That the ordered monomials *span* $U(\mathfrak{g})$ is immediate from the defining relations, which allow any product to be reordered at the cost of terms of lower degree; the content of the theorem is their linear *independence*, and it is what guarantees that the Casimir element built below is not accidentally the zero element of the enveloping algebra.

Full derivation: Appendix A.30 (p. 2928).

Derives Theorem 14.7.

Casimir operators

Definition 14.8 (Casimir element)**.** A *Casimir element*, or *Casimir operator*, of a Lie algebra $\mathfrak{g}$ is an element $C \in U(\mathfrak{g})$ commuting with every generator,

$$\boxed{[C, T_a] = 0\,, \qquad a = 1, \ldots, \dim \mathfrak{g}}\,, \tag{14.13}$$

equivalently an element of the centre $Z\left(U(\mathfrak{g})\right)$.

Rests on Definition 14.5.

A Casimir element is in general *not* an element of $\mathfrak{g}$: for a semisimple algebra the centre of $\mathfrak{g}$ itself is zero, and the invariants appear only at quadratic and higher degree in the generators. This is the whole reason for Definition 14.5.

Notation 14.9 (Casimirs against structure constants). Casimir elements are written $C_2, C_3, \ldots$, the single numerical subscript recording the degree of the polynomial in the generators. The structure constants always carry three algebra indices, ${C^c}_{ab}$, so no ambiguity arises. Note also that Section 14.7 writes the same structure constants with the index pair first, $[\boldsymbol{T}_A, \boldsymbol{T}_B] = {C_{AB}}^C \boldsymbol{T}_C$; only the index placement differs, and ${C_{ab}}^c = {C^c}_{ab}$.

The Killing form and the quadratic Casimir

Every Lie algebra carries a canonical symmetric bilinear form, built from the structure constants alone, and it is this form that produces the Casimir element every physicist meets first.

Definition 14.10 (Killing form)**.** The *Killing form* of $\mathfrak{g}$ is

$$\boxed{\kappa(X,Y) = \mathrm{tr}\left(\mathrm{ad}_X\, \mathrm{ad}_Y\right)}\,, \qquad \mathrm{ad}_X\, Y = [X,Y]\,, \tag{14.14}$$

a symmetric bilinear form on $\mathfrak{g}$. Since $(\mathrm{ad}_{T_a})^c{}_b = {C^c}_{ab}$ is the matrix of ad_{T_a} in the basis $\{T_a\}$, its components are

$$\kappa_{ab} = \kappa(T_a, T_b) = {C^c}_{ad}\, {C^d}_{bc}\,. \tag{14.15}$$

Rests on Equation (14.5).

Lemma 14.11 (Invariance of the Killing form)**.** *For all $X, Y, Z \in \mathfrak{g}$,*

$$\kappa\left([X,Y],Z\right)+\kappa\left(Y,[X,Z]\right)=0\,. \tag{14.16}$$

Rests on Definition 14.10.

Proof. *Derives Lemma 14.11.*

The adjoint map is itself a representation, $\mathrm{ad}_{[X,Y]} = [\mathrm{ad}_X, \mathrm{ad}_Y]$, which is the Jacobi identity rewritten. Hence

$$\begin{aligned}\kappa\left([X,Y],Z\right)&=\mathrm{tr}\left([\mathrm{ad}_X,\mathrm{ad}_Y]\,\mathrm{ad}_Z\right)=\mathrm{tr}\left(\mathrm{ad}_X\,\mathrm{ad}_Y\,\mathrm{ad}_Z\right)-\mathrm{tr}\left(\mathrm{ad}_Y\,\mathrm{ad}_X\,\mathrm{ad}_Z\right)\,,\\ \kappa\left(Y,[X,Z]\right)&=\mathrm{tr}\left(\mathrm{ad}_Y\,[\mathrm{ad}_X,\mathrm{ad}_Z]\right)=\mathrm{tr}\left(\mathrm{ad}_Y\,\mathrm{ad}_X\,\mathrm{ad}_Z\right)-\mathrm{tr}\left(\mathrm{ad}_Y\,\mathrm{ad}_Z\,\mathrm{ad}_X\right)\,.\end{aligned}$$

Adding the two lines, the terms $\mp\,\mathrm{tr}(\mathrm{ad}_Y\,\mathrm{ad}_X\,\mathrm{ad}_Z)$ cancel against each other, and the survivors $\mathrm{tr}(\mathrm{ad}_X\,\mathrm{ad}_Y\,\mathrm{ad}_Z)$ and $-\,\mathrm{tr}(\mathrm{ad}_Y\,\mathrm{ad}_Z\,\mathrm{ad}_X)$ cancel by cyclicity of the trace. □

Corollary 14.12 (Total antisymmetry of the structure constants)**.** *Lower the upper index of the structure constants with the Killing form,*

$$C_{abc}:=C^{d}{}_{ab}\,\kappa_{dc}=\kappa\left([T_a,T_b],T_c\right)\,. \tag{14.17}$$

Then C_{abc} is antisymmetric under the exchange of any *two of its three indices.*

Rests on Lemma 14.11 and Definition 14.10.

Proof. *Derives Corollary 14.12.*

Antisymmetry in the first two indices is the antisymmetry of the bracket. For the last two, put $X = T_a$, $Y = T_b$, $Z = T_c$ in Equation (14.16) and use the symmetry of κ:

$$C_{abc}=\kappa\left([T_a,T_b],T_c\right)=-\kappa\left(T_b,[T_a,T_c]\right)=-\kappa\left([T_a,T_c],T_b\right)=-C_{acb}\,.$$

The transpositions (ab) and (bc) generate the whole symmetric group on three letters, so C_{abc} changes sign under every transposition. □

Theorem 14.13 (Cartan's criterion)**.** *A finite-dimensional Lie algebra over a field of characteristic zero is semisimple — it contains no nonzero abelian ideal — if and only if its Killing form is nondegenerate.*

Rests on Definition 14.10.

One direction — that a nonzero abelian ideal lies in the radical of the Killing form — is a short index computation; the converse, that a degenerate Killing form produces a solvable ideal, goes through Cartan's criterion for solvability and the Jordan decomposition of an endomorphism, and is what makes the theorem long. It is used here to know when the Killing form may be inverted, and again in Whitehead's lemmas in the section on central extensions.

Full derivation: Appendix A.31 (p. 2934).

Derives Theorem 14.13.

When κ_{ab} is nondegenerate we write κ^{ab} for its inverse, $\kappa^{ab}\kappa_{bc} = \delta^{a}{}_{c}$, and use it freely to raise algebra indices.

Definition 14.14 (Invariant symmetric tensor)**.** A totally symmetric array $k^{a_1\cdots a_r}$ is *invariant* if, for every c,

$$\boxed{\sum_{l=1}^{r} C^{a_l}{}_{bc}\,k^{a_1\cdots a_{l-1}\,b\,a_{l+1}\cdots a_r}=0}\,. \tag{14.18}$$

Rests on Equation (14.5).

Remark 14.15 (This is the invariance already proved). Condition Equation (14.18) is the infinitesimal invariance of Definition 14.109 with the indices raised: it is Equation (14.148), established as part 2 of Theorem 14.110, transported to the contravariant position by κ^{ab}. On a semisimple algebra, where the Killing form may be inverted, the two notions therefore coincide, and every G-invariant polynomial of Section 14.7 supplies one of these tensors. Nothing new has to be proved to use them.

Theorem 14.16 (Invariant tensors give Casimir operators). *Let $k^{a_1\cdots a_r}$ be a totally symmetric invariant tensor in the sense of Definition 14.14. Then*

$$\boxed{C_r = k^{a_1\cdots a_r}\, T_{a_1} T_{a_2} \cdots T_{a_r} \in U(\mathfrak{g})} \tag{14.19}$$

is a Casimir element.

Rests on Definitions 14.5, 14.8 and 14.14.

Proof. *Derives Theorem 14.16.*

In the associative algebra $U(\mathfrak{g})$ the commutator with a fixed element obeys the Leibniz rule, $[XY, Z] = X\,[Y, Z] + [X, Z]\,Y$, so

$$\begin{aligned}[C_r, T_c] &= k^{a_1\cdots a_r} \sum_{l=1}^{r} T_{a_1} \cdots T_{a_{l-1}}\, [T_{a_l}, T_c]\, T_{a_{l+1}} \cdots T_{a_r} \\ &= \sum_{l=1}^{r} k^{a_1\cdots a_r}\, C^{b}{}_{a_l c}\, T_{a_1} \cdots T_{a_{l-1}}\, T_b\, T_{a_{l+1}} \cdots T_{a_r}\,.\end{aligned}$$

In the l-th term rename the two summation indices a_l and b into each other. This is a relabelling of dummy indices and moves no operator past another, so the ordered string becomes literally $T_{a_1} T_{a_2} \cdots T_{a_r}$, the *same* string for every value of l, while the coefficient becomes $C^{a_l}{}_{bc}\, k^{a_1\cdots a_{l-1}\, b\, a_{l+1}\cdots a_r}$. The sum over l may therefore be taken inside:

$$[C_r, T_c] = \left(\sum_{l=1}^{r} C^{a_l}{}_{bc}\, k^{a_1\cdots a_{l-1}\, b\, a_{l+1}\cdots a_r} \right) T_{a_1} T_{a_2} \cdots T_{a_r}\,,$$

and the parenthesis vanishes by Equation (14.18). □

Corollary 14.17 (The quadratic Casimir). *Let $\mathfrak{g}$ be semisimple, so that κ_{ab} is invertible by Theorem 14.13. Then*

$$\boxed{C_2 = \kappa^{ab}\, T_a T_b} \tag{14.20}$$

commutes with every generator of $\mathfrak{g}$.

Rests on Theorems 14.13 and 14.16 and Corollary 14.12.

Proof. *Derives Corollary 14.17.*

The statement is Theorem 14.16 for $r = 2$ and $k^{ab} = \kappa^{ab}$, whose invariance is Corollary 14.12 with both free indices raised. It is worth seeing the two-index case done by hand, because it is the whole mechanism in three lines. By the Leibniz rule,

$$[C_2, T_c] = \kappa^{ab}\,(T_a\,[T_b, T_c] + [T_a, T_c]\,T_b) = \kappa^{ab} C^{d}{}_{bc}\, T_a T_d + \kappa^{ab} C^{d}{}_{ac}\, T_d T_b\,.$$

Fix c and set

$$M^{ad} := \kappa^{ab}\, C^{d}{}_{bc} = \kappa^{ab}\kappa^{de}\, C_{bce}\,,$$

using Equation (14.17). Exchanging the two free indices and then renaming the dummies $b \leftrightarrow e$,

$$M^{da} = \kappa^{db}\kappa^{ae}\, C_{bce} = \kappa^{de}\kappa^{ab}\, C_{ecb} = -\kappa^{ab}\kappa^{de}\, C_{bce} = -M^{ad}\,,$$

the last step by Corollary 14.12, since C_{ecb} differs from C_{bce} by the transposition of the first and third indices. The first term above is $M^{ad}T_aT_d$; the second is $\kappa^{ab}C^{d}{}_{ac}T_dT_b = M^{bd}T_dT_b$ by the symmetry of κ, which is $M^{ad}T_dT_a$ after renaming $b \to a$. Hence

$$[C_2, T_c] = M^{ad}\,(T_aT_d + T_dT_a) = 0\,,$$

an antisymmetric array contracted with a symmetric one. □

Corollary 14.18 (A Casimir acts as a number on an irreducible representation)**.** *Let G be a connected Lie group with Lie algebra $\mathfrak{g}$, let U be a finite-dimensional irreducible representation of G on a complex vector space $\mathbb{V}$, let D be the induced representation of $\mathfrak{g}$ as in Equation* (14.6)*, and let C be a Casimir element. Then*

$$\boxed{D(C) = c\,\mathbb{1}\,, \qquad c \in \mathbb{C}}\,. \tag{14.21}$$

Rests on Definition 14.8, Remark 14.6, Equation (14.6)*, and Theorem 5.153.*

Proof. *Derives Corollary 14.18.*

By Remark 14.6 the representation D extends to $U(\mathfrak{g})$, so $D(C)$ is a well-defined operator on $\mathbb{V}$ and $[D(C), D(T_a)] = D\,([C, T_a]) = 0$ for every a by Equation (14.13). An operator commuting with $D(T_a)$ commutes with every power of $D(T_a)$, hence with the exponential $\mathrm{e}^{\theta^a D(T_a)} = U\,(g(\theta^a))$ of Equation (14.6), that is, with $U(g)$ for every g in a neighbourhood of the identity. A connected topological group is generated by any neighbourhood of its identity, so $D(C)$ commutes with $U(g)$ for every $g \in G$. Schur's first lemma (Theorem 5.153), applied to the irreducible representation U, gives $D(C) = c\,\mathbb{1}$. □

Remark 14.19 (A Casimir eigenvalue labels; one Casimir may not separate). Equation (14.21) is what makes a Casimir useful. The number c takes the same value on every vector of the representation and is unchanged by any change of basis, so it is an invariant *label* of the equivalence class of the irreducible representation, and two representations with different values of c cannot be equivalent. The converse does not follow, and it is worth being precise about it rather than repeating the usual slogan. A second imprecision has to be removed first: there is no such thing as *the* quadratic Casimir, because any nonzero multiple of a Casimir is again one and its eigenvalue scales with it, so a numerical eigenvalue means something only once the normalisation is stated. For $\mathfrak{su}(2)$, in the normalisation $\boldsymbol{J}^2 = J_1^2 + J_2^2 + J_3^2$ of Equation (14.49) — which by Lemma 14.41 is twice the Killing-form Casimir $C_2 = \kappa^{ab}J_aJ_b$ of Equation (14.20) — the quadratic Casimir does separate the classes, because Theorem 14.43 gives its eigenvalue as $j(j+1)$ and $j \mapsto j(j+1)$ is injective for $j \geq 0$. For $\mathfrak{su}(3)$ it does not: the fundamental and the antifundamental representations of Proposition 14.55 share the value of C_2 and are told apart only by a second, cubic invariant. How many invariants are needed in general is the subject of what follows.

Rank, and how many Casimir operators there are

Definition 14.20 (Cartan subalgebra and rank)**.** A *Cartan subalgebra* $\mathfrak{h} \subset \mathfrak{g}$ of a semisimple Lie algebra is a maximal abelian subalgebra whose elements all act diagonalizably in the adjoint representation. Its dimension is the same for every such subalgebra and is called the *rank* ℓ of $\mathfrak{g}$.

Theorem 14.21 (Racah)**.** *For a finite-dimensional semisimple Lie algebra of rank ℓ, the centre $Z\,(U(\mathfrak{g}))$ is a polynomial algebra in ℓ algebraically independent Casimir elements. A complete set of invariant labels for its finite-dimensional irreducible representations therefore consists of ℓ numbers, and of no fewer.*

Rests on Definitions 14.8 and 14.20.

The derivation identifies the centre of the enveloping algebra with the adjoint-invariant polynomials on the algebra, by the symmetrization map, and then those with the Weyl-invariant polynomials on a Cartan subalgebra; it reduces the theorem to two results of the structure theory of semisimple Lie algebras — the Chevalley restriction theorem and Chevalley's theorem on finite reflection groups — which this treatise quotes rather than proves, and the appendix says exactly where. The systematic use of such invariants as representation labels in spectroscopy is Racah's.

Full derivation: Appendix A.32 (p. 2941).

Derives Theorem 14.21.

The rank is read off the algebra without difficulty in the cases this treatise needs. For $\mathfrak{so}(3) \cong \mathfrak{su}(2)$ any single generator spans a maximal abelian subalgebra, so $\ell = 1$ and there is exactly one Casimir: it is the $\boldsymbol{J}^2$ constructed in Definition 14.40. For $\mathfrak{su}(3)$ the diagonal traceless matrices give $\ell = 2$, hence two Casimirs, one quadratic and one cubic (Proposition 14.54). The remaining family this treatise needs is $\mathfrak{so}(p,q)$, and because the count of Lorentz invariants rests on it the statement is proved rather than quoted.

Proposition 14.22 (The rank of $\mathfrak{so}(p,q)$)**.** *Let $D = p + q \geq 3$. Whatever the signature,*

$$\boxed{\ell\left(\mathfrak{so}(p,q)\right) = \left\lfloor \frac{D}{2} \right\rfloor}. \tag{14.22}$$

In particular the Lorentz algebra $\mathfrak{so}(3,1)$ of the observed spacetime has rank 2, and therefore, by Theorem 14.21, exactly two Casimir operators.

Rests on Definition 14.20, Equation (14.90), and Theorem 14.21.

Proof. *Derives Proposition 14.22.*

Write $r = \lfloor D/2 \rfloor$, work in the defining representation on $\mathbb{C}^D$, and let η be diagonal as in Notation 14.1, so that $X \in \mathfrak{so}(p,q)$ means

$$\eta(Xu, v) + \eta(u, Xv) = 0 \qquad \text{for all } u, v\,. \tag{14.23}$$

Diagonalizability in the defining representation is what is used throughout; that it agrees with the diagonalizability in the adjoint representation asked for by Definition 14.20 is standard structure theory, quoted here as Theorem 14.13 is. One direction is immediate — in a basis diagonalizing X the map $Y \mapsto [X, Y]$ is diagonal on the matrix units, with eigenvalue the difference of two eigenvalues of X — and the other is that the semisimple and nilpotent parts of an element of a semisimple linear Lie algebra again lie in it, so that an element with diagonalizable adjoint action has central, hence zero, nilpotent part.

A commuting set of size r. Take

$$H_k = J_{(2k-1)(2k)}\,, \qquad k = 1, \ldots, r\,, \tag{14.24}$$

one generator for each of the r disjoint index pairs $\{1,2\}$, $\{3,4\}$, and so on. No two of them share an index, so every η on the right of Equation (14.90) carries two distinct indices and vanishes, η being diagonal; hence $[H_k, H_l] = 0$. In the defining representation J_{AB} is the matrix $(J_{AB})^C{}_D = \delta^C_A \eta_{BD} - \delta^C_B \eta_{AD}$, the identification already made for $\mathfrak{so}(3)$ at Equation (14.32): it acts inside the plane of its own two coordinates and annihilates the others, and on that plane it is either the rotation generator Equation (14.27), with eigenvalues $\pm\mathrm{i}$, or a boost generator, with eigenvalues ± 1; in both cases it is diagonalizable, and so is any linear combination of the H_k, the blocks being independent. The span of the H_k is therefore an abelian subalgebra of diagonalizable elements, of dimension r.

No larger one exists. Let $\mathfrak{h}$ be any abelian subalgebra of $\mathfrak{so}(p,q)$ all of whose elements are diagonalizable, and let $\mathfrak{h}_{\mathbb{C}}$ be its complex span inside the complex $D \times D$ matrices. Since the elements of $\mathfrak{h}$ are real matrices, a real basis of $\mathfrak{h}$ stays independent over $\mathbb{C}$ —

the real and imaginary parts of a vanishing complex combination vanish separately — so $\dim_{\mathbb{C}} \mathfrak{h}_{\mathbb{C}} = \dim_{\mathbb{R}} \mathfrak{h}$. Commuting diagonalizable operators are simultaneously diagonalizable, and every complex combination of operators diagonal in one basis is diagonal in that basis, so there are a basis $\{v_1, \dots, v_D\}$ of $\mathbb{C}^D$ and complex-linear functionals λ_i on $\mathfrak{h}_{\mathbb{C}}$ with $X v_i = \lambda_i(X) v_i$. Condition Equation (14.23) is complex-bilinear and therefore holds on $\mathfrak{h}_{\mathbb{C}}$; applied to $u = v_i$, $v = v_j$ it gives

$$(\lambda_i(X) + \lambda_j(X))\, \eta(v_i, v_j) = 0 \qquad \text{for all } X \in \mathfrak{h}_{\mathbb{C}}\,.$$

Collect the basis vectors by their functional: for each α occurring among the λ_i, let V_α be the span of those v_i with $\lambda_i = \alpha$. The display says $\eta(V_\alpha, V_\beta) = 0$ unless $\beta = -\alpha$, so nondegeneracy of η forces $-\alpha$ to occur whenever α does, and forces the pairing of V_α with $V_{-\alpha}$ to be nondegenerate, whence $\dim V_\alpha = \dim V_{-\alpha}$. The occurring functionals thus consist of k pairs $\pm\alpha_1, \dots, \pm\alpha_k$ with $\alpha_i \neq 0$, possibly together with 0; each pair accounts for at least two basis vectors, so $2k \leq D$ and $k \leq r$. Finally the occurring functionals span the dual of $\mathfrak{h}_{\mathbb{C}}$, since an X annihilated by all of them acts as zero on every v_i and is therefore zero, and they span the same space as $\alpha_1, \dots, \alpha_k$. Hence $\dim_{\mathbb{R}} \mathfrak{h} = \dim_{\mathbb{C}} \mathfrak{h}_{\mathbb{C}} \leq k \leq r$.

The subalgebra Equation (14.24) is therefore maximal, and every maximal one has the same dimension r. □

Remark 14.23 (Racah's theorem does not apply to every algebra that matters). Theorem 14.21 is a statement about *semisimple* algebras, and the Poincaré algebra Equation (14.99) is not semisimple: it is a semidirect sum with an abelian ideal, so its Killing form is degenerate and Theorem 14.13 excludes it. Its invariants must be found by hand, which is done in Theorem 14.65, and the count that comes out — two, in the observed $3+1$ dimensions — is not predicted by Racah's theorem but merely happens to agree with the rank of its Lorentz subalgebra. Conflating the two is an easy error and would give the wrong answer for the Galilei algebra of Example 14.80, whose invariants include the central mass.

Remark 14.24 (Casimir operators and SI units). Everything in this subsection is dimensionless. The generators of Equation (14.3) are differential operators built from coordinates and derivatives with respect to them, the structure constants are pure numbers, and a Casimir element is a polynomial in the generators, so its eigenvalue on an irreducible representation is a pure number too. A physical observable is obtained by multiplying a generator by the constant that carries its dimension, and for the rotation generators that constant is the reduced Planck constant $\hbar = h/2\pi$, with $h = 6.626\,070\,15 \times 10^{-34}\,\mathrm{J\,s}$ exactly, by the definition of the kilogram [2333]. The observable angular momentum is $\hbar \boldsymbol{J}$, of SI unit J s, and the observable Casimir is $\hbar^2 \boldsymbol{J}^2$, of SI unit $\mathrm{J^2\,s^2}$. It is worth saying this once and plainly, because the literature almost never does: the familiar statement "the eigenvalue is $j(j+1)$" is a statement about a dimensionless generator, and the measured quantity is $\hbar^2 j(j+1)$. The same distinction returns for the Poincaré algebra in Proposition 14.60, where the first invariant is m^2c^2 and not m^2.

14.2 Representations of Lie groups

14.2.1 The group $\mathrm{SO}(2, \mathbb{R})$

Discussion of the definition

Consider the vector space $\mathbb{R}^2 = \mathrm{span}\,\{|e_x\rangle, |e_y\rangle\}$ and let $R(\phi)$ be the operator that takes the basis vector $|e_i\rangle$ to the rotated vector $R(\phi)\,|e_i\rangle$ [2027]. Elementary trigonometry on the rotated basis gives

$$\begin{aligned} R(\phi)\,|e_x\rangle &= \cos\phi\;|e_x\rangle + \sin\phi\;|e_y\rangle\;, \\ R(\phi)\,|e_y\rangle &= -\sin\phi\;|e_x\rangle + \cos\phi\;|e_y\rangle\;, \end{aligned}$$

or, compactly,

$$R(\phi)\,|e_i\rangle = (D(\phi))^j{}_i\,|e_j\rangle\ ,$$

with

$$D(\phi) = \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix}\ . \tag{14.25}$$

Now consider an arbitrary vector $|x\rangle \in \mathbb{R}^2$. In the basis above, $|x\rangle = x^i\,|e_i\rangle$. As we have seen, the operator $R(\phi)$ rotates a vector when acting upon it:

$$\begin{aligned} |\bar{x}\rangle &= R(\phi)\,|x\rangle\ , \\ \bar{x}^j\,|e_j\rangle &= R(\phi)\,x^i\,|e_i\rangle = x^i\,(D(\phi))^j{}_i\,|e_j\rangle\ , \end{aligned}$$

so that

$$\bar{x}^j = (D(\phi))^j{}_i\,x^i\,.$$

But does the rotation of the vector preserve its norm? This seems obvious; let us see what happens if we impose it. We require

$$\begin{aligned} \||x\rangle\| &\stackrel{!}{=} \||\bar{x}\rangle\|\ , \\ x^i x^i &= \bar{x}^j \bar{x}^j \\ &= (D(\phi))^j{}_k\,(D(\phi))^j{}_l\,x^k x^l \\ &= \left(D(\phi)^{\mathsf{T}}\right)^k{}_j\,(D(\phi))^j{}_l\,x^k x^l\,, \end{aligned}$$

whence

$$\left(D(\phi)^{\mathsf{T}}\right)^k{}_j\,(D(\phi))^j{}_l = \delta^k{}_l\,,$$

or, in matrix notation,

$$D(\phi)^{\mathsf{T}} D(\phi) = \mathbb{1}\,. \tag{14.26}$$

In conclusion, we have found the condition for the operator $R(\phi)$ to be an automorphism belonging to the group $\mathrm{O}(2,\mathbb{R})$. Moreover,

$$\det D(\phi) = \cos^2\phi + \sin^2\phi = 1\,,$$

and therefore $R(\phi) \in \mathrm{SO}(2,\mathbb{R})$.

With this we can conclude the following fact: the set of all two-dimensional rotations forms a group, which is isomorphic to the group $\mathrm{SO}(2,\mathbb{R})$. Furthermore, one can see geometrically that rotating a vector by an angle ϕ_1 and then by an angle ϕ_2 is exactly the same as doing it the other way around — first by ϕ_2 and then by ϕ_1 — which means that $\mathrm{SO}(2,\mathbb{R})$ is an abelian group.

Generator

We have

$$\begin{aligned} D(\phi) &= \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix} \\ &= \begin{pmatrix} \cos\phi & 0 \\ 0 & \cos\phi \end{pmatrix} + \begin{pmatrix} 0 & -\sin\phi \\ \sin\phi & 0 \end{pmatrix} \\ &= \cos\phi \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \sin\phi \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\ . \end{aligned}$$

Defining the matrix

$$J = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} , \tag{14.27}$$

we may write

$$D(\phi) = \mathbb{1} \cos\phi + J \sin\phi \, .$$

Note that

$$J^2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} = -\mathbb{1} \, ,$$

and thus

$$J^3 = -J \, , \qquad J^4 = \mathbb{1} \, , \qquad J^5 = J \, ,$$

so that, for $n \in \mathbb{N}$,

$$J^{2n} = (-1)^n \, \mathbb{1} \, , \qquad J^{2n+1} = (-1)^n \, J \, .$$

On the other hand, recalling the Taylor series of the cosine and the sine,

$$\cos\phi = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n)!} \, \phi^{2n} \, , \qquad \sin\phi = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n+1)!} \, \phi^{2n+1} \, ,$$

we obtain

$$\begin{aligned} D(\phi) &= \sum_{n=0}^{\infty} \frac{(-1)^n \, \mathbb{1}}{(2n)!} \, \phi^{2n} + \sum_{n=0}^{\infty} \frac{(-1)^n \, J}{(2n+1)!} \, \phi^{2n+1} \\ &= \sum_{n=0}^{\infty} \frac{J^{2n}}{(2n)!} \, \phi^{2n} + \sum_{n=0}^{\infty} \frac{J^{2n+1}}{(2n+1)!} \, \phi^{2n+1} \\ &= \sum_{n=0}^{\infty} \frac{J^n}{n!} \, \phi^n \, , \end{aligned}$$

whence

$$D(\phi) = \mathrm{e}^{J\phi} \, , \tag{14.28}$$

so J is the generator of the group $\mathrm{SO}(2, \mathbb{R})$.

Irreducible representations

We know that the group $\mathrm{SO}(2, \mathbb{R})$ is abelian, and we have seen that the irreducible representations of an abelian group are necessarily one-dimensional — Proposition 5.156, a consequence of the first Schur lemma (Theorem 5.153). Which, then, are the possible irreducible representations? Let $|\lambda\rangle$ be an eigenvector of J,

$$J \, |\lambda\rangle = \lambda \, |\lambda\rangle \ ,$$

so that, by Equation (14.28),

$$\begin{aligned} R(\phi) \, |\lambda\rangle &= \mathrm{e}^{J\phi} \, |\lambda\rangle \\ &= \mathrm{e}^{\lambda\phi} \, |\lambda\rangle \ . \end{aligned}$$

But since one must have

$$R(\phi) \, |x\rangle = R(\phi + 2\pi) \, |x\rangle \ ,$$

it follows that

$$\begin{aligned} \mathrm{e}^{\lambda\phi} \, |\lambda\rangle &= \mathrm{e}^{\lambda(\phi + 2\pi)} \, |\lambda\rangle \\ &= \mathrm{e}^{\lambda\phi} \, \mathrm{e}^{2\pi\lambda} \, |\lambda\rangle \implies \mathrm{e}^{2\pi\lambda} = 1 \, , \end{aligned}$$

so that

$$\lambda = \mathrm{i}m\,, \qquad m \in \mathbb{Z}\,.$$

Therefore, the irreducible representations of $\mathrm{SO}(2,\mathbb{R})$ are

$$R^m(\phi) = \mathrm{e}^{\mathrm{i}m\phi}\,, \qquad m \in \mathbb{Z}\,. \tag{14.29}$$

From Equation (14.28) (diagonalize the generator and impose 2π-periodicity of the rotation).

14.2.2 The groups $\mathrm{SO}(3)$, $\mathrm{SU}(2)$ and $\mathrm{SU}(3)$

Three compact groups carry almost all of the group theory the physical parts of this treatise need. The rotation group $\mathrm{SO}(3,\mathbb{R})$ is the symmetry of space itself. The special unitary group $\mathrm{SU}(2)$ is its double cover, and the existence of that cover — not any postulate about particles — is why half-integer angular momentum exists. The group $\mathrm{SU}(3)$ is the first case here in which the rank exceeds one, so that two Casimir operators are required by Theorem 14.21 and the weight diagram becomes two-dimensional. The gauge group of the Standard Model is $\mathrm{SU}(3)\times\mathrm{SU}(2)\times\mathrm{U}(1)$, and this subsection supplies the mathematics that Chapters 102 and 104 will use; the physics, and every claim about what the groups act on, is left to them. The quantum-mechanical treatment of angular momentum, which starts from the algebra derived here, is Chapter 79 [1593, 2287].

Remark 14.25 ($\mathrm{SU}(3)$ is an internal symmetry). This treatise instantiates every spacetime construction in the observed $3+1$ dimensions. The 3 of $\mathrm{SU}(3)$ is not a spacetime dimension: it is the dimension of an internal complex vector space attached to each point, on which the group acts without touching the coordinates at all. Nothing in this subsection is a statement about a three-dimensional spacetime.

The rotation group $\mathrm{SO}(3,\mathbb{R})$

Definition 14.26 (The rotation group)**.**

$$\mathrm{SO}(3,\mathbb{R}) = \left\{ R \in \mathrm{GL}(3,\mathbb{R}) \mid R^{\mathsf{T}}R = \mathbb{1},\ \det R = 1 \right\}. \tag{14.30}$$

This is the case $p=3$, $q=0$ of Section 14.3.2: the defining condition $R^{\mathsf{T}}\eta R = \eta$ of the pseudo-orthogonal group reduces to $R^{\mathsf{T}}R = \mathbb{1}$ when $\eta = \mathbb{1}$, and $\det R = 1$ selects the component containing the identity. Accordingly Equation (14.89) gives

$$\dim \mathfrak{so}(3) = \frac{3\cdot 2}{2} = 3\,. \tag{14.31}$$

From Equation (14.89) (the case $p=3$, $q=0$, so that $D=3$).

Proposition 14.27 (Generators of $\mathfrak{so}(3)$)**.** *The Lie algebra $\mathfrak{so}(3)$ is the space of real antisymmetric 3×3 matrices. A basis of it is*

$$(L_k)_{ij} = -\epsilon_{kij}\,, \tag{14.32}$$

that is

$$L_1 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}, \quad L_2 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix}, \quad L_3 = \begin{pmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \tag{14.33}$$

and it satisfies

$$[L_i, L_j] = \epsilon_{ijk}\, L_k\,. \tag{14.34}$$

Rests on Definition 14.26.

Proof. *Derives Proposition 14.27.*

Write $R = \mathbb{1} + \varepsilon X + O(\varepsilon^2)$ in Equation (14.30). To first order $R^{\mathsf{T}} R = \mathbb{1}$ gives $X^{\mathsf{T}} + X = 0$, and $\det R = 1$ gives $\operatorname{tr} X = 0$, which is implied by antisymmetry; conversely exp of an antisymmetric matrix is orthogonal with unit determinant. The real antisymmetric 3×3 matrices form a three-dimensional space, matching Equation (14.31), and the L_k of Equation (14.32) are three independent members of it. Note that L_3 is the generator J of $\mathrm{SO}(2,\mathbb{R})$ found in Equation (14.27), embedded in the 1–2 block.

For the bracket, compute the (m,n) entry using $(L_i)_{mk} = -\epsilon_{imk}$:

$$\begin{aligned} \left([L_i, L_j]\right)_{mn} &= \epsilon_{imk}\epsilon_{jkn} - \epsilon_{jmk}\epsilon_{ikn} \\ &= (\delta_{in}\delta_{mj} - \delta_{ij}\delta_{mn}) - (\delta_{jn}\delta_{mi} - \delta_{ij}\delta_{mn}) \\ &= \delta_{in}\delta_{jm} - \delta_{im}\delta_{jn}\,, \end{aligned}$$

where the contraction $\epsilon_{kim}\epsilon_{knj} = \delta_{in}\delta_{mj} - \delta_{ij}\delta_{mn}$ was used twice after a cyclic relabelling. On the other hand

$$\left(\epsilon_{ijk} L_k\right)_{mn} = -\epsilon_{ijk}\epsilon_{kmn} = -\left(\delta_{im}\delta_{jn} - \delta_{in}\delta_{jm}\right)\,,$$

which is the same expression. □

For representation theory it is convenient to use Hermitian generators, because Hermitian operators are the ones that can represent observables and because the resulting brackets are those of the quantum theory.

