cos(\pi s) \end{pmatrix}, \qquad s\in[0,1]\,. \tag{109.27}$$

The upper block is a boost with rapidity $\chi = \mathrm{i}\pi s$, since $\cosh(\mathrm{i}\pi s) = \cos(\pi s)$ and $\sinh(\mathrm{i}\pi s) = \mathrm{i}\sin(\pi s)$; it is therefore *symmetric*, with both off-diagonal entries equal to $\mathrm{i}\sin(\pi s)$, as a boost matrix always is. The lower block is a rotation by πs in the (x^2,x^3) plane. Each block separately preserves the corresponding part of $\eta_{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$ — the first because a boost does for any complex rapidity, the second because a rotation does — so $\Lambda(s)^{\mathsf{T}}\eta\Lambda(s) = \eta$ for every s, and $\det\Lambda(s) = 1$ because each block has unit determinant: $\cos^2(\pi s) - (\mathrm{i}\sin(\pi s))^2 = \cos^2(\pi s) + \sin^2(\pi s) = 1$ for the boost, and likewise for the rotation. Hence $\Lambda(s)\in L_+(\mathbb{C})$ throughout. At the endpoints

$$\Lambda(0) = \mathbb{1}\,, \qquad \Lambda(1) = \mathrm{diag}(-1,-1,-1,-1) = -\mathbb{1}\,,$$

so the path is continuous, lies in $L_+(\mathbb{C})$, and joins the identity to the total inversion.

Over the reals the same construction is unavailable: a real boost has $\cosh\chi \geq 1$, so the 00 entry of a real proper orthochronous transformation never reaches -1. Indeed $-\mathbb{1}$ has ${\Lambda^0}_0 = -1$, so it fails the condition ${\Lambda^0}_0 \geq 1$ that Definition 39.5 imposes and lies on the non-orthochronous branch; $\det(-\mathbb{1}) = +1$ in four dimensions, so $-\mathbb{1}\in L_+^{\downarrow}$. □

Corollary 109.43 (Total inversion is automatic)**.** *For a Hermitian scalar field the analytic Wightman function satisfies* $\mathcal{W}_n(-\zeta_1,\dots,-\zeta_{n-1}) = \mathcal{W}_n(\zeta_1,\dots,\zeta_{n-1})$ *everywhere on the extended tube, and hence*

$$W_n(x_1,\dots,x_n) = W_n(-x_1,\dots,-x_n) \tag{109.28}$$

at every Jost point. For a field carrying indices the right-hand side carries the factor $(-1)^J$*.*
Rests on Theorems 109.28 and 109.30 and Lemma 109.42.

Derivation. *Derives Corollary 109.43.*

Apply Equation (109.23) with $\Lambda = -\mathbb{1}$, which lies in $L_+(\mathbb{C})$ by Lemma 109.42; the extended tube is $L_+(\mathbb{C})$-invariant by Definition 109.27, so both sides are defined. Restricting to the real points, which are the Jost points by Theorem 109.30, gives Equation (109.28). □

Equation (109.28) is *not* the *PCT* condition: it reverses the signs of the arguments but leaves their order alone, whereas Equation (109.25) reverses both. The content of Jost's theorem is exactly the difference between the two.

Theorem 109.44 (Jost)**.** *A Wightman theory satisfies the PCT condition Equation (109.25) if and only if it satisfies weak local commutativity Equation (109.26) [1115].*
Rests on Definitions 109.40 and 109.41 and Corollary 109.43.

Derivation. *Derives Theorem 109.44.*

Take the scalar case; the index bookkeeping in the general case multiplies both statements by the same $(-1)^J$ and cancels.

($\Leftarrow$) Assume WLC. At a Jost point, combine Equation (109.26) with Equation (109.28):

$$W_n(-x_n,\dots,-x_1) \overset{\text{Equation (109.28)}}{=} W_n(x_n,\dots,x_1) \overset{\text{Equation (109.26)}}{=} W_n(x_1,\dots,x_n)\,,$$

the first step being legitimate because the reversed configuration $(x_n,\dots,x_1)$ is a Jost point whenever $(x_1,\dots,x_n)$ is — the Jost condition of Definition 109.29 is invariant under reversal, since reversing the order replaces each difference ξ_j by $-\xi_{n-j}$ and the defining condition is even. So Equation (109.25) holds on the open set of Jost points. Both sides of Equation (109.25) are boundary values of functions holomorphic on the extended tube, which is connected, and they agree on a real open subset of it; by the identity theorem for holomorphic functions of several variables they agree everywhere, so Equation (109.25) holds as an identity of distributions.

($\Rightarrow$) Assume the *PCT* condition. Reading the same chain backwards, at a Jost point $W_n(x_1,\dots,x_n) = W_n(-x_n,\dots,-x_1) = W_n(x_n,\dots,x_1)$, which is Equation (109.26). □

Corollary 109.45 (Locality implies *PCT*)**.** *Every theory satisfying the Wightman axioms satisfies the PCT condition.*
Rests on Axiom 109.14 and Theorem 109.44.

Derivation. *Derives Corollary 109.45.*

At a Jost point all n arguments are mutually spacelike, so Axiom 109.14 permits an arbitrary permutation of the fields inside Equation (109.13), in particular the total reversal. That is WLC, and Theorem 109.44 applies. □

The last step is to produce the operator.

Theorem 109.46 (Existence of the *PCT* operator)**.** *In a theory satisfying the PCT condition there is an antiunitary operator* Θ *on* $\mathcal{H}$ *with*

$$\Theta\,|0\rangle = |0\rangle\,, \qquad \Theta\,\phi(f)\,\Theta^{-1} = \phi\big(\bar{f}^{-}\big)\,, \qquad f^{-}(x) := f(-x)\,, \tag{109.29}$$

and $\Theta^2 = \mathbb{1}$ *for a Hermitian scalar field. In particular* $[\Theta, P^0] = 0$*, so PCT is an exact symmetry of the dynamics.*
Rests on Definition 109.40 and Axioms 109.9 and 109.13.

Derivation. *Derives Theorem 109.46.*

Define Θ on the dense set of vectors $\Psi = \phi(f_1)\cdots\phi(f_m)\,|0\rangle$ by

$$\Theta\,\phi(f_1)\cdots\phi(f_m)\,|0\rangle := \phi\big(\bar{f}_1^{-}\big)\cdots\phi\big(\bar{f}_m^{-}\big)\,|0\rangle\ , \tag{109.30}$$

extended antilinearly. Two things must be checked: that this preserves inner products in the antilinear sense, and that it is therefore well defined.

Let $\Phi = \phi(g_1)\cdots\phi(g_n)\,|0\rangle$. Then

$$\begin{aligned}\langle\Theta\Psi,\Theta\Phi\rangle &= \langle 0|\,\phi(f_m^{-})\cdots\phi\big(f_1^{-}\big)\,\phi\big(\bar{g}_1^{-}\big)\cdots\phi(\bar{g}_n^{-})\,|0\rangle \\ &= \int\prod \mathrm{d}^4x\,\mathrm{d}^4y\; W_{m+n}(-x_m,\dots,-x_1,-y_1,\dots,-y_n)\prod f_j(x_j)\prod\overline{g_k(y_k)}\end{aligned} \tag{109.31}$$

after the substitutions $x\to -x$, $y\to -y$, whose Jacobian is $+1$. Applying Equation (109.25) to the $(m+n)$-point function turns its argument list into $(y_n,\dots,y_1,x_1,\dots,x_m)$, and the result is exactly

$$\langle 0|\,\phi(\bar{g}_n)\cdots\phi(\bar{g}_1)\phi(f_1)\cdots\phi(f_m)\,|0\rangle = \langle\Phi,\Psi\rangle = \overline{\langle\Psi,\Phi\rangle}\,,$$

which is antiunitarity. Well-definedness follows: if a linear combination of the Ψ has zero norm, so does its image, because norms are preserved. A norm-preserving antilinear map on a dense domain extends to an antiunitary on $\mathcal{H}$.

The relation $\Theta\phi(f)\Theta^{-1} = \phi(\bar{f}^{-})$ is Equation (109.30) read on one factor, and $\Theta\,|0\rangle = |0\rangle$ is the case $m=0$. Applying Equation (109.30) twice returns f, so $\Theta^2 = \mathbb{1}$. Finally, from Equation (109.29) and Equation (109.11), $\Theta U(a,\mathbb{1})\Theta^{-1} = U(-a,\mathbb{1})$; writing both sides with Equation (109.10) and using antilinearity of Θ, which conjugates the i, gives $\Theta P^{\mu}\Theta^{-1} = P^{\mu}$, so Θ commutes with the energy. □

Remark 109.47 (Why PCT and not CP or T). The whole theorem rests on Lemma 109.42: the transformation that the complexified Lorentz group can reach is $-\mathbb{1}$ and nothing else. Space inversion $\Lambda_P = \mathrm{diag}(1,-1,-1,-1)$ and time reversal $\Lambda_T = \mathrm{diag}(-1,1,1,1)$ each have $\det = -1$ and therefore lie outside $L_+(\mathbb{C})$ altogether — not in a different component of it, but not in it at all, since $L_+(\mathbb{C})$ is defined by $\det\Lambda = +1$. No analytic continuation reaches them, and no sharpening of the hypotheses will produce a theorem asserting P, T or CP invariance. That is not a limitation of the proof: P, C and CP are all violated in Nature (Chapters 110 and 111), and a correct theorem cannot prove a false statement.

Remark 109.48 (What the theorem says about experiment). The observable consequences — equal masses, equal total lifetimes and opposite magnetic moments for a particle and its antiparticle — are derived from antiunitarity in Theorems 105.36 to 105.38 and measured in Section 105.5.3, where the sharpest entries are the neutral kaon rest-energy comparison at the level of 6×10^{-19} of m_Kc^2 [2427] and the antihydrogen $1S$–$2S$ frequency at 2×10^{-12}. The point worth carrying back here is that these are tests of Axioms 109.10 and 109.14 and Axiom 109.13 directly, since Corollary 109.45 used nothing else. A confirmed violation would not be a new particle; it would mean that one of the three axioms is false, and with it every theorem of this chapter.

109.3.2 Spin and statistics

This is the standing debt of the book. The connection between spin and statistics is assumed in Chapters 83 and 120, used to force the colour degree of freedom in Section 102.2, used again for the shell model of Chapter 107, and proved in Chapter 99 only for free fields of

spin 0 and spin 1/2 (Theorem 99.46). Here it is proved from the axioms, for any spin, at $3+1$.

Pauli's original argument [854] was that the wrong pairing is catastrophic: a half-integer-spin field quantized with commutators has an energy unbounded below, and an integer-spin field quantized with anticommutators loses microcausality. Those are the two computations carried out in Propositions 99.47 and 99.48 — the second showing that the anticommutator of the real scalar fails to vanish outside the light cone, and that the theory collapses besides, every even local polynomial in ϕ becoming a c-number. The axiomatic statement, due to Lüders and Zumino [1151] and to Burgoyne [1139], is sharper and stranger: a Wightman field with the wrong connection does not merely misbehave, it *vanishes*.

Theorem 109.49 (Spin and statistics)**.** *Let ϕ satisfy Axiom 109.9 to Axiom 109.15 except that Axiom 109.14 is imposed with the wrong bracket: the anticommutator $\{\phi(x),\phi^\dagger(y)\}$ vanishes at spacelike separation for a field of integer spin, or the commutator $[\phi(x),\phi^\dagger(y)]$ vanishes at spacelike separation for a field of half-integer spin. Then $\phi(f)=0$ for every test function f.*

Rests on Theorems 109.28 and 109.34 and Corollary 109.43.

Derivation, integer spin. Derives Theorem 109.49.

Take ϕ a complex scalar field and define the two two-point functions of the difference $\xi = x-y$,

$$F(\xi) := \langle 0|\,\phi(x)\phi^\dagger(y)\,|0\rangle\ , \qquad G(\xi) := \langle 0|\,\phi^\dagger(x)\phi(y)\,|0\rangle\ . \tag{109.32}$$

Note that in *both* the argument x stands on the left, so both are covered by Theorem 109.26 with the same tube: each is the boundary value of a function $\mathcal{F}$, $\mathcal{G}$ holomorphic on the forward tube $\mathcal{T}_1$ and, by Theorem 109.28, on the extended tube $\mathcal{T}_1'$.

Step 1: evenness. By Corollary 109.43 applied to each of $\mathcal{F}$ and $\mathcal{G}$ — these are two-point functions of a scalar field, so $J=0$ —

$$\mathcal{F}(-\zeta)=\mathcal{F}(\zeta)\,, \qquad \mathcal{G}(-\zeta)=\mathcal{G}(\zeta)\,, \qquad \zeta\in\mathcal{T}_1'\,. \tag{109.33}$$

Step 2: the wrong bracket at a Jost point. For ξ spacelike — which for $n=2$ is exactly the Jost condition — the assumed anticommutation gives $\phi(x)\phi^\dagger(y)=-\phi^\dagger(y)\phi(x)$, so

$$F(\xi) = -\,\langle 0|\,\phi^\dagger(y)\phi(x)\,|0\rangle = -G(-\xi) \overset{\text{Equation (109.33)}}{=} -G(\xi)\,, \tag{109.34}$$

the middle equality because G was defined with its arguments in the order (dagger, no dagger) and here they appear at y and x, i.e. with difference $y-x=-\xi$.

Step 3: analytic propagation. $\mathcal{F}+\mathcal{G}$ is holomorphic on the connected domain $\mathcal{T}_1'$ and, by Step 2, vanishes on the open set of real Jost points contained in it (Theorem 109.30 and Proposition 109.31). A holomorphic function vanishing on a real open subset of its domain vanishes identically, so $\mathcal{F}=-\mathcal{G}$ on all of $\mathcal{T}_1'$, and taking boundary values from the same tube,

$$F(\xi) = -G(\xi) \qquad \text{as distributions, for all } \xi\,. \tag{109.35}$$

Step 4: positivity kills it. Smear Equation (109.35) with $\overline{g(x)}\,g(y)$ for an arbitrary $g\in\mathcal{S}(\mathbb{R}^4)$. The left side gives $\langle 0|\,\phi(\bar g)\phi^\dagger(g)\,|0\rangle = \left\|\phi^\dagger(g)\,|0\rangle\right\|^2$, since $\phi(\bar g)=\left(\phi^\dagger(g)\right)^\dagger$; the right side gives $-\langle 0|\,\phi^\dagger(\bar g)\phi(g)\,|0\rangle = -\left\|\phi(g)\,|0\rangle\right\|^2$. Hence

$$\left\|\phi^\dagger(g)\,|0\rangle\right\|^2 + \left\|\phi(g)\,|0\rangle\right\|^2 = 0\,, \tag{109.36}$$

a sum of two non-negative numbers, so both vanish: $\phi(g)\,|0\rangle=0$ for every g.

Step 5: from the vacuum to the operator. Take g supported in a bounded open region, whose spacelike complement is non-empty. By Theorem 109.34(ii) the vacuum is separating for that region, so $\phi(g)=0$. Such g are dense in $\mathcal{S}$, and ϕ is continuous in g by Axiom 109.12, so $\phi=0$. □

Derivation, half-integer spin. *Derives Theorem 109.49.*

The only change is in Step 1. A field in the (A, B) representation of $\mathrm{SL}(2,\mathbb{C})$ carries $2A$ undotted and $2B$ dotted spinor indices, and Theorem 109.28 for such a field multiplies the right-hand side of Equation (109.23) by the analytic continuation of $S(\Lambda)$. Along the path Equation (109.27) that continuation returns, at $s = 1$, the factor $(-1)^{2A+2B} = (-1)^{2s_\phi}$ on the two-point function, where s_ϕ is the spin. For half-integer spin this is -1, so Equation (109.33) becomes $\mathcal{G}(-\zeta) = -\mathcal{G}(\zeta)$. The assumed *commutator* at spacelike separation gives, in place of Equation (109.34), $F(\xi) = +G(-\xi) = -G(\xi)$ — the same relation as before. Steps 3 to 5 are unchanged, and again $\phi = 0$. □

Corollary 109.50 (The connection between spin and statistics)**.** *A non-trivial Wightman field of integer spin commutes at spacelike separation and a non-trivial Wightman field of half-integer spin anticommutes there. Consequently the states of identical integer-spin quanta are symmetric under exchange and those of identical half-integer-spin quanta are antisymmetric.*

Rests on Theorem 109.49.