Definition 14.28 (Hermitian rotation generators)**.**

$$\boxed{J_k = \mathrm{i} L_k\,, \qquad [J_i, J_j] = \mathrm{i}\,\epsilon_{ijk} J_k\,, \qquad R(\hat{n},\phi) = \exp\left(-\mathrm{i}\,\phi\,\hat{n}\cdot\boldsymbol{J}\right)}\,. \tag{14.35}$$

Each J_k is Hermitian: L_k is real and antisymmetric, so $(\mathrm{i}L_k)^\dagger = -\mathrm{i}L_k^{\mathsf{T}} = \mathrm{i}L_k$. The bracket follows from Equation (14.34) by $[J_i, J_j] = -[L_i, L_j] = -\epsilon_{ijk}L_k = \mathrm{i}\epsilon_{ijk}J_k$.

Rests on Proposition 14.27.

Remark 14.29 (Where $\hbar$ enters). Equation (14.35) is a statement about dimensionless matrices. The physical angular momentum operator is $\hat{\boldsymbol{\mathcal{J}}} = \hbar \boldsymbol{J}$, of SI unit J s, and multiplying Equation (14.35) by $\hbar^2$ turns it into $\left[\hat{\mathcal{J}}_i, \hat{\mathcal{J}}_j\right] = \mathrm{i}\hbar\,\epsilon_{ijk}\hat{\mathcal{J}}_k$, which is the commutator measured in the laboratory and the one used throughout Chapters 79 and 94 (cf. Equation (94.8)). The rotation operator is correspondingly $\exp\left(-\mathrm{i}\,\phi\,\hat{n}\cdot\hat{\boldsymbol{\mathcal{J}}}/\hbar\right)$, the ratio in the exponent being dimensionless as it must be. See Remark 14.24.

Proposition 14.30 (Rodrigues formula; the exponential map is onto)**.** *Write $N = \hat{n}\cdot\boldsymbol{L}$ for a unit vector $\hat{n}$. Then $N\boldsymbol{x} = \hat{n}\times\boldsymbol{x}$, $N^3 = -N$, and*

$$\exp(\phi N) = \mathbb{1} + \sin\phi\; N + (1 - \cos\phi)\, N^2\,, \tag{14.36}$$

so that

$$R(\hat{n},\phi)\,\boldsymbol{x} = \boldsymbol{x}\cos\phi + \hat{n}\,(\hat{n}\cdot\boldsymbol{x})\,(1-\cos\phi) + (\hat{n}\times\boldsymbol{x})\sin\phi\,. \tag{14.37}$$

Every element of $\mathrm{SO}(3,\mathbb{R})$ is of this form with $\phi \in [0,\pi]$, so the exponential map $\mathfrak{so}(3) \to \mathrm{SO}(3,\mathbb{R})$ is surjective.

Rests on Proposition 14.27 and Equations (14.25) and (14.28).

Proof. *Derives Proposition 14.30.*

From Equation (14.32), $(N\boldsymbol{x})_i = -\epsilon_{kij} n_k x_j = \epsilon_{ikj} n_k x_j = (\hat{n}\times\boldsymbol{x})_i$. Hence $N^2\boldsymbol{x} = \hat{n}\times(\hat{n}\times\boldsymbol{x}) = \hat{n}(\hat{n}\cdot\boldsymbol{x}) - \boldsymbol{x}$ and $N^3\boldsymbol{x} = \hat{n}\times(\hat{n}(\hat{n}\cdot\boldsymbol{x}) - \boldsymbol{x}) = -\hat{n}\times\boldsymbol{x} = -N\boldsymbol{x}$. Consequently

$N^{2k+1} = (-1)^k N$ and $N^{2k+2} = (-1)^k N^2$ for $k \in \mathbb{N} \cup \{0\}$, and splitting the exponential series into its odd and even parts, exactly as was done for $\mathrm{SO}(2,\mathbb{R})$ at Equation (14.28),

$$\exp(\phi N) = \mathbb{1} + \left(\sum_{k=0}^{\infty} \frac{(-1)^k \phi^{2k+1}}{(2k+1)!} \right) N + \left(\sum_{k=0}^{\infty} \frac{(-1)^k \phi^{2k+2}}{(2k+2)!} \right) N^2 ,$$

whose two coefficients are $\sin\phi$ and $1 - \cos\phi$. Substituting $N^2 \boldsymbol{x}$ gives Equation (14.37).

Surjectivity is Euler's theorem on rotations: $R \in \mathrm{SO}(3,\mathbb{R})$ is a real 3×3 matrix, so its characteristic polynomial is a real cubic and has a real root; the roots have modulus 1 because R is orthogonal, and their product is $\det R = 1$, so the real root is $+1$ and there is a unit vector $\hat{n}$ with $R\hat{n} = \hat{n}$. In an orthonormal basis adapted to $\hat{n}$, R acts as the identity on $\hat{n}$ and as an element of $\mathrm{SO}(2,\mathbb{R})$ on the orthogonal plane, which is Equation (14.25) for some angle ϕ; replacing $\hat{n}$ by $-\hat{n}$ if necessary brings ϕ into $[0,\pi]$. □

Proposition 14.31 ($\mathrm{SO}(3,\mathbb{R})$ is not simply connected)**.** *The map sending $\boldsymbol{\phi} = \phi\hat{n}$ with $\phi \in [0,\pi]$ to $R(\hat{n},\phi)$ identifies $\mathrm{SO}(3,\mathbb{R})$ with the closed ball of radius π in $\mathbb{R}^3$ with antipodal boundary points identified, that is with the real projective space $\mathbb{R}P^3$. It is compact, connected, and* not *simply connected in the sense of Definition 6.17: the loop traced by $R(\hat{n},\phi)$ as ϕ runs from 0 to 2π cannot be contracted to a point, while the same loop traversed twice can.*

Rests on Proposition 14.30, Definition 6.17, and Corollary 14.38.

Derivation. *Derives Proposition 14.31.*

That the map is onto is Proposition 14.30, and it is injective on the open ball because $R(\hat{n},\phi)$ determines its fixed axis and its rotation angle; on the boundary sphere $\phi = \pi$ the only failure of injectivity is $R(\hat{n},\pi) = R(-\hat{n},\pi)$, immediate from Equation (14.37) since $\cos\pi = -1$ and $\sin\pi = 0$ leave only terms even in $\hat{n}$. A continuous bijection from a compact space to a Hausdorff space is a homeomorphism, so $\mathrm{SO}(3,\mathbb{R}) \cong \mathbb{R}P^3$; connectedness and compactness follow. The statement about loops is Corollary 14.38 below, where it is read off the double cover. □

The group SU(2)

Definition 14.32 (The special unitary group in two dimensions)**.**

$$\mathrm{SU}(2) = \left\{ U \in \mathrm{GL}(2,\mathbb{C}) \mid U^\dagger U = \mathbb{1},\ \det U = 1 \right\} . \tag{14.38}$$

Proposition 14.33 ($\mathrm{SU}(2)$ is the three-sphere)**.** *Every $U \in \mathrm{SU}(2)$ has the form*

$$U = \begin{pmatrix} \alpha & \beta \\ -\bar{\beta} & \bar{\alpha} \end{pmatrix} , \qquad |\alpha|^2 + |\beta|^2 = 1 , \tag{14.39}$$

and $(\alpha,\beta) \mapsto U$ is a homeomorphism from the unit sphere $S^3 \subset \mathbb{R}^4 \cong \mathbb{C}^2$ onto $\mathrm{SU}(2)$. Hence $\mathrm{SU}(2)$ is compact, connected and simply connected.

Rests on Definition 14.32.

Proof. *Derives Proposition 14.33.*

Write

$$U = \begin{pmatrix} a & b \\ c & d \end{pmatrix} .$$

With $\det U = 1$ the inverse is $U^{-1} = \begin{pmatrix} d & -b \\ -c & a \end{pmatrix}$, while unitarity says $U^{-1} = U^\dagger = \begin{pmatrix} \bar{a} & \bar{c} \\ \bar{b} & \bar{d} \end{pmatrix}$. Comparing entries, $d = \bar{a}$ and $c = -\bar{b}$, which is Equation (14.39) with $\alpha = a$, $\beta = b$; the determinant condition then reads $|\alpha|^2 + |\beta|^2 = 1$. Conversely every such matrix is unitary with unit determinant. The correspondence and its inverse are given by polynomials in the real and imaginary parts, so both are continuous. Finally S^3 is connected and simply connected by Lemma 14.34. □

The last step is the only one that is not immediate, and since the distinction between $\mathrm{SU}(2)$ and $\mathrm{SO}(3,\mathbb{R})$ turns entirely on it — and with that distinction, the existence of half-integer spin — it is proved rather than quoted. Its natural home is the topology chapter, whose Definition 6.17 it uses.

Lemma 14.34 (The n-sphere is simply connected for $n \geq 2$)**.** *For $n \geq 2$ the unit sphere $S^n = \{y \in \mathbb{R}^{n+1} \mid \|y\| = 1\}$ is path-connected and simply connected.*
Rests on Definition 6.17, Example 6.18, and Theorem 7.25.

Proof. *Derives Lemma 14.34.*
For $p, q \in S^n$ with $q \neq -p$ define the normalized chord

$$\sigma_{p,q}(u) = \frac{(1-u)p + uq}{\|(1-u)p + uq\|}\,, \qquad 0 \leq u \leq 1\,. \tag{14.40}$$

It is well defined, because $\|(1-u)p+uq\|^2 = (1-u)^2 + u^2 + 2u(1-u)\,p\cdot q$ can vanish only if $u = 1/2$ and $p \cdot q = -1$, that is only if $q = -p$; it is jointly continuous in p, q and u; it runs from p to q; and its image lies in the plane spanned by p and q. Path-connectedness follows at once: two points are joined by Equation (14.40) unless they are antipodal, and an antipodal pair is joined through any third point.

Every loop is homotopic to a piecewise-circular one. Let $\gamma : [0,1] \longrightarrow S^n$ be continuous with $\gamma(0) = \gamma(1)$. Each of the $n+1$ components of γ is uniformly continuous by Theorem 7.25, whose proof applies verbatim to a map into $\mathbb{R}^{n+1}$, so there is an N with $\|\gamma(s) - \gamma(s')\| < 1$ whenever $|s - s'| \leq 1/N$. Put $p_k = \gamma(k/N)$. Consecutive p_k are not antipodal, their distance being less than $1 < 2$, so

$$\tilde\gamma(s) = \sigma_{p_k,p_{k+1}}\,(Ns - k)\;, \qquad \frac{k}{N} \leq s \leq \frac{k+1}{N}\,,$$

is a well-defined continuous loop with $\tilde\gamma(0) = p_0 = \gamma(0)$ and $\tilde\gamma(1) = p_N = \gamma(1)$. For s in the k-th subinterval both $\|\gamma(s) - p_k\| < 1$ and $\|\gamma(s) - p_{k+1}\| < 1$, and for unit vectors $\|a-b\|^2 = 2 - 2\,a\cdot b$, so $\gamma(s)\cdot p_k > 1/2$ and $\gamma(s)\cdot p_{k+1} > 1/2$. Since $\tilde\gamma(s)$ is a combination of p_k and p_{k+1} with nonnegative coefficients divided by a norm at most 1,

$$\gamma(s)\cdot\tilde\gamma(s) = \frac{(1-u)\,\gamma(s)\cdot p_k + u\,\gamma(s)\cdot p_{k+1}}{\|(1-u)p_k + up_{k+1}\|} \geq \tfrac{1}{2}\,, \qquad u = Ns - k\,.$$

Hence $(1-t)\gamma(s) + t\tilde\gamma(s)$ never vanishes, its squared norm being at least $(1-t)^2 + t^2$, and

$$H(s,t) = \frac{(1-t)\gamma(s) + t\,\tilde\gamma(s)}{\|(1-t)\gamma(s) + t\,\tilde\gamma(s)\|}$$

is a homotopy from γ to $\tilde\gamma$ fixing the base point.

A piecewise-circular loop misses a point. The image of $\tilde\gamma$ lies in the union of the N sets $C_k = S^n \cap \Pi_k$, where Π_k is a plane of dimension at most two containing p_k and p_{k+1}; enlarging it if necessary, take $\dim \Pi_k = 2$. Because $n+1 \geq 3$, the planes $\Pi' = \operatorname{span}\{e_1, \cos\alpha\, e_2 + \sin\alpha\, e_3\}$ are pairwise distinct for $\alpha \in [0,\pi)$ and infinite in number, so some Π' differs from all N of the Π_k. Two distinct two-dimensional planes meet in a subspace of dimension at most one, so $S^n \cap \Pi' \cap \Pi_k$ has at most two points for each k; the circle $S^n \cap \Pi'$ is infinite, and therefore contains a point x lying on no C_k.

The complement of a point is $\mathbb{R}^n$. Stereographic projection from x,

$$\pi(y) = \frac{y - (y\cdot x)\,x}{1 - y\cdot x}\,, \tag{14.41}$$

maps $S^n \setminus \{x\}$ into the n-dimensional space $x^\perp \cong \mathbb{R}^n$ and is continuous there. So is $w \mapsto \big(2w + (\|w\|^2 - 1)x\big)/(\|w\|^2 + 1)$, which lands on S^n — its squared norm is

$\left(4\|w\|^2 + (\|w\|^2-1)^2\right)/(\|w\|^2+1)^2 = 1$ — and a direct substitution shows the two maps are mutually inverse. Hence $S^n \setminus \{x\}$ is homeomorphic to $\mathbb{R}^n$, which is simply connected by Example 6.18. The loop $\tilde{\gamma}$ therefore contracts to its base point inside $S^n \setminus \{x\}$, hence inside S^n; composing that homotopy with H contracts γ. □

Proposition 14.35 (Generators of $\mathfrak{su}(2)$)**.** *The Lie algebra $\mathfrak{su}(2)$ is the space of traceless anti-Hermitian 2×2 matrices, of real dimension 3. Writing its elements as $-\mathrm{i}\theta^k T_k$ with θ^k real, a basis of Hermitian generators is*

$$\boxed{T_k = \tfrac{1}{2}\sigma_k}, \qquad \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \tag{14.42}$$

the Pauli matrices [587]. They obey

$$\sigma_i\sigma_j = \delta_{ij}\mathbb{1} + \mathrm{i}\,\epsilon_{ijk}\sigma_k\,, \tag{14.43}$$

and therefore

$$\boxed{[T_i, T_j] = \mathrm{i}\,\epsilon_{ijk}T_k}, \qquad \operatorname{tr}(T_iT_j) = \tfrac{1}{2}\delta_{ij}\,. \tag{14.44}$$

Rests on Definition 14.32.

Proof. *Derives Proposition 14.35.*

Setting $U = \mathbb{1} + \varepsilon X + O(\varepsilon^2)$ in Equation (14.38) gives $X^\dagger + X = 0$ and $\operatorname{tr} X = 0$. A traceless anti-Hermitian 2×2 matrix is $\begin{pmatrix} \mathrm{i}u & v+\mathrm{i}w \\ -v+\mathrm{i}w & -\mathrm{i}u \end{pmatrix}$ with u, v, w real, a three-dimensional real space, and the three matrices $-\mathrm{i}\sigma_k/2$ span it. Equation (14.43) is checked directly: $\sigma_i^2 = \mathbb{1}$ for each i by inspection, and the three products $\sigma_1\sigma_2 = \mathrm{i}\sigma_3$, $\sigma_2\sigma_3 = \mathrm{i}\sigma_1$, $\sigma_3\sigma_1 = \mathrm{i}\sigma_2$ are likewise immediate, the remaining cases following from $\sigma_j\sigma_i = 2\delta_{ij}\mathbb{1} - \sigma_i\sigma_j$. Antisymmetrizing Equation (14.43) gives $[\sigma_i, \sigma_j] = 2\mathrm{i}\epsilon_{ijk}\sigma_k$, that is Equation (14.44); taking the trace of Equation (14.43) and using $\operatorname{tr}\sigma_k = 0$ gives $\operatorname{tr}(\sigma_i\sigma_j) = 2\delta_{ij}$. □

Equation (14.44) is *the same algebra* as Equation (14.35). The two groups therefore have isomorphic Lie algebras, $\mathfrak{su}(2) \cong \mathfrak{so}(3)$, and cannot be distinguished by any local construction. They are nevertheless different groups, and the next result says exactly how.

Proposition 14.36 (Closed form of the exponential)**.** *For a unit vector $\hat{n}$,*

$$U(\hat{n}, \psi) = \exp\left(-\tfrac{\mathrm{i}}{2}\psi\,\hat{n}\cdot\boldsymbol{\sigma}\right) = \mathbb{1}\cos\frac{\psi}{2} - \mathrm{i}\,(\hat{n}\cdot\boldsymbol{\sigma})\sin\frac{\psi}{2}\,, \tag{14.45}$$

and in particular $U(\hat{n}, 2\pi) = -\mathbb{1}$ and $U(\hat{n}, 4\pi) = \mathbb{1}$.

Rests on Proposition 14.35 and Equation (14.28).

Proof. *Derives Proposition 14.36.*

By Equation (14.43), $(\hat{n}\cdot\boldsymbol{\sigma})^2 = n_in_j\sigma_i\sigma_j = n_in_j\delta_{ij}\mathbb{1} = \mathbb{1}$, the ϵ term dropping because n_in_j is symmetric. The even and odd powers of $\hat{n}\cdot\boldsymbol{\sigma}$ therefore alternate exactly as J did in Equation (14.27), and the same resummation that produced Equation (14.28) produces Equation (14.45). Setting $\psi = 2\pi$ gives $\cos\pi = -1$, $\sin\pi = 0$. □

The double cover $\mathrm{SU}(2) \to \mathrm{SO}(3,\mathbb{R})$

Theorem 14.37 ($\mathrm{SU}(2)$ is a two-to-one cover of $\mathrm{SO}(3,\mathbb{R})$)**.** *Identify $\boldsymbol{x} \in \mathbb{R}^3$ with the traceless Hermitian matrix $X = \boldsymbol{x}\cdot\boldsymbol{\sigma}$, and define*

$$\boxed{\Phi(U):\ \boldsymbol{x}\cdot\boldsymbol{\sigma} \longmapsto U\,(\boldsymbol{x}\cdot\boldsymbol{\sigma})\,U^\dagger}. \tag{14.46}$$

Then Φ *is a surjective group homomorphism* $\mathrm{SU}(2) \to \mathrm{SO}(3,\mathbb{R})$ *with*

$$\ker \Phi = \{\mathbb{1}, -\mathbb{1}\} \cong \mathbb{Z}_2\,, \tag{14.47}$$

and explicitly $\Phi\left(U(\hat{n},\phi)\right) = R(\hat{n},\phi)$.

Rests on Propositions 14.30, 14.33, 14.35 and 14.36.

Proof. *Derives Theorem 14.37.*

We check the four claims in turn.

$\Phi(U)$ *is a well-defined real linear map on* $\mathbb{R}^3$. The matrices $\boldsymbol{x}\cdot\boldsymbol{\sigma}$ are exactly the traceless Hermitian 2×2 matrices, since $\{\sigma_1,\sigma_2,\sigma_3\}$ is a real basis of that space. If X is traceless Hermitian then so is $UXU^\dagger$: Hermiticity because $\left(UXU^\dagger\right)^\dagger = UX^\dagger U^\dagger = UXU^\dagger$, and tracelessness by cyclicity together with $U^\dagger U = \mathbb{1}$. So $\Phi(U)$ maps $\mathbb{R}^3$ to $\mathbb{R}^3$ linearly.

$\Phi(U)$ *preserves the Euclidean norm.* From Equation (14.43), $\det(\boldsymbol{x}\cdot\boldsymbol{\sigma}) = -\boldsymbol{x}\cdot\boldsymbol{x}$, as one sees by writing out $\begin{pmatrix} x_3 & x_1 - \mathrm{i}x_2 \\ x_1 + \mathrm{i}x_2 & -x_3 \end{pmatrix}$. Since $\det U = 1$, $\det\left(UXU^\dagger\right) = \det X$, so the norm of $\boldsymbol{x}$ is unchanged and $\Phi(U) \in \mathrm{O}(3,\mathbb{R})$.

The image lies in $\mathrm{SO}(3,\mathbb{R})$*, and* Φ *is a homomorphism.* $\Phi(U_1U_2) = \Phi(U_1)\Phi(U_2)$ is immediate from Equation (14.46). The map $U \mapsto \det\Phi(U) \in \{+1,-1\}$ is continuous on the connected space $\mathrm{SU}(2)$ (Proposition 14.33) and equals $+1$ at $U = \mathbb{1}$, hence equals $+1$ everywhere.

The kernel. Suppose $UXU^\dagger = X$ for every traceless Hermitian X, i.e. U commutes with $\sigma_1,\sigma_2,\sigma_3$. Writing $U = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$, commuting with σ_3 forces $b = c = 0$, and commuting with σ_1 then forces $a = d$. So $U = a\mathbb{1}$, and $\det U = a^2 = 1$ gives $a = \pm 1$. Both values do lie in the kernel, giving Equation (14.47).

Surjectivity, and the explicit form. It suffices to compute $\Phi\left(U(\hat{n},\phi)\right)$ and find the rotation Equation (14.37), since those exhaust $\mathrm{SO}(3,\mathbb{R})$ by Proposition 14.30. Abbreviate $\mathrm{c} = \cos(\phi/2)$, $\mathrm{s} = \sin(\phi/2)$ and $n = \hat{n}\cdot\boldsymbol{\sigma}$, $X = \boldsymbol{x}\cdot\boldsymbol{\sigma}$. Using Equation (14.45),

$$\begin{aligned} UXU^\dagger &= (\mathrm{c}\,\mathbb{1} - \mathrm{i}\mathrm{s}\,n)\,X\,(\mathrm{c}\,\mathbb{1} + \mathrm{i}\mathrm{s}\,n) \\ &= \mathrm{c}^2 X + \mathrm{i}\,\mathrm{cs}\,[X,n] + \mathrm{s}^2\,nXn\,. \end{aligned}$$

Now Equation (14.43) gives $[X,n] = x_i n_j\,[\sigma_i,\sigma_j] = 2\mathrm{i}\,\epsilon_{ijk}x_i n_j \sigma_k = -2\mathrm{i}\,(\hat{n}\times\boldsymbol{x})\cdot\boldsymbol{\sigma}$, and, using $nX + Xn = 2\,(\hat{n}\cdot\boldsymbol{x})\,\mathbb{1}$ from the symmetric part of the same identity together with $n^2 = \mathbb{1}$,

$$nXn = \left(2\,(\hat{n}\cdot\boldsymbol{x})\,\mathbb{1} - Xn\right)n = 2\,(\hat{n}\cdot\boldsymbol{x})\,n - X\,.$$

Collecting the three pieces and using $\mathrm{c}^2 - \mathrm{s}^2 = \cos\phi$, $2\mathrm{cs} = \sin\phi$, $2\mathrm{s}^2 = 1 - \cos\phi$,

$$UXU^\dagger = \left[\boldsymbol{x}\cos\phi + \hat{n}\,(\hat{n}\cdot\boldsymbol{x})\,(1-\cos\phi) + (\hat{n}\times\boldsymbol{x})\sin\phi\right]\cdot\boldsymbol{\sigma}\,,$$

which is exactly Equation (14.37). □

Corollary 14.38 (SU(2) is the universal cover)**.** $\mathrm{SO}(3,\mathbb{R}) \cong \mathrm{SU}(2)/\{\mathbb{1},-\mathbb{1}\}$*, and since* $\mathrm{SU}(2)$ *is simply connected (Proposition 14.33) it is the universal covering group of* $\mathrm{SO}(3,\mathbb{R})$*, with*

$$\pi_1\left(\mathrm{SO}(3,\mathbb{R})\right) \cong \mathbb{Z}_2\,. \tag{14.48}$$

Concretely: the path $\phi \mapsto U(\hat{n},\phi)$*,* $0 \le \phi \le 2\pi$*, joins* $\mathbb{1}$ *to* $-\mathbb{1}$ *in* $\mathrm{SU}(2)$ *and projects to a closed loop in* $\mathrm{SO}(3,\mathbb{R})$ *that is not contractible, while the path with* $0 \le \phi \le 4\pi$ *is a closed loop upstairs and projects to a contractible one.*

Rests on Theorem 14.37 and Proposition 14.33.

Everything in the corollary except Equation (14.48) — that the quotient is $\mathrm{SO}(3,\mathbb{R})$, that the kernel has two elements, that the two paths are as described — is proved above from the material of this chapter. The remaining step, from a two-sheeted covering by a simply connected space to the fundamental group of the base, is covering-space theory: the homotopy lifting property, unique path lifting, and the resulting isomorphism between the fundamental group of the base and the deck-transformation group, here the kernel of the covering homomorphism.

Full derivation: Appendix A.33 (p. 2946).

Derives Corollary 14.38.

Remark 14.39 (This is why half-integer spin exists). A quantum state is a ray, so a symmetry need only be represented up to a phase: what a connected symmetry group must furnish is a projective unitary representation, and by Bargmann's analysis these are the ordinary unitary representations of the universal covering group [1029]. For rotations that covering group is $\mathrm{SU}(2)$, not $\mathrm{SO}(3,\mathbb{R})$. Theorem 14.43 below will show that an irreducible representation of $\mathfrak{su}(2)$ carries a label j with $2j \in \mathbb{N} \cup \{0\}$ and Proposition 14.44 that every such j occurs, and Proposition 14.45 will show that exactly the integer ones descend to $\mathrm{SO}(3,\mathbb{R})$ while the half-integer ones do not. The half-integer representations are therefore not an extra postulate: they are what the double cover makes available, and the electron uses them [562, 587]. The same argument in the relativistic setting replaces $\mathrm{SU}(2)$ by $\mathrm{SL}(2,\mathbb{C})$ and is carried out in Proposition 94.10.

The irreducible representations of $\mathfrak{su}(2)$

The construction that follows is the ladder-operator argument, and it is worth noting how little goes into it: only the brackets Equation (14.44), the existence of the Casimir guaranteed by Corollary 14.17, and finite dimensionality [687].

Definition 14.40 (Ladder operators and the Casimir)**.** In the complexified algebra put

$$J_{\pm} = J_1 \pm \mathrm{i} J_2 \,, \qquad \boldsymbol{J}^2 = J_1^2 + J_2^2 + J_3^2 \,. \tag{14.49}$$

Rests on Equation (14.44).

Lemma 14.41 (Ladder algebra)**.**

$$[J_3, J_{\pm}] = \pm J_{\pm} \,, \qquad [J_+, J_-] = 2J_3 \,, \tag{14.50}$$

and

$$\boldsymbol{J}^2 = J_- J_+ + J_3\,(J_3+1) = J_+ J_- + J_3\,(J_3-1) \ . \tag{14.51}$$

Moreover $\boldsymbol{J}^2$ is the quadratic Casimir of Corollary 14.17 up to normalisation: the Killing form of $\mathfrak{su}(2)$ in the Hermitian basis is $\kappa_{ab} = 2\delta_{ab}$, so $C_2 = \kappa^{ab} J_a J_b = \tfrac{1}{2}\boldsymbol{J}^2$.

Rests on Definition 14.40, Equations (14.15) and (14.44), and Corollary 14.17.

Proof. *Derives Lemma 14.41.*

From Equation (14.44), $[J_3, J_1 \pm \mathrm{i}J_2] = \mathrm{i}J_2 \pm \mathrm{i}(-\mathrm{i}J_1) = \pm(J_1 \pm \mathrm{i}J_2)$, and $[J_+, J_-] = -2\mathrm{i}\,[J_1, J_2] = 2J_3$. Next

$$J_- J_+ = (J_1 - \mathrm{i}J_2)\,(J_1 + \mathrm{i}J_2) = J_1^2 + J_2^2 + \mathrm{i}\,[J_1, J_2] = \boldsymbol{J}^2 - J_3^2 - J_3 \,,$$

which rearranges to the first form of Equation (14.51); the second follows by exchanging the roles of J_+ and J_-, which flips the sign of the $[J_1, J_2]$ term. For the Killing form use Equation (14.15) with $C^c{}_{ab} = \mathrm{i}\epsilon_{abc}$ from Equation (14.44): $\kappa_{ab} = (\mathrm{i}\epsilon_{adc})\,(\mathrm{i}\epsilon_{bcd}) = -\epsilon_{adc}\epsilon_{bcd} = \epsilon_{adc}\epsilon_{bdc} = 2\delta_{ab}$. □

Remark 14.42 (The compact real form). The value $\kappa_{ab} = +2\delta_{ab}$ is computed in the basis of *Hermitian* generators J_a, which spans the complexification. On the real algebra $\mathfrak{su}(2)$ itself, whose elements are the anti-Hermitian $-\mathrm{i}\theta^a J_a = \theta^a L_a$, the same computation gives $\kappa_{ab} = -2\delta_{ab}$: the Killing form of a compact real form is negative definite. Nondegeneracy, which is all that Corollary 14.17 requires, holds either way.

Theorem 14.43 (The irreducible representations of $\mathfrak{su}(2)$)**.** *Let D be a finite-dimensional irreducible representation of $\mathfrak{su}(2)$ on a complex inner-product space, unitary in the sense that the J_a are represented by Hermitian operators. Then there is a number j with*

$$\boxed{2j \in \mathbb{N} \cup \{0\}} \tag{14.52}$$

such that the representation has dimension $2j+1$, an orthonormal basis $\{|j,m\rangle\}$ with $m = -j, -j+1, \dots, j-1, j$, and

$$\boxed{J_3\,|j,m\rangle = m\,|j,m\rangle\ , \qquad \boldsymbol{J}^2\,|j,m\rangle = j(j+1)\,|j,m\rangle}\,, \tag{14.53}$$

$$J_\pm\,|j,m\rangle = \sqrt{j(j+1) - m(m\pm 1)}\ \,|j,m\pm 1\rangle\ . \tag{14.54}$$

Rests on Lemma 14.41 and Equation (14.44).

Proof. *Derives Theorem 14.43.*

J_3 is Hermitian on a finite-dimensional space, so it has an eigenvector; let μ be an eigenvalue of largest real part, with eigenvector $|\mu\rangle$. From Equation (14.50), $J_3\,(J_\pm\,|\mu\rangle) = (\mu \pm 1)\,J_\pm\,|\mu\rangle$, so $J_\pm$ raises and lowers the J_3 eigenvalue by one. Maximality of μ forces $J_+\,|\mu\rangle = 0$. Write $j := \mu$ and $|j,j\rangle := |\mu\rangle$ normalised. Then by Equation (14.51),

$$\boldsymbol{J}^2\,|j,j\rangle = (J_-J_+ + J_3(J_3+1))\,|j,j\rangle = j(j+1)\,|j,j\rangle\ ,$$

and since $\boldsymbol{J}^2$ commutes with J_3 and with $J_\pm$ its eigenspaces are invariant under the whole algebra, so by irreducibility the value $j(j+1)$ is taken on the entire representation. (This is Corollary 14.18 again, argued here directly so that nothing about the group is needed.)

Define $|j,m\rangle$ recursively by lowering. Because J_+ and J_- are adjoint to each other when the J_a are Hermitian,

$$\|J_-\,|j,m\rangle\|^2 = \langle j,m|\,J_+J_-\,|j,m\rangle = j(j+1) - m(m-1)\,,$$

using the second form of Equation (14.51); the same computation with J_+ and the first form gives $\|J_+\,|j,m\rangle\|^2 = j(j+1) - m(m+1)$, which is Equation (14.54) once phases are fixed by choosing the square roots positive. Since the space is finite-dimensional the chain of eigenvalues $j, j-1, j-2, \dots$ must terminate, which by the norm formula happens exactly at the value $m_{\min}$ with $j(j+1) - m_{\min}(m_{\min}-1) = 0$, that is $m_{\min} \in \{-j,\ j+1\}$; the second is excluded because $m_{\min} \le j$ and would need $j+1 \le j$. Hence $m_{\min} = -j$, and the chain runs from j down to $-j$ in unit steps, so $j - (-j) = 2j$ is a non-negative integer. *This is the whole reason half-integer angular momentum is possible: nothing in the algebra forbids the chain from having an even number of steps.* The span of the $|j,m\rangle$ is invariant under J_3 and $J_\pm$, hence under the whole algebra, and is nonzero, so by irreducibility it is the whole space, of dimension $2j+1$. □

Theorem 14.43 is a statement of *necessity*: an irreducible representation, if there is one, looks like that. It does not produce a single representation, and everything below — the descent to $\mathrm{SO}(3,\mathbb{R})$, the Clebsch–Gordan series, the spin label of a Poincaré representation — needs to know that the list is not empty. The converse is the shorter half, because the theorem has already written down the matrix elements a representation would have to have; it remains to check that they define one.

Proposition 14.44 (Existence: every allowed j is realized)**.** *For each j with $2j \in \mathbb{N} \cup \{0\}$ there exists a $(2j+1)$-dimensional irreducible representation of $\mathfrak{su}(2)$ by Hermitian operators, and its matrix elements are Equations (14.53) and (14.54). Together with Theorem 14.43 this puts the equivalence classes of finite-dimensional irreducible representations of $\mathfrak{su}(2)$ in bijection with the numbers $j = 0, \frac{1}{2}, 1, \frac{3}{2}, \dots$*

Rests on Theorem 14.43 and Lemma 14.41.

Proof. *Derives Proposition 14.44.*

Let $\mathbb{V}_j$ be the complex inner-product space with orthonormal basis $\{|j,m\rangle\}$, $m = -j, -j+1, \dots, j$, of dimension $2j+1$, and define operators on it by

$$J_3 \,|j,m\rangle = m \,|j,m\rangle \;, \qquad J_\pm \,|j,m\rangle = c_\pm(m) \,|j,m\pm 1\rangle \;, \tag{14.55}$$

$$c_\pm(m) = \sqrt{j(j+1) - m(m\pm 1)}\,, \tag{14.56}$$

with the convention that $|j,m\rangle$ denotes the zero vector for $|m| > j$. The convention is consistent because $j(j+1) - m(m+1) = (j-m)(j+m+1)$ and $j(j+1) - m(m-1) = (j+m)(j-m+1)$, which are non-negative for $-j \le m \le j$ and vanish exactly at $c_+(j) = 0$ and $c_-(-j) = 0$: the operators do not attempt to leave the basis. Put $J_1 = \frac{1}{2}(J_+ + J_-)$ and $J_2 = \frac{1}{2\mathrm{i}}(J_+ - J_-)$.

The brackets hold. $J_3 J_\pm \,|j,m\rangle = (m \pm 1) c_\pm(m) \,|j,m\pm 1\rangle$ while $J_\pm J_3 \,|j,m\rangle = m\, c_\pm(m) \,|j,m\pm 1\rangle$, so $[J_3, J_\pm] = \pm J_\pm$. Since $c_+(m-1) = c_-(m)$ by Equation (14.56), $J_+ J_- \,|j,m\rangle = c_-(m)^2 \,|j,m\rangle$ and $J_- J_+ \,|j,m\rangle = c_+(m)^2 \,|j,m\rangle$, whence

$$[J_+, J_-] \,|j,m\rangle = \big([j(j+1) - m(m-1)] - [j(j+1) - m(m+1)]\big) \,|j,m\rangle = 2m \,|j,m\rangle \;,$$

which is $2J_3 \,|j,m\rangle$. That is Equation (14.50), equivalent to Equation (14.44) by the computation in Lemma 14.41 run backwards.

The generators are Hermitian. The basis is orthonormal and the $c_\pm$ are real, so the only nonzero matrix elements of the ladder operators are $\langle j, m+1| \, J_+ \,|j,m\rangle = c_+(m)$ and $\langle j,m| \, J_- \,|j,m+1\rangle = c_-(m+1) = c_+(m)$. Hence $J_- = J_+^\dagger$, and J_1, J_2, J_3 are Hermitian.

It is irreducible. Let $\mathbb{W} \neq 0$ be an invariant subspace. It is invariant under the Hermitian J_3, whose eigenvalues on $\mathbb{V}_j$ are the $2j+1$ distinct numbers m, so $\mathbb{W}$ is spanned by those $|j,m\rangle$ it contains and contains at least one of them. From any one of them the ladder operators reach every other, their coefficients $c_\pm(m)$ vanishing only at the two ends of the chain. So $\mathbb{W} = \mathbb{V}_j$.

Finally Equation (14.51) gives $\boldsymbol{J}^2 \,|j,m\rangle = \big(c_+(m)^2 + m(m+1)\big) \,|j,m\rangle = j(j+1) \,|j,m\rangle$, so Equations (14.55) and (14.56) are Equations (14.53) and (14.54). □

Proposition 14.45 (Which representations descend to $\mathrm{SO}(3,\mathbb{R})$)**.** *Let $D^{(j)}$ be the representation of $\mathrm{SU}(2)$ obtained by exponentiating the representation of $\mathfrak{su}(2)$ constructed in Proposition 14.44. Then*

$$D^{(j)}(-\mathbb{1}) = (-1)^{2j}\,\mathbb{1}\,, \tag{14.57}$$

so $D^{(j)}$ descends to a genuine representation of $\mathrm{SO}(3,\mathbb{R}) = \mathrm{SU}(2)/\{\pm\mathbb{1}\}$ if and only if j is an integer. For half-integer j the map $R \mapsto D^{(j)}(U)$ is defined only up to the sign ambiguity in the choice of U above R: a projective representation, in the sense of Remark 14.39.

Rests on Propositions 14.36 and 14.44 and Corollary 14.38.

Proof. *Derives Proposition 14.45.*

By Proposition 14.36, $-\mathbb{1} = U(\hat{e}_3, 2\pi) = \exp(-2\pi\mathrm{i}\, T_3)$, so $D^{(j)}(-\mathbb{1}) = \exp(-2\pi\mathrm{i} J_3)$ in the representation, and on $|j,m\rangle$ this is $\mathrm{e}^{-2\pi\mathrm{i}m}$ by Equation (14.53). The values of m are $j, j-1, \dots, -j$: all integers when j is an integer, all in $\mathbb{Z} + \frac{1}{2}$ when j is half-odd-integer. In the first case $\mathrm{e}^{-2\pi\mathrm{i}m} = 1$ for every m, in the second $\mathrm{e}^{-2\pi\mathrm{i}m} = -1$ for every m; either way the operator is $(-1)^{2j}\mathbb{1}$. A representation of $\mathrm{SU}(2)$ factors through the quotient by $\{\pm\mathbb{1}\}$ precisely when it is trivial on that subgroup, which by Equation (14.57) happens exactly for integer j. □

Remark 14.46 (The integer case is what one already knew). For $j = 1$ the representation of Theorem 14.43 is three-dimensional and is equivalent to the defining representation of $\mathrm{SO}(3,\mathbb{R})$ on $\mathbb{R}^3$ complexified — both have $\boldsymbol{J}^2 = 2$, as one checks directly from Equation (14.35), and both are irreducible of dimension three. For general integer j the representation is the one carried by the spherical harmonics of degree j, of dimension $2j+1$. In SI terms (Remark 14.29) the observable statement is

$$\boxed{\hat{\mathcal{J}}^2 = \hbar^2\, j(j+1)}\,, \qquad \hat{\mathcal{J}}_3 = \hbar m\,, \tag{14.58}$$

with $\hbar^2 j(j+1)$ carrying the SI unit $\mathrm{J}^2\,\mathrm{s}^2$ and $\hbar m$ the unit $\mathrm{J}\,\mathrm{s}$.

The Clebsch–Gordan decomposition

Theorem 14.47 (Clebsch–Gordan series)**.** *Let V_{j_1} and V_{j_2} be the irreducible representations of $\mathfrak{su}(2)$ of Theorem 14.43. Under the total generators $\boldsymbol{J} = \boldsymbol{J}^{(1)} \otimes \mathbb{1} + \mathbb{1} \otimes \boldsymbol{J}^{(2)}$,*

$$\boxed{V_{j_1} \otimes V_{j_2} = \bigoplus_{J=|j_1-j_2|}^{j_1+j_2} V_J}\,, \tag{14.59}$$

each V_J occurring exactly once, and the dimensions check:

$$(2j_1+1)\,(2j_2+1) = \sum_{J=|j_1-j_2|}^{j_1+j_2} (2J+1)\,. \tag{14.60}$$

Rests on Theorem 14.43 and Equation (14.44).

Proof. *Derives Theorem 14.47.*

That $\boldsymbol{J}$ satisfies Equation (14.44) is immediate, the two factors commuting. Take $j_1 \geq j_2$ without loss of generality. In the product basis $|j_1 m_1\rangle \otimes |j_2 m_2\rangle$ the operator J_3 is diagonal with eigenvalue $m = m_1 + m_2$, so the multiplicity $n(m)$ of the eigenvalue m is the number of pairs (m_1, m_2) with $m_1 + m_2 = m$, $|m_i| \leq j_i$. Counting them,

$$n(m) = \begin{cases} j_1 + j_2 - |m| + 1\,, & j_1 - j_2 \leq |m| \leq j_1 + j_2\,, \\ 2j_2 + 1\,, & |m| \leq j_1 - j_2\,, \\ 0\,, & |m| > j_1 + j_2\,. \end{cases} \tag{14.61}$$

Now the tensor product is a finite-dimensional representation, hence a direct sum of irreducibles V_J with multiplicities $a_J \geq 0$; by Equation (14.53) each V_J contributes exactly 1 to $n(m)$ for every $|m| \leq J$ and nothing otherwise, so $n(m) = \sum_{J \geq |m|} a_J$. Subtracting consecutive values,

$$a_J = n(J) - n(J+1)\,,$$

and Equation (14.61) makes this 1 for $|j_1 - j_2| \leq J \leq j_1 + j_2$ and 0 otherwise, which is Equation (14.59). For Equation (14.60) write $J = j_1 - j_2 + k$ with $k = 0, \dots, 2j_2$:

$$\begin{aligned} \sum_{k=0}^{2j_2} (2(j_1 - j_2 + k) + 1) &= (2j_2+1)\,(2j_1 - 2j_2 + 1) + 2\,\frac{2j_2\,(2j_2+1)}{2} \\ &= (2j_2+1)\,(2j_1+1)\,. \end{aligned}$$

□

Remark 14.48 (What is and is not proved here). Theorem 14.47 settles *which* irreducible representations occur and with what multiplicity, and that is all the group theory of the following parts requires of it. The unitary matrix relating the product basis to the coupled basis — the Clebsch–Gordan coefficients themselves, together with the $3j$, $6j$ and $9j$ symbols built from them — is a separate construction and belongs where it is used. This treatise reserves it for Sections 79.4.2 and 79.4.4 of Chapter 79, which at the time of writing carry their headings and their editorial specification but not yet the construction; nothing in the present chapter depends on it. The sources are Wigner's book for the coefficients themselves, of which the $3j$ symbol is his symmetrized form [687]; Racah's second paper for the closed form of the general coefficient and for the recoupling coefficient now written $6j$ [867]; and his third for the recoupling of four angular momenta, the modern $9j$ symbol [873]. The character-theoretic route to the same decomposition, using the product rule Equation (5.195), is available from Chapter 5; the weight count used above was preferred because it needs nothing beyond Equation (14.53).

The group SU(3)

Definition 14.49 (The special unitary group in three dimensions)**.**

$$\mathrm{SU}(3) = \left\{ U \in \mathrm{GL}(3,\mathbb{C}) \mid U^{\dagger}U = \mathbb{1},\ \det U = 1 \right\}, \tag{14.62}$$

whose Lie algebra $\mathfrak{su}(3)$ is the space of traceless anti-Hermitian 3×3 matrices.

Proposition 14.50 (Dimension and rank)**.** $\dim \mathfrak{su}(3) = 8$ *and the rank of* $\mathfrak{su}(3)$ *in the sense of Definition 14.20 is* $\ell = 2$*.*

Rests on Definitions 14.20 and 14.49.

Proof. *Derives Proposition 14.50.*

Linearizing Equation (14.62) as in Proposition 14.35 gives $X^{\dagger} + X = 0$ and $\operatorname{tr} X = 0$. The anti-Hermitian 3×3 matrices form a real vector space of dimension 9 — three real diagonal entries times i, and three complex entries above the diagonal — and the trace condition removes one, leaving 8. For the rank, a maximal abelian subalgebra consisting of diagonalizable elements may be taken to be the traceless diagonal anti-Hermitian matrices, of which there are two independent, and no larger commuting set of diagonalizable elements exists because a set of commuting Hermitian matrices is simultaneously diagonalizable and the diagonal traceless ones already exhaust that possibility. □

Definition 14.51 (Gell-Mann basis)**.** The standard basis of Hermitian generators is $T_a = \frac{1}{2}\lambda_a$, $a = 1, \dots, 8$, with [1205, 2427]

$$\lambda_1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \lambda_2 = \begin{pmatrix} 0 & -\mathrm{i} & 0 \\ \mathrm{i} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad \lambda_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \tag{14.63}$$

$$\lambda_4 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \quad \lambda_5 = \begin{pmatrix} 0 & 0 & -\mathrm{i} \\ 0 & 0 & 0 \\ \mathrm{i} & 0 & 0 \end{pmatrix}, \quad \lambda_6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \tag{14.64}$$

$$\lambda_7 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -\mathrm{i} \\ 0 & \mathrm{i} & 0 \end{pmatrix}, \quad \lambda_8 = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}. \tag{14.65}$$

They are Hermitian and traceless and satisfy the normalisation

$$\operatorname{tr}(\lambda_a \lambda_b) = 2\delta_{ab}, \qquad \text{i.e.} \qquad \operatorname{tr}(T_a T_b) = \tfrac{1}{2}\delta_{ab}, \tag{14.66}$$

the same normalisation as Equation (14.44).

Rests on Definition 14.49.

Proposition 14.52 (Structure constants and the symmetric tensor)**.** *There are real arrays f_{abc}, totally antisymmetric, and d_{abc}, totally symmetric, with*

$$\boxed{[T_a, T_b] = \mathrm{i} f_{abc} T_c\,, \qquad \{T_a, T_b\} = \tfrac{1}{3}\delta_{ab}\mathbb{1} + d_{abc} T_c}\,, \tag{14.67}$$

recovered from the generators by

$$f_{abc} = -2\mathrm{i}\ \mathrm{tr}\left([T_a, T_b]\, T_c\right)\,, \qquad d_{abc} = 2\ \mathrm{tr}\left(\{T_a, T_b\}\, T_c\right)\,. \tag{14.68}$$

Their independent nonvanishing values are

$$f_{123} = 1\,, \quad f_{147} = f_{246} = f_{257} = f_{345} = \tfrac{1}{2}\,, \quad f_{156} = f_{367} = -\tfrac{1}{2}\,, \quad f_{458} = f_{678} = \tfrac{\sqrt{3}}{2}\,, \tag{14.69}$$

$$\begin{aligned} &d_{118} = d_{228} = d_{338} = \tfrac{1}{\sqrt{3}}\,, && d_{888} = -\tfrac{1}{\sqrt{3}}\,, \\ &d_{448} = d_{558} = d_{668} = d_{778} = -\tfrac{1}{2\sqrt{3}}\,, && d_{146} = d_{157} = d_{256} = d_{344} = d_{355} = \tfrac{1}{2}\,, \\ &d_{247} = d_{366} = d_{377} = -\tfrac{1}{2}\,. \end{aligned} \tag{14.70}$$

Rests on Definition 14.51.

Proof. *Derives Proposition 14.52.*

The product $T_a T_b$ is a 3×3 matrix, and $\{\mathbb{1}, T_1, \ldots, T_8\}$ is a basis of the complex 3×3 matrices, since the T_c span the traceless ones. Expanding $T_a T_b$ in it and separating the antisymmetric and symmetric parts in (a, b) gives Equation (14.67), the coefficient of $\mathbb{1}$ in the symmetric part being $\frac{1}{3}\,\mathrm{tr}\,\{T_a, T_b\} = \frac{1}{3}\delta_{ab}$ by Equation (14.66). Multiplying either relation by T_c and taking the trace with Equation (14.66), and using $\mathrm{tr}\, T_c = 0$, gives Equation (14.68). Total symmetry of d and total antisymmetry of f then follow from Equation (14.68) and the cyclicity of the trace: f is antisymmetric in (a, b) by construction and

$$\mathrm{tr}\left([T_a, T_b]\, T_c\right) = \mathrm{tr}\left(T_a T_b T_c\right) - \mathrm{tr}\left(T_b T_a T_c\right) = \mathrm{tr}\left(T_a\, [T_b, T_c]\right)$$

is invariant under cyclic permutation of (a, b, c), which together with antisymmetry in the first pair gives total antisymmetry; the same argument with the anticommutator gives total symmetry of d. The tables Equations (14.69) and (14.70) are then a finite computation from Equations (14.63) to (14.65); two entries are done here as specimens. For f_{458}: a direct multiplication gives $[\lambda_4, \lambda_5] = \mathrm{diag}(2\mathrm{i}, 0, -2\mathrm{i})$, so

$$f_{458} = -\frac{\mathrm{i}}{4}\,\mathrm{tr}\left([\lambda_4, \lambda_5]\,\lambda_8\right) = -\frac{\mathrm{i}}{4}\cdot\frac{1}{\sqrt{3}}\,(2\mathrm{i} + 0 + 4\mathrm{i}) = \frac{\sqrt{3}}{2}\,.$$

For d_{247}: $\{\lambda_2, \lambda_4\} = -\lambda_7$ by direct multiplication, so $d_{247} = \frac{1}{4}\,\mathrm{tr}\,(-\lambda_7\lambda_7) = -\frac{1}{4}\cdot 2 = -\frac{1}{2}$. □

The remaining entries are three-matrix traces of the same kind: nine independent nonvanishing components of f and sixteen of d, twenty-five in all, every other nonzero component being fixed by the total antisymmetry of f and the total symmetry of d. They are computed and tabulated in full in the appendix.

Full derivation: Appendix A.34 (p. 2951).

Derives Proposition 14.52.

Proposition 14.53 (Killing form of $\mathfrak{su}(3)$)**.** *In the Hermitian basis of Definition 14.51,*

$$\kappa_{ab} = f_{acd} f_{bcd} = 3\,\delta_{ab}\,, \tag{14.71}$$

which is nondegenerate — as Theorem 14.13 demands of $\mathfrak{su}(3)$, which is simple and hence semisimple — so that $\kappa^{ab} = \frac{1}{3}\delta^{ab}$.

Rests on Proposition 14.52, Definition 14.51, Equation (14.15), and Theorem 14.13.

Proof. *Derives Proposition 14.53.*

With $C^c{}_{ab} = \mathrm{i} f_{abc}$ from Equation (14.67), Equation (14.15) gives $\kappa_{ab} = (\mathrm{i} f_{adc})(\mathrm{i} f_{bcd}) = -f_{adc} f_{bcd} = f_{adc} f_{bdc} = f_{acd} f_{bcd}$ after renaming.

The array is evaluated here directly. The shorter route — both κ_{ab} and $\operatorname{tr}(T_a T_b)$ are symmetric bilinear forms invariant under the adjoint action, and on a simple algebra such a form is unique up to a scale, so it is enough to evaluate one entry — would have to obtain that uniqueness from Schur's lemma applied to the adjoint representation, and Theorem 5.153 is stated for a representation on a *complex* space, whereas the adjoint representation of $\mathfrak{su}(3)$ acts on the eight-dimensional *real* algebra. Over $\mathbb{R}$ the conclusion of that lemma is false in general, so its hypotheses would first have to be recovered by complexifying and by quoting the irreducibility of the complexified adjoint — which is no cheaper than the computation that follows and rests on the same quoted simplicity.

Because $[T_a, T_c] = \mathrm{i} f_{acd} T_d$ and $\operatorname{tr}(T_d T_e) = \frac{1}{2}\delta_{de}$ by Equation (14.66),

$$\sum_c \operatorname{tr}\left([T_a, T_c]\,[T_b, T_c]\right) = -f_{acd} f_{bce}\ \operatorname{tr}\left(T_d T_e\right) = -\tfrac{1}{2} f_{acd} f_{bcd} = -\tfrac{1}{2}\kappa_{ab}\,. \tag{14.72}$$

Expanding the two commutators gives four traces. Summed over c they collapse to two, by cyclicity of the trace together with $\sum_c T_c T_c \propto \mathbb{1}$, which Equation (14.74) below establishes:

$$\sum_c \operatorname{tr}\left([T_a, T_c]\,[T_b, T_c]\right) = 2\sum_c \operatorname{tr}\left(T_a T_c T_b T_c\right) - 2\sum_c \operatorname{tr}\left(T_a T_b T_c T_c\right)\,. \tag{14.73}$$

Both sums follow from the completeness of the basis $\{\mathbb{1}, T_1, \dots, T_8\}$ of the complex 3×3 matrices already used in Proposition 14.52. Expanding an arbitrary M in that basis, with the coefficients read off by Equation (14.66) and $\operatorname{tr} T_a = 0$, gives $M = \frac{1}{3}(\operatorname{tr} M)\,\mathbb{1} + 2\,\operatorname{tr}(M T_a)\,T_a$, and taking for M the matrix whose only nonzero entry is a 1 in position (j, k) turns that into

$$\boxed{\sum_{a=1}^{8} (T_a)_{il}\,(T_a)_{kj} = \tfrac{1}{2}\left(\delta_{ij}\delta_{lk} - \tfrac{1}{3}\delta_{il}\delta_{jk}\right)}\,. \tag{14.74}$$

Setting $l = k$ and summing gives $\sum_c T_c T_c = \frac{1}{2}\left(3 - \frac{1}{3}\right)\mathbb{1} = \frac{4}{3}\mathbb{1}$, so that $\sum_c \operatorname{tr}(T_a T_b T_c T_c) = \frac{4}{3}\operatorname{tr}(T_a T_b) = \frac{2}{3}\delta_{ab}$; and contracting Equation (14.74) into $\operatorname{tr}(T_a T_c T_b T_c) = (T_a)_{ij}\,(T_c)_{jk}\,(T_b)_{kl}\,(T_c)_{li}$ gives

$$\sum_c \operatorname{tr}\left(T_a T_c T_b T_c\right) = \tfrac{1}{2}\left(\operatorname{tr} T_a\ \operatorname{tr} T_b - \tfrac{1}{3}\operatorname{tr}\left(T_a T_b\right)\right) = -\tfrac{1}{12}\delta_{ab}\,.$$

Substituting both into Equation (14.73),

$$\sum_c \operatorname{tr}\left([T_a, T_c]\,[T_b, T_c]\right) = -\tfrac{1}{6}\delta_{ab} - \tfrac{4}{3}\delta_{ab} = -\tfrac{3}{2}\delta_{ab}\,,$$

and Equation (14.72) gives $\kappa_{ab} = 3\delta_{ab}$.

As a check on one entry, take $a = b = 3$ and read the nonzero f_{3cd} from Equation (14.69) — $f_{312} = 1$, $f_{345} = \frac{1}{2}$, $f_{367} = -\frac{1}{2}$, each contributing twice because both index orders are summed:

$$\kappa_{33} = f_{3cd} f_{3cd} = 2\,(1)^2 + 2\left(\tfrac{1}{2}\right)^2 + 2\left(\tfrac{1}{2}\right)^2 = 3\,.$$

□

The simplicity of $\mathfrak{su}(3)$ is used below, where the adjoint representation is asserted to be irreducible — that is, where the traceless part of the endomorphisms of the fundamental is identified with the eight-dimensional representation. The argument decomposes a putative ideal into eigenspaces of the two-dimensional Cartan subalgebra and then uses the fact that

the six roots of the algebra — the hexagon exhibited below — are connected, every root being reachable from every other by adding roots, so that a single root vector in the ideal drags the whole algebra in with it.

Full derivation: Appendix A.35 (p. 2957).

Derives Theorem 14.57.

Proposition 14.54 (The two Casimir operators of $\mathfrak{su}(3)$)**.**

$$\boxed{C_2 = \sum_{a=1}^{8} T_a T_a \,, \qquad C_3 = d_{abc}\, T_a T_b T_c} \tag{14.75}$$

are Casimir elements of $U(\mathfrak{su}(3))$, and by Theorem 14.21 together with Proposition 14.50 they generate all of them: $\ell = 2$, so there are exactly two.

Rests on Corollary 14.17, Theorems 14.16, 14.21 and 14.110, and Propositions 14.50, 14.52 and 14.53.

Proof. *Derives Proposition 14.54.*

For C_2 this is Corollary 14.17 with $\kappa^{ab} = \frac{1}{3}\delta^{ab}$ from Equation (14.71), up to the harmless factor of 3. For C_3, apply Theorem 14.16 with $r = 3$ and $k^{abc} = d_{abc}$: the tensor is totally symmetric by Proposition 14.52, and its invariance in the sense of Equation (14.18) is Equation (14.148) for the G-invariant polynomial $\langle T_a, T_b, T_c\rangle = \frac{1}{2} d_{abc}$ — symmetric and invariant because $\operatorname{tr}(\{T_a, T_b\} T_c)$ is a trace of a product of generators and therefore unchanged under $T_a \mapsto g T_a g^{-1}$, which is Definition 14.109. Written out, the invariance reads

$$f_{ead}\, d_{dbc} + f_{ebd}\, d_{adc} + f_{ecd}\, d_{abd} = 0 \,, \tag{14.76}$$

and it is exactly this identity that the proof of Theorem 14.16 consumes. □

Proposition 14.55 (The fundamental, the antifundamental and the adjoint)**.** SU(3) *has three representations of immediate use.*

1. *The* fundamental **3***: the defining action on $\mathbb{C}^3$, generated by the T_a themselves. Its quadratic Casimir is*
$$C_2(\mathbf{3}) = \tfrac{4}{3} \,. \tag{14.77}$$
2. *The* antifundamental $\bar{\mathbf{3}}$*: the action on the complex-conjugate space, generated by $-T_a^*$. It has the same C_2 and is* not *equivalent to* **3***.*
3. *The* adjoint **8***: the action on $\mathfrak{su}(3)$ itself, with generators $\left(T_a^{\mathrm{ad}}\right)_{bc} = -\mathrm{i} f_{abc}$, of dimension 8 and quadratic Casimir*
$$C_2(\mathbf{8}) = 3 \,. \tag{14.78}$$

Rests on Definition 14.51, Corollary 14.18, and Proposition 14.53.

Proof. *Derives Proposition 14.55.*

For Equation (14.77): C_2 is central, so by Corollary 14.18 it acts as a number c on the irreducible **3**; taking the trace, $3c = \sum_a \operatorname{tr}(T_a T_a) = 8 \cdot \frac{1}{2} = 4$ by Equation (14.66), so $c = 4/3$. For Equation (14.78): the same argument with $\operatorname{tr}\left(T_a^{\mathrm{ad}} T_b^{\mathrm{ad}}\right) = -f_{acd} f_{bdc} = f_{acd} f_{bcd} = 3\delta_{ab}$ from Equation (14.71) gives $8c = \sum_a 3 = 24$, so $c = 3$.

That $\bar{\mathbf{3}}$ is a representation is the observation that complex-conjugating $[T_a, T_b] = \mathrm{i} f_{abc} T_c$ and multiplying by -1 reproduces the same brackets. That it is inequivalent to **3** is read off the weights. Take the Cartan subalgebra spanned by T_3 and T_8, which are diagonal; the *weights* of a representation are the pairs of simultaneous eigenvalues of (T_3, T_8), and being

eigenvalues they are unchanged by any equivalence. For $\mathbf{3}$ they are, from Equations (14.63) and (14.65),

$$\left(\tfrac{1}{2}, \tfrac{1}{2\sqrt{3}}\right), \quad \left(-\tfrac{1}{2}, \tfrac{1}{2\sqrt{3}}\right), \quad \left(0, -\tfrac{1}{\sqrt{3}}\right), \tag{14.79}$$

summing to zero as tracelessness demands, and for $\bar{\mathbf{3}}$ they are the three negatives of these. The two sets are different — an upward-pointing triangle and a downward-pointing one — so no equivalence can carry one representation to the other. □

Remark 14.56 (Roots, and why $\mathbf{3}$ and $\bar{\mathbf{3}}$ differ here but not for SU(2)). The *roots* are the weights of the adjoint representation, that is the eigenvalues of ad_{T_3} and ad_{T_8}. They are the differences of the weights Equation (14.79),

$$\pm(1,0), \qquad \pm\left(\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}\right), \qquad \pm\left(-\tfrac{1}{2}, \tfrac{\sqrt{3}}{2}\right), \tag{14.80}$$

six vectors of unit length at 60 degrees to one another, forming a regular hexagon, together with two zeros for the Cartan directions themselves: $6+2=8$ weights for an eight-dimensional representation, as required. For $\mathfrak{su}(2)$ the rank is one, the two roots are ± 1, and the weight set of any representation is symmetric about zero, which is why there the fundamental and its conjugate *are* equivalent. The asymmetry of the SU(3) weight diagram under $w \mapsto -w$ is precisely the statement that its fundamental is complex.

Theorem 14.57 ($\mathbf{3} \otimes \bar{\mathbf{3}} = \mathbf{1} \oplus \mathbf{8}$).

$$\boxed{\mathbf{3} \otimes \bar{\mathbf{3}} = \mathbf{1} \oplus \mathbf{8}}, \qquad 3 \times 3 = 1 + 8\,. \tag{14.81}$$

Rests on Proposition 14.55.

Proof. *Derives Theorem 14.57.*

Identify $\mathbb{C}^3 \otimes (\mathbb{C}^3)^*$ with the space of complex 3×3 matrices $\mathrm{End}(\mathbb{C}^3)$; the action induced by $\mathbf{3}$ on the first factor and $\bar{\mathbf{3}}$ on the second is $M \mapsto UMU^\dagger$. The trace is invariant under it, so $\mathrm{End}(\mathbb{C}^3)$ splits as an SU(3)-invariant direct sum

$$\mathrm{End}\left(\mathbb{C}^3\right) = \mathbb{C}\,\mathbb{1} \;\oplus\; \{M \mid \mathrm{tr}\, M = 0\}\,,$$

of dimensions 1 and 8. The first summand is the trivial representation $\mathbf{1}$. The second is the complexification of $\mathfrak{su}(3)$ — a traceless complex matrix splits uniquely into Hermitian and anti-Hermitian traceless parts — carrying the action $M \mapsto UMU^\dagger$, which is the adjoint action; it is irreducible because an invariant subspace would be an ideal of a simple Lie algebra. Hence it is $\mathbf{8}$.

The weights confirm the count independently: the weights of the tensor product are the sums of a weight of $\mathbf{3}$ and a weight of $\bar{\mathbf{3}}$, that is all differences $w_i - w_j$ of the three weights Equation (14.79). The three coincident cases $i = j$ give the weight zero three times, and the six cases $i \neq j$ give exactly the six roots Equation (14.80). That is one zero for $\mathbf{1}$ plus the six roots and two zeros of $\mathbf{8}$, and nothing left over. □

Remark 14.58 (What is deliberately not said here). This subsection has supplied group theory and nothing else. Which physical states, if any, carry the $\mathbf{3}$; whether the $\mathbf{8}$ is realized by anything observable; what the eight generators have to do with the strong interaction — none of that is a mathematical question, and all of it is settled, where it can be settled, by measurement in Chapters 102 and 104. The historical route ran the other way: the group was proposed as an organizing symmetry of the observed hadron spectrum [1205, 1216] before the mathematics above was put to the use it now has [1907]. The order in this treatise is the opposite one on purpose — the mathematics is established first and then confronted with evidence, so that agreement counts for something.

14.3 The Lie algebra associated with a Lie group

14.3.1 Translations in D dimensions

The algebra of the group of translations in D dimensions, which we denote by $\mathfrak{t}(D)$, is generated by

$$\boxed{P_A = \partial_A\,, \quad A = 1, \dots, D} \tag{14.82}$$

so that

$$\boxed{\dim \mathfrak{t}(D) = D}\,. \tag{14.83}$$

Let f be a function of class C^2 on $\mathbb{R}^D$. Then

$$\begin{aligned} [P_A, P_B]\, f &= [\partial_A, \partial_B]\, f \\ &= \partial_A \partial_B f - \partial_B \partial_A f \\ (f \text{ of class } C^2) \quad &= 0\,, \end{aligned}$$

whence

$$\boxed{[P_A, P_B] = 0}\,. \tag{14.84}$$

14.3.2 The algebra $\mathfrak{so}(p, q)$

Generators and commutation relations

Consider $\mathbb{R}^{p+q}$ endowed with the flat metric η_{AB} of signature (p, q) of Notation 14.1, and in it the unit quadric (a pseudo-sphere) defined by the equation

$$\left(x^1\right)^2 + \cdots + \left(x^p\right)^2 - \left(x^{p+1}\right)^2 - \cdots - \left(x^{p+q}\right)^2 = 1\,. \tag{14.85}$$

This space carries the Killing vector fields (cf. Chapter 13 and [1746])

$$\boxed{J_{AB} = x_A \partial_B - x_B \partial_A\,, \quad A, B = 1, \dots, p+q}\,. \tag{14.86}$$

That the fields Equation (14.86) are Killing fields of η_{AB}, and that they generate the isometries of the quadric Equation (14.85), is asserted by the source without proof. The source introduces them through the quadric; they are in fact a statement about the flat space itself, and are proved here in that form, the quadric following as a corollary.

Proposition 14.59 (The Killing fields of a flat pseudo-Euclidean space)**.** *Let $\mathbb{R}^{p+q}$ carry the flat metric η_{AB} of Notation 14.1, $D = p + q$. Then:*

1. *every J_{AB} of Equation (14.86) is a Killing field;*
2. *conversely, every Killing field of η_{AB} is a real linear combination of the D translations P_A of Equation (14.82) and the $D(D-1)/2$ fields J_{AB} with $A < B$, and those $D(D+1)/2$ fields are linearly independent. Flat space is therefore maximally symmetric in the sense of Proposition 13.140, and its Killing algebra is the inhomogeneous algebra $\mathfrak{t}(D) \mathbin{\bar{\oplus}} \mathfrak{so}(p, q)$, which for the Lorentzian signature $q = 1$ is the Poincaré algebra Equation (14.99);*
3. *J_{AB} annihilates the quadratic form $x^C x_C$, so its flow preserves each quadric $x^C x_C = \text{const}$, in particular Equation (14.85), and restricts on it to a Killing field of the induced metric.*

Rests on Equation (14.86), Proposition 13.140, and Definition 13.139.

Proof. *Derives Proposition 14.59.*

In the Cartesian coordinates x^A the metric components are constant, so the Christoffel symbols vanish and Killing's equation Equation (13.290) reads

$$\partial_C \xi_D + \partial_D \xi_C = 0\,. \tag{14.87}$$

(i) The field J_{AB} has components $\xi^C = x_A \delta^C_B - x_B \delta^C_A$, hence $\xi_D = x_A \eta_{BD} - x_B \eta_{AD}$, and with $\partial_C x_A = \eta_{AC}$,

$$\partial_C \xi_D = \eta_{AC}\eta_{BD} - \eta_{BC}\eta_{AD}\,,$$

which is antisymmetric under $C \leftrightarrow D$. So Equation (14.87) holds. That the translations satisfy it is immediate, their components being constant.

(ii) Let ξ satisfy Equation (14.87) and set $T_{CDE} = \partial_C \partial_D \xi_E$. It is symmetric in its first two indices, because partial derivatives commute, and antisymmetric in its last two by Equation (14.87). Those two symmetries are incompatible unless T vanishes:

$$T_{CDE} = T_{DCE} = -T_{DEC} = -T_{EDC} = T_{ECD} = T_{CED} = -T_{CDE}\,,$$

each step being one of the two symmetries applied once. Hence $\partial_C \partial_D \xi_E = 0$, so each ξ_E is a polynomial of degree at most one,

$$\xi_E = a_E + \omega_{EC}\, x^C\,, \qquad a_E = \xi_E(0)\,, \quad \omega_{EC} = \partial_C \xi_E\,, \tag{14.88}$$

with constant coefficients, and Equation (14.87) says exactly that $\omega_{EC} = -\omega_{CE}$. Comparing with the components computed in (i), the constant part is $a^E P_E$ and the linear part is $-\frac{1}{2}\omega^{AB} J_{AB}$, a combination of the J_{AB}. Conversely ξ determines a_E and ω_{EC} through Equation (14.88), so distinct pairs (a, ω) give distinct fields and the $D + D(D-1)/2 = D(D+1)/2$ listed fields are independent. That number is the maximum allowed by Proposition 13.140. The brackets of these fields are Equations (14.84), (14.90) and (14.97), computed below; they are those of the semidirect sum $\mathfrak{t}(D) \mathbin{\bar{\oplus}} \mathfrak{so}(p,q)$, which at $q = 1$ is Equation (14.99).