Derivation. *Derives Corollary 109.50.*

The first sentence is the contrapositive of Theorem 109.49. For the second, let $a^\dagger$ denote the creation part of the field in the sense of Section 109.3.4; the exchange symmetry of a two-quantum state $a^\dagger(f)a^\dagger(g)\,|0\rangle$ is the sign in the bracket relating $a^\dagger(f)$ and $a^\dagger(g)$, which is inherited from the field's spacelike bracket by the asymptotic construction. That is the symmetrization postulate assumed at Section 83.1.4, which is a postulate there because none of the hypotheses used here — Lorentz covariance, positivity of the energy, locality — is available in nonrelativistic quantum mechanics. □

Derivation pending #184

The analytic continuation of the finite-dimensional representation matrix $S([\Lambda])$ along the path joining the identity to the total inversion in the complex Lorentz group, which is what supplies the factor $(-1)^{2s}$ used in the half-integer case. The path itself and the scalar case are derived in full in the text; the index bookkeeping for arbitrary spin follows Burgoyne and belongs in Appendix A with the Bargmann–Hall–Wightman theorem it rests on.

Remark 109.51 (What has and has not been proved)*.* Four points, because this theorem is quoted loosely more often than any other in the subject.

It is a statement about which hypotheses are compatible. Nothing forbids constructing anticommuting scalars; the Faddeev–Popov ghosts of Chapters 102 and 106 are exactly that. They evade Theorem 109.49 by failing its hypotheses — they are not observables, they carry indefinite metric, and Axiom 109.9 with its positive-definite Hilbert space does not hold in the enlarged space where they live. The same qualification appears in Remark 99.49.

It is a $3+1$ theorem. Lemma 109.42 used four dimensions twice: the boost–rotation pairing needs two commuting planes, and $\det(-\mathbb{1}) = +1$ needs an even dimension. In $2+1$ dimensions neither holds, and the conclusion is false — anyons exist. This treatise does not treat $2+1$ physics (editorial rule on dimensions), and the observation is recorded only because it shows the theorem is not a formal triviality.

It needs a positive-definite metric. Step 4 is the whole proof, and it is nothing but the non-negativity of a norm. Every known counterexample is a theory in which that fails.

The consequences are measured. The exclusion principle is bounded directly: the Ramberg–Snow experiment and its successors limit the probability of a Pauli-violating atomic transition to below 1.7×10^{-26} (Section 99.7.2). That a statement about complex Lorentz transformations underwrites the periodic table, the chemistry of Chapter 88 and

the degeneracy pressure of Chapter 49 is one of the stranger facts in physics, and it is not a coincidence: both follow from locality and positivity of the energy.

109.3.3 The Källén–Lehmann representation

Every renormalized propagator in Chapters 100 and 106 rests on a decomposition of the exact two-point function that is usually quoted and rarely derived. It follows from the axioms in half a page, is exact rather than perturbative, and its positivity is again nothing but the positivity of the Hilbert-space metric.

Notation 109.52 (Spectral variable and state normalization). The spectral variable s is a *squared momentum*, of dimension $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$, matching the mass-shell condition $p^2=m^2c^2$ of Equation (100.1). States of sharp four-momentum are labelled by the wave vector $\boldsymbol{k}=\boldsymbol{p}/\hbar$ and normalized covariantly,

$$\langle \lambda_{\boldsymbol{k}} | \lambda_{\boldsymbol{k}'} \rangle = (2\pi)^3 \, \frac{2\omega_{\boldsymbol{k}}}{c} \, \delta^3(\boldsymbol{k}-\boldsymbol{k}') \,, \tag{109.37}$$

so that the resolution of the identity on the sector λ is $\int \mathrm{d}^3k\, c\, |\lambda_{\boldsymbol{k}}\rangle\langle\lambda_{\boldsymbol{k}}| \,/\, \big[(2\pi)^3 2\omega_{\boldsymbol{k}}\big]$, in which the measure $\mathrm{d}^3k\,c/(2\omega_{\boldsymbol{k}})$ is Lorentz invariant.

Definition 109.53 (Free positive-frequency function)**.** For a squared momentum $s\geq 0$,

$$\Delta^+(\xi;s) := \hbar c^2 \int \frac{\mathrm{d}^3k}{(2\pi)^3\, 2\omega_{\boldsymbol{k}}} \, \mathrm{e}^{-\mathrm{i}k\cdot\xi} \,, \qquad \omega_{\boldsymbol{k}} = c\sqrt{\boldsymbol{k}^2 + \frac{s}{\hbar^2}} \,, \tag{109.38}$$

which is Equation (109.1) for a free field with $s=m^2c^2$ and carries $[\phi]^2=\mathrm{J/m}$.

Theorem 109.54 (Källén–Lehmann)**.** *Let ϕ be a Hermitian scalar Wightman field with $\langle 0|\,\phi(x)\,|0\rangle = 0$. Then there is a positive measure $\rho(s)\mathrm{d}s$ on $[0,\infty)$, of dimension $\mathrm{s}^2/(\mathrm{kg}^2\,\mathrm{m}^2)$, such that*

$$\langle 0|\,\phi(x)\phi(y)\,|0\rangle = \int_0^\infty \mathrm{d}s\; \rho(s)\, \Delta^+(x-y;s) \,, \qquad \rho(s)\geq 0 \,. \tag{109.39}$$

If in addition ϕ obeys the canonical equal-time commutation relation with $\pi = c^{-2}\partial_t\phi$, then

$$\int_0^\infty \mathrm{d}s\; \rho(s) = 1 \,. \tag{109.40}$$

Rests on Axioms 109.10 and 109.13 and Definition 109.53.

Derivation. *Derives Theorem 109.54.*

Insert a complete set of states between the fields. By Axiom 109.10 every state has four-momentum in $\overline{V}^+$; group the states by their sector label λ and their invariant mass m_λ, and use Notation 109.52. The vacuum contributes $|\langle 0|\,\phi(0)\,|0\rangle|^2=0$ by hypothesis, so

$$\langle 0|\,\phi(x)\phi(y)\,|0\rangle = \sum_{\lambda} \int \frac{\mathrm{d}^3k}{(2\pi)^3}\, \frac{c}{2\omega_{\boldsymbol{k}}} \; \langle 0|\,\phi(x)\,|\lambda_{\boldsymbol{k}}\rangle\, \langle \lambda_{\boldsymbol{k}}|\,\phi(y)\,|0\rangle \;. \tag{109.41}$$

Translation covariance, Equation (109.10) with $\phi(x)=U(x)\phi(0)U(x)^{-1}$ and $P^\mu|0\rangle=0$, gives $\langle 0|\,\phi(x)\,|\lambda_{\boldsymbol{k}}\rangle = \mathrm{e}^{-\mathrm{i}k\cdot x}\,\langle 0|\,\phi(0)\,|\lambda_{\boldsymbol{k}}\rangle$, so the x and y dependence collapses to $\mathrm{e}^{-\mathrm{i}k\cdot(x-y)}$ and the matrix elements enter only through $|\langle 0|\,\phi(0)\,|\lambda_{\boldsymbol{k}}\rangle|^2$.

Lorentz covariance, Equation (109.11), says that this modulus squared is invariant: acting with $U(\Lambda)$ on both sides sends $|\lambda_{\boldsymbol{k}}\rangle$ to a state of the same sector with boosted wave vector, and Equation (109.37) is constructed to be invariant, so $|\langle 0|\,\phi(0)\,|\lambda_{\boldsymbol{k}}\rangle|^2$ depends on $\boldsymbol{k}$ only through the invariant $\hbar^2 k\cdot k = m_\lambda^2c^2$ — that is, not at all within a sector. Call it c_λ.

Now insert $1 = \int_0^\infty \mathrm{d}s\, \delta(s - m_\lambda^2 c^2)$ and define

$$\rho(s) := \frac{1}{\hbar c} \sum_\lambda c_\lambda\, \delta\Big(s - m_\lambda^2 c^2\Big)\,, \tag{109.42}$$

whose positivity is manifest, each c_λ being a squared modulus. Exchanging the order of the s and $\boldsymbol{k}$ integrations and comparing with Equation (109.38) gives Equation (109.39). The prefactor is the ratio of the two measures, not of the two prefactors: Equation (109.41) carries $\mathrm{d}^3k\, c/\left[(2\pi)^3 2\omega_{\boldsymbol{k}}\right]$ while Equation (109.38) carries $\hbar c^2\, \mathrm{d}^3k/\left[(2\pi)^3 2\omega_{\boldsymbol{k}}\right]$, and $c/(\hbar c^2) = 1/(\hbar c)$. The extra power of c is supplied by the Lorentz-invariant state measure of Notation 109.52, and it is what makes the bookkeeping close: that normalization gives $|\lambda_{\boldsymbol{k}}\rangle$ the dimension m, so $c_\lambda = |\langle 0|\, \phi(0)\, |\lambda_{\boldsymbol{k}}\rangle|^2$ carries $\mathrm{J\,m} = [\hbar c]$, the quotient $c_\lambda/(\hbar c)$ is a pure number, and ρ inherits the dimension $\mathrm{s}^2/(\mathrm{kg}^2\,\mathrm{m}^2)$ of the delta function alone — that is, $1/[s]$, so that Equation (109.40) is a statement between pure numbers. For a free field of mass m the single sector has $c_\lambda = \hbar c$ and $\rho(s) = \delta(s - m^2c^2)$, as it must.

For the sum rule, subtract Equation (109.39) from its $x \leftrightarrow y$ transpose:

$$[\phi(x), \phi(y)] = \int_0^\infty \mathrm{d}s\; \rho(s)\, \mathrm{i}\hbar c^2\, \Delta(x - y; s)\,, \tag{109.43}$$

with Δ the Pauli–Jordan function of Equation (105.101) for squared momentum s. Now $\Delta(\xi; s)$ vanishes at equal times and

$$\partial_{t_x} \Delta(x - y; s)\Big|_{t_x = t_y} = -\delta^3(\boldsymbol{x} - \boldsymbol{y})\,, \tag{109.44}$$

which is *independent of* s: differentiating Equation (105.101) brings down $\mp\mathrm{i}\omega_{\boldsymbol{k}}$ from the two exponentials, which cancels the $1/(2\omega_{\boldsymbol{k}})$ and leaves $-\int \mathrm{d}^3k\, \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{y})}/(2\pi)^3$ regardless of the mass. Therefore

$$[\phi(t, \boldsymbol{x}), \pi(t, \boldsymbol{y})] = \frac{1}{c^2} \partial_{t_y} [\phi(x), \phi(y)]\Big|_{t_x = t_y} = \mathrm{i}\hbar\, \delta^3(\boldsymbol{x} - \boldsymbol{y}) \int_0^\infty \mathrm{d}s\; \rho(s)\,,$$

using $\partial_{t_y} = -\partial_{t_x}$ on a function of $x - y$. Comparing with the canonical commutator $[\phi, \pi] = \mathrm{i}\hbar\, \delta^3 \mathbb{1}$ gives Equation (109.40). □

Corollary 109.55 (The field-strength constant is bounded)**.** *Suppose the spectrum contains an isolated one-particle state of mass m, so that $\rho(s) = Z\, \delta(s - m^2c^2) + \sigma(s)$ with $\sigma \geq 0$ supported on $s \geq s_{thr} > m^2c^2$. Then*

$$0 \leq Z = 1 - \int_{s_{thr}}^\infty \mathrm{d}s\; \sigma(s) \leq 1\,, \tag{109.45}$$

with $Z = 1$ if and only if $\sigma \equiv 0$, that is if and only if the field creates nothing but the one-particle state.

Rests on Equation (109.40)*.*

Derivation. Derives Corollary 109.55.

Substitute the decomposition into Equation (109.40). Both Z and $\int \sigma$ are non-negative because ρ is, and they sum to one, which gives Equation (109.45). For the equality case, $Z = 1$ forces $\int \sigma = 0$, and a non-negative measure of vanishing total mass is the zero measure, so $\sigma \equiv 0$; conversely $\sigma \equiv 0$ gives $Z = 1$ by the same sum rule. □

Remark 109.56 (From a free two-point function to a free field). It is tempting to end the corollary with "— a free field", and the conclusion is true, but it is a further theorem and not a restatement. What $\sigma \equiv 0$ says is that the *two-point* function of ϕ coincides with that of a free field of mass m; that all the higher Wightman functions are then the free ones as well, so that ϕ itself satisfies the Klein–Gordon equation $(\Box + m^2c^2/\hbar^2)\, \phi = 0$ and is a free field, is the Jost–Schroer theorem [1297, 1312]. It is proved from analyticity, not from the sum rule.

Derivation pending #185

The Jost–Schroer theorem: a Wightman field whose two-point function is that of a free field of mass m is a free field. The argument runs through the analyticity of the truncated Wightman functions in the extended tube and the vanishing of the truncated two-point function's support off the mass shell; it belongs in Appendix A beside the other analyticity results of this chapter.

This is the structural fact Remark 100.38 appeals to, in the case this chapter can prove it: a Hermitian scalar field, with the sum rule coming from the canonical equal-time *commutator*. The residue of the exact propagator at its pole is Z; the deficit $1 - Z$ is the probability weight the interacting field puts on multiparticle states; and the inequality $Z \leq 1$ is not a perturbative estimate but a consequence of the axioms. What Remark 100.38 owes is the *fermion* case — the same representation for the exact electron two-point function, with the sum rule taken instead from the canonical equal-time anticommutator, bounding Z_2 rather than Z. That derivation is not carried out here, and the pending entry standing beside Remark 100.38 remains live; nor would Corollary 109.55 transfer to it unchanged, for the reason given in Remark 109.57 below. In momentum space the same content reads as Equation (106.61), whose Feynman-ordered form follows from Equation (109.39) by the standard contour prescription; the branch point at $s = s_{\mathrm{thr}}$ visible there is the threshold of Corollary 109.55, and for a self-interacting scalar of mass m it sits at $(2mc)^2$.

Remark 109.57 (Why the representation is exact). Nothing in the derivation expanded in a coupling. Only three ingredients were used: completeness of the states, the spectrum condition Axiom 109.10, and Lorentz covariance Axiom 109.13. The result is therefore a constraint on *any* theory satisfying the axioms, and it is why $Z \leq 1$ can be quoted against a perturbative calculation that appears to violate it: such a calculation has an error, or the scheme in which it is performed is not one in which Z is the residue of a physical pole. The corresponding statement for the electron propagator, where the one-particle "pole" is not isolated because a charged state is accompanied by arbitrarily soft photons, is the infraparticle difficulty of Remark 109.18 and Section 100.6: there Z_2 is infrared divergent and Corollary 109.55 does not apply, because its hypothesis fails.

109.3.4 Asymptotic states and LSZ

Nothing so far mentions particles. The axioms describe fields and states; a particle is an extra structure, and the theorem that produces it from the axioms is the Haag–Ruelle construction.

Definition 109.58 (Isolated mass shell)**.** The theory has a *one-particle state of mass m* if the joint spectrum of P^μ contains an isolated hyperboloid $p^2 = m^2c^2$, $p^0 > 0$, separated from the rest of the spectrum by a gap: the continuum begins at $s_{\mathrm{thr}} > m^2c^2$.

Theorem 109.59 (Haag–Ruelle)**.** *Let a Wightman theory have an isolated mass shell of mass m and let ϕ have non-vanishing overlap with it, $\langle 0|\,\phi(0)\,|p\rangle \neq 0$. Choose f with $\tilde f$ supported in a neighbourhood of that shell meeting no other part of the spectrum, and set*

$$B_f(t) := \frac{\mathrm{i}}{\hbar c^2}\int \mathrm{d}^3x\,\left[\phi(t,\boldsymbol{x})\,\partial_t \overline{f(t,\boldsymbol{x})} - (\partial_t\phi(t,\boldsymbol{x}))\,\overline{f(t,\boldsymbol{x})}\right], \tag{109.46}$$

with f a positive-frequency solution of the Klein–Gordon equation of mass m. The prefactor $\mathrm{i}/(\hbar c^2)$ is the one that makes $\left[B_f, B_g^\dagger\right]$ the Klein–Gordon inner product of the two packets and a pure number, since the equal-time commutator is $[\phi, \partial_t\phi] = \mathrm{i}\hbar c^2\delta^3$; f is normalized accordingly. Then the limits

$$|f_1, \dots, f_n\rangle_{in}^{out} = \lim_{t\to\pm\infty} B_{f_1}(t)\cdots B_{f_n}(t)\,|0\rangle \tag{109.47}$$

exist in norm, are independent of the interpolating field within its Borchers class, and span Fock spaces of free particles of mass m on which the Poincaré group acts as it does on free states.

Rests on Definition 109.58 and Equation (109.19).

Status and mechanism. Derives Theorem 109.59.

The mechanism is a competition of rates. A single $B_f(t)$ applied to the vacuum is t-independent: its one-particle component is exact, because $\tilde{f}$ meets only the one-particle shell and Equation (109.46) is the Klein–Gordon inner product, which is conserved. For a product of n such operators the t-dependence comes from the overlap of the wave packets, and cluster decomposition Equation (109.19) makes connected contributions fall off faster than $t^{-3/2}$ per pair while the number of pairs is fixed; the Cauchy criterion then gives norm convergence. What must be supplied is the quantitative decay estimate, which uses the mass gap of Definition 109.58 and stationary phase. □

Derivation pending #186

The Haag–Ruelle convergence estimate: that the vectors of the displayed limit form a Cauchy family, with the rate supplied by cluster decomposition together with the stationary-phase decay of a wave packet built on an isolated mass shell. The construction and its mechanism are given in the text; the estimate is a page of analysis and belongs in Appendix A.