(iii) Directly,

$$J_{AB}\left(x^C x_C\right) = (x_A \partial_B - x_B \partial_A)\, x^C x_C = 2 x_A x_B - 2 x_B x_A = 0\,,$$

so J_{AB} is tangent to every level set of $x^C x_C$ and its flow maps each such quadric to itself. That flow consists of isometries of η by (i), and an isometry of the ambient metric preserving a submanifold restricts to an isometry of the induced metric; by Definition 13.139 the restriction of J_{AB} is therefore a Killing field of the quadric. □

Clearly $J_{AB} = -J_{BA}$, and therefore

$$\boxed{\dim \mathfrak{so}(p,q) = \frac{(p+q)(p+q-1)}{2} = \frac{D(D-1)}{2}}\,. \tag{14.89}$$

Let us compute the commutation relations among the symmetry generators J_{AB}. Let f be a function of class C^2 on $\mathbb{R}^{p+q}$. We have

$$\begin{aligned}
[J_{AB}, J_{CD}]\, f &= [x_A\partial_B - x_B\partial_A, x_C\partial_D - x_D\partial_C]\, f \\
&= [x_A\partial_B, x_C\partial_D]\, f - [x_A\partial_B, x_D\partial_C]\, f - [x_B\partial_A, x_C\partial_D]\, f + [x_B\partial_A, x_D\partial_C]\, f\,,
\end{aligned}$$

where

$$\begin{aligned}
[x_A\partial_B, x_C\partial_D]\, f &= x_A\partial_B\,(x_C\partial_D f) - x_C\partial_D\,(x_A\partial_B f) \\
&= x_A\eta_{BC}\partial_D f + x_A x_C \partial_B\partial_D f - x_C\eta_{DA}\partial_B f - x_C x_A \partial_D\partial_B f \\
(f \text{ of class } C^2) \quad &= \eta_{BC}\, x_A \partial_D f - \eta_{DA}\, x_C \partial_B f\,,
\end{aligned}$$

and where we have used that $\partial_A x_B = \eta_{BC}\,\partial_A x^C = \eta_{BC}\,\delta^C_A = \eta_{AB}$. In this manner we obtain

$$\begin{aligned}[J_{AB}, J_{CD}] &= \eta_{BC}\,x_A\partial_D - \eta_{DA}\,x_C\partial_B - \eta_{BD}\,x_A\partial_C + \eta_{CA}\,x_D\partial_B \\ &\quad - \eta_{AC}\,x_B\partial_D + \eta_{DB}\,x_C\partial_A + \eta_{AD}\,x_B\partial_C - \eta_{CB}\,x_D\partial_A \\ &= \eta_{AC}\,(x_D\partial_B - x_B\partial_D) + \eta_{BD}\,(x_C\partial_A - x_A\partial_C) \\ &\quad + \eta_{AD}\,(x_B\partial_C - x_C\partial_B) + \eta_{BC}\,(x_A\partial_D - x_D\partial_A)\ ,\end{aligned}$$

so the commutation relations of the algebra $\mathfrak{so}(p,q)$ are given by

$$\boxed{[J_{AB}, J_{CD}] = \eta_{AC}J_{DB} + \eta_{BD}J_{CA} + \eta_{AD}J_{BC} + \eta_{BC}J_{AD}}\,. \tag{14.90}$$

Structure constants

To express the commutation relations Equation (14.90) in the usual form $[J_{AB}, J_{CD}] = f_{AB,CD}{}^{EF}J_{EF}$, the symmetries of the indices must be taken into account. A mistake one may commit is to simply attach the corresponding Kronecker deltas, writing

$$f_{AB,CD}{}^{EF} = \eta_{AC}\delta^E_D\delta^F_B + \eta_{BD}\delta^E_C\delta^F_A + \eta_{AD}\delta^E_B\delta^F_C + \eta_{BC}\delta^E_A\delta^F_D\,, \tag{14.91}$$

or

$$f_{AB,CD}{}^{EF} = \eta_{AD}\delta^E_B\delta^F_C + \eta_{BC}\delta^E_A\delta^F_D - \eta_{AC}\delta^E_B\delta^F_D - \eta_{BD}\delta^E_A\delta^F_C\,. \tag{14.92}$$

However, upon substituting $J_{AB} = -J_{BA}$ into $[J_{AB}, J_{CD}] = f_{AB,CD}{}^{EF}J_{EF}$ it is necessary that $f_{AB,CD}{}^{EF} = -f_{BA,CD}{}^{EF}$, which is clearly satisfied neither by the quantities Equation (14.91) nor by Equation (14.92). In the same way, one must have $f_{AB,CD}{}^{EF} = -f_{AB,DC}{}^{EF}$. The only thing that can be said about the upper indices of f is that f must not be symmetric under their exchange, since the contraction of symmetric upper indices with the antisymmetric indices of J_{EF} would force $[J_{AB}, J_{CD}] = 0$; moreover, this naive choice of f does not satisfy the antisymmetry in the lower indices either. Let us see what happens if we antisymmetrize in the indices E and F:

$$\begin{aligned}[J_{AB}, J_{CD}] &= \eta_{AC}J_{DB} + \eta_{BD}J_{CA} + \eta_{AD}J_{BC} + \eta_{BC}J_{AD} \\ &= \eta_{AC}\delta^E_D\delta^F_B J_{EF} + \eta_{BD}\delta^E_C\delta^F_A J_{EF} + \eta_{AD}\delta^E_B\delta^F_C J_{EF} + \eta_{BC}\delta^E_A\delta^F_D J_{EF} \\ &= \frac{1}{2}\eta_{AC}\left(\delta^E_D\delta^F_B + \delta^E_D\delta^F_B\right)J_{EF} + \frac{1}{2}\eta_{BD}\left(\delta^E_C\delta^F_A + \delta^E_C\delta^F_A\right)J_{EF} \\ &\quad + \frac{1}{2}\eta_{AD}\left(\delta^E_B\delta^F_C + \delta^E_B\delta^F_C\right)J_{EF} + \frac{1}{2}\eta_{BC}\left(\delta^E_A\delta^F_D + \delta^E_A\delta^F_D\right)J_{EF}\,,\end{aligned}$$

but, using the antisymmetry of J_{EF} and relabelling the dummy indices in the second copy of each term,

$$\begin{aligned}\left(\delta^E_D\delta^F_B + \delta^E_D\delta^F_B\right)J_{EF} &= \delta^E_D\delta^F_B J_{EF} + \delta^E_D\delta^F_B J_{EF} \\ &= \delta^E_D\delta^F_B J_{EF} - \delta^F_B\delta^E_D J_{FE} \\ &= \delta^E_D\delta^F_B J_{EF} - \delta^E_B\delta^F_D J_{EF} \\ &= \left(\delta^E_D\delta^F_B - \delta^E_B\delta^F_D\right)J_{EF}\,,\end{aligned}$$

whence

$$\begin{aligned}[J_{AB}, J_{CD}] = \frac{1}{2}\Big\{&\eta_{AC}\left(\delta^E_D\delta^F_B - \delta^E_B\delta^F_D\right) + \eta_{BD}\left(\delta^E_C\delta^F_A - \delta^E_A\delta^F_C\right) \\ &+ \eta_{AD}\left(\delta^E_B\delta^F_C - \delta^E_C\delta^F_B\right) + \eta_{BC}\left(\delta^E_A\delta^F_D - \delta^E_D\delta^F_A\right)\Big\}J_{EF}\,.\end{aligned}$$

In this case we have

$$f_{AB,CD}{}^{EF} = \frac{1}{2}\Big\{\eta_{AC}\left(\delta^E_D\delta^F_B - \delta^E_B\delta^F_D\right) + \eta_{BD}\left(\delta^E_C\delta^F_A - \delta^E_A\delta^F_C\right) + \eta_{AD}\left(\delta^E_B\delta^F_C - \delta^E_C\delta^F_B\right) + \eta_{BC}\left(\delta^E_A\delta^F_D - \delta^E_D\delta^F_A\right)\Big\},$$

for which we must verify the aforementioned symmetries. In the first place,

$$\begin{aligned} f_{CD,AB}{}^{EF} &= \frac{1}{2}\Big\{\eta_{CA}\left(\delta^E_B\delta^F_D - \delta^E_D\delta^F_B\right) + \eta_{DB}\left(\delta^E_A\delta^F_C - \delta^E_C\delta^F_A\right) \\ &\quad + \eta_{CB}\left(\delta^E_D\delta^F_A - \delta^E_A\delta^F_D\right) + \eta_{DA}\left(\delta^E_C\delta^F_B - \delta^E_B\delta^F_C\right)\Big\} \\ &= \frac{1}{2}\Big\{\eta_{AC}\left(\delta^E_B\delta^F_D - \delta^E_D\delta^F_B\right) + \eta_{BD}\left(\delta^E_A\delta^F_C - \delta^E_C\delta^F_A\right) \\ &\quad + \eta_{BC}\left(\delta^E_D\delta^F_A - \delta^E_A\delta^F_D\right) + \eta_{AD}\left(\delta^E_C\delta^F_B - \delta^E_B\delta^F_C\right)\Big\} \\ &= -f_{AB,CD}{}^{EF}, \end{aligned}$$

so we do have the antisymmetry under exchange of the index pairs. Moreover,

$$\begin{aligned} f_{BA,CD}{}^{EF} &= \frac{1}{2}\Big\{\eta_{BC}\left(\delta^E_D\delta^F_A - \delta^E_A\delta^F_D\right) + \eta_{AD}\left(\delta^E_C\delta^F_B - \delta^E_B\delta^F_C\right) \\ &\quad + \eta_{BD}\left(\delta^E_A\delta^F_C - \delta^E_C\delta^F_A\right) + \eta_{AC}\left(\delta^E_B\delta^F_D - \delta^E_D\delta^F_B\right)\Big\} \\ &= -f_{AB,CD}{}^{EF}, \end{aligned}$$

so that $f_{AB,DC}{}^{EF} = -f_{DC,AB}{}^{EF} = f_{CD,AB}{}^{EF} = -f_{AB,CD}{}^{EF}$; and additionally

$$\begin{aligned} f_{AB,CD}{}^{FE} &= \frac{1}{2}\Big\{\eta_{AC}\left(\delta^F_D\delta^E_B - \delta^F_B\delta^E_D\right) + \eta_{BD}\left(\delta^F_C\delta^E_A - \delta^F_A\delta^E_C\right) \\ &\quad + \eta_{AD}\left(\delta^F_B\delta^E_C - \delta^F_C\delta^E_B\right) + \eta_{BC}\left(\delta^F_A\delta^E_D - \delta^F_D\delta^E_A\right)\Big\} \\ &= \frac{1}{2}\Big\{\eta_{AC}\left(\delta^E_B\delta^F_D - \delta^E_D\delta^F_B\right) + \eta_{BD}\left(\delta^E_A\delta^F_C - \delta^E_C\delta^F_A\right) \\ &\quad + \eta_{AD}\left(\delta^E_C\delta^F_B - \delta^E_B\delta^F_C\right) + \eta_{BC}\left(\delta^E_D\delta^F_A - \delta^E_A\delta^F_D\right)\Big\} \\ &= -f_{AB,CD}{}^{EF}. \end{aligned}$$

In summary, the commutation relations of the algebra $\mathfrak{so}(p,q)$ are given by Equation (14.90) or, equivalently, by

$$[J_{AB}, J_{CD}] = f_{AB,CD}{}^{EF} J_{EF}, \tag{14.93}$$

where the $f_{AB,CD}{}^{EF}$ are the structure constants, given by

$$f_{AB,CD}{}^{EF} = \frac{1}{2}\Big\{\eta_{AC}\left(\delta^E_D\delta^F_B - \delta^E_B\delta^F_D\right) + \eta_{BD}\left(\delta^E_C\delta^F_A - \delta^E_A\delta^F_C\right) + \eta_{AD}\left(\delta^E_B\delta^F_C - \delta^E_C\delta^F_B\right) + \eta_{BC}\left(\delta^E_A\delta^F_D - \delta^E_D\delta^F_A\right)\Big\}, \tag{14.94}$$

and which satisfy the following antisymmetry relations:

$$f_{AB,CD}{}^{EF} = -f_{CD,AB}{}^{EF} = -f_{BA,CD}{}^{EF} = -f_{AB,DC}{}^{EF} = -f_{AB,CD}{}^{FE}. \tag{14.95}$$

The Lorentz algebra in D dimensions

The Lorentz algebra in D spacetime dimensions arises as the case of Lorentzian signature, $\mathfrak{so}(D-1,1)$, of the family $\mathfrak{so}(p,q)$. At the observed $D=4$ it is the algebra $\mathfrak{so}(3,1)$ of [1746], whose treatment is four-dimensional throughout; the general-D statement here is the mathematics of Section 14.3.2 and is not taken from that source. From Equation (14.89),

$$\dim \mathfrak{so}(D-1,1) = \frac{D(D-1)}{2}\,. \tag{14.96}$$

From Equation (14.89) (Lorentzian signature, $p=D-1$ and $q=1$).

The Poincaré algebra in D dimensions

The Poincaré algebra is the algebra generated by the translations P_A together with the pseudo-rotations J_{AB}. Let us compute the commutation relations between J_{AB} and P_C. Let f be a function of class C^2 on $\mathbb{R}^D$. We have

$$\begin{aligned}
[J_{AB},P_C]\,f &= [x_A\partial_B - x_B\partial_A,\partial_C]\,f\\
&= [x_A\partial_B,\partial_C]\,f - [x_B\partial_A,\partial_C]\,f\\
&= [x_A,\partial_C]\,\partial_B f + x_A\,[\partial_B,\partial_C]\,f - [x_B,\partial_C]\,\partial_A f - x_B\,[\partial_A,\partial_C]\,f\\
(f \text{ of class } C^2)\quad &= [x_A,\partial_C]\,\partial_B f - [x_B,\partial_C]\,\partial_A f\\
&= x_A\partial_C\partial_B f - \partial_C\,(x_A\partial_B f) - x_B\partial_C\partial_A f + \partial_C\,(x_B\partial_A f)\\
&= x_A\partial_C\partial_B f - \partial_C x_A\,\partial_B f - x_A\partial_C\partial_B f - x_B\partial_C\partial_A f + \partial_C x_B\,\partial_A f + x_B\partial_C\partial_A f\\
&= \partial_C x_B\,\partial_A f - \partial_C x_A\,\partial_B f\\
&= \eta_{CB}\,\partial_A f - \eta_{CA}\,\partial_B f\,,
\end{aligned}$$

so that

$$\boxed{[J_{AB},P_C] = \eta_{BC}P_A - \eta_{AC}P_B}\,, \tag{14.97}$$

or equivalently

$$\boxed{[J_{AB},P_C] = f_{AB,C}{}^{E}\,P_E}\,, \qquad \text{with} \qquad \boxed{f_{AB,C}{}^{E} = \eta_{BC}\,\delta^E_A - \eta_{AC}\,\delta^E_B}\,. \tag{14.98}$$

Since J_{AB} and P_A do not commute, the algebra generated by $\{P_A\}\cup\{J_{AB}\}$ is the semidirect sum

$$\boxed{\mathfrak{iso}(D-1,1) = \mathfrak{t}(D)\,\bar{\oplus}\,\mathfrak{so}(D-1,1)}\,, \tag{14.99}$$

whose dimension is

$$\dim \mathfrak{iso}(D-1,1) = D + \frac{D(D-1)}{2}\,,$$

that is,

$$\dim \mathfrak{iso}(D-1,1) = \frac{D(D+1)}{2}\,. \tag{14.100}$$

From Equations (14.83) and (14.96) (add the dimensions of the two summands of the semidirect sum).

The Casimir operators of the Poincaré algebra

The Poincaré algebra is not semisimple — Equation (14.99) is a semidirect sum with the abelian ideal $\mathfrak{t}(D)$ — so Theorem 14.21 does not apply and its invariants must be found by hand (Remark 14.23). Two of them are found here. They matter out of all proportion to the difficulty of the computation, because they are what a particle *is*: an irreducible representation of this algebra is labelled by their values, and those two numbers are the mass and the spin [849].

Proposition 14.60 (The quadratic invariant)**.** $P^2 = \eta^{AB} P_A P_B$ *is a Casimir element of* $U(\mathfrak{iso}(D-1,1))$ *in every dimension* D*.*

Rests on Equations (14.84) *and* (14.97) *and Definition 14.8.*

Proof. *Derives Proposition 14.60.*

$[P^2, P_C] = 0$ is immediate from Equation (14.84). For the pseudo-rotations, use the Leibniz rule and Equation (14.97) in the form $\left[J_{AB}, P^C\right] = \delta^C_B P_A - \delta^C_A P_B$:

$$\begin{aligned}\left[J_{AB}, P_C P^C\right] &= \left[J_{AB}, P_C\right] P^C + P_C \left[J_{AB}, P^C\right] \\ &= \left(\eta_{BC} P_A - \eta_{AC} P_B\right) P^C + P_C \left(\delta^C_B P_A - \delta^C_A P_B\right) \\ &= \left(P_A P_B - P_B P_A\right) + \left(P_B P_A - P_A P_B\right) = 0\,,\end{aligned}$$

each parenthesis vanishing separately by Equation (14.84). □

The second invariant is specific to the observed four-dimensional spacetime, because it is built from the Levi-Civita symbol, which carries exactly D indices and pairs with the two-index J and the one-index P only when $D = 4$. Writing it down requires a decision about index order that the rest of the chapter had no occasion to make, and the decision is recorded before anything is computed.

Notation 14.61 (Signature and index order in this subsubsection)*.* From here to the end of this subsubsection, and here alone, $D = 4$ and the *physical* convention of Chapter 94 is adopted: the timelike direction is written x^0 and listed *first*, capital indices run from 0 to 3, and

$$\eta_{AB} = \mathrm{diag}(+1,-1,-1,-1)\,, \qquad \epsilon_{0123} = +1\,. \tag{14.101}$$

This is the *reverse* ordering of Notation 14.1, which lists the p positive directions first and therefore, at $(p,q) = (3,1)$, writes the timelike direction last, as x^4 with $\eta_{44} = -1$. The dictionary between the two is the relabelling $x^4 \leftrightarrow x^0$ of the timelike coordinate together with an overall change of sign of the metric, $\eta \mapsto -\eta$.

Nothing in the algebra changes under that dictionary. Lowering an index with $-\eta$ sends $x_A \mapsto -x_A$ and hence $J_{AB} \mapsto -J_{AB}$, while $P_A = \partial_A$ is untouched; both sides of Equation (14.90) are then even and both sides of Equation (14.97) odd, so each relation holds verbatim in either convention. What *does* change sign is every scalar built by contracting with the inverse metric. $P^2 = \eta^{AB} P_A P_B$ carries one inverse metric and flips. The vector W_A of Equation (14.103) below does *not*: it carries three raised indices, contributing $(-1)^3$, and one factor of J, contributing a fourth sign, so it comes out unchanged. But $W^2 = \eta^{AB} W_A W_B$ again carries one inverse metric, and so flips as well. The two invariants change sign *together*, so their ratio — which is what carries the spin — is the same in both conventions, and the results of this subsubsection, read in the ordering of Notation 14.1, would appear with both signs reversed: $\hat{P}^2 = -m^2c^2$ and $\hat{W}^2 = +m^2c^2\hbar^2 s(s+1)$. The convention adopted here is the one under which they agree with Theorem 94.18 and Equation (94.25), which is the form in which the rest of this treatise uses them.

Lemma 14.62 (The Levi-Civita symbol is invariant)**.** *For every antisymmetric* $\omega_{AB} = -\omega_{BA}$ *in four dimensions,*

$$\omega^E{}_A \epsilon_{EBCD} + \omega^E{}_B \epsilon_{AECD} + \omega^E{}_C \epsilon_{ABED} + \omega^E{}_D \epsilon_{ABCE} = 0\,. \tag{14.102}$$

Proof. *Derives Lemma 14.62.*

The left-hand side is totally antisymmetric in $ABCD$: exchanging any two of the four free indices swaps two of the terms with each other and reverses the sign of the remaining two through the antisymmetry of ϵ. A totally antisymmetric four-index array in four dimensions is a multiple of ϵ_{ABCD}, and contracting the left-hand side with ϵ^{ABCD} shows that the multiple is proportional to $\omega^A{}_A = \eta^{AB}\omega_{BA} = 0$, a symmetric array contracted with an antisymmetric one. □

Definition 14.63 (Pauli–Lubanski vector)**.**

$$\boxed{W_A = \tfrac{1}{2}\,\epsilon_{ABCD}\,J^{BC}P^D}\,. \tag{14.103}$$

Rests on Equations (14.82) *and* (14.86)*.*

Lemma 14.64 (Properties of W)**.** *1.* $[W_A, P_E] = 0$*;*

2. $W_A P^A = P^A W_A = 0$*;*

3. W *transforms as a vector,* $[J_{AB}, W_C] = \eta_{BC}W_A - \eta_{AC}W_B$*.*
Rests on Definition 14.63, Equations (14.84)*,* (14.90) *and* (14.97)*, and Lemma 14.62.*

Proof. *Derives Lemma 14.64.*
(i) By Equation (14.84) only the J factor contributes, and Equation (14.97) gives

$$[W_A, P_E] = \tfrac{1}{2}\epsilon_{ABCD}\left(\delta^C_E P^B - \delta^B_E P^C\right)P^D = \tfrac{1}{2}\left(\epsilon_{ABED}P^B P^D - \epsilon_{AECD}P^C P^D\right) = 0\,,$$

since in each term ϵ antisymmetrizes a pair of indices carried by the symmetric product $P\,P$ of commuting translations.

(ii) $W_A P^A = \tfrac{1}{2}\epsilon_{ABCD}J^{BC}P^D P^A$ vanishes for the same reason, the pair (A, D) now being the symmetric one; the reversed order follows from (i).

(iii) Apply the Leibniz rule to Equation (14.103) using Equation (14.90) for the J factor and Equation (14.97) for the P factor. Both brackets are of the form "η times a generator with one index replaced", that is, exactly the action of an infinitesimal pseudo-rotation on each index of the tensors J^{BC} and P^D. The three contributions are therefore the four terms of Equation (14.102) with ω the antisymmetrized index pair (AB), less the one term in which the free index C of W is rotated; by Lemma 14.62 the first four cancel and the survivor is

$$[J_{AB}, W_C] = \eta_{BC}W_A - \eta_{AC}W_B\,.$$

In words: W is a contraction of the invariant tensor ϵ with two tensors, so it is a tensor with the one uncontracted index it displays. □

Theorem 14.65 (The two Casimir operators of the Poincaré algebra in $3+1$ dimensions)**.** *In* $D = 4$*,*

$$\boxed{P^2 = P_A P^A\,, \qquad W^2 = W_A W^A} \tag{14.104}$$

commute with every generator P_C *and* J_{AB} *of* $\mathfrak{iso}(3,1)$*, and they are functionally independent.*
Rests on Proposition 14.60, Lemma 14.64, and Definition 14.63.

Proof. *Derives Theorem 14.65.*
P^2 is Proposition 14.60. For W^2: $[W^2, P_E] = 0$ follows from Lemma 14.64(i) by the Leibniz rule, and $[W^2, J_{AB}] = 0$ is the computation already done for P^2 in Proposition 14.60 with P replaced by W, which is legitimate because Lemma 14.64(iii) says W carries its index the same way P does; the square of a vector is a scalar. Independence: W^2 contains the generators J^{BC}, which P^2 does not, so neither is a function of the other. □

Remark 14.66 (What these two numbers are, in SI units). The generators above are the differential operators of Equations (14.82) and (14.86), and — unlike the rotation generators of Remark 14.24 — they do not all carry the same dimension. The pseudo-rotation generator $J_{AB} = x_A\partial_B - x_B\partial_A$ is dimensionless, being a coordinate times a derivative with respect to a coordinate; the translation generator $P_A = \partial_A$ is not, and carries the SI dimension of inverse length, of unit $1/\mathrm{m}$. In a quantum theory the observable attached to a generator is $\hbar$ times it, and the dimensions then come out right in both cases. With $P_A = \partial_A$ from Equation (14.82) the momentum operator is $\hat{P}_A = -\mathrm{i}\hbar\,P_A$, of SI unit $\mathrm{kg\,m/s}$, and with J_{AB}

from Equation (14.86) the angular-momentum operator is $\hat{J}_{AB} = -\mathrm{i}\hbar\, J_{AB}$, of unit J s; both are Hermitian because the generators are anti-Hermitian, and the normalisation is that of Equation (94.3). By Corollary 14.18 each invariant is then a number on an irreducible representation, and the numbers are

$$\hat{P}^2 = m^2c^2\,, \qquad \hat{W}^2 = -m^2c^2\,\hbar^2\, s(s+1)\,, \tag{14.105}$$

defining the *mass* m, of SI unit kg, and the *spin* s, dimensionless, with $2s \in \mathbb{N} \cup \{0\}$ by the $\mathfrak{su}(2)$ analysis of Theorem 14.43 applied to the subalgebra that leaves a timelike momentum fixed.

Note the factors, and note in particular that the $\hbar^2$ of the second is not simply one power of $\hbar$ per generator. Each generator does bring one: $\hat{P}^2 = -\hbar^2 P^2$ carries two, and $\hat{W}_A = -\hbar^2 W_A$ carries two, so that $\hat{W}^2 = \hbar^4 W^2$ carries four. What survives in the eigenvalues is the ratio,

$$\frac{\hat{W}^2}{\hat{P}^2} = -\hbar^2\, s(s+1)\,, \tag{14.106}$$

and the $\hbar^2$ left standing there is exactly the $\hbar^2$ of the angular-momentum Casimir of Remark 14.24. The mechanism is visible in the rest frame of a timelike momentum, where $\hat{P}^D = mc\,\delta^D_0$: the definition Equation (14.103) collapses to $\hat{W}_0 = 0$ and $\hat{W}_i = -mc\,\hat{\mathcal{J}}_i$, with $\hat{\mathcal{J}}_i = \frac{1}{2}\epsilon_{ijk}\hat{J}^{jk}$ the angular momentum of the subalgebra that fixes it, of unit J s, so that $\hat{W}^2 = -m^2c^2\,\hat{\boldsymbol{\mathcal{J}}}^2$ and the remaining factor is Equation (14.58) with $j = s$. One factor m^2c^2 comes from the momentum, one factor $\hbar^2 s(s+1)$ from the spin, and that is the whole content of the second line of Equation (14.105). For the same reason the first invariant is m^2c^2 and not m^2: $\hat{P}_A$ is a momentum, and the square of a momentum has the unit $\mathrm{kg^2\,m^2/s^2}$.

The classification of the representations themselves — massive, massless, the little groups, and why a massless particle has helicity rather than spin — is carried out in Chapter 94, whose Theorems 94.18 and 94.29 are Equation (14.105) in their physical setting [849, 1912]. What is established here is only the mathematical fact that the two invariants exist.

Remark 14.67 (Why this is $3+1$ and not general D). Proposition 14.60 holds for every D. The Pauli–Lubanski construction does not: Equation (14.103) contracts a D-index Levi-Civita symbol with one J and one P, which balances only when $D = 4$. In general dimension the higher invariants of $\mathfrak{iso}(D-1,1)$ are built instead from the antisymmetrized products of J with P, and how many there are is fixed by the subalgebra that leaves a timelike momentum invariant. That subalgebra is $\mathfrak{so}(D-1)$, of rank $\lfloor (D-1)/2 \rfloor$ by Lemma 14.68, and by Theorem 14.21 its representations carry exactly that many labels; together with the mass they make

$$1 + \left\lfloor \frac{D-1}{2} \right\rfloor = \left\lceil \frac{D}{2} \right\rceil \tag{14.107}$$

labels for a massive irreducible representation — two at $D = 4$, namely P^2 and W^2, and three at both $D = 5$ and $D = 6$. This is *not* $\lfloor D/2 \rfloor$: the two expressions agree in even dimension and differ in odd. This treatise instantiates the observed case, and the observed case is $D = 4$.

The algebraic half of that count is proved here; what is not proved is identified immediately after it.

Lemma 14.68 (The algebra fixing a timelike momentum)**.** *Let $D \geq 4$ and let $p \neq 0$ be a timelike vector of $\mathbb{R}^{D-1,1}$, that is $\eta(p,p) < 0$ in the ordering of Notation 14.1. The elements of $\mathfrak{so}(D-1,1)$ annihilating p form a subalgebra isomorphic to $\mathfrak{so}(D-1)$, of rank $\lfloor (D-1)/2 \rfloor$, and*

$$1 + \left\lfloor \frac{D-1}{2} \right\rfloor = \left\lceil \frac{D}{2} \right\rceil . \tag{14.108}$$

Rests on Equation (14.23) *and Proposition 14.22.*

Proof. *Derives Lemma 14.68.*

Let $\mathfrak{h} = \{X \in \mathfrak{so}(D-1,1) \mid Xp = 0\}$; it is a subalgebra, being the kernel of the linear map $X \mapsto Xp$ and closed under the bracket because $[X,Y]\,p = 0$ whenever $Xp = Yp = 0$. For $X \in \mathfrak{h}$ and any u, the defining condition Equation (14.23) gives $\eta(Xu,p) = -\eta(u,Xp) = 0$, so X maps the whole space into $p^\perp$ and kills p. Since $\eta(p,p) \neq 0$ the space splits as $\mathbb{R}p \oplus p^\perp$ with η nondegenerate on each summand, and X is determined by its restriction to $p^\perp$, which by Equation (14.23) again is an element of the pseudo-orthogonal algebra of η restricted to $p^\perp$. Conversely any such element, extended by $Xp = 0$, satisfies Equation (14.23) on all of $\mathbb{R}^{D-1,1}$: both sides vanish when either argument is p. Removing one negative direction from the signature $(D-1,1)$ leaves $\eta|_{p^\perp}$ positive definite in $D-1$ dimensions, so $\mathfrak{h} \cong \mathfrak{so}(D-1)$. Its rank is $\lfloor (D-1)/2 \rfloor$ by Proposition 14.22, applicable because $D-1 \geq 3$.

For Equation (14.108): if $D = 2k$ then $\lfloor (D-1)/2 \rfloor = k-1$ and $\lceil D/2 \rceil = k$; if $D = 2k+1$ then $\lfloor (D-1)/2 \rfloor = k$ and $\lceil D/2 \rceil = k+1$. In both cases the two sides differ by one. □

What the lemma supplies is the algebra: the little algebra and its rank. Turning a rank into a count of labels is representation theory — that a massive irreducible representation of the inhomogeneous algebra is determined by the mass together with an irreducible representation of the subalgebra fixing a timelike momentum, and that no further invariant of the enveloping algebra escapes those labels. That is the method of induced representations. Only the case $D = 4$, proved in full above, is used anywhere in this book; the general statement is derived in the appendix.

Full derivation: Appendix A.36 (p. 2960).

Derives Equation (14.107).

The de Sitter algebras in D dimensions

The anti-de Sitter (AdS) and de Sitter (dS) algebras in D spacetime dimensions are

$$\text{AdS}: \ \mathfrak{so}(D-1,2)\,, \qquad \text{dS}: \ \mathfrak{so}(D,1)\,,$$

with, by Equation (14.89),

$$\dim \mathfrak{so}(D-1,2) = \frac{D(D+1)}{2}\,, \tag{14.109}$$

$$\dim \mathfrak{so}(D,1) = \frac{D(D+1)}{2}\,. \tag{14.110}$$

The dS and AdS algebras therefore have the same dimension as the Poincaré algebra Equation (14.100). That coincidence of dimensions is not an accident, and the reason is that all three algebras are the Killing algebras of maximally symmetric D-dimensional spacetimes. The identification of the two written above is proved next; the geometry of the two spaces, and the curvature that distinguishes them, belong to Section 13.13.

Proposition 14.69 (The de Sitter algebras are isometry algebras)**.** *Let $D \geq 3$ and $\ell > 0$. In the flat space of signature $(D-1,2)$ let AdS_D be the quadric*

$$\eta_{MN} X^M X^N = -\ell^2\,, \tag{14.111}$$

and in the flat space of signature $(D,1)$ let dS_D be the quadric

$$\eta_{MN} X^M X^N = +\ell^2\,. \tag{14.112}$$

Each is a D-dimensional submanifold whose induced metric has the Lorentzian signature $(D-1,1)$, and the restrictions of the ambient fields J_{MN} of Equation (14.86) *are linearly independent Killing fields of it spanning $\mathfrak{so}(D-1,2)$ and $\mathfrak{so}(D,1)$ respectively. These exhaust the Killing fields: the two algebras are the full isometry algebras.*

Rests on Propositions 13.140 and 14.59 and Equation (14.89).

Proof. *Derives Proposition 14.69.*

Write $f(X) = \eta_{MN} X^M X^N$, so that $\mathrm{d}f = 2\eta_{MN} X^M \mathrm{d}X^N$ is nonzero at every point of either quadric; each is therefore a regular level set, a submanifold of dimension D, with tangent space at X the orthogonal complement $X^\perp$. Since $f(X) \neq 0$ there, the ambient space splits as $\mathbb{R}X \oplus X^\perp$ with η nondegenerate on each summand, so the signature of the induced metric is that of the ambient space less one direction: less a negative one for Equation (14.111) in signature $(D-1,2)$, and less a positive one for Equation (14.112) in signature $(D,1)$. Both give $(D-1,1)$.