Theorem 109.60 (LSZ reduction)**.** *Under the hypotheses of Theorem 109.59, the S-matrix elements between the states Equation (109.47) are the residues of the time-ordered Wightman functions at their one-particle poles, in the form Equation (106.62) [1073].*

Rests on Theorems 109.54 and 109.59 and Corollary 109.55.

Derivation. Derives Theorem 109.60.

The pole structure is Theorem 109.54: a leg carrying momentum p has, by Corollary 109.55, an isolated pole of residue proportional to Z at $p^2 = m^2c^2$ and a branch cut starting at s_{thr}, and multiplying by $(p^2 - m^2c^2)$ before taking the limit isolates the first and discards the second. The identification of what survives with a matrix element between Haag–Ruelle states is Theorem 109.59. The algebra is carried out in Theorem 106.48; what this chapter adds is that its two ingredients — the analytic structure of the two-point function and the existence of asymptotic states — are theorems of the axioms rather than assumptions of the path integral. □

Remark 109.61 (Three honest qualifications)*. Asymptotic completeness is an assumption.* The Haag–Ruelle states span *a* subspace of $\mathcal{H}$; that they span all of it is an additional hypothesis. It is what allows the S matrix to be unitary, and hence what underwrites the optical theorem and every cross-section normalization of Chapter 86. It has never been proved in an interacting four-dimensional model, and it is false in some soluble lower-dimensional ones.

Massless particles break the construction. The gap in Definition 109.58 is used essentially, and for a massless particle there is no gap: the one-particle shell touches the two-particle continuum at the origin. This is not a technicality. In quantum electrodynamics a charged particle is always accompanied by an indefinite number of soft photons and is not an eigenvector of the mass operator at all — an *infraparticle*, in the analysis of Buchholz and Fredenhagen [1684], whose superselection structure is that of Section 109.4.2 rather than that of a Wigner particle. The infrared divergences cancelled by hand in Section 100.6 are the perturbative shadow of this.

Confined fields have no shell at all. The quark and gluon fields of Chapter 102 have no isolated one-particle hyperboloid in the physical spectrum, so Theorem 109.59 does not

apply to them. This is a precise statement of what confinement would mean in this language, and the reason Section 102.7.3 must argue from evidence rather than from theorem.

109.4 Algebraic quantum field theory

109.4.1 Haag–Kastler nets

Corollary 109.39 showed that the field is a convention. The algebraic formulation takes that seriously and drops the field from the list of primitive objects, keeping only what is measurable.

Definition 109.62 (Local net of observables)**.** A *Haag–Kastler net* assigns to every bounded open region $\mathcal{O} \subset \mathbb{R}^4$ a von Neumann algebra $\mathcal{A}(\mathcal{O})$ of bounded operators on a Hilbert space, subject to

1. **isotony**: $\mathcal{O}_1 \subset \mathcal{O}_2$ implies $\mathcal{A}(\mathcal{O}_1) \subset \mathcal{A}(\mathcal{O}_2)$;
2. **locality**: if $\mathcal{O}_1$ and $\mathcal{O}_2$ are spacelike separated, every element of $\mathcal{A}(\mathcal{O}_1)$ commutes with every element of $\mathcal{A}(\mathcal{O}_2)$;
3. **covariance**: there is a unitary representation $U(a,\Lambda)$ with $U(a,\Lambda)\mathcal{A}(\mathcal{O})U(a,\Lambda)^{-1} = \mathcal{A}(\Lambda\mathcal{O}+a)$, with spectrum in $\overline{V}^{+}$ and an invariant vacuum.

The *quasilocal algebra* $\mathfrak{A}$ is the norm closure of $\bigcup_{\mathcal{O}} \mathcal{A}(\mathcal{O})$, an inductive limit directed by isotony, and is a C^*-algebra [1280].

Remark 109.63 (Why bounded operators, and where the units went)*.* A Wightman field is unbounded and its domain problems are real (Remark 109.3); the algebraic formulation avoids them by taking as generators bounded functions of the smeared fields, for example the unitaries $\exp(\mathrm{i}\phi(f)/[\phi])$ with the exponent made dimensionless by the field's own normalization. All elements of $\mathfrak{A}$ are therefore *dimensionless* bounded operators, and every dimensioned quantity of this chapter — the J/m of $[\phi]^2$, the kg m/s of P^μ, the $\hbar$ in Equation (109.10) — enters only through the particular fields chosen to generate the net and through the representation of the translations. That is not a loss: it is the statement that the physical content is in the net and its symmetry, not in the units of whatever field was used to write it down.

The physical argument for the shift is short. A measurement occupies a bounded region of spacetime, so what it can determine is an element of $\mathcal{A}(\mathcal{O})$ for that region; the field is not such an element, it is merely a convenient set of generators, and by Theorem 109.38 a whole class of fields generates the same net. Everything physical — the particle content, the statistics, the charges, the S matrix — must therefore be recoverable from the net alone. Section 109.4.2 shows that it is.

Remark 109.64 (Curved spacetime)*.* The Wightman axioms of Section 109.2.1 cannot be transplanted to a curved spacetime, because a generic solution of the Einstein equations (Chapter 44) has no Poincaré group, no preferred vacuum and no global momentum operator, so Axioms 109.9 to 109.11 all fail to parse. Definition 109.62 survives, because isotony and locality are statements about regions and their causal relations, which a Lorentzian manifold still has. The replacement of covariance is *local covariance*: the assignment of an algebra to a region must be functorial under isometric embeddings of one spacetime into another, so that the same physics holds in every small enough neighbourhood [2013]. This is how a quantum field on a curved background is formulated when it is formulated carefully — including the Hawking process [1549], the prediction that a black hole radiates thermally. That prediction shares the status recorded in Remark 109.75 for the acceleration temperature, and for the

same arithmetic reason: it has never been observed, no astrophysical black hole is anywhere near hot enough against the microwave background, and the laboratory work on it measures analogue systems obeying the same equations rather than the physical claim. It is named here for completeness; no theorem of this chapter uses it, and nothing in this book rests on it.

109.4.2 States, GNS and superselection

Once the observables are an abstract algebra, a state is not a vector but a rule assigning expectations to observables — Segal's formulation of quantum mechanics [904] — and the Hilbert space is something one constructs from it.

Definition 109.65 (State on an algebra)**.** A *state* on a C^*-algebra $\mathfrak{A}$ with unit is a linear functional $\omega : \mathfrak{A} \to \mathbb{C}$ with $\omega(A^*A) \geq 0$ for all A and $\omega(\mathbb{1}) = 1$.

Theorem 109.66 (Gelfand–Naimark–Segal)**.** *For every state ω on a C^*-algebra $\mathfrak{A}$ there is a Hilbert space $\mathcal{H}_\omega$, a representation π_ω of $\mathfrak{A}$ by bounded operators on it, and a unit vector $|\omega\rangle \in \mathcal{H}_\omega$, cyclic for $\pi_\omega(\mathfrak{A})$, such that*

$$\omega(A) = \langle \omega | \, \pi_\omega(A) \, | \omega \rangle \qquad \text{for all } A \in \mathfrak{A} \,. \tag{109.48}$$

The triple is unique up to unitary equivalence [871, 904].
Rests on Definition 109.65.

Derivation. *Derives Theorem 109.66.*

Put $\langle A, B \rangle_\omega := \omega(A^*B)$ on $\mathfrak{A}$ regarded as a vector space. This is sesquilinear and non-negative, hence satisfies Cauchy–Schwarz, $|\omega(A^*B)|^2 \leq \omega(A^*A)\,\omega(B^*B)$.

Let $\mathfrak{N} := \{A : \omega(A^*A) = 0\}$. By Cauchy–Schwarz, $A \in \mathfrak{N}$ implies $\omega(B^*A) = 0$ for all B, so $\mathfrak{N}$ is a subspace; and for $A \in \mathfrak{N}$, $\omega((BA)^*(BA)) = \omega(A^*B^*BA) \leq \|B^*B\|\,\omega(A^*A) = 0$ using the C^* inequality $A^*CA \leq \|C\|\,A^*A$ for $C \geq 0$. So $\mathfrak{N}$ is a left ideal.

Let $\mathcal{H}_\omega$ be the completion of $\mathfrak{A}/\mathfrak{N}$ in the induced — now definite — inner product, write $[A]$ for the class of A, and set $\pi_\omega(B)[A] := [BA]$, well defined because $\mathfrak{N}$ is a left ideal and bounded because $\|[BA]\|^2 = \omega(A^*B^*BA) \leq \|B\|^2\,\|[A]\|^2$. That π_ω is a $*$-homomorphism is immediate from the definitions. Take $|\omega\rangle := [\mathbb{1}]$: then $\langle \omega | \, \pi_\omega(A) \, | \omega \rangle = \omega(\mathbb{1}^*A\mathbb{1}) = \omega(A)$, which is Equation (109.48), and cyclicity holds because $\pi_\omega(\mathfrak{A})\,|\omega\rangle = \mathfrak{A}/\mathfrak{N}$ is dense by construction. Uniqueness: two such triples are intertwined by $\pi_\omega(A)\,|\omega\rangle \mapsto \pi'_\omega(A)\,|\omega\rangle'$, which preserves inner products by Equation (109.48) and is densely defined by cyclicity. □

Remark 109.67 (The reconstruction theorem again). Theorem 109.66 and Theorem 109.21 are the same construction. In the Wightman case the algebra is the Borchers tensor algebra Equation (109.17), the state is the collection of Wightman functions, and property (v) of Proposition 109.20 is $\omega(A^*A) \geq 0$. This is why a positivity condition is the one axiom that cannot be relaxed in either formulation, and why it appears a third time as reflection positivity in Section 109.5.1. In the commutative case the same piece of mathematics is the classical moment problem — reconstructing a measure from its moments, the condition being positivity of the Hankel form built from them. That problem is not treated anywhere in this book, and is recorded here only to name the mathematics the reconstruction theorem generalizes.

Definition 109.68 (Superselection sector)**.** Two states on $\mathfrak{A}$ lie in the same *superselection sector* if their GNS representations are unitarily equivalent. Inequivalent representations describe states between which no observable has a matrix element, so no coherent superposition of them is preparable.

Remark 109.69 (Why sectors are unavoidable in field theory). For finitely many canonical pairs the Stone–von Neumann theorem makes all irreducible representations equivalent and the notion is empty. In field theory it is not: Corollary 109.5 is the statement that a free and an interacting theory are inequivalent representations of the same canonical relations, and the several vacua of a spontaneously broken theory (Section 104.3) are inequivalent representations too — which is the precise sense in which choosing a vacuum is not choosing a state within one theory but choosing a theory within one algebra. The remark in Chapter 25 that this is a feature and not a pathology is Definition 109.68.

Theorem 109.70 (Doplicher–Haag–Roberts; imported)**.** *Let the sectors of a net satisfying Definition 109.62 be restricted to those that look like the vacuum sector when observed outside any bounded region — the* localizable *charges. Then the set of such sectors carries the structure of the representation category of a unique compact group G, the global gauge group; each sector is labelled by an irreducible representation of G; a permutation statistics is attached to each sector, and in $3+1$ dimensions it is necessarily Bose or Fermi with a definite integer order (para-statistics of order d, reducible to ordinary statistics of d-component fields); and a field algebra generating the sectors from the vacuum exists, on which G acts with the observables as its fixed points [1445, 1525].*

Rests on Definitions 109.62 and 109.68.

Remark 109.71 (What the theorem accomplishes). It is the strongest structural result in the subject. The input is a net of local observables and nothing else: no fields, no gauge group, no charges, no statistics. The output contains all four. That the internal symmetry group of a theory is compact, that charges are labelled by its irreducible representations, that the exchange statistics is Bose or Fermi and not something else, and that a field algebra exists at all are *derived*, not postulated — whereas in Chapter 104 the gauge group is chosen to fit the data and the fields are chosen to carry it. The result is a theorem about the framework and carries no prediction that distinguishes one Standard Model from another; it says that the shape of the Standard Model is the only shape a local theory can have.

Two honest limitations. The analysis assumes charges localizable in a bounded region, which excludes the electric charge itself — Gauss's law makes it measurable at infinity, and charged states in quantum electrodynamics are the infraparticles of Remark 109.61. And the conclusion about Bose or Fermi statistics uses $3+1$ dimensions, through the connectedness of the spacelike complement of a bounded region; the same conclusion fails in lower dimension, which is the algebraic counterpart of the dimensional caveat in Remark 109.51.

Derivation pending #187

The Doplicher–Haag–Roberts reconstruction: that localizable superselection sectors of a local net form the representation category of a compact group, with Bose or Fermi statistics forced in $[3+1]$ dimensions, and that a field algebra carrying that group exists. The statement, its inputs and its two limitations are given in the text; the proof is long and belongs in Appendix A.

109.4.3 Modular theory

The Reeh–Schlieder theorem, Theorem 109.34, says the vacuum is cyclic and separating for a local algebra. That is exactly the hypothesis of a theorem of operator algebras which then hands back a canonical dynamics that nobody put in.

Theorem 109.72 (Tomita–Takesaki; imported)**.** *Let $\mathcal{M}$ be a von Neumann algebra with a cyclic and separating vector $|\Psi\rangle$. Define S on the dense set $\mathcal{M}\,|\Psi\rangle$ by $S\,A\,|\Psi\rangle := A^{*}\,|\Psi\rangle$,*

and let $S = J\Delta^{1/2}$ be its polar decomposition, with J antiunitary and $\Delta > 0$ self-adjoint. Then

$$\Delta^{\mathrm{i}\tau}\,\mathcal{M}\,\Delta^{-\mathrm{i}\tau} = \mathcal{M} \quad \text{for all } \tau \in \mathbb{R}\,, \qquad J\mathcal{M}J = \mathcal{M}'\,, \tag{109.49}$$

where $\mathcal{M}'$ is the commutant [1436].

Rests on Theorem 109.34.

The one-parameter group $\sigma_\tau(A) = \Delta^{\mathrm{i}\tau} A \Delta^{-\mathrm{i}\tau}$ is the *modular automorphism group*: an intrinsic time evolution of the algebra, determined by the algebra and the state alone. In general it has no geometric meaning. For one class of regions it does, and the fact is remarkable.

Theorem 109.73 (Bisognano–Wichmann; imported)**.** *Let $\mathcal{A}(W)$ be the algebra of the right wedge $W = \{x : x^1 > |x^0|\}$ in a Wightman theory, and $|0\rangle$ the vacuum. Then the modular group of $(\mathcal{A}(W), |0\rangle)$ is the one-parameter group of Lorentz boosts preserving W,*

$$\Delta^{\mathrm{i}\tau} = U(\Lambda_W(-2\pi\tau))\ , \tag{109.50}$$

$\Lambda_W(\eta)$ being the boost of rapidity η in the (x^0, x^1) plane; and the modular conjugation is $J = \Theta\, U(R_1(\pi))$, the PCT operator of Theorem 109.46 composed with a rotation by π about the x^1 axis [1540, 1572].

Rests on Theorems 109.46 and 109.72.

Proposition 109.74 (The vacuum is thermal in a wedge)**.** *Restricted to $\mathcal{A}(W)$, the vacuum satisfies the KMS condition with respect to the boost flow at inverse temperature 2π in the rapidity. Consequently, for an observer moving on a worldline of constant proper acceleration a inside W, whose proper time τ_p and rapidity are related by $\eta = a\tau_p/c$, the vacuum is a thermal state at*

$$T = \frac{\hbar a}{2\pi c\, k_B}\,. \tag{109.51}$$

Rests on Theorems 109.72 and 109.73 and Proposition 40.3.

Derivation. *Derives Proposition 109.74.*

The KMS condition characterizing a thermal state at temperature T with respect to a time evolution α_t is that $t \mapsto \omega(A\,\alpha_t(B))$ extends analytically to the strip $0 < \operatorname{im} t < \hbar/(k_B T)$ with $\omega\big(A\,\alpha_{t+\mathrm{i}\hbar/k_BT}(B)\big) = \omega(\alpha_t(B)\,A)$; equivalently the correlation functions are periodic in imaginary time with period $\hbar/(k_BT)$. Tomita–Takesaki delivers exactly this for σ_τ with period 1 in τ, which is a general property of the modular group; by Equation (109.50) the flow is the boost with rapidity $\eta = -2\pi\tau$, so the vacuum correlation functions are periodic in imaginary rapidity with period 2π.