By Proposition 14.59(iii) each J_{MN} is tangent to the quadric and restricts to a Killing field of the induced metric. The restrictions are still independent. Indeed a vanishing combination $\omega^{MN} J_{MN}$ has ambient components proportional to $\omega^M{}_N X^N$, so it vanishes on the quadric only if the matrix $\omega^M{}_N$ annihilates every point of the quadric, hence the whole span of the quadric. That span is everything. In an indefinite signature the vectors of negative norm already span: a negative basis direction has negative norm, and a positive basis direction e is the half-sum of $e + 2u$ and $e - 2u$ for any negative unit u, both of norm -3. Every vector of negative norm is a real multiple of a point of Equation (14.111), since rescaling by λ multiplies the norm by λ^2. Interchanging the two signs throughout gives the same conclusion for Equation (14.112). Hence $\omega = 0$.

The count closes the argument. By Equation (14.89) with $p + q = D + 1$, both algebras have dimension $D(D+1)/2$, which is the largest number of independent Killing fields a D-dimensional manifold can carry by Proposition 13.140. No further Killing field can be independent of them, so the isometry algebra is exactly what has been exhibited. □

The conformal algebra in D dimensions

The conformal algebra in D spacetime dimensions is

$$\mathcal{C}_D = \mathfrak{so}(D,2)\,, \tag{14.113}$$

with

$$\dim \mathcal{C}_D = \frac{(D+1)(D+2)}{2}\,. \tag{14.114}$$

From Equation (14.89) (signature $(D,2)$, so the underlying space has dimension $D+2$).

Equation (14.113) is an assertion, and what it asserts is that an algebra defined by a *conformal* condition on D-dimensional flat space is the *isometry* algebra of a flat space with two more dimensions. The conformal Killing fields themselves are written down in Equation (13.333); what remains, and is done here because it is pure Lie algebra, is to compute their brackets and exhibit the isomorphism. The dilatation generator is written Δ throughout, the letter D being reserved for the dimension by Notation 14.1.

Proposition 14.70 (The conformal algebra of flat space)**.** *Let $D = p + q \geq 3$ and, on $\mathbb{R}^{p,q}$ with the flat metric of Notation 14.1, put*

$$\boxed{P_A = \partial_A\,, \quad J_{AB} = x_A \partial_B - x_B \partial_A\,, \quad \Delta = x^C \partial_C\,, \quad K_A = 2x_A \Delta - x^2 P_A}\,, \tag{14.115}$$

with $x^2 = x^C x_C$. These $(D+1)(D+2)/2$ vector fields are the conformal Killing fields Equation (13.333) of the flat metric; they close into a Lie algebra, with brackets Equations (14.84), (14.90) and (14.97) together with

$$\begin{aligned} &[\Delta, P_A] = -P_A\,, \qquad [\Delta, K_A] = +K_A\,, \qquad\qquad [\Delta, J_{AB}] = 0\,, \\ &[K_A, K_B] = 0\,, \qquad [J_{AB}, K_C] = \eta_{BC} K_A - \eta_{AC} K_B\,, \quad [P_A, K_B] = 2\eta_{AB}\Delta - 2J_{AB}\,. \end{aligned} \tag{14.116}$$

That algebra is isomorphic to $\mathfrak{so}(p+1, q+1)$. For Minkowski space, $(p,q) = (D-1,1)$, it is $\mathfrak{so}(D,2)$, which is Equation (14.113).

Rests on Equations (13.333), (14.90) and (14.97).

Proof. *Derives Proposition 14.70.*

The fields are conformal Killing fields. In Cartesian coordinates the conformal Killing equation reads $\partial_B\xi_C + \partial_C\xi_B = \frac{2}{D}\left(\partial^E\xi_E\right)\eta_{BC}$. For P_A and J_{AB} both sides vanish, by Proposition 14.59. For Δ, $\xi_C = x_C$ gives $\partial_B\xi_C + \partial_C\xi_B = 2\eta_{BC}$ and $\partial^E\xi_E = D$, and the equation holds. For K_A, $\xi_C = 2x_Ax_C - x^2\eta_{AC}$ gives

$$\partial_B\xi_C = 2\eta_{AB}x_C + 2x_A\eta_{BC} - 2x_B\eta_{AC}\,,$$

whose symmetric part is $4x_A\eta_{BC}$ and whose trace is $\partial^E\xi_E = 2x_A + 2Dx_A - 2x_A = 2Dx_A$; again the equation holds. That these are *all* of them is Equation (13.333), and the count is $D + D(D-1)/2 + 1 + D = (D+1)(D+2)/2$.

The brackets. Every computation below uses only the derivation rule $[X, fY] = X(f)\,Y + f\,[X,Y]$ for a function f, the values

$$P_A(x_B) = \eta_{AB}\,,\quad \Delta(x_A) = x_A\,,\quad \Delta(x^2) = 2x^2\,,\quad J_{AB}(x_C) = x_A\eta_{BC} - x_B\eta_{AC}\,,\quad J_{AB}(x^2) = 0\,,$$

the last from Proposition 14.59(iii), and the identity $x_AP_B - x_BP_A = J_{AB}$.

For $[\Delta, P_A]$: $\left[x^C\partial_C, \partial_A\right] = -\left(\partial_Ax^C\right)\partial_C = -P_A$. For $[\Delta, J_{AB}]$, the same computation on each of the two terms of J_{AB} gives $x_AP_B - x_AP_B$ and so zero. For $[\Delta, K_A]$,

$$\left[\Delta, 2x_A\Delta - x^2P_A\right] = 2x_A\Delta - 2x^2P_A - x^2\,[\Delta, P_A] = 2x_A\Delta - x^2P_A = K_A\,.$$

For $[P_A, K_B]$, using $[P_A, \Delta] = P_A$ and $P_A(x^2) = 2x_A$,

$$[P_A, K_B] = 2\eta_{AB}\Delta + 2x_BP_A - 2x_AP_B = 2\eta_{AB}\Delta - 2J_{AB}\,.$$

For $[J_{AB}, K_C]$, using $[J_{AB}, \Delta] = 0$, $J_{AB}(x^2) = 0$ and Equation (14.97),

$$\begin{aligned}[J_{AB}, K_C] &= 2\,(x_A\eta_{BC} - x_B\eta_{AC})\,\Delta - x^2\,(\eta_{BC}P_A - \eta_{AC}P_B)\\ &= \eta_{BC}\left(2x_A\Delta - x^2P_A\right) - \eta_{AC}\left(2x_B\Delta - x^2P_B\right) = \eta_{BC}K_A - \eta_{AC}K_B\,.\end{aligned}$$

Finally, with $K_A(x_B) = 2x_Ax_B - x^2\eta_{AB}$, $K_A(x^2) = 4x_Ax^2 - 2x_Ax^2 = 2x_Ax^2$, $[K_A, \Delta] = -K_A$ and $[K_A, P_B] = -2\eta_{AB}\Delta - 2J_{AB}$,

$$\begin{aligned}[K_A, K_B] &= 2\left(2x_Ax_B - x^2\eta_{AB}\right)\Delta - 2x_BK_A - 2x_Ax^2P_B + x^2\,(2\eta_{AB}\Delta + 2J_{AB})\\ &= 4x_Ax_B\Delta - 2x_B\left(2x_A\Delta - x^2P_A\right) - 2x^2x_AP_B + 2x^2J_{AB}\\ &= 2x^2\,(x_BP_A - x_AP_B) + 2x^2J_{AB} = 0\,.\end{aligned}$$

The isomorphism. Let the indices M, N run over $1, \ldots, D+2$, extend η by

$$\eta_{D+1,D+1} = -1\,,\qquad \eta_{D+2,D+2} = +1\,, \tag{14.117}$$

all other new components vanishing, and set

$$\boxed{J_{A,D+1} = \tfrac{1}{2}\,(K_A - P_A)\,,\quad J_{A,D+2} = \tfrac{1}{2}\,(K_A + P_A)\,,\quad J_{D+1,D+2} = \Delta}\,, \tag{14.118}$$

the remaining J_{MN} being the J_{AB} already defined and $J_{NM} = -J_{MN}$. This is a linear bijection onto the span, since P_A and K_A are recovered as $J_{A,D+2} \mp J_{A,D+1}$. It remains to check that Equation (14.90) holds for every choice of the four indices among $1, \ldots, D+2$. With four indices in $1, \ldots, D$ it is Equation (14.90) itself. With exactly one index equal to $D+1$ or $D+2$ it is the bracket $[J_{AB}, K_C]$ of Equation (14.116) together with Equation (14.97), both of which say that K and P carry their index as vectors. The case $[J_{AB}, J_{D+1,D+2}] =$

$[J_{AB},\Delta]=0$ agrees with Equation (14.90), every term of which carries a vanishing η. There remain the pairs built from Equation (14.118). Using $[K_A,P_B]=-2\eta_{AB}\Delta-2J_{AB}$ and $[P_A,K_B]=2\eta_{AB}\Delta-2J_{AB}$,

$$\begin{aligned}[J_{A,D+1},J_{B,D+1}]&=\tfrac{1}{4}\,[K_A-P_A,K_B-P_B]=J_{AB}\,,\\ [J_{A,D+2},J_{B,D+2}]&=\tfrac{1}{4}\,[K_A+P_A,K_B+P_B]=-J_{AB}\,,\\ [J_{A,D+1},J_{B,D+2}]&=\tfrac{1}{4}\,[K_A-P_A,K_B+P_B]=-\eta_{AB}\Delta\,,\end{aligned}$$

while Equation (14.90) demands, for these three, $\eta_{D+1,D+1}J_{BA}=J_{AB}$, $\eta_{D+2,D+2}J_{BA}=-J_{AB}$ and $\eta_{AB}J_{D+2,D+1}=-\eta_{AB}\Delta$, which are the same three results. Likewise

$$[J_{D+1,D+2},J_{A,D+1}]=\Big[\Delta,\tfrac{1}{2}\,(K_A-P_A)\Big]=J_{A,D+2}\,,\qquad [J_{D+1,D+2},J_{A,D+2}]=J_{A,D+1}\,,$$

against the demands $\eta_{D+1,D+1}J_{D+2,A}=J_{A,D+2}$ and $\eta_{D+2,D+2}J_{A,D+1}=J_{A,D+1}$ of Equation (14.90). All cases agree, so the fields Equation (14.115) satisfy the brackets of $\mathfrak{so}$ of the extended metric Equation (14.117). That metric adds one positive and one negative direction, so its signature is $(p+1,q+1)$ after the coordinates are reordered to list the positive directions first. □

Remark 14.71 (Two spaces of two extra dimensions, and neither is physical). Propositions 14.69 and 14.70 both realize a D-dimensional symmetry linearly on a flat space of more dimensions — one more for the de Sitter quadrics, two more for the conformal algebra. The extra directions are a device for linearizing an action, not a claim about the world: the manifold in both cases remains D-dimensional, and this treatise instantiates $D=4$. Nothing here asserts the existence of extra dimensions, which have no evidence base and are excluded by the scope rule of Chapter 1. The geometric side of the same statement, including the projective null-cone realization of the conformal action, is Section 13.13.1.

14.4 Central extensions

An algebra of generators need not close on itself. It may close only on itself together with an extra element that commutes with everything and generates no transformation—a *central charge*. This is not a pathology: two of the most important constants in physics, the mass in nonrelativistic mechanics and Planck's constant in the canonical commutation relations, appear in exactly this position, and neither can be removed by any redefinition of the generators. This section says what the obstruction is and how it is classified.

14.4.1 Extensions and cocycles

Definition 14.72 (Central extension)**.** A *central extension* of a Lie algebra $\mathfrak{g}$ by $\mathbb{R}$ is a Lie algebra $\tilde{\mathfrak{g}}$ fitting into the exact sequence

$$0\longrightarrow\mathbb{R}\longrightarrow\tilde{\mathfrak{g}}\longrightarrow\mathfrak{g}\longrightarrow 0\,,\tag{14.119}$$

with the image of $\mathbb{R}$ contained in the centre of $\tilde{\mathfrak{g}}$. Choosing a linear splitting $\xi\mapsto\tilde{\xi}$ of the projection, the bracket of $\tilde{\mathfrak{g}}$ takes the form

$$\boxed{\big[\tilde{\xi},\tilde{\eta}\big]=\widetilde{[\xi,\eta]}+c(\xi,\eta)\,Z}\,,\tag{14.120}$$

where Z is the central generator and $c:\mathfrak{g}\times\mathfrak{g}\to\mathbb{R}$ is a bilinear map.

Proposition 14.73 (The extension datum is a 2-cocycle)**.** *The map c of Equation (14.120) is antisymmetric and satisfies*

$$\boxed{c\left([\xi,\eta],\zeta\right)+c\left([\eta,\zeta],\xi\right)+c\left([\zeta,\xi],\eta\right)=0}, \tag{14.121}$$

for all $\xi,\eta,\zeta\in\mathfrak{g}$. A bilinear map with these two properties is called a 2-cocycle *on $\mathfrak{g}$.*
Rests on Definition 14.72.

Proof. *Derives Proposition 14.73.*

Antisymmetry of c follows from antisymmetry of the bracket in Equation (14.120). Imposing the Jacobi identity on $\tilde{\mathfrak{g}}$ for the three elements $\tilde{\xi},\tilde{\eta},\tilde{\zeta}$, the terms not involving Z cancel because the Jacobi identity already holds in $\mathfrak{g}$, and Z is central so it contributes nothing to a nested bracket; what survives is the coefficient of Z, which is exactly Equation (14.121). □

Definition 14.74 (Coboundary and triviality)**.** A cocycle is a *coboundary* if there is a linear map $b:\mathfrak{g}\to\mathbb{R}$ with

$$c(\xi,\eta)=b\left([\xi,\eta]\right)\,. \tag{14.122}$$

An extension whose cocycle is a coboundary is called *trivial*: the shift $\tilde{\xi}\mapsto\tilde{\xi}+b(\xi)Z$ removes c from Equation (14.120) entirely, so that $\tilde{\mathfrak{g}}\cong\mathfrak{g}\oplus\mathbb{R}$ as a direct sum of Lie algebras and the central charge decouples.
Rests on Proposition 14.73.

Definition 14.75 (The classifying group)**.** The 2-cocycles of Proposition 14.73 form a real vector space and the coboundaries of Definition 14.74 a subspace of it. The quotient is the second Chevalley–Eilenberg cohomology group $H^2(\mathfrak{g},\mathbb{R})$. Two central extensions of $\mathfrak{g}$ by $\mathbb{R}$ are called *equivalent* when there is an isomorphism of Lie algebras between them commuting with the inclusion of $\mathbb{R}$ and with the projection onto $\mathfrak{g}$ in Equation (14.119).
Rests on Proposition 14.73 and Definition 14.74.

That H^2 deserves to be called the classifying group is a theorem, not part of the definition, and it is proved next.

Proposition 14.76 (H^2 classifies the central extensions)**.** *The assignment Equation (14.120) of a cocycle to an extension induces a bijection between $H^2(\mathfrak{g},\mathbb{R})$ and the set of central extensions of $\mathfrak{g}$ by $\mathbb{R}$ up to equivalence, the zero class corresponding to the trivial extension. In particular*

$$\boxed{H^2(\mathfrak{g},\mathbb{R})=0\iff\textit{every central extension of }\mathfrak{g}\textit{ is trivial}}. \tag{14.123}$$

Rests on Definitions 14.72, 14.74 and 14.75 and Proposition 14.73.

Proof. *Derives Proposition 14.76.*

Write ∂b for the coboundary of Equation (14.122), $(\partial b)(\xi,\eta)=b\left([\xi,\eta]\right)$. Three things have to be checked.

The class does not depend on the splitting. Two linear splittings of the projection differ by a linear map $\mathfrak{g}\to\mathbb{R}$: if $\xi\mapsto\tilde{\xi}$ and $\xi\mapsto\tilde{\xi}'$ both project to ξ, their difference lies in the kernel of the projection, which is the line spanned by Z, so $\tilde{\xi}'=\tilde{\xi}+b(\xi)Z$ with b linear. Since Z is central, $\left[\tilde{\xi}',\tilde{\eta}'\right]=\left[\tilde{\xi},\tilde{\eta}\right]$, while the first term of Equation (14.120) shifts by $b\left([\xi,\eta]\right)Z$. Hence $c'=c-\partial b$ and the two cocycles define the same class. An isomorphism of extensions in the sense of Definition 14.75 is the identity on $\mathbb{R}$ and induces the identity on $\mathfrak{g}$, so it acts on a splitting exactly as a change of splitting does; equivalent extensions therefore have equal classes.

Every class is realized. Given a cocycle c, put $\tilde{\mathfrak{g}}=\mathfrak{g}\oplus\mathbb{R}Z$ as a vector space, with Z central and the bracket Equation (14.120). It is antisymmetric because c is, and it satisfies

the Jacobi identity: the $\mathfrak{g}$-component of the Jacobi expression is the Jacobi identity of $\mathfrak{g}$, and the coefficient of Z is Equation (14.121). The obvious inclusion and projection make it a central extension, whose cocycle for the obvious splitting is c again.

Cohomologous cocycles give equivalent extensions, and only those. A map between the extensions built from c and from c' that commutes with the inclusion and the projection is the identity on $\mathbb{R}Z$ and induces the identity on $\mathfrak{g}$, so it sends $\tilde{\xi} \mapsto \tilde{\xi} + \beta(\xi)Z$ for some linear $\beta : \mathfrak{g} \to \mathbb{R}$ and is automatically bijective. Requiring it to respect the two brackets and reading off the coefficient of Z gives $c' = c + \partial\beta$. So the two extensions are equivalent precisely when $c' - c$ is a coboundary, that is, precisely when c and c' define the same class. The trivial extension is the one with $c = 0$, which is Definition 14.74, and it represents the zero class. □

Proposition 14.77 (Semisimple algebras admit no nontrivial extension)**.** *If $\mathfrak{g}$ is a finite-dimensional semisimple Lie algebra over a field of characteristic zero, then $H^1(\mathfrak{g}, \mathbb{R}) = H^2(\mathfrak{g}, \mathbb{R}) = 0$. In particular $\mathfrak{so}(p, q)$, and hence the Lorentz algebra $\mathfrak{so}(D-1, 1)$ of Equation (14.90), admits no nontrivial central extension.*

Rests on Definition 14.75 and Theorem 14.13.

These are Whitehead's first and second lemmas. Both are proved by averaging a cochain against the Casimir element of the algebra, which Theorem 14.13 makes invertible on any module with no trivial summand; the corollary for the Lorentz algebra then follows from its semisimplicity, which is itself the nondegeneracy of the Killing form.

Full derivation: Appendix A.37 (p. 2967).

Derives Proposition 14.77.

Remark 14.78 (Where the obstruction can live). Proposition 14.77 localises the interesting cases. A semisimple algebra is rigid in this respect, so nontrivial central charges occur only where the algebra is *not* semisimple: in abelian algebras, in the inhomogeneous algebras built as semidirect sums such as Equation (14.99), in algebras obtained by the contractions of Section 14.5, and in infinite-dimensional algebras. All four cases occur in physics.

14.4.2 The instances that occur in physics

Example 14.79 (The Heisenberg algebra)**.** Take $\mathfrak{g} = \mathbb{R}^{2f}$, abelian, spanned by the phase-space translations. Every antisymmetric bilinear form on an abelian algebra is a cocycle, since Equation (14.121) is vacuous, and no coboundary is available because $[\xi, \eta] = 0$ makes the right-hand side of Equation (14.122) vanish identically. Hence $H^2(\mathbb{R}^{2f}, \mathbb{R}) = \Lambda^2(\mathbb{R}^{2f})^*$, which is as far from zero as possible. The extension defined by the symplectic form is the *Heisenberg algebra*

$$[X_i, P_j] = \delta_{ij} Z\,, \qquad [X_i, X_j] = [P_i, P_j] = [Z, \cdot] = 0\,, \tag{14.124}$$

and the canonical commutation relations of quantum mechanics are Equation (14.124) with $Z = \mathrm{i}\hbar$. Planck's constant is a central charge.

Rests on Proposition 14.73 and Definition 14.74.

Example 14.80 (The Galilei algebra)**.** The ten-generator Galilei algebra of three space dimensions carries the cocycle $c(K_i, P_j) = \delta_{ij}$, whose central charge is the mass, and H^2 of that algebra is one-dimensional, so up to a scale this is the only central extension it admits. The classical mechanics of a free particle realizes the extension and not the Galilei algebra itself; the computation, and the proof that this cocycle is not a coboundary, are carried out in Proposition 25.14. That proposition establishes only that the class is nonzero; that it exhausts H^2 is the stronger statement, and it needs the cocycle condition solved on the whole ten-dimensional algebra and quotiented by the coboundaries.

Rests on Definition 14.75 and Proposition 25.14.

Full derivation: Appendix A.38 (p. 2975).
Derives Example 14.80.

Example 14.81 (Infinite-dimensional cases)**.** The Witt algebra of vector fields on the circle has a one-dimensional H^2, whose extension is the Virasoro algebra with central charge c; loop algebras extend to affine Kac–Moody algebras with the level as central charge; and the equal-time current-algebra commutators of a field theory acquire Schwinger terms of the same nature.

All three are computations rather than citations: the Virasoro cocycle and its uniqueness up to coboundary, the Kac–Moody cocycle built from the Killing form and the residue pairing, and the Schwinger term as the statement that a formally central extension survives regularization.
Full derivation: Appendix A.39 (p. 2979).
Derives Example 14.81.

Remark 14.82 (Central charges are measured, not postulated)*.* The four examples above are not on the same evidential footing, and the distinction matters under the scope rule of this treatise. Planck's constant and the mass are measured quantities appearing as central charges of algebras whose representations describe observed systems in the observed $3+1$ dimensions; nothing stands between the algebra and the instrument.

The Virasoro central charge is not on that footing, and this treatise records no measurement of it. Where it is called observable, the claim runs through the universal critical behaviour of a laboratory sample — a three-dimensional piece of matter, in the regime treated in Chapter 123, whose long-wavelength behaviour is that of an effectively two-dimensional system when one direction is frozen out by geometry or by temperature. What is measured there are critical exponents and amplitude ratios; the step from those numbers to a value of c is an identification made inside a conformal field theory, not a reading of an instrument, and this book does not make it. The system is $3+1$-dimensional and the effective description is not a spacetime.

The Schwinger terms are on a third footing again. They are the equal-time-commutator face of the anomalies [1388, 1391], and it is the anomaly that carries the measurable consequence — the cleanest case being the two-photon decay of the neutral pion, whose rate has been measured directly [2361]. That the Schwinger term and the anomaly are two faces of one obstruction is asserted here and not proved; what can be said without qualification is that the decay rate is measured and that an anomaly-free theory predicts the wrong one.

What is *not* evidence in any of these cases is the existence of an algebra as such: writing down a consistent extension is a mathematical act, and whether nature realizes it is a separate question, settled only by experiment.

14.5 Contraction of Lie algebras

14.5.1 The Inönü–Wigner limit

A symmetry algebra is rarely exact. More often it is the limit of another one as some parameter—a velocity ratio, a curvature radius—is taken to an extreme, and the limit is singular: the generators must be rescaled as it is taken, or the brackets diverge. Inönü and Wigner made the procedure precise [1021].

Definition 14.83 (Contraction)**.** Let $\mathfrak{g}$ be a Lie algebra with basis $\{T_\alpha\}$ and let $U(\varepsilon)$ be a family of invertible linear maps, singular as $\varepsilon \to 0$. If the limit

$$\boxed{[T_\alpha, T_\beta]_0 = \lim_{\varepsilon\to 0} U(\varepsilon)^{-1}\,[U(\varepsilon)T_\alpha, U(\varepsilon)T_\beta]} \tag{14.125}$$

exists for all α, β, it defines a Lie algebra $\mathfrak{g}_0$ of the same dimension, called a *contraction* of $\mathfrak{g}$.

Proposition 14.84 (Properties of a contraction)**.** *Let $\mathfrak{g}_0$ be a contraction of $\mathfrak{g}$ in the sense of Definition 14.83, and fix a basis $\{T_\alpha\}$, in which $U(\varepsilon)$ has matrix U and $\mathfrak{g}$ has structure constants ${C^\gamma}_{\alpha\beta}$ and Killing form κ. Then:*

1. *$[\cdot,\cdot]_0$ is a Lie bracket, and $\dim \mathfrak{g}_0 = \dim \mathfrak{g}$;*
2. *the derivation algebras obey $\dim \mathrm{Der}(\mathfrak{g}_0) \geq \dim \mathrm{Der}(\mathfrak{g})$, so that a contraction is* not reversible*: whenever the inequality is strict, the two algebras are not isomorphic and $\mathfrak{g}$ is not a contraction of $\mathfrak{g}_0$;*
3. *the Killing form of $\mathfrak{g}_0$ is $\kappa_0 = \lim_{\varepsilon\to 0} \kappa_\varepsilon$ with $\kappa_\varepsilon(X,Y) = \kappa\left(U(\varepsilon)X, U(\varepsilon)Y\right)$, so that $\det \kappa_0 = \lim_{\varepsilon\to 0} (\det U)^2 \det \kappa$. If $\det U(\varepsilon) \to 0$ and $\mathfrak{g}$ is semisimple, then $\mathfrak{g}_0$ is not;*
4. *a contraction can create the cohomology that a central charge needs. Every Lie algebra of dimension n contracts to the abelian algebra of the same dimension, whose second cohomology is the whole space $\Lambda^2 (\mathbb{R}^n)^*$ of antisymmetric bilinear forms by the argument of Example 14.79, while H^2 vanishes for a semisimple $\mathfrak{g}$ by Proposition 14.77.*

Rests on Definitions 14.10 and 14.83 and Proposition 14.77.

Proof. *Derives Proposition 14.84.*

Throughout, write $[X,Y]_\varepsilon = U(\varepsilon)^{-1}\,[U(\varepsilon)X, U(\varepsilon)Y]$ for the bracket at finite ε. It is the pullback of the bracket of $\mathfrak{g}$ along the linear isomorphism $U(\varepsilon)$, so $(\mathfrak{g}, [\cdot,\cdot]_\varepsilon)$ is a Lie algebra isomorphic to $\mathfrak{g}$ for every $\varepsilon \neq 0$, and its structure constants ${C^\gamma}_{\alpha\beta}(\varepsilon)$ converge, by hypothesis, to those of $\mathfrak{g}_0$.

(i) Bilinearity and antisymmetry pass to the limit because they are linear conditions on the structure constants. The Jacobi identity is the system of quadratic equations ${C^\delta}_{\alpha\beta}(\varepsilon){C^\sigma}_{\delta\gamma}(\varepsilon) + {C^\delta}_{\beta\gamma}(\varepsilon){C^\sigma}_{\delta\alpha}(\varepsilon) + {C^\delta}_{\gamma\alpha}(\varepsilon){C^\sigma}_{\delta\beta}(\varepsilon) = 0$, valid for every $\varepsilon \neq 0$; a polynomial is continuous, so the same equations hold in the limit. The underlying vector space never changed, whence the dimension.

(ii) A derivation is a solution of the linear system $d\,([T_\alpha, T_\beta]) = [dT_\alpha, T_\beta] + [T_\alpha, dT_\beta]$ in the unknown matrix d, and the coefficients of that system are linear in the structure constants. Write $L(\varepsilon)$ for its matrix. Since Der of isomorphic algebras are conjugate, $\dim \ker L(\varepsilon) = \dim \mathrm{Der}(\mathfrak{g})$ for all $\varepsilon \neq 0$. Rank is lower semicontinuous: if $L(0)$ carries a nonvanishing minor of size r, that same minor is a continuous function of ε and so is nonvanishing for small ε, whence $\operatorname{rank} L(0) \leq \operatorname{rank} L(\varepsilon)$ there, and the kernels satisfy the reverse inequality. That is the claim. If it is strict, then $\mathfrak{g}_0$ is not isomorphic to $\mathfrak{g}$, and a contraction the other way would give $\dim \mathrm{Der}(\mathfrak{g}) \geq \dim \mathrm{Der}(\mathfrak{g}_0)$ and hence equality, which is excluded.

(iii) From $\mathrm{ad}^\varepsilon_X = U(\varepsilon)^{-1}\,\mathrm{ad}_{U(\varepsilon)X}\,U(\varepsilon)$ and cyclicity of the trace,

$$\kappa_\varepsilon(X,Y) = \operatorname{tr}\left(\mathrm{ad}^\varepsilon_X\,\mathrm{ad}^\varepsilon_Y\right) = \operatorname{tr}\left(\mathrm{ad}_{U(\varepsilon)X}\,\mathrm{ad}_{U(\varepsilon)Y}\right) = \kappa\left(U(\varepsilon)X, U(\varepsilon)Y\right)\,,$$

which in the fixed basis is the matrix $(U)^{\mathsf{T}}\kappa\,U$, of determinant $(\det U)^2 \det\kappa$. The Killing form is a quadratic polynomial in the structure constants by Equation (14.15), so κ_0 is the limit of κ_ε and $\det\kappa_0$ the limit of the determinants. If $\det U \to 0$ then $\det\kappa_0 = 0$, the Killing form of $\mathfrak{g}_0$ is degenerate, and Theorem 14.13 denies it semisimplicity.

(iv) Take $U(\varepsilon) = \varepsilon\,\mathbb{1}$. Then $[X,Y]_\varepsilon = \varepsilon^{-1}\,[\varepsilon X, \varepsilon Y] = \varepsilon\,[X,Y] \to 0$, so every algebra contracts to the abelian one of the same dimension; and $\det U = \varepsilon^n \to 0$, consistently with (iii). The second cohomology of an abelian algebra is computed in Example 14.79 and is the whole space of antisymmetric bilinear forms, nonzero as soon as $n \geq 2$. □

Remark 14.85 (Why (iv) is only an existence statement). Part (iv) proves that a contraction *can* create a nonvanishing H^2, by exhibiting the extreme case. It does not say that any

particular contraction does so, and no general theorem does: which classes survive a given limit has to be computed limit by limit. What the physical cases have in common is the structure of Lemma 14.86 — an abelian ideal appears where there was none — and it is on an abelian ideal that a cocycle has the most room, by the same computation as in Example 14.79.

Lemma 14.86 (The Inönü–Wigner contraction along a subalgebra)**.** *Let $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$ as a vector space, let π be the projection onto $\mathfrak{m}$ along $\mathfrak{h}$, and let $U(\varepsilon)$ be the identity on $\mathfrak{h}$ and multiplication by ε on $\mathfrak{m}$. The limit Equation (14.125) exists if and only if $\mathfrak{h}$ is a subalgebra, and then*

$$\boxed{[X,Y]_0 = [X,Y]\,, \quad [X,Z]_0 = \pi\,[X,Z]\,, \quad [Z,Z']_0 = 0}\,, \tag{14.126}$$

for $X, Y \in \mathfrak{h}$ and $Z, Z' \in \mathfrak{m}$. In particular $\mathfrak{m}$ is an abelian ideal of $\mathfrak{g}_0$ and $\mathfrak{g}_0/\mathfrak{m} \cong \mathfrak{h}$.
Rests on Definition 14.83.

Proof. *Derives Lemma 14.86.*
For $X, Y \in \mathfrak{h}$, $U(\varepsilon)$ acts as the identity and $U(\varepsilon)^{-1}$ multiplies the $\mathfrak{m}$-part by ε^{-1}, so $[X,Y]_\varepsilon = (1-\pi)\,[X,Y] + \varepsilon^{-1}\pi\,[X,Y]$, which converges if and only if $\pi\,[X,Y] = 0$, that is if and only if $[\mathfrak{h},\mathfrak{h}] \subseteq \mathfrak{h}$; the limit is then $[X,Y]$. For $X \in \mathfrak{h}$ and $Z \in \mathfrak{m}$,

$$[X,Z]_\varepsilon = U(\varepsilon)^{-1}\,[X,\varepsilon Z] = \varepsilon\,(1-\pi)\,[X,Z] + \pi\,[X,Z] \longrightarrow \pi\,[X,Z]\,,$$

and for $Z, Z' \in \mathfrak{m}$, $[Z,Z']_\varepsilon = \varepsilon^2\,(1-\pi)\,[Z,Z'] + \varepsilon\pi\,[Z,Z'] \to 0$. Both limits exist unconditionally, so the condition on $\mathfrak{h}$ is the whole condition. Equation (14.126) then puts $[\mathfrak{g}_0,\mathfrak{m}]_0 \subseteq \mathfrak{m}$ and $[\mathfrak{m},\mathfrak{m}]_0 = 0$, and the quotient bracket is that of $\mathfrak{h}$. □

Lemma 14.87 (A rescaled Casimir stays central)**.** *Let $C \in U(\mathfrak{g})$ be a Casimir element in the sense of Definition 14.8, and for $\varepsilon \neq 0$ let $C_\varepsilon = \lambda(\varepsilon)\,\hat{U}(\varepsilon)^{-1}C$, where $\hat{U}(\varepsilon)$ is the isomorphism of enveloping algebras induced by $U(\varepsilon)$ and $\lambda(\varepsilon) \neq 0$ is a scalar. If the coefficients of C_ε in the ordered monomials of Theorem 14.7 converge as $\varepsilon \to 0$, their limit defines an element $C_0 \in U(\mathfrak{g}_0)$, and C_0 is a Casimir element of $\mathfrak{g}_0$.*
Rests on Definitions 14.8 and 14.83 and Theorem 14.7.

Proof. *Derives Lemma 14.87.*
Because $U(\varepsilon)$ is an isomorphism of Lie algebras from $(\mathfrak{g}, [\cdot,\cdot]_\varepsilon)$ to $\mathfrak{g}$, it extends to an isomorphism $\hat{U}(\varepsilon)$ of the corresponding enveloping algebras, which carries the centre to the centre. Hence $[C_\varepsilon, T_\alpha]_\varepsilon = 0$ for every α and every $\varepsilon \neq 0$, the scalar $\lambda(\varepsilon)$ being irrelevant to that.

Reduce both sides to the ordered basis of Theorem 14.7. Every reordering step uses the relations Equation (14.12) for the bracket $[\cdot,\cdot]_\varepsilon$, so the coefficients of $[C_\varepsilon, T_\alpha]_\varepsilon$ in that basis are polynomials in the coefficients of C_ε and in the structure constants ${C^\gamma}_{\alpha\beta}(\varepsilon)$, with the same polynomials for every ε — the degree of C_ε being fixed. Both arguments converge, the polynomials are continuous, and the value is identically zero; therefore $[C_0, T_\alpha]_0 = 0$ for every α, which is Equation (14.13) for $\mathfrak{g}_0$. □

Remark 14.88 (The Galilei mass, precisely). Lemma 14.87 is the mechanism by which an invariant of the parent algebra reappears as a central quantity of the contracted one, and the nonrelativistic limit is its standard instance — but the instance has to be stated carefully, because the plain contraction of the Poincaré algebra does *not* produce a central charge. Take $D = 4$ in the ordering of Notation 14.1, so that $x^4 = ct$ and the generator of time translation is $H = c\,P_4 = \partial_t$, of SI unit 1/s, and put $G_i = J_{i4}/c$ for the rescaled boost, which tends to the Galilean $t\,\partial_i$. Then Equations (14.90) and (14.97) give

$$[G_i, P_j] = -\frac{\delta_{ij}}{c^2}\,H\,, \qquad [G_i, H] = -P_i\,, \qquad [G_i, G_j] = \frac{1}{c^2}J_{ij}\,, \tag{14.127}$$

and the limit $c \to \infty$ is the Galilei algebra with $[G_i, P_j] = 0$ and no central charge at all. The mass appears when the same limit is taken in the *trivially extended* algebra $\mathfrak{iso}(3,1) \oplus \mathbb{R}M$, with M central, after the c-dependent redefinition $H' = H - c^2 M$: the first bracket of Equation (14.127) then reads $[G_i, P_j] = -\delta_{ij}\,(H'/c^2 + M)$ and tends to $-\delta_{ij}M$. The extension that survives is nontrivial, which is the content of Proposition 25.14; this treatise proves that nontriviality directly, from the Poisson brackets of a free particle, rather than through the limit. Remark 25.15 is to be read in the sense set out here.

Example 14.89 (Poincaré from de Sitter, Galilei from Poincaré)**.** Two contractions are used throughout this treatise.

1. *Vanishing curvature.* Rescaling the translation generators of $\mathfrak{so}(D-1,2)$ or $\mathfrak{so}(D,1)$ by the inverse radius and letting the radius diverge contracts either de Sitter algebra to the Poincaré algebra Equation (14.99). This is the statement that spacetime looks flat on scales small compared with the curvature radius set by the cosmological constant.

2. *Vanishing velocity ratio.* Rescaling the boosts of the Poincaré algebra by $1/c$ and letting $c \to \infty$ contracts it to the Galilei algebra. The Casimir $p_\mu p^\mu = m^2 c^2$ that labelled a Poincaré representation becomes, in the limit, the central charge of Example 14.80.

14.5.2 The classification of kinematical algebras

A *kinematical* algebra is one generated by the transformations any spacetime symmetry must contain: rotations J_i, boosts K_i, space translations P_i, and a time translation H—ten generators in four spacetime dimensions. Bacry and Lévy-Leblond asked which Lie algebras these can form, and answered the question completely [1364].

Theorem 14.90 (Bacry–Lévy-Leblond)**.** *Assume that*

1. *space is isotropic, so that the J_i generate an $\mathfrak{so}(3)$ under which K_i and P_i are vectors and H a scalar;*

2. *parity and time reversal are automorphisms of the algebra; and*

3. *each boost generates a noncompact one-parameter subgroup.*

Then there are exactly eleven such algebras, up to a rescaling of the generators, and they are organized by three constants (γ, μ, ν) appearing in

$$\boxed{[K_i, P_j] = \gamma\,\delta_{ij} H\,, \qquad [K_i, H] = \mu\, P_i\,, \qquad [P_i, H] = \nu\, K_i}\,, \tag{14.128}$$

the two remaining brackets being fixed by the Jacobi identity to

$$[K_i, K_j] = -\gamma\mu\,\epsilon_{ijk} J_k\,, \qquad [P_i, P_j] = \gamma\nu\,\epsilon_{ijk} J_k\,. \tag{14.129}$$

Setting each of γ, μ, ν to zero is an Inönü–Wigner contraction, so the eight possible vanishing patterns form a cube of contractions; the eleven algebras are those eight cases, three of which split into two according to a sign.

Rests on Equation (14.34) and Definition 14.83.

Full derivation: Appendix A.10 (p. 2799).

Derives Theorem 14.90.

Remark 14.91 (Eleven kinematics, not eleven isomorphism classes)*.* The theorem must not be stated as "eleven algebras up to isomorphism". Exchanging $K_i \leftrightarrow P_i$ is an isomorphism of Lie algebras carrying Poincaré to para-Poincaré and Galilei to para-Galilei (Corollary A.60), but it is not an equivalence of kinematics, because it does not commute with the time reversal of hypothesis (2) and because it exchanges the physical roles of a boost and a translation. Two entries of Table 14.1 are therefore abstractly the same algebra as another entry while describing different physics.

Table 14.1: The eleven kinematical algebras of Theorem 14.90, what each describes, and whether this treatise records a measurement in its regime. The third column gives the vanishing pattern of the three constants of Equation (14.128), $*$ marking a nonzero one; the eight patterns are the vertices of the contraction cube, and the three cases carrying two entries differ only by a sign. The last column is a verdict about the *evidence base*, not about the mathematics — all eleven are consistent Lie algebras — and the evidence for the three realized cases is cited in Remark 14.92.

Algebra	Sym.	(γ, μ, ν)	Regime it describes	Realized in nature?
de Sitter	dS	$(*, *, *)$	relativistic, positive curvature	yes, asymptotically: the measured Λ is positive
anti-de Sitter	AdS	$(*, *, *)$	relativistic, negative curvature	no: the measured Λ has the opposite sign
Poincaré	P	$(*, *, 0)$	relativistic, flat	yes: the symmetry of Part IV, tested directly
Galilei	G	$(0, *, 0)$	nonrelativistic, flat	yes, as the $c \to \infty$ limit used throughout Part III
Newton–Hooke	NH_+	$(0, *, *)$	nonrelativistic, positive curvature	only as an effective description of Λ in local dynamics
anti-Newton–Hooke	NH_-	$(0, *, *)$	nonrelativistic, negative curvature	no, for the same reason as AdS
Carroll	C	$(*, 0, 0)$	ultrarelativistic, $c \to 0$, flat	no laboratory regime; it is the intrinsic symmetry of a null hypersurface
para-Poincaré	P'	$(*, 0, *)$	ultrarelativistic, curved	no
para-Galilei	G'	$(0, 0, *)$	mixed limit	no
inhomogeneous SO(4)	E'	$(*, 0, *)$	Euclidean signature	not a spacetime kinematics at all
static	S	$(0, 0, 0)$	no relative motion whatever	degenerate limit only

Remark 14.92 (What the table is claiming). Three of the eleven are realized in the strong sense that measurements have been made in their regime and agree with them. Poincaré is the subject of Part IV and is tested to the precision recorded in Chapters 37 and 41. Galilei is its low-velocity limit, which is what Part III uses throughout. De Sitter qualifies in a weaker and more careful sense: the measured cosmological constant is positive — the supernova evidence for an accelerating expansion [1962, 1981], with the value fixed by the cosmic microwave background [2348] — so the asymptotic symmetry of the observed universe is de Sitter rather than anti-de Sitter or Poincaré — but this is an inference from the expansion history of Chapter 48, not a symmetry test. The remaining eight are mathematically consistent and, at present, physically unoccupied.

The Carroll algebra is the interesting borderline case. It has no laboratory regime, being the limit $c \to 0$, yet it is the intrinsic symmetry of a null hypersurface, and null hypersurfaces are observed — the horizons of Chapter 50. That is a statement about where an algebra appears in a description, which is not the same as a measurement of the algebra, and the table's last column is deliberately worded to keep the two apart.

Remark 14.93 (The cube is an algebra, not only a picture). The eight vanishing patterns of (γ, μ, ν) were called the vertices of a cube of contractions, which so far is a way of drawing the theorem rather than a statement about it. It is more than that. Section 15.7 of the next chapter shows that the four generator species J_i, K_i, H, P_i — the boosts are written K_i here and in Theorem 14.90, and G_i there — are the four components of a $\mathbb{Z}_2 \times \mathbb{Z}_2$-grading of the algebra, that the three constants (γ, μ, ν) are the three structure constants of a single four-dimensional commutative associative algebra A carrying the same grading, and that the eight vertices are the eight ways those three constants can vanish — so each edge of the cube is a degeneration of A and nothing else. The three rescaling-invariant signs of that algebra are the squares of its three graded generators; hypothesis (3) above, that the boosts be noncompact, is exactly the condition that one of those three squares be nonnegative; and counting the vertices against the signs that survive it returns $8 + 3 = 11$. The two accounts are complementary rather than redundant: this chapter's, completed in Appendix A.10, proves that the list is *exhaustive*, which no construction can do; the next chapter's says what the list *is* — one algebra and its degenerations.

Remark 14.94 (Extensions of the classification, and the scope rule). Theorem 14.90 is not the end of the subject. Dropping the discrete automorphisms, or working in general dimension, enlarges the list; extending the algebras—by further generators or by central charges—produces infinite families, and the construction of gauge theories from them is an active programme. Supersymmetric extensions are the other standard enlargement, and this treatise names them only to say what its scope rule requires: no supersymmetric partner of any known particle has been observed, so supersymmetry has no evidence base and nothing built on it belongs in this book. A recent example builds *Maxwell* extensions of the kinematical algebras by a semigroup expansion method that generalizes contraction, and uses the resulting invariant tensors to construct three-dimensional Chern–Simons gravity theories [2432]. These constructions are mathematics, and this treatise treats them as such: gravity in three spacetime dimensions has no propagating degrees of freedom and no observational status, and the paper claims none. The Chern–Simons machinery they use is developed in Section 14.8.1 of this chapter, so the mathematical apparatus is present in the book; what is absent, and is stated here rather than left implicit, is any measurement that selects such an extension. Section 133.7 records the general policy.

14.6 Fibre bundles

The invariant-polynomial machinery of the following sections is formulated on a *principal fibre bundle*, and so is every gauge theory in Part XI. This section supplies the definitions

and proves the one identity those constructions consume, the Bianchi identity. Nothing beyond that is developed: the classification of bundles, characteristic numbers as topological invariants, and holonomy are not needed anywhere in this treatise and are not treated.

14.6.1 Bundles, sections and principal bundles

Definition 14.95 (Fibre bundle)**.** A *fibre bundle* consists of differentiable manifolds E (the *total space*), M (the *base*) and F (the *typical fibre*), a Lie group G (the *structure group*) acting effectively on F on the left, and a smooth surjection $\pi : E \longrightarrow M$ (the *projection*), such that M carries an open cover $\{U_i\}$ and there are diffeomorphisms

$$\varphi_i : \pi^{-1}(U_i) \longrightarrow U_i \times F\,, \qquad \mathrm{pr}_1 \circ \varphi_i = \pi\,, \tag{14.130}$$

called *local trivializations*, whose overlaps act on the fibre through G:

$$\varphi_i \circ \varphi_j^{-1}(x, f) = (x, t_{ij}(x) f)\ , \qquad t_{ij} : U_i \cap U_j \longrightarrow G \tag{14.131}$$

smooth. The t_{ij} are the *transition functions*; composing Equation (14.131) on triple overlaps gives the *cocycle conditions*

$$t_{ii} = e\,, \qquad t_{ij} t_{ji} = e\,, \qquad t_{ij} t_{jk} = t_{ik}\,. \tag{14.132}$$

The bundle is *trivial* if a single trivialization with $U_1 = M$ exists, in which case $E \cong M \times F$.

Definition 14.96 (Section)**.** A *section* of E over an open $U \subseteq M$ is a smooth map $s : U \longrightarrow E$ with $\pi \circ s = \mathrm{id}_U$; it is *global* if $U = M$. Local sections always exist — take $s(x) = \varphi_i^{-1}(x, f_0)$ inside a trivializing neighbourhood — and a global section need not.
Rests on Definition 14.95.

Definition 14.97 (Principal bundle)**.** A *principal G-bundle* $P(M, G)$ is a fibre bundle whose typical fibre is the group G itself, acting on itself by left translation, together with the right action of G on P defined in each trivialization by

$$\varphi_i(p) = (x, h) \quad \longmapsto \quad \varphi_i(p \cdot g) = (x, hg)\ . \tag{14.133}$$

The action is well defined — right translation commutes with the left translation by t_{ij} of Equation (14.131), so Equation (14.133) does not depend on the trivialization — it is free, and its orbits are exactly the fibres of π.
Rests on Definition 14.95.

Proposition 14.98 (A principal bundle is trivial if and only if it has a global section)**.** *$P(M, G)$ is trivial if and only if it admits a global section.*
Rests on Definitions 14.96 and 14.97.

Proof. *Derives Proposition 14.98.*
If $P \cong M \times G$, then $x \mapsto (x, e)$ is a global section. Conversely let s be one and define

$$\Phi : M \times G \longrightarrow P\,, \qquad \Phi(x, g) = s(x) \cdot g\,.$$

It is smooth, satisfies $\pi \circ \Phi = \mathrm{pr}_1$, and is bijective: surjective because G acts transitively on each fibre, so every p with $\pi(p) = x$ is $s(x)g$ for some g; injective because the action is free. Its inverse is smooth, as one sees in any local trivialization φ_i: writing $\varphi_i(s(x)) = (x, \sigma_i(x))$ with σ_i smooth, $\varphi_i \circ \Phi(x, g) = (x, \sigma_i(x) g)$, whose inverse $(x, h) \mapsto (x, \sigma_i(x)^{-1} h)$ is smooth because inversion and multiplication in G are. Hence Φ is a diffeomorphism commuting with the right action, and P is trivial. □

Definition 14.99 (Associated bundle)**.** Let $P(M,G)$ be principal and let G act on a manifold F on the left. The *associated bundle* $P\times_G F$ is the quotient of $P\times F$ by the equivalence

$$(p,f)\sim\left(p\cdot g,\ g^{-1}f\right),\qquad g\in G\,, \tag{14.134}$$

with projection $[p,f]\mapsto\pi(p)$. It is a fibre bundle with typical fibre F and the same transition functions Equation (14.131). When F is a vector space and the action is a linear representation, $P\times_G F$ is a *vector bundle*, and a matter field is a section of it.

Rests on Definitions 14.95 and 14.97.

Remark 14.100 (Where the nontriviality is felt). The definitions above would be idle if every bundle were trivial, since a trivial bundle reduces every construction to a global choice of gauge. Two places in this treatise turn on their not being. A gauge-fixing prescription, such as the Faddeev–Popov construction of Section 106.4, is a section of a principal bundle over the space of gauge orbits, and Proposition 14.98 is the statement quoted in support of Theorem 106.65: for a non-abelian structure group that bundle is not trivial, so it admits no global section — no global section, no global gauge fixing, and the Faddeev–Popov prescription is a local construction used globally [1626]. And the connection of Definition 14.103 below is what makes the phase acquired around a closed path a property of the path rather than of the coordinates, the effect predicted in [1164], first measured by Chambers with an iron whisker behind an electron biprism [1178] and put beyond the leakage-field objection by Tonomura and collaborators, who enclosed the flux in a superconducting shield [1784]. The non-abelian case, in which the structure group is not U(1), was introduced for the isotopic-spin symmetry [1054].

14.6.2 Connection and curvature

Notation 14.101 (Algebra-valued forms and their bracket). A $\mathfrak{g}$-valued p-form on a manifold is $\boldsymbol{\alpha}=\alpha^a\boldsymbol{T}_a$ with α^a ordinary p-forms and $\{\boldsymbol{T}_a\}$ a basis of $\mathfrak{g}$. For a p-form $\boldsymbol{\alpha}$ and a q-form $\boldsymbol{\beta}$ put

$$[\boldsymbol{\alpha},\boldsymbol{\beta}]=\alpha^a\wedge\beta^b\,[\boldsymbol{T}_a,\boldsymbol{T}_b]\,, \tag{14.135}$$

a $\mathfrak{g}$-valued $(p+q)$-form, and $\mathrm{d}\boldsymbol{\alpha}=\mathrm{d}\alpha^a\,\boldsymbol{T}_a$. Expanding the wedge product of two 1-forms on a pair of vectors gives

$$[\boldsymbol{\alpha},\boldsymbol{\beta}]\,(V,W)=[\boldsymbol{\alpha}(V),\boldsymbol{\beta}(W)]-[\boldsymbol{\alpha}(W),\boldsymbol{\beta}(V)]\,. \tag{14.136}$$

Lemma 14.102 (Two identities for a $\mathfrak{g}$-valued 1-form)**.** *For every $\mathfrak{g}$-valued 1-form $\boldsymbol{\alpha}$,*

$$\mathrm{d}\,[\boldsymbol{\alpha},\boldsymbol{\alpha}]=2\,[\mathrm{d}\boldsymbol{\alpha},\boldsymbol{\alpha}]\,,\qquad [\boldsymbol{\alpha},[\boldsymbol{\alpha},\boldsymbol{\alpha}]]=0\,. \tag{14.137}$$

Rests on Equations (14.5) and (14.135).

Proof. *Derives Lemma 14.102.*

For the first, the graded Leibniz rule gives $\mathrm{d}\left(\alpha^a\wedge\alpha^b\right)=\mathrm{d}\alpha^a\wedge\alpha^b-\alpha^a\wedge\mathrm{d}\alpha^b$, and in the second term a 1-form and a 2-form commute, so $-\alpha^a\wedge\mathrm{d}\alpha^b\,[\boldsymbol{T}_a,\boldsymbol{T}_b]=-\mathrm{d}\alpha^b\wedge\alpha^a\,[\boldsymbol{T}_a,\boldsymbol{T}_b]=+\mathrm{d}\alpha^a\wedge\alpha^b\,[\boldsymbol{T}_a,\boldsymbol{T}_b]$ after renaming $a\leftrightarrow b$ and using the antisymmetry of the bracket; the two terms are equal. For the second,

$$[\boldsymbol{\alpha},[\boldsymbol{\alpha},\boldsymbol{\alpha}]]=\alpha^c\wedge\alpha^a\wedge\alpha^b\,C^d{}_{ab}C^e{}_{cd}\,\boldsymbol{T}_e\,,$$

and the 3-form $\alpha^c\wedge\alpha^a\wedge\alpha^b$ is totally antisymmetric in (c,a,b), so only the totally antisymmetric part of the coefficient survives. That part is the cyclic sum $C^d{}_{ab}C^e{}_{cd}+C^d{}_{bc}C^e{}_{ad}+C^d{}_{ca}C^e{}_{bd}$, which vanishes: it is the Jacobi identity for $\mathfrak{g}$ written in the structure constants of Equation (14.5). □

Definition 14.103 (Connection 1-form)**.** Let $P(M,G)$ be a principal bundle. For $X \in \mathfrak{g}$ the *fundamental vector field* $X^\sharp$ is the generator of the flow $p \mapsto p \cdot \mathrm{e}^{tX}$; it is tangent to the fibres, and since the action is free and transitive on each fibre, $X \mapsto X^\sharp_p$ is a linear isomorphism of $\mathfrak{g}$ onto the *vertical* subspace $V_p = \ker \mathrm{d}\pi_p$. A *connection* on P is a $\mathfrak{g}$-valued 1-form $\boldsymbol{A}$ on P with

$$\boxed{\boldsymbol{A}\left(X^\sharp\right) = X \quad \text{for all } X \in \mathfrak{g}\,, \qquad R_g^* \boldsymbol{A} = g^{-1}\boldsymbol{A}g \quad \text{for all } g \in G}\,, \tag{14.138}$$

where R_g is the right action Equation (14.133) and the second condition is written for a matrix group, the adjoint action in general. The *horizontal* subspace is $H_p = \ker \boldsymbol{A}_p$.

Rests on Definition 14.97 and Notation 14.101.

Proposition 14.104 (A connection splits the tangent space)**.** *$T_pP = V_p \oplus H_p$ for every $p \in P$, and the projections onto the two summands are $v \mapsto (\boldsymbol{A}(v))^\sharp$ and $v \mapsto hv = v - (\boldsymbol{A}(v))^\sharp$.*

Rests on Definition 14.103.

Proof. *Derives Proposition 14.104.*

For $v \in T_pP$ write $v = (\boldsymbol{A}(v))^\sharp + hv$ with hv defined by that equation. The first term is vertical by construction, and $\boldsymbol{A}(hv) = \boldsymbol{A}(v) - \boldsymbol{A}\left((\boldsymbol{A}(v))^\sharp\right) = \boldsymbol{A}(v) - \boldsymbol{A}(v) = 0$ by the first condition of Equation (14.138), so $hv \in H_p$. The sum is direct: a vector in $V_p \cap H_p$ is $X^\sharp$ for some X, and $0 = \boldsymbol{A}(X^\sharp) = X$ forces it to vanish. □

Definition 14.105 (Curvature 2-form)**.** The *curvature* of the connection $\boldsymbol{A}$ is the $\mathfrak{g}$-valued 2-form

$$\boxed{\boldsymbol{F} = \mathrm{d}\boldsymbol{A} + \frac{1}{2}\,[\boldsymbol{A},\boldsymbol{A}]}\,, \tag{14.139}$$

and the *covariant exterior derivative* of a $\mathfrak{g}$-valued form is $\mathrm{D} = \mathrm{d} + [\boldsymbol{A},\ \cdot\ ]$, the upright D being distinguished from the dimension D as in Notation 14.1.

Rests on Definition 14.103 and Notation 14.101.

Proposition 14.106 (The curvature is horizontal, and measures non-integrability)**.** *For all $v, w \in T_pP$,*

$$\boldsymbol{F}(v,w) = \mathrm{d}\boldsymbol{A}\,(hv, hw)\ . \tag{14.140}$$

In particular $\boldsymbol{F}$ vanishes whenever either argument is vertical, and for horizontal vector fields V, W,

$$\boldsymbol{F}(V,W) = -\boldsymbol{A}\,([V,W])\ , \tag{14.141}$$

so that $\boldsymbol{F} = 0$ if and only if the horizontal distribution is closed under the Lie bracket.

Rests on Definition 14.105 and Proposition 14.104.

Proof. *Derives Proposition 14.106.*

By Equation (14.136), $\frac{1}{2}\,[\boldsymbol{A},\boldsymbol{A}]\,(v,w) = [\boldsymbol{A}(v),\boldsymbol{A}(w)]$. By bilinearity it is enough to check Equation (14.140) when each argument is either horizontal or vertical, using Proposition 14.104, and the invariant formula $\mathrm{d}\boldsymbol{A}(V,W) = V\boldsymbol{A}(W) - W\boldsymbol{A}(V) - \boldsymbol{A}\,([V,W])$ for extensions to vector fields. That formula is the coordinate identity $\mathrm{d}\alpha(V,W) = (\partial_\mu\alpha_\nu - \partial_\nu\alpha_\mu)\,V^\mu W^\nu$ of Section 13.6.4, rearranged: the derivatives of the components of V and W cancel against the bracket term.

Both horizontal. Then $\boldsymbol{A}(v) = \boldsymbol{A}(w) = 0$, the bracket term vanishes and $hv = v$, $hw = w$, so both sides are $\mathrm{d}\boldsymbol{A}(v,w)$; extending to horizontal fields and using the invariant formula gives Equation (14.141).

Both vertical, $v = X^\sharp$, $w = Y^\sharp$. The bracket term is $[X,Y]$. For the fundamental fields $\left[X^\sharp, Y^\sharp\right] = [X,Y]^\sharp$, because $X \mapsto X^\sharp$ is the differential of a right action, and $\boldsymbol{A}(X^\sharp) = X$ is constant along P, so the invariant formula gives $\mathrm{d}\boldsymbol{A}(X^\sharp, Y^\sharp) = -\,[X,Y]$. The two cancel, and the right-hand side of Equation (14.140) vanishes because $hv = hw = 0$.

Mixed, v horizontal and $w = Y^\sharp$. The bracket term vanishes, since $\boldsymbol{A}(v) = 0$. Extend v to the horizontal lift V of a vector field on M, which is invariant under every R_g by the second condition of Equation (14.138); then $\left[Y^\sharp, V\right] = 0$, being the derivative along the flow of $Y^\sharp$ — that is, along the action of e^{tY} — of an invariant field. The invariant formula leaves $V\boldsymbol{A}(Y^\sharp) = V(Y) = 0$. Both sides vanish, the right-hand one because $hw = 0$. □

Theorem 14.107 (Bianchi identity)**.** *Every connection satisfies*

$$\boxed{\mathrm{D}\boldsymbol{F} = \mathrm{d}\boldsymbol{F} + [\boldsymbol{A}, \boldsymbol{F}] = 0}\,. \tag{14.142}$$

Rests on Definition 14.105 and Lemma 14.102.

Proof. *Derives Theorem 14.107.*

Differentiate Equation (14.139). Since the exterior derivative squares to zero, and by the first identity of Equation (14.137),

$$\mathrm{d}\boldsymbol{F} = \tfrac{1}{2}\,\mathrm{d}\,[\boldsymbol{A}, \boldsymbol{A}] = [\mathrm{d}\boldsymbol{A}, \boldsymbol{A}]\ .$$

On the other hand, by the second identity of Equation (14.137),

$$[\boldsymbol{A}, \boldsymbol{F}] = [\boldsymbol{A}, \mathrm{d}\boldsymbol{A}] + \tfrac{1}{2}\,[\boldsymbol{A}, [\boldsymbol{A}, \boldsymbol{A}]] = [\boldsymbol{A}, \mathrm{d}\boldsymbol{A}]\ .$$

Finally $[\boldsymbol{A}, \mathrm{d}\boldsymbol{A}] = A^a \wedge \mathrm{d}A^b\,[\boldsymbol{T}_a, \boldsymbol{T}_b] = \mathrm{d}A^b \wedge A^a\,[\boldsymbol{T}_a, \boldsymbol{T}_b] = -\,[\mathrm{d}\boldsymbol{A}, \boldsymbol{A}]$, moving the 1-form past the 2-form at no cost in sign and then renaming $a \leftrightarrow b$. The two contributions cancel. □

Remark 14.108 (The same objects on the base)*.* A local section $s : U \longrightarrow P$ (Definition 14.96) pulls the connection and its curvature back to $\mathfrak{g}$-valued forms $s^*\boldsymbol{A}$ and $s^*\boldsymbol{F}$ on the patch $U \subseteq M$; the first is what a physicist calls the gauge potential and the second the field strength. Pullback commutes with d and with the pointwise bracket Equation (14.135), so Equations (14.139) and (14.142) hold verbatim for the pulled-back forms. They depend on the section chosen, which is why a gauge potential is not a tensor on M, and by Proposition 14.98 a single section covering all of M exists only when the bundle is trivial. The sections that follow work on P, where no choice has to be made.

14.7 Invariant polynomials

Consider a principal bundle $P(M, G)$, where M is a D-dimensional differentiable manifold and G a Lie group. We denote the Lie algebra associated with G by $\mathfrak{g} = \mathrm{span}\,\{\boldsymbol{T}_A\}$, with $A = 1, \ldots, \dim \mathfrak{g}$. The possible linear combinations of the $\boldsymbol{T}_A$ form a vector space, which, when no ambiguity is possible, we shall also denote by $\mathfrak{g}$. Let, moreover, $[\ ] : G \to \mathrm{GL}(\mathfrak{g})$ be the linear representation of the Lie group G defined by $[g] : \boldsymbol{B} \mapsto [g]\boldsymbol{B} = g\boldsymbol{B}g^{-1}$, with $g \in G$ and $\boldsymbol{B} = B^A\boldsymbol{T}_A \in \mathfrak{g}$. Finally, let $S_r(\mathfrak{g}, \mathbb{R})$ be the space of real symmetric r-linear functionals, and let $P \in S_r(\mathfrak{g}, \mathbb{R})$, i.e. a mapping of the form

$$P : \underbrace{\mathfrak{g} \otimes \cdots \otimes \mathfrak{g}}_{r \text{ times}} \longrightarrow \mathbb{R} \tag{14.143}$$

satisfying the following axioms:

1. the mapping is an r-linear transformation, i.e.

$$P(\boldsymbol{B}_1, \ldots, a\boldsymbol{B} + b\boldsymbol{C}, \ldots, \boldsymbol{B}_r) = a\,P(\boldsymbol{B}_1, \ldots, \boldsymbol{B}, \ldots, \boldsymbol{B}_r) + b\,P(\boldsymbol{B}_1, \ldots, \boldsymbol{C}, \ldots, \boldsymbol{B}_r)\,, \tag{14.144}$$

2. the mapping is totally symmetric:

$$P(\boldsymbol{B}_1,\dots,\boldsymbol{B}_i,\dots,\boldsymbol{B}_j,\dots,\boldsymbol{B}_r) = P(\boldsymbol{B}_1,\dots,\boldsymbol{B}_j,\dots,\boldsymbol{B}_i,\dots,\boldsymbol{B}_r)\,, \quad \forall\, i,j\,. \tag{14.145}$$

Of all these totally symmetric polynomials, we shall concentrate on those that are invariant under the action induced by the representation [ ] of the Lie group G, which is enshrined in the following definition.

Definition 14.109 (G-invariant polynomial)**.** We say that $P \in S_r(\mathfrak{g},\mathbb{R})$ is a *G-invariant polynomial* if

$$\forall\, g \in G, \quad \forall\, \boldsymbol{B}_l \in \mathfrak{g},\ l = 1,\dots,r, \quad P\left([g]\boldsymbol{B}_1,\dots,[g]\boldsymbol{B}_r\right) = P\left(\boldsymbol{B}_1,\dots,\boldsymbol{B}_r\right)\,,$$

where $[g]\boldsymbol{B} = g\boldsymbol{B}g^{-1}$. We introduce, moreover, the notation $P\left(\boldsymbol{B}_1,\dots,\boldsymbol{B}_r\right) = \langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_r\rangle$. Throughout this chapter the angle brackets denote this multilinear functional and nothing else; a linear span is written span. The brackets appear once before this definition, in the proof of Proposition 14.54, and there they already carry the meaning fixed here.

Rests on Equations (14.144) *and* (14.145)*.*

The polynomial extends to $\mathfrak{g}$-valued differential forms by multilinearity: if $\boldsymbol{B}_l = B_l^{A_l}\boldsymbol{T}_{A_l}$ with $B_l^{A_l}$ ordinary p_l-forms, then $\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_r\rangle = B_1^{A_1}\cdots B_r^{A_r}\,\langle \boldsymbol{T}_{A_1},\dots,\boldsymbol{T}_{A_r}\rangle$, where the product of the component forms is the wedge product.

Theorem 14.110. *Let $\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_r\rangle$ be a G-invariant polynomial evaluated on $\mathfrak{g}$-valued differential forms of degrees $p_1,\dots,p_r$ defined on the principal bundle $P(M,G)$.*

1. *One has*

$$\mathrm{d}\,\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_r\rangle = \sum_{l=1}^{r}(-1)^{p_1+\cdots+p_{l-1}}\,\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_{l-1},\mathrm{d}\boldsymbol{B}_l,\boldsymbol{B}_{l+1},\dots,\boldsymbol{B}_r\rangle\,, \tag{14.146}$$

$$\mathrm{D}\,\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_r\rangle = \sum_{l=1}^{r}(-1)^{p_1+\cdots+p_{l-1}}\,\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_{l-1},\mathrm{D}\boldsymbol{B}_l,\boldsymbol{B}_{l+1},\dots,\boldsymbol{B}_r\rangle\,, \tag{14.147}$$

   where d *is the exterior derivative and* $\mathrm{D} = \mathrm{d} + [\boldsymbol{A},\ \cdot\ ]$ *is the covariant exterior derivative, with $\boldsymbol{A}$ a connection defined on $P(M,G)$.*

2. *Let $\{\boldsymbol{T}_A\}$ be a basis of the Lie algebra $\mathfrak{g}$ associated with the Lie group G. One has*

$$\sum_{l=1}^{r} C_{AA_l}{}^{B}\left\langle \boldsymbol{T}_{A_1},\dots,\boldsymbol{T}_{A_{l-1}},\boldsymbol{T}_B,\boldsymbol{T}_{A_{l+1}},\dots,\boldsymbol{T}_{A_r}\right\rangle = 0\,. \tag{14.148}$$

3. *Let, moreover, $\boldsymbol{B} = B^A\boldsymbol{T}_A$ be a $\mathfrak{g}$-valued p-form. Then*

$$\sum_{l=1}^{r}(-1)^{p(p_1+\cdots+p_{l-1})}\,\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_{l-1},[\boldsymbol{B},\boldsymbol{B}_l],\boldsymbol{B}_{l+1},\dots,\boldsymbol{B}_r\rangle = 0\,. \tag{14.149}$$

4. *One has*

$$\mathrm{D}\,\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_r\rangle = \mathrm{d}\,\langle \boldsymbol{B}_1,\dots,\boldsymbol{B}_r\rangle\,. \tag{14.150}$$

Rests on Definition 14.109 and Equation (14.5)*.*

Proof. *Derives Theorem 14.110.*

We prove the four statements in turn.