Now convert to the proper time of the accelerated observer. A worldline of constant proper acceleration a in W is an orbit of the boost, and the relation $\eta = a\tau_p/c$ is not quoted from elsewhere but follows in two lines. Parametrize the orbit by the boost rapidity η of Definition 38.21, so that the four-velocity of Definition 40.2 is

$$u^\mu = c\,(\cosh\eta,\ \sinh\eta,\ 0,\ 0)\ ,$$

which has $u^2 = c^2$ as Proposition 40.3 requires. The four-acceleration is then $a^\mu = \mathrm{d}u^\mu/\mathrm{d}\tau_p = c\,(\sinh\eta, \cosh\eta, 0, 0)\,\mathrm{d}\eta/\mathrm{d}\tau_p$, whose invariant square is $a^\mu a_\mu = -c^2\,(\mathrm{d}\eta/\mathrm{d}\tau_p)^2$. The proper acceleration is the magnitude of this spacelike vector, $a = \sqrt{-a^\mu a_\mu} = c\,\mathrm{d}\eta/\mathrm{d}\tau_p$, so a constant integrates to $\eta = a\tau_p/c$, and c/a is the length scale of the resulting hyperbola. Periodicity in imaginary η with period 2π is therefore periodicity in imaginary τ_p with period $2\pi c/a$, and equating this to $\hbar/(k_BT)$ gives Equation (109.51). Dimensional check: $\hbar a$ has $\mathrm{J\,s} \times \mathrm{m/s^2} = \mathrm{J\,m/s}$, and dividing by c leaves J, so $\hbar a/(2\pi c k_B)$ is a temperature. □

Remark 109.75 (The honest status of the acceleration temperature). Equation (109.51) is the Unruh temperature [1590], and it has never been observed. The reason is arithmetic: an acceleration of $g = 9.806\,65\,\mathrm{m/s^2}$ gives $T = 3.98 \times 10^{-20}\,\mathrm{K}$, and reaching $T = 1\,\mathrm{K}$ requires $a = 2.47 \times 10^{20}\,\mathrm{m/s^2}$. No apparatus accelerates a detector at that rate for long enough to thermalize it.

Two things follow, and neither is a hedge. First, this chapter's theorems — Theorems 109.72 and 109.73 — are mathematics and stand independently of whether the temperature is ever measured; what is unobserved is a physical consequence, not the structure. Second, proposals to see an analogue of the effect in condensed-matter or optical systems [1675] measure an analogue: a laboratory system engineered to obey the same equations, whose agreement confirms the mathematics and not the physical claim about the quantum vacuum. Under the evidence rule of this treatise the distinction is not a technicality, and the entry stands as: theorem established, prediction untested.

Remark 109.76 (Modular theory and the entanglement of the vacuum). The operator Δ is the field-theoretic analogue of a reduced density matrix: for a finite quantum system with a bipartition, $\Delta = \rho_L \otimes \rho_R^{-1}$ and the modular flow is $\rho^{\mathrm{i}\tau} \cdot \rho^{-\mathrm{i}\tau}$. The reason field theory needs the modular operator rather than the density matrix is that $\mathcal{A}(\mathcal{O})$ is a von Neumann algebra of type III, in which no trace exists and no density matrix can be written — which is the structural reason the entanglement entropy of a region diverges, and the sense in which the divergence flagged in Chapter 84 is not an artefact of a cutoff but a property of the algebra. Theorem 109.34 is what makes $|0\rangle$ cyclic and separating and hence makes all of this available; the two theorems are the same fact told twice.

Derivation pending #188

Modular theory: the Tomita–Takesaki theorem, that the polar decomposition of the Tomita operator yields a modular automorphism group preserving the algebra and a conjugation exchanging it with its commutant; and the Bisognano–Wichmann identification of that group, for a wedge in a Wightman theory, with the boosts preserving the wedge. Both are stated with their hypotheses and used only through the KMS property, from which the acceleration temperature is derived in full in the text. The two proofs are long and belong in Appendix A.

109.5 The Euclidean route

109.5.1 Osterwalder–Schrader axioms

Nothing above suggests how to *construct* a theory. The one route that has ever produced an interacting example runs through imaginary time, where the oscillatory weight $\exp(\mathrm{i}S/\hbar)$ of Chapter 106 becomes the positive weight $\exp(-S_E/\hbar)$ of a probability measure, and the problem becomes one in classical statistical mechanics.

Definition 109.77 (Schwinger functions)**.** The Schwinger functions $S_n(x_1, \dots, x_n)$ are the moments of that measure, Equation (106.29), with the x_i distinct points of Euclidean $\mathbb{R}^4$ and the fourth coordinate $x^4 = \mathrm{i}ct$.

Theorem 109.78 (Osterwalder–Schrader)**.** *A family of Schwinger functions satisfying regularity, Euclidean covariance under* $\mathrm{SO}(4) \ltimes \mathbb{R}^4$*, reflection positivity, permutation symmetry and cluster decomposition is the analytic continuation of the Wightman functions of a unique Wightman theory in* $3+1$ *Minkowski dimensions, and conversely [1510, 1555]. The precise statement, with the five conditions written out, is Theorem 106.20.*

Rests on Definition 109.77 and Theorem 106.20.

The reconstruction of the Wightman functions from the Schwinger functions by analytic continuation in the time arguments, and the verification of the spectrum condition and of locality for the result, are not carried out here; they are owed in Appendix A, and the pending entry that records the debt is the one attached to Theorem 106.20, which is not duplicated here. What is derived below is the half that carries the physics.

Proposition 109.79 (Reflection positivity is Hilbert positivity)**.** *Under the correspondence of Theorem 109.78, the reflection positivity condition Equation* (106.30) *is the Euclidean form of property (v) of Proposition 109.20, and the operator* $\mathrm{e}^{-\tau H/\hbar}$ *reconstructed from Euclidean time translation is a self-adjoint contraction semigroup, so the Hamiltonian it generates is self-adjoint and bounded below.*

Rests on Theorem 109.78, Equation (106.30)*, and Proposition 109.20.*

Derivation. *Derives Proposition 109.79.*

Let $\mathcal{E}_+$ be the space of functionals of the field supported in $x^4 > 0$, and θ the reflection $x^4 \mapsto -x^4$. Reflection positivity says that $\langle F, G\rangle := \left\langle \overline{\theta F}\, G \right\rangle$ is a non-negative sesquilinear form on $\mathcal{E}_+$. Quotient by its null space and complete, exactly as in Theorem 109.66: the result is a Hilbert space $\mathcal{H}$ with a positive-definite inner product, which is property (v).

Euclidean time translation T_τ by $\tau > 0$ maps $\mathcal{E}_+$ into itself, and $\langle F, T_\tau G\rangle = \left\langle T_{\tau/2}F, T_{\tau/2}G \right\rangle$ by translation invariance and the reflection property, so T_τ descends to a self-adjoint operator on $\mathcal{H}$, positive by the same identity with $F = G$.

That T_τ is a *contraction* takes one step more than Cauchy–Schwarz alone. Write $g(\tau) := \|T_\tau F\|$, so that $g(0) = \|F\|$. The identity above with $G = F$ gives $g(\tau/2)^2 = \langle F, T_\tau F\rangle$, and Cauchy–Schwarz bounds the right-hand side by $\|F\|\,\|T_\tau F\|$, so

$$g(\tau/2)^2 \le g(0)\, g(\tau) \qquad \text{equivalently} \qquad g(\tau)^2 \le g(0)\, g(2\tau)\,.$$

This relates two *different* times and by itself bounds nothing; it must be iterated. Feeding it into itself n times,

$$g(\tau) \le g(0)^{1-2^{-n}}\, g(2^n\tau)^{2^{-n}}\,,$$

and if g is bounded uniformly in τ — which is what the regularity condition of Remark 109.80 is there to supply — then $g(2^n\tau)^{2^{-n}} \to 1$ as $n \to \infty$ and $g(\tau) \le g(0)$, that is $\|T_\tau\| \le 1$. A self-adjoint contraction semigroup is $\mathrm{e}^{-\tau H/\hbar}$ for a unique self-adjoint $H \ge 0$, and the factor $\hbar$ is fixed by the Euclidean weight $\mathrm{e}^{-S_E/\hbar}$ from which T_τ was built. The quantum-mechanical case of this argument, with the operator chain written out explicitly, is Proposition 106.21. □

Remark 109.80 (The linear-growth condition, and why it was added)*.* The first paper [1510] stated a regularity condition that proved too weak: it did not control the growth of S_n with n well enough to guarantee that the reconstructed objects are operator-valued *tempered* distributions rather than something wilder. The second paper [1555] replaced it by a linear-growth condition bounding $\|S_n\|$ by $n!\,(\text{const})^n$ times a Schwartz seminorm. The episode is worth recording as an example of an axiom system being corrected, and of why the correction matters: without it Theorem 109.78 would reconstruct a theory whose fields need not satisfy Axiom 109.12, and Theorem 109.26 — on which the whole of Section 109.3 rests — would be unavailable.

Remark 109.81 (What the Euclidean route buys)*.* Three things, and they are why every constructive success is Euclidean. The weight $\mathrm{e}^{-S_E/\hbar}$ is a positive measure, so the whole apparatus of probability — correlation inequalities, cluster expansions, the theory of Gibbs measures — becomes available. None of those three is developed in this book, whose probability chapter Chapter 11 covers the inferential statistics the experimental parts need rather than the theory of random fields; they are taken here from the constructive literature [1792]. The Euclidean symmetry group SO(4) is compact, unlike the Lorentz group, so its

representation theory is far better behaved. And a cutoff on a lattice respects reflection positivity exactly (Section 109.5.2), so the approximating theories are themselves quantum theories rather than formal expressions. What is bought is a construction problem in classical probability; what is paid is that the continuation back to real time must be established, and that is where Theorem 109.78 does the work.

109.5.2 Reflection positivity and the lattice

Proposition 109.82 (Wilson's action is reflection positive)**.** *The lattice gauge action of Equation* (106.81) *[1537], being a sum of plaquette terms each of which involves link variables on at most two adjacent time slices, satisfies Equation* (106.30) *for reflection in a plane midway between two slices. Consequently the lattice theory has a positive self-adjoint transfer operator* $T = \mathrm{e}^{-aH/(\hbar c)}$*, with* a *the lattice spacing in* m*, and hence a Hilbert space with a Hamiltonian bounded below.*

Rests on Equations (106.30) *and* (106.81) *and Proposition 106.21.*

Derivation. *Derives Proposition 109.82.*

Write the Euclidean action as a sum over time slices, $S_E = \sum_n [V(U_n) + K(U_n, U_{n+1})]$, in which V involves only the links within slice n and K only the links of two adjacent slices — this is exactly the plaquette structure, since a plaquette either lies in one slice or joins two neighbours. The functional integral then factorizes into a product of kernels, and reflection about the plane between slice 0 and slice 1 exchanges the two halves while conjugating, so that $\langle \overline{\theta F}\, F \rangle$ is the squared norm of the vector obtained by applying the half-chain to the ground state — the argument of Proposition 106.21, with the continuous evolution replaced by a finite product of kernels. Positivity of the transfer operator follows because the kernel e^{-K} is a positive-definite function of the pair of slice configurations, and self-adjointness because K is symmetric under exchange of the two slices. The exponent $aH/(\hbar c)$ is dimensionless because H is an energy and a/c a time.

The converse warning is Remark 106.22: an action coupling next-to-nearest time slices generally breaks the factorization, and the resulting transfer operator can have negative eigenvalues, whose signature is a correlator oscillating in Euclidean time. □

Proposition 109.83 (Mass gap and correlation length)**.** *In a reflection-positive Euclidean theory with a mass gap* $\Delta = Mc^2$ *above the vacuum, the connected correlation function of any local operator* O *decays as*

$$\langle O(0)\, O(r) \rangle_c \;\sim\; |\langle 0|\, O\, |1\rangle|^2 \, \mathrm{e}^{-r/\xi}, \qquad \xi = \frac{\hbar c}{\Delta} = \frac{\hbar}{Mc}, \tag{109.52}$$

for Euclidean separation r *in the time direction, where* $|1\rangle$ *is the lowest state with a non-zero overlap. The correlation length is the Compton wavelength of the lightest such state.*

Rests on Proposition 109.79.

Derivation. *Derives Proposition 109.83.*

By Proposition 109.79, Euclidean time translation is $\mathrm{e}^{-\tau H/\hbar}$. Inserting a complete set of energy eigenstates between the two operators and subtracting the vacuum contribution,

$$\langle O(0) O(\tau) \rangle_c = \sum_{n \neq 0} |\langle 0|\, O\, |n\rangle|^2 \, \mathrm{e}^{-(E_n - E_0)\tau/\hbar},$$

which for large τ is dominated by the smallest gap. Writing $\tau = r/c$ for the Euclidean distance r in metres and $E_1 - E_0 = \Delta$ gives Equation (109.52). With $\Delta = Mc^2$, $\xi = \hbar c/(Mc^2) = \hbar/(Mc)$. □

Example 109.84 (The pion sets the range of the strong force)**.** For quantum chromodynamics the lightest state carrying the quantum numbers of the *charged* component of the isovector pseudoscalar current is the charged pion, of rest energy $(139.570\,39 \pm 0.000\,18)\,\mathrm{MeV}$ [2427]. The neutral pion is lighter, $(134.9768 \pm 0.0005)\,\mathrm{MeV}$ [2427], and is equally an isovector pseudoscalar; the charged pion is the one taken here because it is the exchanged quantum in the nuclear-force estimate this example is written to match. By Equation (109.52) the corresponding correlation length is

$$\xi = \frac{\hbar c}{m_\pi c^2} = \frac{197.326\,980\,4\,\mathrm{MeV\,fm}}{139.570\,39\,\mathrm{MeV}} = 1.4138\,\mathrm{fm}\,, \tag{109.53}$$

which is the range of the nuclear force used throughout Chapter 107. That the range of a force and the decay rate of a Euclidean correlator are the same number is Proposition 109.83, and it is why a lattice computation measures masses by fitting exponentials.

Remark 109.85 (What the lattice does and does not establish)*.* Proposition 109.82 is what makes lattice gauge theory a candidate *constructive* route rather than merely a numerical method: each lattice theory is a bona fide quantum theory with a positive Hilbert space, so a continuum limit of them — if it exists and if the limit inherits reflection positivity, Euclidean invariance and the growth bound — would satisfy Theorem 109.78 and hence produce a Wightman theory. Neither the existence of the limit nor the inheritance has been proved.

What has been done is numerical, and it is impressive. With improved actions, physical quark masses, several spacings extrapolated to zero and several volumes extrapolated to infinity, the light hadron spectrum is reproduced at the percent level from the quark masses and the coupling alone [2122]; the details of the procedure are in Remark 102.61. The spectrum so computed begins at a non-zero mass, which is evidence that the gap exists. It is not a proof, for two reasons that must both be stated: the computation is performed at finite spacing and finite volume and extrapolated, with the extrapolation controlled by fits rather than by bounds; and a numerical demonstration that the lowest state has non-zero mass to within a stated error is not the statement $\Delta > 0$ that Section 109.7.3 requires.

109.6 The operator product expansion

Wilson conjectured that the singular behaviour of a product of local operators at short separation is carried entirely by c-number coefficient functions, the operator content being regular [1410]. It is the structural statement behind every short-distance calculation in the book.

Definition 109.86 (Operator product expansion)**.** Local operators A and B admit an *operator product expansion* if, as $\xi = x - y \to 0$,

$$A(x)\,B(y) \;\sim\; \sum_{n} C_n^{AB}(\xi)\,\mathcal{O}_n(y)\,, \tag{109.54}$$

asymptotically in the sense that truncating the sum after finitely many terms leaves a remainder vanishing faster than the last coefficient retained, when both sides are inserted into any correlation function. The C_n are c-number distributions carrying all the singularity; the $\mathcal{O}_n$ are local operators, ordered by increasing dimension.

Example 109.87 (The free scalar field)**.** For a free Hermitian scalar of mass m,

$$\phi(x)\phi(y) = \Delta^{+}(\xi; m^2c^2)\,\mathbb{1} + {:}\phi(x)\phi(y){:}\,, \tag{109.55}$$

by Wick's theorem (Theorem 99.41), and the second term is regular at $\xi = 0$, where it becomes ${:}\phi^2(y){:}$. Expanding it in ξ produces the higher operators $\xi^\mu\,{:}\phi\partial_\mu\phi{:}$ and so on. The whole

singularity therefore sits in the identity coefficient $\Delta^{+}(\xi; m^2c^2)$. Evaluating Equation (109.38) at equal times and spatial separation $r = |\boldsymbol{\xi}|$ small compared with the Compton wavelength $\hbar/(mc)$, the mass drops out of the integrand and $\int \mathrm{d}^3k\, \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{\xi}}/\left[(2\pi)^3\,|\boldsymbol{k}|\right] = 1/(2\pi^2 r^2)$, so

$$\Delta^{+} \to \frac{\hbar c}{4\pi^2 r^2}\,, \tag{109.56}$$

an inverse square in the separation times $\hbar c$, of dimension J m, which delivers the J/m of $[\phi]^2$ as it must.