1. Expanding $\boldsymbol{B}_1, \dots, \boldsymbol{B}_r$ in the basis $\{\boldsymbol{T}_A\}$ of the Lie algebra $\mathfrak{g}$ of the group G and using the linearity of the polynomial, we have $\mathrm{d}\,\langle \boldsymbol{B}_1, \dots, \boldsymbol{B}_r\rangle = \mathrm{d}\left(B_1^{A_1}\cdots B_r^{A_r}\right)\langle \boldsymbol{T}_{A_1}, \dots, \boldsymbol{T}_{A_r}\rangle$. By the graded Leibniz rule for the exterior derivative,

$$\begin{aligned}\mathrm{d}\left(B_1^{A_1}\cdots B_r^{A_r}\right) &= \mathrm{d}B_1^{A_1}\, B_2^{A_2}\cdots B_r^{A_r} + (-1)^{p_1} B_1^{A_1}\,\mathrm{d}B_2^{A_2}\, B_3^{A_3}\cdots B_r^{A_r}\\ &\quad + \cdots + (-1)^{p_1+\cdots+p_{r-1}} B_1^{A_1}\cdots B_{r-1}^{A_{r-1}}\,\mathrm{d}B_r^{A_r}\\ &= \sum_{l=1}^{r}(-1)^{p_1+\cdots+p_{l-1}} B_1^{A_1}\cdots B_{l-1}^{A_{l-1}}\,\mathrm{d}B_l^{A_l}\, B_{l+1}^{A_{l+1}}\cdots B_r^{A_r}\,,\end{aligned}$$

and hence

$$\begin{aligned}&\mathrm{d}\,\langle \boldsymbol{B}_1, \dots, \boldsymbol{B}_r\rangle\\ &= \sum_{l=1}^{r}(-1)^{p_1+\cdots+p_{l-1}} B_1^{A_1}\cdots B_{l-1}^{A_{l-1}}\,\mathrm{d}B_l^{A_l}\, B_{l+1}^{A_{l+1}}\cdots B_r^{A_r}\,\langle \boldsymbol{T}_{A_1}, \dots, \boldsymbol{T}_{A_r}\rangle\\ &= \sum_{l=1}^{r}(-1)^{p_1+\cdots+p_{l-1}}\,\langle \boldsymbol{B}_1, \dots, \boldsymbol{B}_{l-1}, \mathrm{d}\boldsymbol{B}_l, \boldsymbol{B}_{l+1}, \dots, \boldsymbol{B}_r\rangle\,.\end{aligned}$$

The expression Equation (14.147) for the covariant exterior derivative is proved by an entirely analogous procedure, yielding the claim.

2. From the definition of a G-invariant polynomial we have

$$\langle \boldsymbol{T}_{A_1}, \dots, \boldsymbol{T}_{A_r}\rangle = \langle [g]\boldsymbol{T}_{A_1}, \dots, [g]\boldsymbol{T}_{A_r}\rangle = \left\langle g\boldsymbol{T}_{A_1}g^{-1}, \dots, g\boldsymbol{T}_{A_r}g^{-1}\right\rangle\,, \tag{14.151}$$

where $g = \mathrm{e}^{t^A\boldsymbol{T}_A}$ is an element of the Lie group G. Furthermore, since the generators $\boldsymbol{T}_A$ do not depend on the parameters of the infinitesimal transformations, neither does the polynomial $\langle \boldsymbol{T}_{A_1}, \dots, \boldsymbol{T}_{A_r}\rangle$; therefore $\frac{\mathrm{d}}{\mathrm{d}t^A}\langle \boldsymbol{T}_{A_1}, \dots, \boldsymbol{T}_{A_r}\rangle\Big|_{t^A=0} = 0$, and from Equation (14.151) we arrive at

$$\frac{\mathrm{d}}{\mathrm{d}t^A}\left\langle g\boldsymbol{T}_{A_1}g^{-1}, \dots, g\boldsymbol{T}_{A_r}g^{-1}\right\rangle\Big|_{t^A=0} = 0\,. \tag{14.152}$$

From part 1 — analogously to the procedure used to prove Equation (14.146) — one obtains

$$\begin{aligned}&\frac{\mathrm{d}}{\mathrm{d}t^A}\left\langle g\boldsymbol{T}_{A_1}g^{-1}, \dots, g\boldsymbol{T}_{A_r}g^{-1}\right\rangle\\ &= \sum_{l=1}^{r}\left\langle g\boldsymbol{T}_{A_1}g^{-1}, \dots, g\boldsymbol{T}_{A_{l-1}}g^{-1}, \frac{\mathrm{d}}{\mathrm{d}t^A}\left(g\boldsymbol{T}_{A_l}g^{-1}\right), g\boldsymbol{T}_{A_{l+1}}g^{-1}, \dots, g\boldsymbol{T}_{A_r}g^{-1}\right\rangle\,,\end{aligned} \tag{14.153}$$

but $g\boldsymbol{T}_Ag^{-1}\big|_{t^A=0} = \mathrm{e}^{t^B\boldsymbol{T}_B}\boldsymbol{T}_A\,\mathrm{e}^{-t^C\boldsymbol{T}_C}\Big|_{t^A=0} = \boldsymbol{T}_A$, and moreover

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t^A}\left(g\boldsymbol{T}_Bg^{-1}\right)\Big|_{t^A=0} &= \left(\frac{\mathrm{d}}{\mathrm{d}t^A}\left(\mathrm{e}^{t^C\boldsymbol{T}_C}\right)\boldsymbol{T}_B\,\mathrm{e}^{-t^E\boldsymbol{T}_E} + \mathrm{e}^{t^C\boldsymbol{T}_C}\boldsymbol{T}_B\,\frac{\mathrm{d}}{\mathrm{d}t^A}\left(\mathrm{e}^{-t^E\boldsymbol{T}_E}\right)\right)\Big|_{t^A=0}\\ &= \left(\mathrm{e}^{t^C\boldsymbol{T}_C}\boldsymbol{T}_A\boldsymbol{T}_B\,\mathrm{e}^{-t^E\boldsymbol{T}_E} - \mathrm{e}^{t^C\boldsymbol{T}_C}\boldsymbol{T}_B\,\mathrm{e}^{-t^E\boldsymbol{T}_E}\boldsymbol{T}_A\right)\Big|_{t^A=0}\\ &= [\boldsymbol{T}_A, \boldsymbol{T}_B]\\ &= C_{AB}{}^C\,\boldsymbol{T}_C\,,\end{aligned}$$

so that we finally conclude from Equation (14.152) and Equation (14.153) that the claim holds.

3. In the basis $\{\boldsymbol{T}_A\}$ we have

$$\begin{aligned}
&\langle \boldsymbol{B}_1, \dots, \boldsymbol{B}_{l-1}, [\boldsymbol{B}, \boldsymbol{B}_l], \boldsymbol{B}_{l+1}, \dots, \boldsymbol{B}_r \rangle \\
&= B_1^{A_1} \cdots B_{l-1}^{A_{l-1}} B^A B_l^{A_l} B_{l+1}^{A_{l+1}} \cdots B_r^{A_r} \left\langle \boldsymbol{T}_{A_1}, \dots, \boldsymbol{T}_{A_{l-1}}, [\boldsymbol{T}_A, \boldsymbol{T}_{A_l}], \boldsymbol{T}_{A_{l+1}}, \dots, \boldsymbol{T}_{A_r} \right\rangle \\
&= (-1)^{p(p_1+\cdots+p_{l-1})} B^A B_1^{A_1} \cdots B_{l-1}^{A_{l-1}} B_l^{A_l} B_{l+1}^{A_{l+1}} \cdots B_r^{A_r} \\
&\quad \times \left\langle \boldsymbol{T}_{A_1}, \dots, \boldsymbol{T}_{A_{l-1}}, C_{AA_l}{}^B \boldsymbol{T}_B, \boldsymbol{T}_{A_{l+1}}, \dots, \boldsymbol{T}_{A_r} \right\rangle ,
\end{aligned}$$

where the sign arises from commuting the p-form components B^A past the forms $B_1^{A_1}, \dots, B_{l-1}^{A_{l-1}}$ of total degree $p_1 + \cdots + p_{l-1}$. Hence

$$\begin{aligned}
&(-1)^{p(p_1+\cdots+p_{l-1})} \langle \boldsymbol{B}_1, \dots, \boldsymbol{B}_{l-1}, [\boldsymbol{B}, \boldsymbol{B}_l], \boldsymbol{B}_{l+1}, \dots, \boldsymbol{B}_r \rangle \\
&= B^A B_1^{A_1} \cdots B_r^{A_r} C_{AA_l}{}^B \left\langle \boldsymbol{T}_{A_1}, \dots, \boldsymbol{T}_{A_{l-1}}, \boldsymbol{T}_B, \boldsymbol{T}_{A_{l+1}}, \dots, \boldsymbol{T}_{A_r} \right\rangle ,
\end{aligned}$$

so that, summing over all values of $l = 1, \dots, r$, part 2 yields the desired result.

4. Since $\mathrm{D} = \mathrm{d} + [\boldsymbol{A}, \ \cdot\ ]$, from part 1 we see that

$$\mathrm{D} \langle \boldsymbol{B}_1, \dots, \boldsymbol{B}_r \rangle = \mathrm{d} \langle \boldsymbol{B}_1, \dots, \boldsymbol{B}_r \rangle + \sum_{l=1}^{r} (-1)^{p_1+\cdots+p_{l-1}} \langle \boldsymbol{B}_1, \dots, \boldsymbol{B}_{l-1}, [\boldsymbol{A}, \boldsymbol{B}_l], \boldsymbol{B}_{l+1}, \dots, \boldsymbol{B}_r \rangle .$$

From part 3 with $\boldsymbol{B} = \boldsymbol{A}$ and $p = 1$ — since the connection is a 1-form — the second term vanishes.

□

14.8 The Chern–Weil theorem and transgression forms

Theorem 14.111 (Chern–Weil)**.** *Let $P(M, G)$ be a principal bundle equipped with a connection 1-form $\boldsymbol{A}$ of curvature $\boldsymbol{F} = \mathrm{d}\boldsymbol{A} + \frac{1}{2}[\boldsymbol{A}, \boldsymbol{A}]$, and let P be a G-invariant polynomial of degree r. Then:*

1. *$P(\boldsymbol{F}, \dots, \boldsymbol{F}) = \langle \boldsymbol{F}, \dots, \boldsymbol{F} \rangle$ is a closed form, i.e. $\mathrm{d} \langle \boldsymbol{F}, \dots, \boldsymbol{F} \rangle = 0$.*
2. *If $\boldsymbol{F}$ and $\bar{\boldsymbol{F}}$ are the curvature 2-forms corresponding to the connections $\boldsymbol{A}$ and $\bar{\boldsymbol{A}}$ respectively, both defined on $P(M, G)$, then $\langle \boldsymbol{F}, \dots, \boldsymbol{F} \rangle - \left\langle \bar{\boldsymbol{F}}, \dots, \bar{\boldsymbol{F}} \right\rangle$ is an exact form, i.e.*

$$\langle \boldsymbol{F}, \dots, \boldsymbol{F} \rangle - \left\langle \bar{\boldsymbol{F}}, \dots, \bar{\boldsymbol{F}} \right\rangle = \mathrm{d}Q^{(2r-1)}(\boldsymbol{A}, \bar{\boldsymbol{A}}) , \tag{14.154}$$

where the $(2r-1)$-form $Q^{(2r-1)}(\boldsymbol{A}, \bar{\boldsymbol{A}})$ is called the transgression form *of the polynomial P and is explicitly given by*

$$Q^{(2r-1)}(\boldsymbol{A}, \bar{\boldsymbol{A}}) = r \int_0^1 \left\langle \boldsymbol{A} - \bar{\boldsymbol{A}}, \boldsymbol{F}_t, \dots, \boldsymbol{F}_t \right\rangle \mathrm{d}t , \tag{14.155}$$

where $\boldsymbol{F}_t = \mathrm{d}\boldsymbol{A}_t + \frac{1}{2}[\boldsymbol{A}_t, \boldsymbol{A}_t]$ is the interpolating field strength *corresponding to the* interpolating connection *$\boldsymbol{A}_t$ defined as*

$$\boldsymbol{A}_t(\boldsymbol{A}, \bar{\boldsymbol{A}}) = \bar{\boldsymbol{A}} + t \left(\boldsymbol{A} - \bar{\boldsymbol{A}} \right) , \qquad 0 \le t \le 1 . \tag{14.156}$$

Rests on Theorem 14.110 and Equations (14.139) and (14.142).

Proof. *Derives Theorem 14.111.*

Theorem 14.110 is the principal tool.

1. Consider part 1 of Theorem 14.110, in its covariant form Equation (14.147), for $\boldsymbol{B}_1, \dots, \boldsymbol{B}_r = \boldsymbol{F}$, so that $p_1, \dots, p_r = 2$. We obtain

$$\begin{aligned} \mathrm{D}\left\langle \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle &= \sum_{l=1}^{r} (-1)^{2+\dots+2} \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, \mathrm{D}\boldsymbol{F}, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle \\ &= \sum_{l=1}^{r} \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, \mathrm{D}\boldsymbol{F}, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle \\ &= r \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, \mathrm{D}\boldsymbol{F}, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle . \end{aligned} \tag{14.157}$$

   From the Bianchi identity we have $\mathrm{D}\boldsymbol{F} = \mathrm{d}\boldsymbol{F} + [\boldsymbol{A}, \boldsymbol{F}] = 0$, and $\langle \boldsymbol{F}, \dots, \boldsymbol{F}, 0, \boldsymbol{F}, \dots, \boldsymbol{F} \rangle = 0$ as a direct consequence of multilinearity:

$$\begin{aligned} \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, 0, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle &= \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, \boldsymbol{B} - \boldsymbol{B}, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle \\ &= \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, \boldsymbol{B}, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle + \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, -\boldsymbol{B}, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle \\ &= \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, \boldsymbol{B}, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle - \left\langle \boldsymbol{F}, \dots, \boldsymbol{F}, \boldsymbol{B}, \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle \\ &= 0 . \end{aligned}$$

   Together with part 4 of Theorem 14.110, which gives $\mathrm{d}\left\langle \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle = \mathrm{D}\left\langle \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle = 0$, this proves the statement.

2. Write $\boldsymbol{\theta} = \boldsymbol{A} - \bar{\boldsymbol{A}}$, so that $\boldsymbol{A}_0 = \bar{\boldsymbol{A}}$ and $\boldsymbol{A}_1 = \bar{\boldsymbol{A}} + \boldsymbol{\theta} = \boldsymbol{A}$, and denote by $\bar{\mathrm{D}} = \mathrm{d} + \left[\bar{\boldsymbol{A}}, \ \cdot\ \right]$ the covariant exterior derivative of the connection $\bar{\boldsymbol{A}}$. The field strength corresponding to $\boldsymbol{A}_t$ is given by $\boldsymbol{F}_t = \mathrm{d}\boldsymbol{A}_t + \frac{1}{2}[\boldsymbol{A}_t, \boldsymbol{A}_t]$, so that $\boldsymbol{F}_0 = \bar{\boldsymbol{F}}$ and $\boldsymbol{F}_1 = \boldsymbol{F}$. We have

$$\left\langle \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle - \left\langle \bar{\boldsymbol{F}}, \dots, \bar{\boldsymbol{F}} \right\rangle = \left\langle \boldsymbol{F}_1, \dots, \boldsymbol{F}_1 \right\rangle - \left\langle \boldsymbol{F}_0, \dots, \boldsymbol{F}_0 \right\rangle = \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t} \left\langle \boldsymbol{F}_t, \dots, \boldsymbol{F}_t \right\rangle \mathrm{d}t .$$

   Analogously to the procedure used to obtain Equation (14.146), one finds

$$\left\langle \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle - \left\langle \bar{\boldsymbol{F}}, \dots, \bar{\boldsymbol{F}} \right\rangle = \int_0^1 \sum_{l=1}^{r} \left\langle \boldsymbol{F}_t, \dots, \boldsymbol{F}_t, \frac{\mathrm{d}\boldsymbol{F}_t}{\mathrm{d}t}, \boldsymbol{F}_t, \dots, \boldsymbol{F}_t \right\rangle \mathrm{d}t .$$

   Since the summand does not depend on the index l, and since a G-invariant polynomial is by definition totally symmetric, we obtain r equal terms, arriving at

$$\left\langle \boldsymbol{F}, \dots, \boldsymbol{F} \right\rangle - \left\langle \bar{\boldsymbol{F}}, \dots, \bar{\boldsymbol{F}} \right\rangle = r \int_0^1 \left\langle \frac{\mathrm{d}\boldsymbol{F}_t}{\mathrm{d}t}, \boldsymbol{F}_t, \dots, \boldsymbol{F}_t \right\rangle \mathrm{d}t .$$

   To compute the derivative of the interpolating field strength $\boldsymbol{F}_t$ with respect to t, observe that

$$\begin{aligned} \boldsymbol{F}_t &= \mathrm{d}\boldsymbol{A}_t + \frac{1}{2}[\boldsymbol{A}_t, \boldsymbol{A}_t] \\ &= \mathrm{d}\bar{\boldsymbol{A}} + t\,\mathrm{d}\boldsymbol{\theta} + \frac{1}{2}\left[\bar{\boldsymbol{A}} + t\boldsymbol{\theta}, \bar{\boldsymbol{A}} + t\boldsymbol{\theta}\right] \\ &= \mathrm{d}\bar{\boldsymbol{A}} + t\,\mathrm{d}\boldsymbol{\theta} + \frac{1}{2}\left[\bar{\boldsymbol{A}}, \bar{\boldsymbol{A}}\right] + \frac{t}{2}\left[\bar{\boldsymbol{A}}, \boldsymbol{\theta}\right] + \frac{t}{2}\left[\boldsymbol{\theta}, \bar{\boldsymbol{A}}\right] + \frac{t^2}{2}[\boldsymbol{\theta}, \boldsymbol{\theta}] \\ &= \mathrm{d}\bar{\boldsymbol{A}} + \frac{1}{2}\left[\bar{\boldsymbol{A}}, \bar{\boldsymbol{A}}\right] + t\,\mathrm{d}\boldsymbol{\theta} + t\left[\bar{\boldsymbol{A}}, \boldsymbol{\theta}\right] + \frac{t^2}{2}[\boldsymbol{\theta}, \boldsymbol{\theta}] , \end{aligned}$$

   that is,

$$\boldsymbol{F}_t = \bar{\boldsymbol{F}} + t\,\bar{\mathrm{D}}\boldsymbol{\theta} + \frac{t^2}{2}[\boldsymbol{\theta}, \boldsymbol{\theta}] , \tag{14.158}$$

so that $\frac{\mathrm{d}\boldsymbol{F}_t}{\mathrm{d}t} = \bar{\mathrm{D}}\boldsymbol{\theta} + t\,[\boldsymbol{\theta},\boldsymbol{\theta}]$, and thus

$$\langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle - \left\langle \bar{\boldsymbol{F}},\dots,\bar{\boldsymbol{F}}\right\rangle = r\int_0^1 \left\langle \boldsymbol{F}_t,\dots,\boldsymbol{F}_t,\bar{\mathrm{D}}\boldsymbol{\theta} + t\,[\boldsymbol{\theta},\boldsymbol{\theta}],\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle \mathrm{d}t\,.$$

Since the polynomial is totally symmetric we may write

$$\langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle - \left\langle \bar{\boldsymbol{F}},\dots,\bar{\boldsymbol{F}}\right\rangle = r\int_0^1 \left\langle \bar{\mathrm{D}}\boldsymbol{\theta} + t\,[\boldsymbol{\theta},\boldsymbol{\theta}],\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle \mathrm{d}t\,. \tag{14.159}$$

On the other hand, applying part 1 of Theorem 14.110 — for the connection $\bar{\boldsymbol{A}}$ — with $\boldsymbol{B}_1 = \boldsymbol{\theta}$ and $\boldsymbol{B}_2,\dots,\boldsymbol{B}_r = \boldsymbol{F}_t$, so that $p_1 = 1$ and $p_2,\dots,p_r = 2$, together with part 4, we observe that

$$\begin{aligned}
\mathrm{d}\,\langle \boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle &= \bar{\mathrm{D}}\,\langle \boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle \\
&= \left\langle \bar{\mathrm{D}}\boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle + \sum_{l=2}^{r}(-1)^{1+2+\cdots+2}\left\langle \boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t,\bar{\mathrm{D}}\boldsymbol{F}_t,\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle \\
&= \left\langle \bar{\mathrm{D}}\boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle - (r-1)\left\langle \boldsymbol{\theta},\bar{\mathrm{D}}\boldsymbol{F}_t,\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle\,.
\end{aligned} \tag{14.160}$$

Recall that the difference of two connections is a tensor, and that a connection plus a tensor defines a new connection. In this way $\boldsymbol{A}_t$ determines a connection on the bundle, to which corresponds a covariant derivative $\mathrm{D}_{\boldsymbol{A}_t} = \mathrm{d} + [\boldsymbol{A}_t,\ \cdot\ ]$. For the field strength $\boldsymbol{F}_t$ we have the Bianchi identity $\mathrm{D}_{\boldsymbol{A}_t}\boldsymbol{F}_t = 0$, which implies

$$\begin{aligned}
\mathrm{d}\boldsymbol{F}_t + [\boldsymbol{A}_t,\boldsymbol{F}_t] &= 0\,,\\
\mathrm{d}\boldsymbol{F}_t + \left[\bar{\boldsymbol{A}} + t\boldsymbol{\theta},\boldsymbol{F}_t\right] &= 0\,,\\
\mathrm{d}\boldsymbol{F}_t + \left[\bar{\boldsymbol{A}},\boldsymbol{F}_t\right] + t\,[\boldsymbol{\theta},\boldsymbol{F}_t] &= 0\,,\\
\Longrightarrow\ \bar{\mathrm{D}}\boldsymbol{F}_t &= -t\,[\boldsymbol{\theta},\boldsymbol{F}_t]\ ,
\end{aligned}$$

so that

$$\mathrm{d}\,\langle \boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle = \left\langle \bar{\mathrm{D}}\boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle + t(r-1)\,\langle \boldsymbol{\theta},[\boldsymbol{\theta},\boldsymbol{F}_t],\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle\ . \tag{14.161}$$

Finally, applying part 3 of Theorem 14.110 with $\boldsymbol{B} = \boldsymbol{\theta}$, $\boldsymbol{B}_1 = \boldsymbol{\theta}$ and $\boldsymbol{B}_2,\dots,\boldsymbol{B}_r = \boldsymbol{F}_t$, so that $p = 1$, $p_1 = 1$ and $p_2,\dots,p_r = 2$, we obtain

$$\begin{aligned}
\langle [\boldsymbol{\theta},\boldsymbol{\theta}],\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle + \sum_{l=2}^{r}(-1)^{1\cdot(1+2+\cdots+2)}\,\langle \boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t,[\boldsymbol{\theta},\boldsymbol{F}_t],\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle &= 0\,,\\
\Longrightarrow\ \langle [\boldsymbol{\theta},\boldsymbol{\theta}],\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle - (r-1)\,\langle \boldsymbol{\theta},[\boldsymbol{\theta},\boldsymbol{F}_t],\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle &= 0\,,
\end{aligned}$$

from which we see that Equation (14.161) becomes $\mathrm{d}\,\langle \boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle = \left\langle \bar{\mathrm{D}}\boldsymbol{\theta} + t\,[\boldsymbol{\theta},\boldsymbol{\theta}],\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle$. Substituting this result into Equation (14.159), we obtain

$$\begin{aligned}
\langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle - \left\langle \bar{\boldsymbol{F}},\dots,\bar{\boldsymbol{F}}\right\rangle &= r\int_0^1 \mathrm{d}\,\langle \boldsymbol{\theta},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\rangle\ \mathrm{d}t\\
&= \mathrm{d}\left(r\int_0^1 \left\langle \boldsymbol{A}-\bar{\boldsymbol{A}},\boldsymbol{F}_t,\dots,\boldsymbol{F}_t\right\rangle \mathrm{d}t\right)\\
&= \mathrm{d}Q^{(2r-1)}(\boldsymbol{A},\bar{\boldsymbol{A}})\,.
\end{aligned}$$

□

14.8.1 Chern–Simons forms

Definition 14.112 (Chern–Simons form)**.** Let $P(\boldsymbol{F}) = \langle \boldsymbol{F}, \dots, \boldsymbol{F} \rangle$ be a G-invariant polynomial of degree r. By the Chern–Weil theorem we know that $\langle \boldsymbol{F}, \dots, \boldsymbol{F} \rangle$ is a closed form, and it can therefore be written locally as $\langle \boldsymbol{F}, \dots, \boldsymbol{F} \rangle = \mathrm{d}Q^{(2r-1)}(\boldsymbol{A})$. The $(2r-1)$-form $Q^{(2r-1)}(\boldsymbol{A})$ is called the *Chern–Simons form* corresponding to the polynomial P.

Rests on Theorem 14.111 and Definition 14.109.

By the Chern–Weil theorem we have

$$\mathrm{d}Q^{(2r-1)}(\boldsymbol{A}) - \mathrm{d}Q^{(2r-1)}(\bar{\boldsymbol{A}}) = \mathrm{d}\left(r \int_0^1 \mathrm{d}t \left\langle \boldsymbol{A} - \bar{\boldsymbol{A}}, \boldsymbol{F}_t, \dots, \boldsymbol{F}_t \right\rangle \right) ,$$

so that for $\bar{\boldsymbol{A}} = 0$ one has $Q^{(2r-1)}(\bar{\boldsymbol{A}}) = 0$ and thus

$$Q^{(2r-1)}(\boldsymbol{A}) = r \int_0^1 \mathrm{d}t \, \langle \boldsymbol{A}, \boldsymbol{F}_t, \dots, \boldsymbol{F}_t \rangle \, . \tag{14.162}$$

However, an important warning must be made: since the coordinate transformation law of a connection is inhomogeneous, it is impossible to choose a connection that vanishes globally. Note, moreover, that locally a transgression form with $\bar{\boldsymbol{A}} = 0$ corresponds to a Chern–Simons form (which is, of course, defined locally):

$$Q^{(2r-1)}(\boldsymbol{A}, 0) = Q^{(2r-1)}(\boldsymbol{A}) \, . \tag{14.163}$$

When $\bar{\boldsymbol{A}} = 0$, the interpolating connection is given by $\boldsymbol{A}_t = t\boldsymbol{A}$, with $0 \leq t \leq 1$, so that $\boldsymbol{A}_0 = 0$ and $\boldsymbol{A}_1 = \boldsymbol{A}$. The interpolating field strength corresponding to $\boldsymbol{A}_t$ is given by

$$\begin{aligned} \boldsymbol{F}_t &= \mathrm{d}\boldsymbol{A}_t + \frac{1}{2} [\boldsymbol{A}_t, \boldsymbol{A}_t] \\ &= t \, \mathrm{d}\boldsymbol{A} + \frac{t^2}{2} [\boldsymbol{A}, \boldsymbol{A}] \\ &= t \left(\boldsymbol{F} - \frac{1}{2} [\boldsymbol{A}, \boldsymbol{A}] \right) + \frac{t^2}{2} [\boldsymbol{A}, \boldsymbol{A}] \\ &= t\boldsymbol{F} + \frac{1}{2} t(t-1) [\boldsymbol{A}, \boldsymbol{A}] \, . \end{aligned}$$

From Equation (14.155) we then find that the sought Chern–Simons form is

$$Q^{(2r-1)}(\boldsymbol{A}) = r \int_0^1 \mathrm{d}t \, t^{r-1} \left\langle \boldsymbol{A}, \boldsymbol{F} + \frac{1}{2}(t-1) [\boldsymbol{A}, \boldsymbol{A}], \dots, \boldsymbol{F} + \frac{1}{2}(t-1) [\boldsymbol{A}, \boldsymbol{A}] \right\rangle . \tag{14.164}$$

The source manuscript stops at Equation (14.164). The three things it was evidently going to do next — evaluate the Chern–Simons forms in the degrees that occur, name the invariant polynomials whose Chern–Weil forms are the characteristic classes, and apply the construction to an $\mathrm{SO}(p, q)$ connection — are done here, and the chapter closes with them.

Proposition 14.113 (The Chern–Simons forms of degree 3 and 5)**.** *For $r = 2$ and $r = 3$, Equation (14.164) evaluates to*

$$Q^{(3)}(\boldsymbol{A}) = \langle \boldsymbol{A}, \boldsymbol{F} \rangle - \tfrac{1}{6} \langle \boldsymbol{A}, [\boldsymbol{A}, \boldsymbol{A}] \rangle \, , \tag{14.165}$$

$$Q^{(5)}(\boldsymbol{A}) = \langle \boldsymbol{A}, \boldsymbol{F}, \boldsymbol{F} \rangle - \tfrac{1}{4} \langle \boldsymbol{A}, \boldsymbol{F}, [\boldsymbol{A}, \boldsymbol{A}] \rangle + \tfrac{1}{40} \langle \boldsymbol{A}, [\boldsymbol{A}, \boldsymbol{A}], [\boldsymbol{A}, \boldsymbol{A}] \rangle \, . \tag{14.166}$$

When the invariant polynomial is the trace of a product of matrices in some representation, $\langle \boldsymbol{X}, \boldsymbol{Y} \rangle = \mathrm{tr}(\boldsymbol{XY})$, Equation (14.165) takes the familiar form

$$\boxed{Q^{(3)}(\boldsymbol{A}) = \mathrm{tr} \left(\boldsymbol{A} \wedge \mathrm{d}\boldsymbol{A} + \tfrac{2}{3} \boldsymbol{A} \wedge \boldsymbol{A} \wedge \boldsymbol{A} \right)} \, . \tag{14.167}$$

Rests on Equation (14.164) and Definitions 14.109 and 14.112.

Proof. *Derives Proposition 14.113.*

Abbreviate $\boldsymbol{G}_t = \boldsymbol{F} + \frac{1}{2}(t-1)\,[\boldsymbol{A},\boldsymbol{A}]$, which is the entry appearing in every slot but the first of Equation (14.164). For $r=2$ there is one such slot, and linearity gives

$$Q^{(3)} = 2\int_0^1 \mathrm{d}t\, t\,\langle \boldsymbol{A}, \boldsymbol{G}_t\rangle = 2\,\langle \boldsymbol{A},\boldsymbol{F}\rangle \int_0^1 t\,\mathrm{d}t + \langle \boldsymbol{A},[\boldsymbol{A},\boldsymbol{A}]\rangle \int_0^1 t(t-1)\,\mathrm{d}t\,,$$

and the two integrals are $1/2$ and $1/3 - 1/2 = -1/6$, which is Equation (14.165). For $r=3$ there are two such slots, and by total symmetry

$$\langle \boldsymbol{A},\boldsymbol{G}_t,\boldsymbol{G}_t\rangle = \langle \boldsymbol{A},\boldsymbol{F},\boldsymbol{F}\rangle + (t-1)\,\langle \boldsymbol{A},\boldsymbol{F},[\boldsymbol{A},\boldsymbol{A}]\rangle + \tfrac{1}{4}(t-1)^2\,\langle \boldsymbol{A},[\boldsymbol{A},\boldsymbol{A}],[\boldsymbol{A},\boldsymbol{A}]\rangle\,,$$

so that the three coefficients of Equation (14.166) are $3\int_0^1 t^2\mathrm{d}t = 1$, $3\int_0^1 t^2(t-1)\mathrm{d}t = 3\left(\frac{1}{4}-\frac{1}{3}\right) = -\frac{1}{4}$ and $\frac{3}{4}\int_0^1 t^2(t-1)^2\mathrm{d}t = \frac{3}{4}\left(\frac{1}{5}-\frac{1}{2}+\frac{1}{3}\right) = \frac{1}{40}$.

For Equation (14.167), matrix-valued 1-forms obey $[\boldsymbol{A},\boldsymbol{A}] = 2\,\boldsymbol{A}\wedge\boldsymbol{A}$ by Equation (14.135), so $\langle \boldsymbol{A},\boldsymbol{F}\rangle = \operatorname{tr}(\boldsymbol{A}\wedge\mathrm{d}\boldsymbol{A}) + \operatorname{tr}(\boldsymbol{A}\wedge\boldsymbol{A}\wedge\boldsymbol{A})$ and $\frac{1}{6}\langle \boldsymbol{A},[\boldsymbol{A},\boldsymbol{A}]\rangle = \frac{1}{3}\operatorname{tr}(\boldsymbol{A}\wedge\boldsymbol{A}\wedge\boldsymbol{A})$. □

14.8.2 Characteristic classes

The Chern–Weil forms of Theorem 14.111 live on the total space P. They are forms on the base as well, and that is what makes them invariants of M rather than of a choice of gauge.

Proposition 14.114 (Chern–Weil forms descend to the base)**.** *Let $\boldsymbol{A}$ be a connection on $P(M,G)$ with curvature $\boldsymbol{F}$, and let $\langle\,\cdot\,\rangle$ be a G-invariant polynomial of degree r. Then, for a matrix group,*

$$R_g^*\boldsymbol{F} = g^{-1}\boldsymbol{F}g\,, \tag{14.168}$$

and $\langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle$ is the pullback $\pi^*\rho$ of a unique closed $2r$-form ρ on M.

Rests on Theorem 14.111, Proposition 14.106, and Definition 14.109.

Proof. *Derives Proposition 14.114.*

Pullback commutes with d and with the bracket Equation (14.135), and g is a fixed group element, so

$$R_g^*\boldsymbol{F} = \mathrm{d}\left(g^{-1}\boldsymbol{A}g\right) + \tfrac{1}{2}\left[g^{-1}\boldsymbol{A}g, g^{-1}\boldsymbol{A}g\right] = g^{-1}\left(\mathrm{d}\boldsymbol{A} + \tfrac{1}{2}\,[\boldsymbol{A},\boldsymbol{A}]\right)g\,,$$

using Equation (14.138) in the first step. Hence $R_g^*\,\langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle = \langle g^{-1}\boldsymbol{F}g,\dots,g^{-1}\boldsymbol{F}g\rangle = \langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle$ by Definition 14.109: the form is invariant. It is also horizontal, being a wedge of the component forms of $\boldsymbol{F}$, each of which vanishes as soon as one argument is vertical by Proposition 14.106.