Proposition 109.88 (Dimensional counting fixes the leading power)**.** *If A, B and $\mathcal{O}_n$ have engineering mass dimensions d_A, d_B, d_n — defined so that an operator of dimension d scales as $(\text{length})^{-d}$ — and the theory is scale invariant at short distance, then*

$$C_n^{AB}(\xi) \;\propto\; |\xi|^{\,d_n - d_A - d_B + \gamma_n}\,, \tag{109.57}$$

where γ_n is the anomalous dimension of $\mathcal{O}_n$.

Rests on Definition 109.86.

Derivation. *Derives Proposition 109.88.*

Both sides of Equation (109.54) must scale the same way under $x \to \lambda x$. At a fixed point of the renormalization group the operator $\mathcal{O}_n$ scales with the power $d_n + \gamma_n$ rather than d_n, the correction being generated by the same loop effects that make the coupling run; matching powers gives Equation (109.57). The operator with the *smallest* $d_n + \gamma_n$ dominates as $\xi \to 0$, which is why the expansion is useful: an infinite sum is controlled by its first few terms at short distance, and the accuracy improves as the separation shrinks. The identity operator has $d = 0$ and no anomalous dimension, so it always leads, and the leading singularity is $|\xi|^{-d_A - d_B}$ as in Example 109.87, where $d_A = d_B = 1$ gives $|\xi|^{-2}$. □

Remark 109.89 (Status of the expansion). Within renormalized perturbation theory the expansion is established order by order: the technology is Zimmermann's convergence proof for momentum-space subtraction [1411], in which a normal-product expansion of a composite operator is defined and its short-distance behaviour controlled, and the expansion of Equation (109.54) follows for the theories treated there. Outside perturbation theory it remains a hypothesis in the Wightman framework, verified in soluble models and assumed elsewhere; the exception is the Euclidean setting, where it is a theorem in some constructed models. The anomalous dimensions appearing in Equation (109.57) are computed in practice by continuing the dimension of spacetime away from four and expanding in the deviation, the device Wilson and Fisher introduced for critical exponents [1489]; that is a calculational continuation of the same kind as the dimensional regularization of Chapter 100, not a claim about physics in a non-integer dimension.

An alternative to the whole regularization apparatus is the causal construction of Epstein and Glaser [1498], which builds the time-ordered products directly as distributions by extending them from the region of non-coincident points to the diagonal. There the only ambiguity is the finite freedom in that extension, and it is exactly the renormalization freedom; no divergence appears at any stage, because none was ever written down. It is the cleanest way to see that renormalization is a statement about products of distributions, not about infinities.

The applications are what make the expansion indispensable. The short-distance analysis of Chapter 102 uses it to separate a calculable coefficient from a non-perturbative matrix element, which is what makes a strongly coupled theory predictive at all; the deep-inelastic sum rules belong to Chapter 116; and the anomalous dimensions of Equation (109.57) are what the renormalization group of Chapter 108 organizes. In every case the logical structure is the same: Equation (109.54) converts a product of operators at nearly coincident points

— which is precisely the object Proposition 109.1 declared not to exist — into a sum of well-defined operators with singular numerical coefficients. The expansion is how the theory answers the objection that opened this chapter.

109.7 Constructive results and what is missing

109.7.1 Models below four dimensions

Remark 109.90 (Dimensional flag). This subsection names models in spacetimes of dimension two and three. They are cited as facts about the *axiomatic framework* — as evidence that the axioms of Section 109.2.1 are consistent and that non-trivial solutions of them exist at all — and never as physics of the observed world, which is $3+1$ and to which the dimensional rule of this treatise confines every physical claim. No result of this subsection is used anywhere else in the book, and none of the numbers below is a measurement of anything.

Glimm and Jaffe constructed the two-dimensional φ^4 theory without cutoffs [1371], verifying that the interacting Hamiltonian is self-adjoint and bounded below and that the removal of the ultraviolet and volume cutoffs leaves a theory satisfying the axioms. The three-dimensional case is harder because the coupling has positive mass dimension there, and the positivity of the Hamiltonian — the step that fails first — was established later [1500]. The programme and its methods are set out in [1792].

Example 109.91 (Which axioms are verified)**.** For the two-dimensional model, all of them: the Hilbert space and its positive metric, the unitary representation of the Poincaré group of that spacetime with spectrum in the forward cone, a unique vacuum, fields as operator-valued distributions on a common domain, covariance and local commutativity, and cyclicity. The scattering theory was constructed and the theory shown to be non-trivial, in the sense that the S matrix is not the identity. For the three-dimensional model the same list holds with more work; in both cases the route is Euclidean, through Theorem 109.78, so what is actually built is a measure and what is verified is reflection positivity.

Remark 109.92 (Why four dimensions is different, in one sentence). The number of ultraviolet divergences a theory has is governed by the mass dimension of its coupling, and for φ^4 that dimension falls from positive in two and three dimensions — where only finitely many diagrams diverge and a finite number of subtractions suffices — to exactly zero in four, where every order diverges and the subtractions must be organized to all orders. That is the whole difference, and it is the same marginality that makes the coupling run logarithmically (Chapter 108) and that Section 109.7.2 is about.

109.7.2 Triviality of the four-dimensional scalar

For the simplest candidate in four dimensions the evidence points not merely to difficulty but to impossibility.

Theorem 109.93 (Triviality of φ^4; imported)**.** *The continuum limit of the lattice φ^4 theory, taken along the critical line, is a free field: in more than four spacetime dimensions by the correlation-inequality proofs of Aizenman [1662] and, independently, Fröhlich [1688]; and in the marginal case of exactly four dimensions by Aizenman and Duminil-Copin [2371], who show that the scaling limits of the critical four-dimensional Ising and φ^4 models are Gaussian.*

Rests on Theorem 109.78.

Derivation pending #189

Triviality of the four-dimensional scalar: the correlation-inequality argument bounding the connected four-point function of the lattice model above dimension four, and the tree-diagram bound that settles the marginal four-dimensional case. Both are results in classical probability rather than in field theory and are quoted here with their citations; they belong in Appendix A. What is derived in the text is the consequence, the scale at which the isolated scalar coupling diverges.

Remark 109.94 (What "trivial" means and does not mean). It does not mean that a scalar field theory is useless, nor that lattice φ^4 at finite spacing is free — it is not, and its correlation functions are perfectly non-Gaussian. It means that the *limit* of removing the cutoff while holding the physical mass fixed drives the renormalized coupling to zero. A self-interacting scalar in $3+1$ dimensions can therefore exist only as an effective theory carrying a finite cutoff, with its interaction strength tied to how far away that cutoff sits.

Proposition 109.95 (Where the cutoff must sit for the Higgs)**.** *Take the Standard Model scalar sector in isolation, dropping the gauge and Yukawa couplings, so that Equation* (104.72) *reduces to* $16\pi^2 \mathrm{d}\hat{\lambda}/\mathrm{d}\ln\mu = 24\hat{\lambda}^2$*. Then* $\hat{\lambda}$ *diverges at*

$$\mu_L = \mu_0 \exp\!\left(\frac{2\pi^2}{3\hat{\lambda}(\mu_0)}\right), \tag{109.58}$$

and with the measured value $\hat{\lambda} = 0.126$ *at* $\mu_0 = m_t c^2 = 172.57\,\mathrm{GeV}$ *[2427] this gives* $\mu_L \approx 8 \times 10^{24}\,\mathrm{GeV}$*, some* 6.7×10^5 *times the Planck energy* $1.22 \times 10^{19}\,\mathrm{GeV}$*.*

Rests on Equation (104.72)*.*

Derivation. *Derives Proposition 109.95.*

Write $\beta = \mathrm{d}\hat{\lambda}/\mathrm{d}\ln\mu = 24\hat{\lambda}^2/(16\pi^2) = 3\hat{\lambda}^2/(2\pi^2)$. Separating variables, $\mathrm{d}\hat{\lambda}/\hat{\lambda}^2 = 3\,\mathrm{d}\ln\mu/(2\pi^2)$, so

$$\frac{1}{\hat{\lambda}(\mu_0)} - \frac{1}{\hat{\lambda}(\mu)} = \frac{3}{2\pi^2}\ln\frac{\mu}{\mu_0},$$

and the right-hand side reaches $1/\hat{\lambda}(\mu_0)$ — at which point $1/\hat{\lambda}(\mu) = 0$ — when $\ln(\mu/\mu_0) = 2\pi^2/\big(3\hat{\lambda}(\mu_0)\big)$, which is Equation (109.58). Numerically $2\pi^2/(3 \times 0.126) = 52.2201$ and $\mathrm{e}^{52.2201} = 4.7743 \times 10^{22}$, so $\mu_L = 172.57 \times 4.7743 \times 10^{22} = 8.24 \times 10^{24}\,\mathrm{GeV}$; the fourth figure of the exponential is carried because rounding it to 4.77×10^{22} would move the answer to 8.23×10^{24}. The Planck energy is $E_P = \sqrt{\hbar c^5/G} = 1.956 \times 10^9\,\mathrm{J} = 1.221 \times 10^{19}\,\mathrm{GeV}$ from $\hbar = 1.054\,571\,817 \times 10^{-34}\,\mathrm{J\,s}$, $c = 299\,792\,458\,\mathrm{m/s}$ and $G = 6.674\,30 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$ [2431], giving the stated ratio. □

Remark 109.96 (How much this argument is worth). Less than the arithmetic suggests, and the honest accounting is short. The one-loop pure-scalar running used above is not the Standard Model running: the top Yukawa term $-6\hat{y}_t^4$ in Equation (104.72) outweighs $24\hat{\lambda}^2$ by a factor of order ten at m_t, so the actual quartic coupling runs *down* and crosses zero near $10^{10}\,\mathrm{GeV}$ (Remark 104.67) rather than blowing up at $10^{25}\,\mathrm{GeV}$. Equation (109.58) is therefore not a statement about the Higgs boson; it is a statement about the isolated scalar theory to which Theorem 109.93 applies, and it is quoted here to show that even in that theory the triviality obstruction is astronomically remote from any accessible scale.

What survives is the point of principle. A pure φ^4 theory in $3+1$ dimensions cannot be a fundamental theory: either it carries a cutoff, or it is free. The parallel obstruction on the other side of quantum electrodynamics is the Landau pole of the running fine structure constant, the same phenomenon in a theory that is also not asymptotically free; both belong to Chapter 108, which is where the running is organized. That the strong coupling of

Chapter 102 runs the other way — to zero at short distance — is exactly why Yang–Mills theory, and not the scalar, is the candidate for a four-dimensional construction.

109.7.3 The Yang–Mills mass gap

Definition 109.97 (The open problem, stated precisely)**.** Prove that for any compact simple gauge group G a non-trivial quantum Yang–Mills theory exists on $\mathbb{R}^4$ — that is, a family of Wightman functions satisfying Axiom 109.9 to Axiom 109.15, or equivalently a family of Schwinger functions satisfying the hypotheses of Theorem 109.78 — whose classical limit is the Yang–Mills action, and prove that it has a mass gap: a number $\Delta > 0$ such that every state other than the vacuum has energy at least Δ in the rest frame [2097].

Remark 109.98 (Why one end is tractable and the other is not)*.* The ultraviolet end is favourable. Asymptotic freedom (Section 102.4) makes the coupling vanish logarithmically at short distance, so the theory becomes weakly coupled exactly where the divergences are, and the continuum limit is approached along a trajectory on which perturbation theory is a good guide — the opposite of the situation in Section 109.7.2, where the coupling grows at short distance and the limit is forced to zero. This is the strongest structural reason to expect that a four-dimensional interacting theory exists at all.

The infrared end is where everything is hard, and the mass gap is an infrared statement. The Lagrangian contains no mass; the gap, if it exists, is generated dynamically and is a pure number times Λ_{QCD}, which Equation (102.45) defines as an energy — matching Δ, which Definition 109.97 likewise states as an energy. The corresponding mass is $\Delta/c^2 = M$ in the notation of Proposition 109.83. No expansion is available there — the coupling is large, the strong coupling expansion of the lattice is valid only at spacings far from the continuum, and no controlled interpolation between the two regimes has been constructed.

Remark 109.99 (The evidence, and why it is not a proof)*.* Three independent lines of evidence say the gap exists.

No massless hadron. The observed spectrum begins at the pion, of rest energy $(139.570\,39 \pm 0.000\,18)$ MeV [2427], and the pion is light for a reason the theory explains — it is the pseudo-Goldstone boson of chiral symmetry breaking (Chapter 102) — not because the spectrum approaches zero. Nothing massless has ever been seen carrying colour or built from gluons, and a massless strongly interacting particle would produce a long-range force that is conspicuously absent (Example 109.84).

The glueball spectrum. Lattice computations in the pure gauge theory, which has no quarks and hence no chiral mechanism, find a lowest state of non-zero mass. That is the cleanest numerical statement of the gap, since in that theory the gap is the whole question.

The light hadron spectrum from first principles. Taking as input only the quark masses and the coupling, [2122] reproduces the measured masses at the percent level (Phenomenon 102.64), which would be impossible if the theory did not have the spectrum it is being asked to have.

None of this is a proof, and the distinction is not pedantry. Every one of these is a computation at finite lattice spacing and finite volume, extrapolated; the extrapolations are controlled by fits with estimated errors, not by bounds; and the statement to be proved is a statement about a limit that has not been shown to exist. The treatise's own rules make the position sharp: the confinement of quarks and the mass gap are observed facts of Nature for which no derivation exists, and they are recorded as such in Section 102.7 and Section 133.6 rather than being quietly upgraded to results.

109.7.4 What axiomatics does and does not secure

The balance sheet, drawn honestly.

Secured. The *PCT* theorem (Theorems 109.44 and 109.46), from locality, covariance and the spectrum condition alone — so that the measurements of Section 105.5.3 test those three axioms and nothing else. The spin–statistics connection (Theorem 109.49), which discharges the debt owed by Chapters 83, 102, 107 and 120 and underwrites the exclusion principle, the periodic table and degeneracy pressure. The Källén–Lehmann representation and the bound $0 \le Z \le 1$ (Theorem 109.54 and Corollary 109.55), exact rather than perturbative, which every renormalized propagator in Chapter 100 presumes. The Reeh–Schlieder theorem and its two faces, vacuum entanglement and the impossibility of a local operator annihilating the vacuum (Theorem 109.34 and Corollary 109.35). Cluster decomposition as the equivalent of a unique vacuum (Proposition 109.23). The irrelevance of the choice of interpolating field (Theorem 109.38), assumed without comment wherever a field is redefined. And the structural results of Section 109.4: that superselection sectors carry the representation theory of a compact group and that the vacuum's modular flow in a wedge is a geometric boost.

Not secured. The existence of any interacting model satisfying the axioms in $3 + 1$ dimensions, the Standard Model included. Nothing in Part XI has been shown to be a theory in the sense of Section 109.2.1; what has been shown is that a particular calculational scheme, order by order in a coupling, reproduces measurement to extraordinary accuracy. Asymptotic completeness — that the scattering states exhaust the Hilbert space — is an assumption of Chapter 86 and not a theorem. The mass gap of Definition 109.97 is open. And for the simplest four-dimensional candidate the answer is known and is negative (Theorem 109.93).

Remark 109.100 (The position this book takes). The Standard Model is an extraordinarily well-tested effective theory whose mathematical existence is unproven. Both halves of that sentence are load-bearing. The first is why Part XI computes with it without apology: agreement with the electron's anomalous moment at about one part in 10^9 of a_e, which Chapter 112 shows is the precision of the input α rather than of the measurement, is evidence of a kind that no foundational anxiety outweighs. The second is why this chapter exists and why Section 133.6 lists the gap among the open problems rather than among the technicalities.

Neither half licenses the third position sometimes taken, that because the theory does not exist mathematically it should be replaced. There is no evidence-based replacement — the programmes usually named in this connection are excluded from this treatise for exactly that reason (Section 133.7) — and a theory that predicts to nine significant figures is not overthrown by the absence of a proof that it exists. The correct response is the one the constructive programme has been making for sixty years: build the object, and see.

A survey of the state of the subject as it stood after its first two decades, still the clearest short account of what the axioms deliver, is [1562].

Chapter 110

Experiment: Parity Violation

Tests Phenomena 101.26, 104.55 and 105.16.

Assuming Propositions 101.15, 101.27, 105.19 and 105.20.

Parity conservation was, until 1956, treated as a law of nature rather than as a hypothesis under test. This chapter records the experiment that ended that status: the cobalt-60 beta-decay asymmetry measured by Wu, Ambler, Hayward, Hoppes and Hudson [1133], prompted by the observation of Lee and Yang [1091] that not one existing measurement bore on parity in the weak interaction, and confirmed within days by the pion–muon–electron chain [1109, 1110]. The chapter sits immediately after the weak-interaction theory of Chapter 101 and the discrete-symmetry formalism of Chapter 105, because it is the measurement those chapters exist to explain; it is the direct experimental root of the two-component neutrino of Chapter 96, of the helicity measurement in Chapter 98, and of the chiral gauge structure that Chapter 104 builds on.

The division of labour with those chapters is worth stating at the outset, because it decides what is and is not repeated here. The formal apparatus — the space-inversion operator on states and on Dirac fields, the classification of bilinears, the $V - A$ current, the relation between chirality and helicity — is derived in Sections 101.4 and 105.2 and is used here, not rebuilt. What this chapter owes is the measurement: what the source physically was, how cold it had to be and why, what the counters saw, what numbers came out with what uncertainties, and by what controls a counting-rate difference of a few tens of per cent was shown to be a property of the weak interaction rather than of a photomultiplier in a magnetic field. Its second half follows the same pseudoscalar observable out of nuclear beta decay and into neutral-current physics — atomic parity violation [1519, 1946], polarized deep-inelastic scattering [1625, 1643] and the weak charge of the proton [2301] — where parity violation has become a precision tool for measuring the weak mixing angle rather than a surprise.

110.1 Historical context and the prediction under test

110.1.1 Parity as a conserved quantum number

Space inversion is the map

$$P : \boldsymbol{x} \longmapsto -\boldsymbol{x}\,, \tag{110.1}$$

implemented on quantum states by a unitary operator $\mathcal{P}$ with $\mathcal{P}\psi(\boldsymbol{x},t) = \eta_P\,\psi(-\boldsymbol{x},t)$. Applying it twice returns every position to itself, so $\mathcal{P}^2$ is a symmetry operation that does nothing; with the usual convention that it is the identity, $\mathcal{P}^2 = \mathbb{1}$ and the eigenvalues of $\mathcal{P}$ are ± 1. That is the whole of the kinematics, and it is why parity is a two-valued quantum number rather than a continuous one: there is no infinitesimal space inversion, so parity has no associated conserved current and no Noether charge, only a multiplicative selection rule.

Wigner introduced parity as a conserved quantum number of atomic states in 1927 [592], and the evidence for its conservation in the electromagnetic interaction was, and remains, overwhelming. It is carried chiefly by Laporte's rule: an electric dipole transition connects only atomic states of opposite parity, because the dipole operator $-e\boldsymbol{x}$ is itself parity-odd. The rule is derived as Proposition 105.1; here we need only its status as evidence. Every line in every atomic spectrum that obeys it — and every line whose absence it explains — is a measurement that the electromagnetic Hamiltonian commutes with $\mathcal{P}$, and the accumulated precision of atomic and nuclear spectroscopy by 1956 bounded any parity-violating admixture in the nuclear force at the level of 10^{-7} in amplitude [1091].

The observables of a physical theory divide, under Equation (110.1), into four classes according to how they transform. A *scalar* is unchanged; a *pseudoscalar* changes sign; a *vector* (or polar vector) reverses; an *axial vector* (or pseudovector) does not. The position $\boldsymbol{x}$, the momentum $\boldsymbol{p} = m\mathrm{d}\boldsymbol{x}/\mathrm{d}t$ and the electric field $\boldsymbol{E}$ are polar; the angular momentum $\boldsymbol{J} = \boldsymbol{x} \times \boldsymbol{p}$, the spin $\boldsymbol{S}$ and the magnetic field $\boldsymbol{B}$ are axial, because a cross product of two polar vectors acquires two sign changes and therefore none. Consequently $\boldsymbol{J} \cdot \boldsymbol{p}$, $\boldsymbol{S} \cdot \boldsymbol{p}$ and $\boldsymbol{E} \cdot \boldsymbol{B}$ are pseudoscalars. The complete table of Dirac bilinears and their behaviour is Table 105.1.

The entire experimental programme of this chapter rests on one statement about pseudoscalars, and it is worth isolating it because everything else is instrumentation.

Proposition 110.1 (A pseudoscalar mean vanishes if parity holds)**.** *Let Ω be a pseudoscalar observable, $\mathcal{P}\Omega\mathcal{P}^{-1} = -\Omega$, and let ρ be the state of a system prepared by an interaction that commutes with $\mathcal{P}$ from an initial state that is itself parity invariant, $\mathcal{P}\rho\mathcal{P}^{-1} = \rho$. Then*

$$\langle \Omega \rangle = \operatorname{tr}(\rho\,\Omega) = 0\,. \tag{110.2}$$

A measured $\langle\Omega\rangle \neq 0$ therefore proves that the interaction responsible does not commute with $\mathcal{P}$, with no dynamical input of any kind.

Rests on Equation (110.1)*.*

Proof. *Derives Proposition 110.1.*

Insert $\mathbb{1} = \mathcal{P}^{-1}\mathcal{P}$ twice under the trace and use its cyclic property:

$$\langle \Omega \rangle = \operatorname{tr}(\rho\,\Omega) = \operatorname{tr}\Big(\mathcal{P}\rho\mathcal{P}^{-1}\,\mathcal{P}\Omega\mathcal{P}^{-1}\Big) = \operatorname{tr}(\rho\,(-\Omega)) = -\,\langle \Omega \rangle\ ,$$

whence $\langle\Omega\rangle = 0$. The two hypotheses are exactly the two things an experiment must arrange or verify: that the state was prepared without reference to a handedness — a magnetic field is axial, so polarizing a sample with a solenoid does *not* introduce one — and that Ω is genuinely parity-odd. Nothing is assumed about the Hamiltonian beyond $[\mathcal{P}, H] = 0$, which is why one number settles a question that decades of spectroscopy had not thought to ask. □

Remark 110.2 (Why a magnetic field is a legitimate preparation)*.* The point deserves emphasis because it is the commonest misreading of Wu's experiment. Aligning nuclear spins with a solenoid does not smuggle a handedness into the apparatus: $\boldsymbol{B}$ is an axial vector, so the mirror image of the polarized source is a source polarized *in the same direction* with the current in the coil reversed — and reversing a current is not a physical change of the state prepared, only of the wiring. The mirror image of "spins up, electrons preferentially down" is "spins up, electrons preferentially up". Those two statements are about the same physical preparation and they disagree, which is the whole content of the result.

110.1.2 The tau–theta puzzle

The pressure to test parity came from two strange mesons. The θ^+ decayed to $\pi^+\pi^0$ and the τ^+ to $\pi^+\pi^+\pi^-$; by 1955 their masses agreed to better than a per cent and their

lifetimes to within the experimental errors, and the modern values — one particle, the K^+, with $m_K c^2 = (493.677 \pm 0.015)\,\mathrm{MeV} = (7.9095 \pm 0.0002) \times 10^{-11}\,\mathrm{J}$ and mean life $\tau_K = (1.2380 \pm 0.0020) \times 10^{-8}\,\mathrm{s}$ [2427] — say why the coincidence was intolerable. But the parities of the two final states are opposite: by Equation (105.31) a state of n pions with no relative orbital angular momentum has parity $(-1)^n$, so $\eta_P(\pi\pi) = +1$ while $\eta_P(\pi\pi\pi) = -1$.

Only two escapes existed. Either θ and τ were genuinely distinct particles with an unexplained mass and lifetime degeneracy, or the three-pion decay carried a unit of relative orbital angular momentum, in which case the parent would have spin ≥ 1 and the parities could agree. Dalitz closed the second by inventing the plot that bears his name [1016]: for a three-body decay at rest the density of events in the (T_1, T_2) plane of two of the kinetic energies is the squared matrix element and nothing else, so a uniform population is a direct measurement that the decay amplitude is constant — no relative orbital angular momentum, no spin. The observed τ plot was uniform. The construction and its derivation are given at Section 105.2.1, which also carries the phase-space calculation behind Equation (105.32); the point here is only that by 1956 the escape route through angular momentum had been closed experimentally, not assumed away.

110.1.3 Lee and Yang: parity untested in the weak interaction

Lee and Yang responded with an audit rather than a mechanism [1091]. They asked what the experimental evidence for parity conservation actually consisted of, and found that all of it came from strong and electromagnetic processes. In the weak interaction there was none: not one experiment had ever been designed to detect a parity-odd observable in a weak decay, and the reason was structural rather than accidental. Every weak measurement then existing was a lifetime, a branching ratio or an energy spectrum, and each of those is a scalar; by Proposition 110.1 a scalar is insensitive to parity violation at leading order, since the parity-odd part of the interaction contributes to a scalar only through its square. A theory in which parity was violated maximally would have reproduced every weak number known in 1956.

What makes the paper a model of method is its second half, which lists the experiments that would settle the question. Each proposal is the mean of a pseudoscalar:

- the correlation $\langle \boldsymbol{J} \rangle \cdot \boldsymbol{p}_e$ between the polarization of an oriented nucleus and the momentum of the emitted electron — an axial vector dotted into a polar one;
- the longitudinal polarization $\langle \boldsymbol{s} \rangle \cdot \boldsymbol{p}$ of the electron emitted in an unoriented beta decay, which requires no cryogenics but a polarimeter;
- in the chain $\pi^+ \to \mu^+ \nu_\mu$ followed by $\mu^+ \to e^+ \nu_e \bar{\nu}_\mu$, the correlation between the muon direction and the positron direction, which is nonzero only if the muon is produced longitudinally polarized.

All three were carried out within a year of the paper, by three independent groups with no common apparatus, and all three returned the largest answer the kinematics permits. The first is the subject of this chapter; the second was done by Frauenfelder and collaborators with Mott-scattering polarimetry on the electrons from ^{60}Co itself [1108] and by Schopper through the circular polarization of the accompanying gamma rays [1131]; the third is Section 110.6 below. Lee and Yang received the 1957 Nobel prize, in the same year as the measurements they proposed.

110.1.4 The observable and what a measurement must deliver

The observable of the cobalt experiment is the correlation between the nuclear polarization and the electron momentum. Write $\hat{\boldsymbol{n}}$ for the unit vector along the mean nuclear spin and $\hat{\boldsymbol{p}}_e$

for the electron direction. The most general angular distribution linear in that correlation is

$$W(\theta) \propto 1 + A\,\frac{v}{c}\,f\cos\theta\,, \qquad \cos\theta = \hat{\boldsymbol{n}}\cdot\hat{\boldsymbol{p}}_e\,, \tag{110.3}$$

in which three factors appear that the experiment must supply separately, and the failure to supply any one of them makes the number uninterpretable:

1. the *asymmetry coefficient* A, the quantity of physical interest, dimensionless, and predicted by the theory of the interaction;
2. the *degree of nuclear polarization* $f = |\langle \boldsymbol{J}\rangle|\,/J$, a property of the source and its temperature, which must be measured independently and which decays to zero as the source warms;
3. the *electron speed* v/c, which enters because the chirality projected out by the interaction is converted into helicity only up to a factor v/c (Proposition 105.20), and which for a continuous beta spectrum means an average weighted by the counter's acceptance.

What a counter measures is not $W(\theta)$ but a rate, and rates depend on solid angles, detector efficiencies and source strength — all of which drift. The design of the experiment therefore forms the observable as a ratio in which those cancel.

Proposition 110.3 (The measured quantity)**.** *Let $N_\uparrow$ and $N_\downarrow$ be the counts recorded in one fixed counter during equal intervals with the polarizing field in the two opposite senses. Then*

$$\varepsilon \equiv \frac{N_\uparrow - N_\downarrow}{N_\uparrow + N_\downarrow} = A\,\frac{v}{c}\,f\;\langle\cos\theta\rangle\;, \tag{110.4}$$

where $\langle\cos\theta\rangle$ is the average of $\cos\theta$ over the counter's acceptance and equals 1 for a counter subtending a small solid angle on the polarization axis. Every geometric and efficiency factor cancels in the ratio, and the statistical uncertainty on ε is $\sigma_\varepsilon = 1/\sqrt{N}$ with $N = N_\uparrow + N_\downarrow$.
Rests on Equation (110.3).

Proof. *Derives Proposition 110.3.*
Reversing the solenoid current reverses $\hat{\boldsymbol{n}}$ and hence the sign of $\cos\theta$ at fixed counter position, so with a common normalization K containing the solid angle, the efficiency and the source activity,

$$N_\uparrow = K\big(1 + A\tfrac{v}{c}f\,\langle\cos\theta\rangle\big)\;, \qquad N_\downarrow = K\big(1 - A\tfrac{v}{c}f\,\langle\cos\theta\rangle\big)\;.$$

Forming the ratio Equation (110.4) cancels K identically. For the error, write $\varepsilon = (N_\uparrow - N_\downarrow)/N$ with N fixed; the numerator is a difference of Poisson counts of variance $N_\uparrow + N_\downarrow = N$, so $\sigma_\varepsilon^2 = N/N^2 = 1/N$ up to a correction of relative order ε^2, negligible here. □

The last statement fixes the scale of the whole enterprise. Reaching a statistical precision of $1\,\%$ on ε requires $N = 10^4$ counts, and — because the polarization survives only a few minutes — those counts must be accumulated in of order $60\,\mathrm{s}$. The counter must therefore see a rate of order $2\times10^2/\mathrm{s}$. With a solid-angle fraction of a few per cent and an escape-and-detection efficiency of order one half, the source activity must be at least

$$\mathcal{A} \gtrsim \frac{2\times10^2/\mathrm{s}}{0.05\times0.5} \approx 1\times10^4\,\mathrm{Bq}\,, \tag{110.5}$$

which is a modest laboratory source but a hard lower bound: a weaker one cannot deliver the statistics inside the warm-up window however long the experiment runs, because the signal is gone before the counts accumulate. Equation (110.5) is the reason the measurement had to wait for a source preparation technique and a cryostat that were compatible with each other.

110.2 Apparatus

110.2.1 The polarized cobalt-60 source

Table 110.1: Properties of the ^{60}Co source and of its decay, in SI units with the customary nuclear units alongside. Energies are given in joules and in electronvolts because the two appear throughout the experimental literature; the half-life and the gamma energies are standard nuclear data, the mass-difference input being the atomic-mass evaluation [2393]. The nuclear magnetic moment is quoted in units of the nuclear magneton $\mu_N = (5.050\,783\,739\,3 \pm 0.000\,000\,001\,6) \times 10^{-27}\,\mathrm{J/T}$ [2431].

Quantity	Value (SI)	Customary form
Parent spin and parity	—	5^+
Daughter level fed	—	4^+ of ^{60}Ni
Half-life	$1.6635 \times 10^{8}\,\mathrm{s}$	$(5.2714 \pm 0.0005)\,\mathrm{yr}$
Decay constant	$4.1667 \times 10^{-9}\,/\mathrm{s}$	—
Beta endpoint kinetic energy	$5.098 \times 10^{-14}\,\mathrm{J}$	$318.2\,\mathrm{keV}$
First cascade gamma	$1.8797 \times 10^{-13}\,\mathrm{J}$	$1173.23\,\mathrm{keV}$
Second cascade gamma	$2.1349 \times 10^{-13}\,\mathrm{J}$	$1332.49\,\mathrm{keV}$
Nuclear magnetic moment	$1.919 \times 10^{-26}\,\mathrm{J/T}$	$3.799\,\mu_N$
Minimum activity required, Equation (110.5)	$1 \times 10^{4}\,\mathrm{Bq}$	—
Corresponding number of ^{60}Co atoms	2.4×10^{12}	—

The choice of nucleus is not incidental; it is forced by four requirements that almost no other nuclide satisfies at once, and Table 110.1 collects the numbers.

First, the transition must be *allowed and pure Gamow–Teller*, so that the predicted asymmetry coefficient is the maximal $A = -1$ of Proposition 101.27 rather than a mixture of Fermi and Gamow–Teller amplitudes with an unknown ratio. The decay $^{60}\mathrm{Co}\,(5^+) \to {}^{60}\mathrm{Ni}^*\,(4^+)$ has $\Delta J = 1$ with no parity change, which by the allowed selection rules of Proposition 101.15 is pure Gamow–Teller: a Fermi transition cannot change J at all.

Second, the parent spin must be *large*. The polarization attainable at a given temperature grows with J, because the Zeeman ladder has $2J + 1$ rungs and the Boltzmann factor acts across all of them; $J = 5$ is among the largest available in a convenient beta emitter.

Third, the decay must be followed by a *gamma cascade*, because that cascade is the only practical thermometer for the nuclear orientation. The 4^+ daughter level de-excites through $4^+ \to 2^+ \to 0^+$, emitting photons of $1173.23\,\mathrm{keV}$ and $1332.49\,\mathrm{keV}$, and the angular distribution of those photons relative to the orientation axis is anisotropic whenever the parent nuclei are aligned. Without an independent measurement of f, Equation (110.4) determines only the product Af, and the experiment would establish that parity is violated without measuring by how much.

Fourth, the half-life must be long enough that the source does not decay away during preparation and short enough that a usable activity fits in a thin layer. At $(5.2714 \pm 0.0005)\,\mathrm{yr} = 1.6635 \times 10^{8}\,\mathrm{s}$ the decay constant is $\lambda = \ln 2 / t_{1/2} = 4.1667 \times 10^{-9}\,/\mathrm{s}$, so Equation (110.5) is met by $N = \mathcal{A}/\lambda \approx 2.4 \times 10^{12}$ atoms, a quantity of ^{60}Co of order $2.4 \times 10^{-10}\,\mathrm{g}$. The active material is therefore a trace, and the layer thickness is set by beta absorption rather than by chemistry.

Remark 110.4 (The endpoint energy quoted in 1957). The 1957 literature quotes a beta endpoint of $0.312\,\mathrm{MeV}$; the modern value, from the mass difference of [2393] less the

excitation energy of the daughter level, is 0.3182 MeV. The two per cent shift is irrelevant to the result — it moves v/c by about half a per cent — but it is recorded here so that a reader comparing this chapter with the original paper is not left wondering which number is wrong.

Why the active layer must be thin The source is a layer of ^{60}Co grown on the surface of the paramagnetic salt crystal, and its thickness is the leading systematic. An electron created inside the layer loses energy before it escapes, which lowers v/c and hence, by Equation (110.4), the observed asymmetry; a thick layer also scatters electrons, which randomizes $\cos\theta$ and dilutes the asymmetry a second time. Both effects reduce $|\varepsilon|$, so they cannot manufacture the result — but they do prevent the extraction of A.

Proposition 110.5 (Tolerable source thickness)**.** *For a beta electron of kinetic energy near* 150 keV*, which is representative of the counted part of the* ^{60}*Co spectrum, the practical range in a solid of density* $\rho \approx 2\times10^{3}\,\mathrm{kg/m^3}$ *is about* $1.3\times10^{-4}\,\mathrm{m}$*. A source layer of a few tens of micrometres therefore costs the average escaping electron of order* 10 keV *and a tenth of its range, which is tolerable; a layer of a hundred micrometres would not be.*

Rests on Equation (110.4)*.*

Derivation. *Derives Proposition 110.5.*

The empirical range–energy relation for electrons in the range 0.01–3 MeV, expressed as a mass thickness $R\rho$ in $\mathrm{kg/m^2}$ with the kinetic energy T in MeV, is

$$R\rho = 4.12\,\mathrm{kg/m^2}\;T^{\,1.265-0.0954\ln T}\,. \tag{110.6}$$

At $T=0.15$ the exponent is $1.265+0.181=1.446$ and $T^{1.446}=0.0644$, giving $R\rho = 0.265\,\mathrm{kg/m^2}$; at $\rho=2\times10^{3}\,\mathrm{kg/m^3}$ this is $R=1.33\times10^{-4}\,\mathrm{m}$. At the endpoint $T=0.318$ the same formula gives $R\rho=0.855\,\mathrm{kg/m^2}$, i.e. $R=4.3\times10^{-4}\,\mathrm{m}$. A layer of thickness $d=3\times10^{-5}\,\mathrm{m}$ presents an average path of $d/2$ to an isotropically emitted electron that escapes forwards, that is $0.03\,\mathrm{kg/m^2}$, about 11 % of the 150 keV range. Inverting Equation (110.6) for the energy that has $0.235\,\mathrm{kg/m^2}$ of range left gives $T=139.4$ keV, so the mean energy loss is of order 11 keV, and by $\mathrm{d}(v/c)/(v/c)=(T+m_ec^2)^{-1}(1-v^2/c^2)\,\mathrm{d}T\cdot(c/v)^2$ this shifts $v/c=0.63$ downwards by about 2.5 % — the same figure the exact ratio $\beta(139.4\,\mathrm{keV})/\beta(150\,\mathrm{keV})=0.6186/0.6343$ gives. That is the size of the correction the source thickness imposes on the extraction of A from Equation (110.4), and it is why the paper's conclusion is stated as "$|A|$ consistent with the maximum" rather than as a number with a small error bar. □

110.2.2 Adiabatic demagnetization and the cryostat

Nuclear orientation requires that the Zeeman splitting of the nuclear sublevels exceed the thermal energy, and that single requirement dictates the entire cryogenic apparatus.

Proposition 110.6 (The orientation condition)**.** *For a nucleus of spin* I *and magnetic moment* μ *in a field* B *at temperature* T*, the degree of polarization* $f=\langle m\rangle/I$ *is a function of the single dimensionless combination*

$$x=\frac{\mu B}{I\,k_B T}\,, \tag{110.7}$$

namely the Brillouin function $f=B_I(Ix)$*. Reaching* $f\approx0.6$ *for* ^{60}*Co, which has* $I=5$ *and* $\mu=3.799\,\mu_N=1.919\times10^{-26}\,\mathrm{J/T}$*, requires* $x=0.378$*, that is*

$$\frac{B}{T}=\frac{x\,I\,k_B}{\mu}\approx 1.4\times10^{3}\,\mathrm{T/K}\,. \tag{110.8}$$

Rests on Equation (79.5)*.*

Derivation. *Derives Proposition 110.6.*

The Hamiltonian of the nuclear moment in the field is $H = -\boldsymbol{\mu}\cdot\boldsymbol{B}$, with eigenvalues $E_m = -(\mu/I)\,B\,m$ for $m = -I, \dots, I$, so the Boltzmann weight of the mth sublevel is e^{xm} with x as in Equation (110.7). Hence

$$f = \frac{1}{I}\,\frac{\sum_{m=-I}^{I} m\,\mathrm{e}^{xm}}{\sum_{m=-I}^{I}\mathrm{e}^{xm}} = \frac{1}{I}\,\frac{\partial}{\partial x}\ln\sum_{m=-I}^{I}\mathrm{e}^{xm}\,, \tag{110.9}$$

which is the Brillouin function and depends on B and T only through their ratio. Evaluating the sum numerically for $I = 5$ gives $f = 0.196$ at $x = 0.1$, $f = 0.513$ at $x = 0.3$, $f = 0.600$ at $x = 0.378$ and $f = 0.837$ at $x = 0.8$. Solving $f = 0.6$ and inserting $I = 5$, $k_B = 1.380\,649 \times 10^{-23}\,\mathrm{J/K}$ [2431] and $\mu = 1.919 \times 10^{-26}\,\mathrm{J/T}$ gives Equation (110.8). □

Equation (110.8) is a severe constraint and it is worth reading it twice. A laboratory solenoid delivering $B = 1\,\mathrm{T}$ would need $T = 0.7\,\mathrm{mK}$, below what any refrigerator of the period could reach and below the ordering temperature of the salt. The way out, and the reason the experiment was possible at all, is that the field acting on the *nucleus* is not the applied field: in a paramagnetic salt containing the active ion, the hyperfine interaction with the ion's own electron shell produces an effective field at the nucleus of order $10\,\mathrm{T}$ once the electronic moments are themselves aligned, and the electronic moments are aligned by a field of a few millitesla because the electronic moment is three orders of magnitude larger than the nuclear one. The applied field steers the electrons; the electrons polarize the nuclei. With $B \sim 10\,\mathrm{T}$, Equation (110.8) demands only $T \lesssim 7\,\mathrm{mK}$.

Cooling by adiabatic demagnetization The millikelvin range was reached by the one technique available in 1957, and its principle is a single line of thermodynamics.

Proposition 110.7 (Adiabatic demagnetization)**.** *For a system of non-interacting magnetic moments the entropy is a function of B/T alone. An isentropic reduction of the field from B_i to a residual internal field b therefore cools the sample as*

$$T_f = T_i\,\frac{b}{\sqrt{B_i^2 + b^2}} \approx T_i\,\frac{b}{B_i} \qquad (b \ll B_i)\,. \tag{110.10}$$

Starting from $T_i = 1.2\,\mathrm{K}$ in $B_i = 1\,\mathrm{T}$ and ending in an internal field $b \approx 3\,\mathrm{mT}$ gives $T_f \approx 3.6\,\mathrm{mK}$.

Rests on Equation (110.7).

Derivation. *Derives Proposition 110.7.*

The single-moment partition function is $Z(B,T) = \sum_m \exp(\mu_e B m/(J_e k_B T))$, which depends on B and T only through B/T. Every thermodynamic quantity derived from $\ln Z$ without an explicit factor of T is therefore a function of B/T, and in particular the entropy $S = k_B(\ln Z - (B/T)\,\partial \ln Z/\partial(B/T))$ is $S = S(B/T)$. Holding S fixed holds B/T fixed, so $T_f/T_i = B_f/B_i$. The demagnetization cannot be carried to $B_f = 0$, because the moments interact: dipolar and exchange couplings inside the crystal act as a residual internal field b, which enters in quadrature since it is randomly oriented with respect to the applied one, giving Equation (110.10). The salt of choice, cerium magnesium nitrate, is used precisely because its internal field is exceptionally small — its magnetic ordering temperature is of order $2\,\mathrm{mK}$, and no other common paramagnetic salt orders so low, so none can be demagnetized so far. □

The sequence is thus: cool the salt to $1.2\,\mathrm{K}$ against a pumped liquid-helium bath, apply about $1\,\mathrm{T}$ and let the heat of magnetization flow out through helium exchange gas, pump the exchange gas away to isolate the salt thermally, then remove the field. The crystal arrives at a few millikelvin thermally disconnected from everything, which is both the point and the limitation.

The heat leak and the observation window Because the sample is isolated, its temperature rises under any residual heat leak, and the polarization decays with it. The measured decay time is about six minutes, and it fixes the leak.

Proposition 110.8 (Size of the residual heat leak)**.** *A warm-up from* 3–10 mK *in* 3.6×10^{2} s *for a crystal of order one gram corresponds to a heat leak of order* 1×10^{-7} W.
Rests on Proposition 110.7.

Derivation. *Derives Proposition 110.8.*

The heat capacity available in this range is magnetic: the entropy stored in the electronic spins is at most $R \ln 2$ per mole of paramagnetic ion for a doublet ground state, and cerium magnesium nitrate, $Ce_2Mg_3(NO_3)_{12} \cdot 24\,H_2O$, has a formula-unit molar mass of $2(140.116) + 3(24.305) + 12(62.005) + 24(18.015) = 1.5296\,\mathrm{kg/mol}$ carrying two cerium ions, so one gram carries $n = 2 \times 1 \times 10^{-3}\,\mathrm{kg}/1.5296\,\mathrm{kg/mol} = 1.31 \times 10^{-3}\,\mathrm{mol}$ of moments. Warming through $\Delta T = 5 \times 10^{-3}\,\mathrm{K}$ at $T \sim 5 \times 10^{-3}\,\mathrm{K}$ absorbs at most $Q \sim T\,\Delta S \sim \Delta T\, n\, R \ln 2 = 5 \times 10^{-3}\,\mathrm{K} \times 1.31 \times 10^{-3}\,\mathrm{mol} \times 5.76\,\mathrm{J/(mol\,K)} = 3.8 \times 10^{-5}\,\mathrm{J}$, and spreading that over 3.6×10^{2} s gives 1.0×10^{-7} W; taking the full 7 mK of the stated warm-up rather than the 5 mK used here raises it to 1.5×10^{-7} W, which is the width of the estimate. A leak of a fraction of a microwatt is what a well-made cryostat of the period achieved, and the agreement is the check that nothing pathological — eddy-current heating from the field reversal, say — dominated the warm-up. □

Finally, the polarizing solenoid. It is a small vertical coil, of a few millitesla, whose sense can be reversed; its only job is to align the electronic moments so that the hyperfine field aligns the nuclei, and reversing it interchanges the two counting directions of Equation (110.4) without moving a single piece of the apparatus. That is the design decision on which the whole measurement turns: the two configurations being compared differ in nothing except the direction of an axial vector.

110.2.3 Beta and gamma detection

The beta counter An anthracene crystal a few centimetres above the source, inside the vacuum space of the cryostat, absorbs the escaping electrons and converts their energy to scintillation light. Anthracene is the reference organic scintillator, with a light yield of about 1.7×10^{4} photons per MeV of electron energy deposited, so a 150 keV electron produces about 2.6×10^{3} photons. The crystal cannot be viewed directly, because a photomultiplier is useless in a magnetic field: its gain depends on the trajectories of low-energy electrons between dynodes, and a field of even 1 mT changes it by a measurable amount. That single fact is the reason for the most conspicuous feature of the apparatus — a lucite light pipe about a metre long, carrying the scintillation light out of the cryostat and out of the fringe field to a photomultiplier standing at room temperature. Even with a transmission of order 10 % through the pipe and a photocathode quantum efficiency of order 10 %, some tens of photoelectrons per event remain, comfortably above the single- photoelectron noise, so pulse-height discrimination against the photomultiplier's dark rate is possible.

The consequence for the physics is that the beta counter has a threshold rather than a spectrometer's resolution. It counts electrons above some minimum energy, which is why v/c in Equation (110.4) is an acceptance-weighted average and not a measured quantity per event, and why 0.6 rather than a number with three digits is the honest value to carry.

The gamma counters Two sodium-iodide scintillation counters view the source from outside the cryostat, one on the polar axis and one in the equatorial plane. They count the 1173.23 keV and 1332.49 keV cascade photons, whose penetration through the cryostat walls is what makes an external gamma counter possible at all where an external beta counter is

not. Their function is not to measure a gamma energy but to compare two rates: the ratio of the polar to the equatorial rate is an anisotropy, and by Proposition 110.9 below it is a thermometer for the nuclear orientation.

Both gamma counters sit at fixed geometry, unaffected by the reversal of the polarizing field, which is what allows the gamma anisotropy and the beta asymmetry to be recorded simultaneously and compared as functions of time through the same warm-up.

Table 110.2: Conditions attained in the cobalt-60 run of 1957. These are settings of the apparatus and states of the sample rather than measured results, and the 1957 paper quotes them as design values without error bars; they are given here to the precision the design supports and no further. The measured numbers, with their uncertainties and their years, are collected separately in Table 110.3. The constants used are CODATA 2022 values [2431].

Quantity	Value	Source
Bath temperature before demagnetization	$1.2\,\mathrm{K}$	apparatus
Magnetizing field	$\sim 1\,\mathrm{T}$	apparatus
Temperature after demagnetization	$\sim 3\,\mathrm{mK}$	Equation (110.10)
Effective field at the nucleus	$\sim 10\,\mathrm{T}$	hyperfine
Orientation parameter x	0.38	Equation (110.7)
Nuclear alignment f_2	≈ 0.26	gamma counters
Gamma anisotropy ε_γ	$\approx 20\,\%$	[1133]
Warm-up time constant	$\approx 3.6 \times 10^{2}\,\mathrm{s}$	[1133]
Residual heat leak	$\sim 1 \times 10^{-7}\,\mathrm{W}$	Proposition 110.8

110.3 Procedure

110.3.1 The run cycle

A run is a cycle of preparation, a few minutes of measurement, and a long recovery, and its steps are:

1. **Pre-cool.** The cryostat is filled and the helium bath pumped to about $1.2\,\mathrm{K}$. Helium exchange gas couples the salt crystal, with its cobalt layer, to the bath.

2. **Magnetize.** A field of order $1\,\mathrm{T}$ is applied along the horizontal axis. The entropy of the electronic moments falls and the heat of magnetization is carried to the bath by the exchange gas; the crystal must be allowed to return to $1.2\,\mathrm{K}$ before the next step, or the demagnetization starts warm and ends warm.

3. **Isolate.** The exchange gas is pumped out. The crystal is now thermally disconnected, and everything that follows happens under the heat leak of Proposition 110.8.

4. **Demagnetize.** The magnetizing field is reduced to zero. By Equation (110.10) the crystal cools to a few millikelvin.

5. **Polarize.** The small vertical solenoid is energized in one sense. The electronic moments align with it, the hyperfine field aligns the cobalt nuclei, and f rises to its maximum within a time short compared with the warm-up.

6. **Count.** Beta counts in the polar anthracene counter and gamma counts in both sodium-iodide counters are recorded in successive short intervals — of order tens of seconds — against a clock, for as long as any anisotropy survives.

7. **Reverse and repeat.** The solenoid sense is reversed and the counting repeated, the whole cycle being restarted from step 1 when the polarization is gone.

110.3.2 Interleaving, and why it is not optional

Proposition 110.3 cancels the geometric and efficiency factors only if they are the same in the two configurations being compared. Over a full cooling cycle they are not: the source decays (negligibly), the photomultiplier gain drifts, the discriminator threshold moves with temperature, and above all the polarization f is itself a function of time. If $N_{\uparrow}$ were taken in one cooling cycle and $N_{\downarrow}$ in the next, the difference would contain the difference of the two cycles' base temperatures — an effect of the same size as the signal.

The measurement is therefore constructed so that the two field senses are compared *within a common warm-up window*, and the comparison is made at equal times after demagnetization. The asymmetry is formed between the counting rate at time t in a run with the field up and the counting rate at the same t in a run with the field down, and the gamma anisotropy recorded in the same intervals certifies that the two runs had the same polarization at that t. Where they did not, the gamma data say so, and the beta data can be corrected by the ratio of the two anisotropies rather than discarded.

110.3.3 The controls

Three null tests separate a genuine asymmetry from an instrumental one, and their logic is worth setting out because it is the part of the experiment that makes the result believable rather than merely striking.

1. **The warm sample.** With the crystal warm — above $1\,\mathrm{K}$, where by Equation (110.7) $x < 10^{-5}$ and f is zero to five decimal places — the polarizing field is applied in both senses and the beta rates compared. Any difference found here is instrumental by construction, since there is nothing to orient. This is the direct test for a magnetic effect on the photomultiplier, on the light pipe, or on the electron trajectories between source and counter.

2. **The warm-up curve itself.** The polarized measurement is not a single number but a time series. If the beta asymmetry and the gamma anisotropy decay to zero on the same time constant, they are both tracking f; an instrumental asymmetry has no reason to depend on the temperature of a salt crystal at all, and a fortiori no reason to share a decay constant with a gamma-ray angular distribution measured by different counters outside the cryostat.

3. **Solenoid sense versus counter position.** Reversing the field and moving the counter to the opposite side of the source are two different ways of reversing $\cos\theta$. They must give the same asymmetry with the same sign. Any effect that depends on the field direction in the laboratory rather than on the angle between the spin and the electron momentum fails this test.

The second of these is the decisive one, and it is what elevates the result above a difference of two counting rates. It converts a comparison between two configurations into a comparison between two *functions of time* measured in the same apparatus by different detectors, and no plausible instrumental effect reproduces it.

110.4 Observations and data

110.4.1 Gamma anisotropy as the polarization thermometer

The gamma counters measure an angular distribution, and an angular distribution of photons from an oriented nucleus is even in $\cos\theta$: a photon distribution cannot distinguish $\hat{\boldsymbol{n}}$ from $-\hat{\boldsymbol{n}}$, because the electromagnetic transition conserves parity. The gammas therefore measure the *alignment* of the ensemble — its second moment — and not the *polarization* — its first moment — which is precisely the quantity Equation (110.4) needs. That the one nevertheless determines the other is a consequence of the Boltzmann distribution, and it is the step in the analysis that is most often passed over.

Proposition 110.9 (Alignment determines polarization)**.** *For nuclei of spin I distributed over the Zeeman sublevels with the Boltzmann weights e^{xm} of Equation (110.9), the polarization $f_1 = \langle m\rangle / I$ and the alignment*

$$f_2 = \frac{3\langle m^2\rangle - I(I+1)}{I(2I-1)} \tag{110.11}$$

are both functions of the single parameter x. A measurement of f_2 therefore fixes x and hence f_1. For $I = 5$, $f_2 = 0.263$ corresponds to $x = 0.378$ and to $f_1 = 0.600$.

Rests on Equation (110.9).

Derivation. *Derives Proposition 110.9.*

Both moments are derivatives of the same generating function: $\langle m\rangle = \partial_x \ln Z$ and $\langle m^2\rangle = \partial_x^2 \ln Z + \langle m\rangle^2$ with $Z(x) = \sum_m \mathrm{e}^{xm}$, so both are functions of x alone, and f_2 is normalized in Equation (110.11) so that a fully polarized ensemble, $m = I$ for every nucleus, gives $f_2 = 1$: then $3I^2 - I(I+1) = 2I^2 - I = I(2I-1)$. Evaluating for $I = 5$ over a grid of x gives the pairs $(x, f_1, f_2) = (0.1, 0.196, 0.025)$, $(0.2, 0.371, 0.093)$, $(0.3, 0.513, 0.186)$, $(0.378, 0.600, 0.263)$, $(0.5, 0.701, 0.380)$, from which the quoted correspondence is read off. The map $x \mapsto f_2$ is strictly increasing, so the inversion is unique. What the gamma counters deliver is the anisotropy

$$\varepsilon_\gamma = \frac{W_\gamma(0) - W_\gamma(\pi/2)}{W_\gamma(\pi/2)}\,, \tag{110.12}$$

which is proportional to f_2 with a coefficient fixed by the multipolarities and spins of the $5^+ \to 4^+ \to 2^+ \to 0^+$ chain — pure nuclear-structure input, independent of the weak interaction, and therefore not something the beta measurement can be accused of assuming. □

The observed behaviour is that ε_γ is of order 20 % immediately after demagnetization and decays to zero over about six minutes as the crystal warms [1133]. Both gamma counters see it, with opposite signs — the polar counter's rate falls while the equatorial counter's rises, or the reverse, according to the sign of the alignment — which is itself a check that the effect is an angular redistribution of a fixed number of photons and not a change in the source.

110.4.2 The beta asymmetry and its warm-up decay

Phenomenon 110.10 (Parity violation in nuclear beta decay)**.** Electrons from the allowed Gamow–Teller decay of ^{60}Co nuclei polarized along a unit vector $\hat{\boldsymbol{n}}$ are emitted preferentially *opposite* to $\hat{\boldsymbol{n}}$. For a fully oriented ensemble — the limit $f = 1$ of Equation (110.3) — their angular distribution has the form

$$W(\theta) \propto 1 + A\,\frac{v}{c}\cos\theta\,, \qquad \cos\theta = \hat{\boldsymbol{n}}\cdot\hat{\boldsymbol{p}}_e\,, \tag{110.13}$$

and a partially oriented one carries the extra factor f there; what a counter sees is the ratio Equation (110.4), in which f appears explicitly. Here $A < 0$ and $|A|$ is close to the largest value the transition admits: the counting-rate difference between the two senses of the polarizing field reached of order 40 % at the polarization achieved, and decayed to zero on the same time constant with which the nuclear orientation itself was lost [1101, 1133].

Rests on Equations (110.3) *and* (110.4) *and Proposition 110.1.*

Derivation. *Derives Phenomenon 110.10.*

What has to be established is negative — that no parity-conserving interaction can produce Equation (110.13) with $A \neq 0$ — and it follows from transformation properties alone, with no nuclear physics whatever. Under the space inversion $P : \boldsymbol{x} \mapsto -\boldsymbol{x}$ a momentum is odd, $\boldsymbol{p}_e \mapsto -\boldsymbol{p}_e$, while an angular momentum is a pseudovector and is even, $\hat{\boldsymbol{n}} \mapsto \hat{\boldsymbol{n}}$; hence $\cos\theta \mapsto -\cos\theta$. If the interaction responsible for the decay commuted with P, the transition rate computed from it would be invariant under P, so the distribution would have to satisfy $W(\theta) = W(\pi - \theta)$ at every angle. Comparing with Equation (110.13),

$$1 + A\,\frac{v}{c}\cos\theta = 1 - A\,\frac{v}{c}\cos\theta \qquad \text{for all } \theta\,,$$

which forces $A = 0$. A measured $A \neq 0$ is therefore not a statement about the nucleus but a proof that the interaction does not commute with P. The correlation $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{p}}_e$ is a pseudoscalar, and the argument just given is Proposition 110.1 applied to the case in hand: find a pseudoscalar observable, show its mean is not zero. □

The arithmetic of the observed number closes as follows, and it does not close without the polarization factor. Equation (110.4) gives $\varepsilon = A\,(v/c)\,f$. With $A = -1$, the value Proposition 101.27 derives for a pure Gamow–Teller transition fed by an interaction that emits only left-chiral electrons, with $v/c \approx 0.63$ for the counted part of the spectrum, and with $f \approx 0.6$ from Proposition 110.9, the prediction is

$$|\varepsilon| = 1 \times 0.63 \times 0.6 = 0.38\,, \tag{110.14}$$

against an observed value of order 0.4. Dropping f would predict 0.63, half again too large; dropping both f and v/c would predict 1. The two dilution factors are not corrections, they are the reason the experiment had to measure the gamma anisotropy at all.

110.4.3 Numerical results

Table 110.3 collects what the measurements delivered. Three features of the cobalt entries are worth reading deliberately.

The first is that the headline number, $|\varepsilon| \approx 0.4$, is enormous by the standards of a symmetry test. A violation at the level of a per cent would have been a discovery; one at the level of 10^{-4} would have been a triumph of technique. Forty per cent means that the parity-odd and parity-even parts of the interaction are of the same size, which is a statement about structure and not about magnitude, and it is the empirical content of "maximal".

The second is that the uncertainty on A is systematic, not statistical. Proposition 110.3 shows that 10^4 counts suffice for a per-cent statistical error, and the source easily delivered them; but A is extracted by dividing ε by $(v/c)\,f$, and both divisors carry several per cent of systematic uncertainty — v/c through the source self-absorption of Proposition 110.5 and the counter threshold, f through the nuclear-structure coefficients relating ε_γ to f_2. Propagating the three in quadrature, $\delta A/A = [(0.01/0.4)^2 + (0.02/0.63)^2 + (0.03/0.60)^2]^{1/2} = 6.4\,\%$, gives the $A = -1.06 \pm 0.07$ of Table 110.3: the statistical term contributes a quarter of the variance and the polarization term more than half. This is why the 1957 result is correctly stated as "$|A|$ consistent with the maximum" rather than as a number, and why the follow-up work with improved polarimetry was needed [1101].

Table 110.3: The measured quantities of this chapter, with their uncertainties and their years. The 1957 cobalt paper reports the effect as large and unambiguous rather than as a number with a formal error bar, so the first five entries carry the error budget reconstructed here: the statistical uncertainty of Proposition 110.3 at $N = 10^4$ counts, the source-thickness uncertainty on v/c of Proposition 110.5, and a 5 % uncertainty on f standing for the several per cent carried by the nuclear-structure coefficients that relate the gamma anisotropy to the alignment. Those three propagate in quadrature to the asymmetry coefficient. The later entries are the published uncertainties of the works cited, and each is discussed where it is introduced. The conditions attained in the cobalt run are separated into Table 110.2; the constants used are CODATA 2022 values [2431].

Quantity	Value	Year	Source
Electron speed v/c, acceptance averaged	0.63 ± 0.02	1957	Proposition 110.5
Nuclear polarization f	0.60 ± 0.03	1957	Proposition 110.9
Beta counting asymmetry $\lvert\varepsilon\rvert$, cold	0.40 ± 0.01	1957	[1133]
Asymmetry coefficient A	-1.06 ± 0.07	1957	Equation (110.14)
Beta counting asymmetry, warm sample	0.00 ± 0.01	1957	[1133]
Muon g factor, pion chain	2.00 ± 0.10	1957	[1110]
Emulsion asymmetry $\lvert a\rvert$	0.174 ± 0.038	1957	[1109]
Caesium $\operatorname{Im} E1_{PNC}/\beta$, in V/m	$0.159\,35 \pm 0.000\,56$	1997	[1946]
E122 $(A/Q^2c^2) \times 10^5$, in $1/\mathrm{GeV}^2$	-9.5 ± 1.6	1978	[1625]
E158 $\sin^2\theta_W$	0.2397 ± 0.0013	2005	[2069]
Qweak asymmetry $A_{PV} \times 10^9$	-226.5 ± 9.3	2018	[2301]
Proton weak charge Q_W^p	0.0719 ± 0.0045	2018	[2301]
Neutron skin of ^{208}Pb, $R_n - R_p$, in fm	0.283 ± 0.071	2021	[2370]

The third is that the most important entry is the one consistent with zero: with the sample warm there is nothing to orient, and the asymmetry vanishes to the statistical precision of the cold run. An experiment that reports only a large effect has reported one number; an experiment that reports a large effect together with its disappearance under a control that removes the cause has reported a measurement.

110.4.4 Systematic checks

The controls of Section 110.3.3 were carried out and the following is what they established.

Field reversal and solenoid sense. The asymmetry reverses sign with the polarizing field and does not depend on which of the two solenoid windings produced the field. An effect of the field on the counters would not know about the winding; an effect of the field on the nuclei is indifferent to it.

The warm sample. With the crystal above 1 K the counting rates in the two field senses are equal within the counting statistics. This is the direct exclusion of a magnetic effect on the photomultiplier or on the electron trajectories, and it is why the light pipe of Section 110.2.3 was worth its optical losses: the photomultiplier is far enough away that the residual field at its photocathode is small, and the warm-sample test verifies that what remains does not matter.

Scattering. Electrons scattered in the source layer, in the crystal, or from the cryostat walls dilute the asymmetry by randomizing $\cos\theta$. Every such process reduces $|\varepsilon|$ towards zero, so none of them can generate the observed effect; they enter as a one-sided systematic on $|A|$ and are the reason the extracted $|A|$ is a lower bound as much as a measurement.

Simultaneous decay of the two signals. The beta asymmetry and the gamma anisotropy vanish together, on the same time constant, as the crystal warms. This is the control that no instrumental explanation survives, and it is the reason the experiment is remembered as decisive rather than suggestive.

Reproduction with better polarimetry. The whole measurement was repeated and extended by the same group with improved nuclear orientation and thinner sources [1101], which is what turned a single striking run into a reproducible number and which added the positron-emitting cases discussed in Section 110.5.2.

110.5 Interpretation

110.5.1 Maximal violation and the V–A structure

A measured $A \neq 0$ proves that the interaction has both a parity-even and a parity-odd part. The *size* of A measures their ratio, and that is the quantitative content of the cobalt result.

Write the beta-decay interaction as a sum of a parity-even piece and a parity-odd piece, with amplitudes a_+ and a_-. The total rate goes as $|a_+|^2 + |a_-|^2$, which is parity-even; the asymmetry goes as the interference $2\,\mathrm{Re}(a_+ a_-^*)$, which is parity-odd. The asymmetry coefficient is therefore

$$A \propto \frac{2\,\mathrm{Re}\left(a_+ a_-^*\right)}{|a_+|^2 + |a_-|^2}\,, \tag{110.15}$$

a ratio bounded by unity, attaining ± 1 if and only if $|a_+| = |a_-|$ and the two are relatively real. An observed $|A|$ of order one is thus not merely evidence of parity violation but the statement that the two parts are equal in magnitude, which is a very much stronger constraint. An interaction whose parity-even and parity-odd parts are equal couples to one chirality and not at all to the other.

That is the empirical origin of the $V - A$ form of the charged weak current, proposed by Feynman and Gell-Mann [1144] and independently by Sudarshan and Marshak [1162], in which the leptonic current appears only through the chiral projector $P_L = \tfrac{1}{2}(1 - \gamma^5)$.

The current is written and its consequences derived at Equation (105.34) and throughout Section 101.4; the proposition that it violates parity maximally in exactly the sense of Equation (110.15) is Proposition 105.19, and the factor v/c that appears in Equation (110.13), and which had to be divided out to reach Equation (110.14), is the chirality-to-helicity conversion of Proposition 105.20. This chapter does not repeat those derivations; what it contributes to them is the number they had to reproduce.

Remark 110.11 (Reading this chapter against the natural-units literature). Every standard account of the weak interaction is written with $\hbar = c = 1$, and a reader moving between that literature and this book needs one rule and one worked case. The rule is that the powers of $\hbar$ and c are recoverable uniquely from dimensions: an energy E and a mass m are related by $E = mc^2$, an energy and an inverse time by $E = \hbar\omega$, a momentum and an inverse length by $p = \hbar k$. The worked case is Fermi's constant, quoted everywhere as $G_F = (1.166\,378\,8 \pm 0.000\,000\,6) \times 10^{-5}/\mathrm{GeV}^2$ — which is a statement about $G_F/(\hbar c)^3$, not about G_F — and equal in SI to $(1.435\,851\,2 \pm 0.000\,000\,7) \times 10^{-62}\,\mathrm{J\,m}^3$. Both numbers appear in this chapter, always labelled, and the conversion between them is set out at Remark 105.18. No derivation in this book is carried out in natural units.

110.5.2 Charge conjugation, CP and CPT

The same data violate charge conjugation. The argument is direct: C maps a process into the process with every particle replaced by its antiparticle, leaving momenta and spins alone. Applied to the cobalt decay it maps electron emission from a polarized nucleus into positron emission from the polarized antinucleus, with the *same* angular distribution — so C invariance would require the two asymmetry coefficients to be equal. In the pion chain, where both charges are available, the prediction is testable directly, and the π^+ and π^- chains show asymmetries of opposite sign [1110]. In the nuclear case the corresponding statement is that a positron-emitting Gamow–Teller decay must show the opposite asymmetry to an electron-emitting one, which is what the follow-up measurements found [1101].

What survives is the product. Under CP a left-handed neutrino maps to a right-handed antineutrino, and both exist; under P alone it would map to a right-handed neutrino, and under C alone to a left-handed antineutrino, neither of which occurs. Landau proposed immediately that CP is the true symmetry of the weak interaction [1118]. That proposal held for seven years, until the neutral-kaon measurement of Chapter 111, whose theory is developed at Section 105.3.

CPT is a different kind of statement. It is not a symmetry that the weak interaction happens to respect but a theorem: any local, Lorentz-invariant quantum field theory with a Hermitian Hamiltonian and the normal spin–statistics connection is invariant under the product of the three operations [1123]. It is proved at Theorem 105.34 and it is the reason that the violation of P and of C carries no threat to the framework, while a violation of CPT would.

110.5.3 Neutrino helicity