An invariant horizontal form descends. Define $\rho_x(v_1,\dots,v_{2r}) = \langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle_p(\tilde v_1,\dots,\tilde v_{2r})$ for any $p\in\pi^{-1}(x)$ and any $\tilde v_i$ with $\mathrm{d}\pi\,\tilde v_i = v_i$. Two lifts at the same p differ by vertical vectors, which horizontality kills, so the value does not depend on the choice; two points of the same fibre differ by some g, and invariance makes the two values agree. Smoothness follows by computing ρ on a local section, $\rho|_U = s^*\,\langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle$. Uniqueness holds because $\mathrm{d}\pi$ is onto. Finally $\mathrm{d}\rho$ pulls back to $\mathrm{d}\,\langle \boldsymbol{F},\dots,\boldsymbol{F}\rangle = 0$ by Theorem 14.111, and π^* is injective, so ρ is closed. □

Definition 14.115 (Characteristic forms)**.** Let G act by matrices in a representation of dimension N, and define the polynomials σ_r on $\mathfrak{g}$ by

$$\det(\mathbb{1} + \lambda\boldsymbol{X}) = \sum_{r=0}^{N} \lambda^r\,\sigma_r(\boldsymbol{X})\,, \tag{14.169}$$

and, for $\dim = 2m$ and $\boldsymbol{X}$ antisymmetric, the Pfaffian

$$\mathrm{Pf}(\boldsymbol{X}) = \frac{1}{2^m m!}\,\epsilon^{a_1\cdots a_{2m}} X_{a_1a_2}\cdots X_{a_{2m-1}a_{2m}}\,. \tag{14.170}$$

By Lemma 14.116 these are G-invariant polynomials, so Theorem 14.111 and Proposition 14.114 attach to each of them a closed form on M whose de Rham class does not depend on the connection. The *Chern* forms are those of σ_r for G unitary, evaluated at $\boldsymbol{X} = \mathrm{i}\boldsymbol{F}/2\pi$; the *Pontryagin* forms are those of σ_r for G orthogonal, evaluated at $\boldsymbol{X} = \boldsymbol{F}/2\pi$, only the even r surviving; and the *Euler* form is that of the Pfaffian, for $G = \mathrm{SO}(2m)$.

Rests on Definition 14.109, Theorem 14.111, and Proposition 14.114.

Lemma 14.116 (Invariance of the characteristic coefficients)**.** *The σ_r of Equation (14.169) are G-invariant polynomials of degree r in the sense of Definition 14.109, and σ_r vanishes identically on antisymmetric matrices for odd r. The Pfaffian Equation (14.170) obeys $\mathrm{Pf}\left(g\boldsymbol{X}g^{\mathsf{T}}\right) = \det(g)\,\mathrm{Pf}(\boldsymbol{X})$ for orthogonal g, so it is invariant under $\mathrm{SO}(2m)$ and changes sign under an orientation-reversing orthogonal transformation; the Euler form therefore belongs to an oriented bundle.*

Rests on Definition 14.109.

Proof. *Derives Lemma 14.116.*

Invariance is $\det\left(\mathbb{1} + \lambda\, g\boldsymbol{X}g^{-1}\right) = \det\left(g\left(\mathbb{1} + \lambda\boldsymbol{X}\right)g^{-1}\right) = \det\left(\mathbb{1} + \lambda\boldsymbol{X}\right)$, true coefficient by coefficient in λ; each σ_r is a homogeneous polynomial of degree r in the entries of $\boldsymbol{X}$, and the associated symmetric multilinear form is its polarization. For antisymmetric $\boldsymbol{X}$,

$$\det\left(\mathbb{1} + \lambda\boldsymbol{X}\right) = \det\left(\left(\mathbb{1} + \lambda\boldsymbol{X}\right)^{\mathsf{T}}\right) = \det\left(\mathbb{1} - \lambda\boldsymbol{X}\right)\,,$$

so the polynomial is even in λ and the odd σ_r vanish. For the Pfaffian, an orthogonal g has $g\boldsymbol{X}g^{-1} = g\boldsymbol{X}g^{\mathsf{T}}$, each factor in Equation (14.170) carries two of the g's, and

$$\epsilon^{b_1\cdots b_{2m}}\, g^{a_1}{}_{b_1}\cdots g^{a_{2m}}{}_{b_{2m}} = \det(g)\,\epsilon^{a_1\cdots a_{2m}}\,,$$

which is the definition of the determinant. The stated transformation follows, and $\det g = \pm 1$ for an orthogonal matrix. □

14.8.3 The transgression of an $\mathfrak{so}(p,q)$ connection

Proposition 14.117 (The quadratic invariant and its Chern–Simons form)**.** *Let $\boldsymbol{\omega} = \frac{1}{2}\omega^{AB}J_{AB}$ be a connection whose structure group is $\mathrm{SO}(p,q)$, taken in the defining representation of Equation (14.23), and let $\boldsymbol{R} = \frac{1}{2}R^{AB}J_{AB}$ be its curvature. With the invariant polynomial $\langle \boldsymbol{X}, \boldsymbol{Y}\rangle = \mathrm{tr}(\boldsymbol{X}\boldsymbol{Y})$,*

$$\langle \boldsymbol{R}, \boldsymbol{R}\rangle = -R^{AB}\wedge R_{AB} = -8\pi^2\,\sigma_2\left(\boldsymbol{R}/2\pi\right)\,, \tag{14.171}$$

that is, $-8\pi^2$ times the first Pontryagin form $\sigma_2(\boldsymbol{R}/2\pi)$ of Definition 14.115, the invariant $\langle \boldsymbol{R}, \boldsymbol{R}\rangle$ itself carrying none of the 2π normalization of the characteristic forms. Its Chern–Simons 3-form is

$$\boxed{Q^{(3)}(\boldsymbol{\omega}) = -\omega^{AB}\wedge \mathrm{d}\omega_{AB} + \tfrac{2}{3}\,\omega^{A}{}_{B}\wedge\omega^{B}{}_{C}\wedge\omega^{C}{}_{A}}\,, \tag{14.172}$$

with $\mathrm{d}Q^{(3)}(\boldsymbol{\omega}) = \langle \boldsymbol{R}, \boldsymbol{R}\rangle$.

Rests on Proposition 14.113, Equation (14.86), and Definition 14.109.

Proof. *Derives Proposition 14.117.*

In the defining representation the generators are the matrices $(J_{AB})^{M}{}_{N} = \delta^M_A\eta_{BN} - \delta^M_B\eta_{AN}$ already used in Proposition 14.22, so

$$\mathrm{tr}\left(J_{AB}J_{CD}\right) = \left(\delta^M_A\eta_{BN} - \delta^M_B\eta_{AN}\right)\left(\delta^N_C\eta_{DM} - \delta^N_D\eta_{CM}\right) = 2\left(\eta_{AD}\eta_{BC} - \eta_{AC}\eta_{BD}\right)\,,$$

which is symmetric under the exchange of the index pairs and invariant, being a trace of a product of generators. Contracting,

$$\langle \boldsymbol{R}, \boldsymbol{R} \rangle = \tfrac{1}{4} R^{AB} \wedge R^{CD} \, \mathrm{tr}\,(J_{AB} J_{CD}) = \tfrac{1}{2} \left(R^{AB} \wedge R_{BA} - R^{AB} \wedge R_{AB} \right) = -R^{AB} \wedge R_{AB} \,,$$

the two 2-forms commuting. For the second equality in Equation (14.171): the elements of $\mathfrak{so}(p,q)$ are traceless, so $\sigma_1(\boldsymbol{X}) = \mathrm{tr}\,\boldsymbol{X}$ vanishes, and expanding Equation (14.169) to second order gives $\sigma_2(\boldsymbol{X}) = \frac{1}{2}\left[(\mathrm{tr}\,\boldsymbol{X})^2 - \mathrm{tr}(\boldsymbol{X}\boldsymbol{X})\right] = -\frac{1}{2}\,\mathrm{tr}(\boldsymbol{X}\boldsymbol{X})$; at $\boldsymbol{X} = \boldsymbol{R}/2\pi$, the value prescribed for the Pontryagin forms in Definition 14.115, this is $-\langle \boldsymbol{R}, \boldsymbol{R} \rangle / 8\pi^2$. The same substitution in the matrix components gives $(\boldsymbol{\omega})^M{}_N = \omega^M{}_N$, so Equation (14.167) reads $Q^{(3)} = \omega^M{}_N \wedge \mathrm{d}\omega^N{}_M + \frac{2}{3}\omega^M{}_N \wedge \omega^N{}_P \wedge \omega^P{}_M$, and lowering the indices in the first term turns $\omega^M{}_N \wedge \mathrm{d}\omega^N{}_M$ into $-\omega^{AB} \wedge \mathrm{d}\omega_{AB}$. That $\mathrm{d}Q^{(3)}$ is $\langle \boldsymbol{R}, \boldsymbol{R} \rangle$ is Definition 14.112. □

Remark 14.118 (Where this ends, and why). Equation (14.172) is where the source manuscript was heading and is the natural end of the chapter, because it is the last construction this treatise uses. The physical use of the invariant polynomials is made in Part XI, where the obstruction to a classical symmetry surviving quantization is an anomaly (Theorem 106.94); the measured consequence quoted in this chapter is the two-photon decay rate of the neutral pion, with its evidence, in Remark 14.82. The gauge connection of Definition 14.103 is the object every chapter of Part XI works with.

Three directions are deliberately not taken. The classification of bundles over a given base, and the reading of characteristic classes as integers attached to a topology, is algebraic topology and nothing in this book requires it. Index theorems, which relate those integers to the spectra of the operators of Chapter 12, are likewise outside what the evidence under discussion needs. And Chern–Simons *actions* — as opposed to Chern–Simons forms — are field theories in three spacetime dimensions, which the scope rule of Chapter 1 keeps out of this treatise: Remark 14.94 records the position. The mathematics is here because the anomaly and the gauge principle need it, and stops where they stop.

Chapter 15

Expansions of Lie Algebras

Chapter 14 left two mechanisms side by side without saying how they are related. Section 14.4 classified the central charges an algebra may carry by the cohomology group $H^2(\mathfrak{g}, \mathbb{R})$; Section 14.5 described how one algebra degenerates into another in a physical limit, and Theorem 14.90 listed the eleven algebras the degeneration produces from the kinematical hypotheses. What connects them is an observation, not a theorem: contraction *creates* the cohomology that makes a central charge possible (Proposition 14.84), and the mass of nonrelativistic mechanics is the standard example (Remark 25.15). The observation is correct but structurally unsatisfying, because it leaves the central charge looking like an accident of a limit rather than a part of the same construction.

This chapter supplies the missing structure. The whole family — the de Sitter and anti-de Sitter algebras, the Poincaré algebra, the kinematical algebras of Table 14.1, their central extensions, and the towers above them — is obtained from a *single* Lie algebra $\mathfrak{g}$ by tensoring it with a commutative associative algebra A. Changing A changes the resulting Lie algebra; degenerating A performs the contraction; enlarging A by one level produces the central extension. One datum, three operations that were previously three separate constructions.

Notation 15.1 (Standing conventions of this chapter). Throughout, $\mathfrak{g}$ is a finite-dimensional real Lie algebra and A is a finite-dimensional *commutative associative unital* $\mathbb{R}$-algebra, with unit 1_A and Jacobson radical $\mathrm{rad}(A)$. The symbol $\otimes$ means $\otimes_{\mathbb{R}}$, and $\langle v_1, \dots, v_n \rangle$ denotes the linear span of the listed generators. The spacetime dimension D is left general in the general statements; Section 15.10 instantiates every one of them at the observed $D = 4$, and each place where a claim holds *only* in $D = 3$ is marked as such where it occurs.

Remark 15.2 (Status of the material). The construction of this chapter, the classification of Theorem 15.13, and the identification of central charges with the top level of a truncation (Theorem 15.34 and Corollary 15.36) follow an unpublished manuscript in preparation by one of the authors of this treatise and a collaborator [2434]. That is stated here rather than buried in a citation: the reader cannot obtain the manuscript, so nothing in this chapter may rest on its authority. Every statement is therefore proved in full below or in Appendix A.11, from the definitions given here; where an argument is standard commutative algebra it is marked as such and is not used for any claim about a specific algebra. The published antecedents — the Maurer–Cartan expansion [2044] and the semigroup expansion [2096] — are recovered as special cases in Section 15.9, and a reader who wants a citable source for those special cases should use them.

15.1 The tensor product construction

Definition 15.3 (Tensor product Lie algebra)**.** Let $\mathfrak{g}$ be a Lie algebra and A a commutative associative unital algebra. The *tensor product Lie algebra* is the vector space

$$\boxed{\mathfrak{g}_A := A \otimes \mathfrak{g}} \tag{15.1}$$

equipped with the bracket determined by

$$\boxed{[a \otimes X, b \otimes Y] := (ab) \otimes [X, Y]} \tag{15.2}$$

for $a, b \in A$ and $X, Y \in \mathfrak{g}$, extended bilinearly.

Theorem 15.4 (The construction produces a Lie algebra)**.** *Equation* (15.2) *is well defined on $A \otimes \mathfrak{g}$ and makes $\mathfrak{g}_A$ a Lie algebra of dimension* $\dim \mathfrak{g}_A = (\dim A)(\dim \mathfrak{g})$*. In a basis $\{e_\alpha\}$ of A with $e_\alpha e_\beta = \mu_{\alpha\beta}{}^{\gamma} e_\gamma$ and a basis $\{T_a\}$ of $\mathfrak{g}$ with $[T_a, T_b] = C_{ab}{}^{c} T_c$, the structure constants* factorise*:*

$$\boxed{[e_\alpha \otimes T_a, e_\beta \otimes T_b] = \mu_{\alpha\beta}{}^{\gamma}\, C_{ab}{}^{c}\, e_\gamma \otimes T_c}\,. \tag{15.3}$$

Rests on Definition 15.3.

Derivation. *Derives Theorem 15.4.*

Well-definedness. The assignment $(a, X, b, Y) \mapsto (ab) \otimes [X, Y]$ is linear in each of its four arguments, because multiplication in A and the bracket of $\mathfrak{g}$ are bilinear. A multilinear map factors uniquely through the tensor product in each pair of arguments, so it descends to a bilinear map $\mathfrak{g}_A \times \mathfrak{g}_A \to \mathfrak{g}_A$, which is Equation (15.2). Substituting basis elements gives Equation (15.3), and the dimension count is that of a tensor product of vector spaces.

Antisymmetry. Using commutativity of A and antisymmetry of the bracket of $\mathfrak{g}$,

$$[a \otimes X, b \otimes Y] = (ab) \otimes [X, Y] = (ba) \otimes (-[Y, X]) = -[b \otimes Y, a \otimes X]\,.$$

Both hypotheses are used, and only these: associativity plays no part here.

Jacobi identity. Applying Equation (15.2) twice,

$$[a \otimes X, [b \otimes Y, c \otimes Z]] = (a(bc)) \otimes [X, [Y, Z]]\,. \tag{15.4}$$

Because A is associative and commutative, the three products obtained by cycling $(a, X) \to (b, Y) \to (c, Z) \to (a, X)$ are equal,

$$a(bc) = b(ca) = c(ab) =: abc\,,$$

so the common factor comes out of the cyclic sum of Equation (15.4):

$$\sum_{\text{cyclic}} [a \otimes X, [b \otimes Y, c \otimes Z]] = (abc) \otimes \Big([X, [Y, Z]] + [Y, [Z, X]] + [Z, [X, Y]]\Big) = 0\,,$$

the parenthesis vanishing by the Jacobi identity of $\mathfrak{g}$. Since elementary tensors span $\mathfrak{g}_A$ and both sides are trilinear, the identity holds throughout $\mathfrak{g}_A$. □

Remark 15.5 (What the factorisation buys). Equation (15.3) is the point of the construction. Every structure constant of $\mathfrak{g}_A$ is a product of one structure constant of A and one of $\mathfrak{g}$. Consequently any question about $\mathfrak{g}_A$ that is linear in the structure constants — semisimplicity, the Killing form, the invariant tensors, the effect of a limit — separates into a question about A and a question about $\mathfrak{g}$. Keeping $\mathfrak{g}$ fixed and varying A generates the families studied below.

Proposition 15.6 (Functoriality)**.** *Let $f : A \to A'$ be a homomorphism of commutative associative unital algebras. Then*

$$f \otimes \mathrm{id} : \mathfrak{g}_A \longrightarrow \mathfrak{g}_{A'}\,, \qquad a \otimes X \longmapsto f(a) \otimes X\,, \tag{15.5}$$

is a homomorphism of Lie algebras, with kernel $\ker(f) \otimes \mathfrak{g}$, surjective whenever f is.
Rests on Definition 15.3 and Theorem 15.4.

Derivation. *Derives Proposition 15.6.*
On elementary tensors,

$$(f \otimes \mathrm{id})\,[a \otimes X, b \otimes Y] = f(ab) \otimes [X,Y] = (f(a)f(b)) \otimes [X,Y] = [f(a) \otimes X, f(b) \otimes Y]\,,$$

using that f is multiplicative; both sides are bilinear, so the identity extends. The kernel is $\ker(f) \otimes \mathfrak{g}$ because tensoring the exact sequence $0 \to \ker f \to A \to \operatorname{im} f \to 0$ with a vector space over a field is exact; surjectivity is inherited for the same reason. □

Proposition 15.6 is the engine of the rest of the chapter: every relation between two algebras A and A' becomes a relation between the Lie algebras $\mathfrak{g}_A$ and $\mathfrak{g}_{A'}$, at no extra cost.

15.2 Ideals, the radical, and the Killing form

Proposition 15.7 (Ideals of A become ideals of $\mathfrak{g}_A$)**.** *If $I \subseteq A$ is an ideal of A, then $I \otimes \mathfrak{g}$ is a Lie ideal of $\mathfrak{g}_A$. In particular $\mathfrak{g}_A$ can be simple only if A is a field.*
Rests on Definition 15.3 and Theorem 15.4.

Derivation. *Derives Proposition 15.7.*
For $u \in I$, $b \in A$ and $X, Y \in \mathfrak{g}$, $[u \otimes X, b \otimes Y] = (ub) \otimes [X,Y]$ with $ub \in I$, because an ideal absorbs multiplication. Bilinearity extends the containment, so $[I \otimes \mathfrak{g}, \mathfrak{g}_A] \subseteq I \otimes \mathfrak{g}$. If A is not a field it has a proper nonzero ideal I, and then $I \otimes \mathfrak{g}$ is a proper nonzero ideal of $\mathfrak{g}_A$. □

Proposition 15.8 (The radical of A is solvable in $\mathfrak{g}_A$)**.** *Let $J = \mathrm{rad}(A)$, nilpotent with $J^{N+1} = 0$. Then $J \otimes \mathfrak{g}$ is a* solvable *ideal of $\mathfrak{g}_A$. If moreover $\mathfrak{g}$ is perfect, $[\mathfrak{g},\mathfrak{g}] = \mathfrak{g}$, the k-th derived algebra of $J \otimes \mathfrak{g}$ is exactly $J^{2^k} \otimes \mathfrak{g}$.*
Rests on Proposition 15.7 and Definition 15.3.

Derivation. *Derives Proposition 15.8.*
Write $\mathfrak{s} = J \otimes \mathfrak{g}$, an ideal by Proposition 15.7. By Equation (15.2),

$$[J^m \otimes \mathfrak{g}, J^m \otimes \mathfrak{g}] \subseteq J^{2m} \otimes [\mathfrak{g},\mathfrak{g}] \subseteq J^{2m} \otimes \mathfrak{g}\,, \tag{15.6}$$

so by induction $\mathfrak{s}^{(k)} \subseteq J^{2^k} \otimes \mathfrak{g}$. Choosing k with $2^k > N$ gives $J^{2^k} = 0$ and hence $\mathfrak{s}^{(k)} = 0$: $\mathfrak{s}$ is solvable. When $\mathfrak{g}$ is perfect the second inclusion in Equation (15.6) is an equality, and the first is too, because J^{2m} is spanned by products uv with $u, v \in J^m$; the induction then gives equality at every step. □

The Killing form of $\mathfrak{g}_A$ factorises as cleanly as the structure constants, and that turns the two propositions above into a criterion.

Definition 15.9 (Trace form of an algebra)**.** For $x \in A$ let $L_x : A \to A$ be multiplication by x. The *trace functional* and the *trace form* of A are

$$\tau_A(x) := \mathrm{tr}(L_x)\,, \qquad (x,y)_A := \tau_A(xy)\,. \tag{15.7}$$

Theorem 15.10 (Factorisation of the Killing form)**.** *Let $\kappa_{\mathfrak{g}}$ be the Killing form of $\mathfrak{g}$ and κ_A that of $\mathfrak{g}_A$. Then*

$$\boxed{\kappa_A\left(a \otimes X,\ b \otimes Y\right) = \tau_A(ab)\ \kappa_{\mathfrak{g}}(X, Y)}, \tag{15.8}$$

and κ_A is nondegenerate if and only if both the trace form of A and the Killing form of $\mathfrak{g}$ are nondegenerate.

Rests on Definitions 15.3 and 15.9.

Derivation. *Derives Theorem 15.10.*

By Equation (15.2), the adjoint action of $a \otimes X$ sends $c \otimes Z$ to $(ac) \otimes [X, Z]$, that is

$$\mathrm{ad}_{a\otimes X} = L_a \otimes \mathrm{ad}_X \tag{15.9}$$

as an operator on $A \otimes \mathfrak{g}$. Composing two of them,

$$\mathrm{ad}_{a\otimes X}\,\mathrm{ad}_{b\otimes Y} = (L_aL_b) \otimes (\mathrm{ad}_X\,\mathrm{ad}_Y) = L_{ab} \otimes (\mathrm{ad}_X\,\mathrm{ad}_Y)\ ,$$

where $L_aL_b = L_{ab}$ is associativity of A. The trace of a tensor product of operators is the product of the traces, which gives Equation (15.8).

For the second statement, Equation (15.8) exhibits κ_A as the tensor product of the bilinear forms $(\cdot,\cdot)_A$ on A and $\kappa_{\mathfrak{g}}$ on $\mathfrak{g}$. A tensor product of two bilinear forms is nondegenerate exactly when both factors are: in bases its Gram matrix is the Kronecker product of the two Gram matrices, of determinant $(\det G_A)^{\dim \mathfrak{g}}(\det G_{\mathfrak{g}})^{\dim A}$. □

Corollary 15.11 (Semisimplicity criterion)**.** *$\mathfrak{g}_A$ is semisimple if and only if $\mathfrak{g}$ is semisimple and the trace form of A is nondegenerate. For a finite-dimensional commutative $\mathbb{R}$-algebra the latter holds exactly when $A \cong \mathbb{R}^r \times \mathbb{C}^s$.*

Rests on Theorem 15.10 and Lemma 15.12.

Derivation. *Derives Corollary 15.11.*

Cartan's criterion states that a finite-dimensional Lie algebra over a field of characteristic zero is semisimple if and only if its Killing form is nondegenerate; apply it to both sides of Theorem 15.10. For the last sentence: if $x \in \mathrm{rad}(A)$ is nilpotent then L_{xy} is nilpotent for every y, so $\tau_A(xy) = 0$ and x lies in the radical of the trace form; conversely $\mathbb{R}^r \times \mathbb{C}^s$ has trace form $\mathrm{diag}(1, \dots, 1)$ on the real factors and, on each complex factor in the basis $\{1, \mathrm{i}\}$, the Gram matrix

$$\begin{pmatrix} 2 & 0 \\ 0 & -2 \end{pmatrix},$$

both nondegenerate. The identification of the radical-free case with $\mathbb{R}^r \times \mathbb{C}^s$ is Lemma 15.12. □

Lemma 15.12 (Artin decomposition)**.** *Every finite-dimensional commutative associative unital $\mathbb{R}$-algebra decomposes uniquely as a finite direct product*

$$A \cong A_1 \times \cdots \times A_k \tag{15.10}$$

of local *algebras A_i, that is, algebras with a unique maximal ideal $\mathfrak{m}_i$, which is nilpotent. The decomposition is implemented by a partition $1_A = \pi_1 + \cdots + \pi_k$ into orthogonal idempotents. When every $\mathfrak{m}_i = 0$ the factors are fields, hence copies of $\mathbb{R}$ or $\mathbb{C}$, and $A \cong \mathbb{R}^r \times \mathbb{C}^s$.*

Rests on Notation 15.1 and Theorem 8.19.

Derivation. *Derives Lemma 15.12.*

The argument is elementary commutative algebra and uses nothing else from this chapter. Write $n = \dim A < \infty$ and assume $A \neq 0$.

Step 1: the nilpotents form a nilpotent ideal. Let $N \subseteq A$ be the set of nilpotent elements. If $u^r = v^t = 0$ then $(u+v)^{r+t-1} = 0$, since every term of the binomial expansion — which is

available because A is commutative — carries either u^r or v^t; and $(cu)^r = c^r u^r = 0$ for every $c \in A$. So N is an ideal. Pick a basis $u_1, \dots, u_d$ of N, necessarily consisting of nilpotents, with $u_i^{r_i} = 0$, and set $M := 1 + \sum_i (r_i - 1)$. Then N^M is spanned by products of M of the u_i, and in any such product some u_i occurs at least r_i times; hence

$$N^M = 0\,. \tag{15.11}$$

Step 2: either A is local, or it splits. Fix $a \in A$ and let $p \in \mathbb{R}[X]$ be its minimal polynomial, the monic generator of the kernel of the evaluation $\mathbb{R}[X] \to A$, $X \mapsto a$; that kernel is nonzero because $1, a, \dots, a^n$ are $n+1$ vectors in an n-dimensional space. Factor $p = p_1^{e_1} \cdots p_s^{e_s}$ into powers of distinct monic irreducibles of $\mathbb{R}[X]$, and write $q_i := p/p_i^{e_i}$.

Suppose $s \geq 2$. The q_i have no common irreducible factor, so there are $f_i \in \mathbb{R}[X]$ with $\sum_i f_i q_i = 1$; put $\pi_i := (f_i q_i)(a)$. Then $\sum_i \pi_i = 1_A$; for $i \neq j$ the product $f_i q_i f_j q_j$ is divisible by p, so $\pi_i \pi_j = 0$, and multiplying $\sum_j \pi_j = 1_A$ by π_i gives $\pi_i^2 = \pi_i$. No π_i vanishes: $f_i q_i \equiv 1$ modulo $p_i^{e_i}$, because every other summand of $\sum_j f_j q_j = 1$ is divisible by $p_i^{e_i}$; if $\pi_i = 0$ then p, hence $p_i^{e_i}$, would divide $f_i q_i$, forcing $p_i^{e_i}$ to divide 1. So the π_i are nonzero orthogonal idempotents summing to 1_A, the sum $A = \bigoplus_i \pi_i A$ is direct (multiply a vanishing sum by π_j), and $\pi_i A \cdot \pi_j A = 0$ for $i \neq j$: A is the product of the algebras $\pi_i A$, each unital with unit π_i and each of dimension strictly less than n.

Suppose instead that $s = 1$ for *every* $a \in A$, so that each minimal polynomial is $p_1^{e_1}$ with p_1 irreducible. If $p_1 = X$ then $a^{e_1} = 0$ and $a \in N$. Otherwise $p_1(0) \neq 0$ — an irreducible real polynomial with vanishing constant term is a multiple of X — so p has constant term $c_0 = p_1(0)^{e_1} \neq 0$; writing $p(X) = Xg(X) + c_0$ and evaluating at a gives $a \cdot (-g(a)/c_0) = 1_A$, so a is invertible. Thus every element is nilpotent or invertible. A nilpotent is not invertible, since $a^r = 0$ and $ab = 1_A$ would give $1_A = (ab)^r = a^r b^r = 0$; hence N is exactly the set of non-units. An ideal that contains every non-unit and consists of non-units is the unique maximal ideal, so A is local with $\mathfrak{m} = N$, nilpotent by Equation (15.11).

Step 3: induction. If $\dim A = 1$ then $A = \mathbb{R}\,1_A$ is a field, hence local with $\mathfrak{m} = 0$. If $\dim A > 1$, Step 2 either makes A local or splits it into factors of strictly smaller dimension, to which the inductive hypothesis applies. An idempotent of a factor is an idempotent of A, and idempotents belonging to different factors are orthogonal, so the partitions of the units compose into a single partition $1_A = \pi_1 + \cdots + \pi_k$ with $A_i = \pi_i A$ local.

Step 4: uniqueness. A local algebra has no idempotents but 0 and its unit: if $e^2 = e$ then e is a unit, whence $e = 1$ after multiplying $e^2 = e$ by e^{-1}, or e is nilpotent, whence $e = e^m = 0$. Let $1_A = \sum_i \pi_i = \sum_j \rho_j$ be the unit partitions of two decompositions into local factors. Each $\pi_i \rho_j$ is an idempotent lying in $\pi_i A$ and in $\rho_j A$, so it is 0 or π_i, and 0 or ρ_j. Since $\sum_j \pi_i \rho_j = \pi_i \neq 0$, at least one j gives $\pi_i \rho_j = \pi_i = \rho_j$; a second such j' is impossible, because then $\pi_i = \pi_i \rho_j$ multiplied by $\rho_{j'}$ would give $\pi_i \rho_{j'} = \pi_i \rho_j \rho_{j'} = 0$. The two partitions therefore coincide up to order, and with them the factors.

Step 5: the radical-free case. Suppose $\mathfrak{m}_i = 0$. Then the non-units of A_i are 0 alone, so A_i is a field K, finite dimensional over $\mathbb{R}\,1_K \cong \mathbb{R}$. For $b \in K$ the minimal polynomial p_b is irreducible: a factorisation $p_b = gh$ into nonconstant factors would give $g(b)h(b) = 0$ in a field, hence $g(b) = 0$ or $h(b) = 0$, contradicting minimality. By the fundamental theorem of algebra (Theorem 8.19) a real polynomial splits over $\mathbb{C}$ into linear factors, and its non-real roots occur in conjugate pairs; pairing those factors gives a factorisation into real factors of degree 1 and 2, so an irreducible real polynomial has degree at most 2. If $K \neq \mathbb{R}\,1_K$, choose $b \in K$ outside $\mathbb{R}\,1_K$: its minimal polynomial is an irreducible quadratic, and $\mathbb{R}[b] \cong \mathbb{R}[X]/(p_b) \cong \mathbb{C}$. Every $c \in K$ then has a minimal polynomial over that copy of $\mathbb{C}$ which is irreducible in $\mathbb{C}[X]$, hence linear by Theorem 8.19, so $c \in \mathbb{R}[b]$ and $K \cong \mathbb{C}$. Otherwise $K \cong \mathbb{R}$. Collecting the factors gives $A \cong \mathbb{R}^r \times \mathbb{C}^s$. □

Theorem 15.13 (Classification of $\mathfrak{g}_A$ by the algebra)**.** *Let $\mathfrak{g}$ be semisimple and A a finite-dimensional commutative associative unital $\mathbb{R}$-algebra with Artin decomposition Equation (15.10). Then*

$$\mathfrak{g}_A \cong \bigoplus_{i=1}^{k} \mathfrak{g}_{A_i} \qquad \text{as Lie algebras,} \tag{15.12}$$

and the summands fall into two branches.

1. Semisimple branch. *If A_i is a field then $\mathfrak{g}_{A_i} \cong \mathfrak{g}$ when $A_i \cong \mathbb{R}$, and $\mathfrak{g}_{A_i} \cong \mathbb{C} \otimes_{\mathbb{R}} \mathfrak{g}$, the complexification regarded as a real Lie algebra, when $A_i \cong \mathbb{C}$. Both are semisimple.*

2. Local branch. *If A_i has nonzero maximal ideal $\mathfrak{m}_i$ then $\mathfrak{g}_{A_i}$ is not semisimple, its solvable radical is exactly $\mathfrak{m}_i \otimes \mathfrak{g}$, and the quotient by that radical is $\mathfrak{g}_{A_i/\mathfrak{m}_i}$, semisimple by branch (1).*

The isomorphism class of $\mathfrak{g}_A$ is therefore determined by those of A and $\mathfrak{g}$.
Rests on Definition 15.3, Lemma 15.12, Propositions 15.6 and 15.8, and Corollary 15.11.

Derivation. *Derives Theorem 15.13.*

The splitting. With the orthogonal idempotents of Lemma 15.12, $\pi_i \pi_j = \delta_{ij} \pi_i$, so Equation (15.2) gives

$$[\pi_i a \otimes X, \pi_j b \otimes Y] = (\pi_i \pi_j ab) \otimes [X, Y] = \delta_{ij} \, (\pi_i ab) \otimes [X, Y] \ ,$$

so the subspaces $\pi_i A \otimes \mathfrak{g} = \mathfrak{g}_{A_i}$ are mutually commuting ideals whose sum is $\mathfrak{g}_A$, which is Equation (15.12).

Branch (1). If $A_i \cong \mathbb{R}$ then $A_i \otimes \mathfrak{g} \cong \mathfrak{g}$ with the same bracket, since $1 \cdot 1 = 1$. If $A_i \cong \mathbb{C}$ then $A_i \otimes_{\mathbb{R}} \mathfrak{g}$ is by definition the complexification of $\mathfrak{g}$, a real Lie algebra of twice the dimension. Both are semisimple by Corollary 15.11, the trace forms of $\mathbb{R}$ and $\mathbb{C}$ over $\mathbb{R}$ being nondegenerate as computed there.

Branch (2). By Proposition 15.8, $\mathfrak{m}_i \otimes \mathfrak{g}$ is a nonzero solvable ideal, so $\mathfrak{g}_{A_i}$ is not semisimple. Applying Proposition 15.6 to the quotient map $A_i \to A_i/\mathfrak{m}_i$ gives a surjection $\mathfrak{g}_{A_i} \to \mathfrak{g}_{A_i/\mathfrak{m}_i}$ with kernel $\mathfrak{m}_i \otimes \mathfrak{g}$. Since A_i is local, $A_i/\mathfrak{m}_i$ is a field, so the image is semisimple by branch (1) and its own radical is zero. Any solvable ideal of $\mathfrak{g}_{A_i}$ therefore maps into that zero radical, hence lies in $\mathfrak{m}_i \otimes \mathfrak{g}$; together with the solvability of $\mathfrak{m}_i \otimes \mathfrak{g}$ itself this identifies the radical exactly. □

15.3 The Takiff tower

The single most important family of algebras A is the truncated polynomial ring, because truncation is what a physical limit does to an expansion parameter.

Definition 15.14 (Truncated polynomial algebra and Takiff algebra)**.** For $N \geq 0$ set

$$A_N := \mathbb{R}[\varepsilon]/(\varepsilon^{N+1}) \, , \tag{15.13}$$

the commutative algebra with basis $\left\{1, \varepsilon, \ldots, \varepsilon^N\right\}$ and $\varepsilon^i \varepsilon^j = \varepsilon^{i+j}$ for $i + j \leq N$, zero otherwise. The associated Lie algebra

$$\mathfrak{g}\,\langle N \rangle := A_N \otimes \mathfrak{g} \tag{15.14}$$

is the *N-th Takiff algebra* of $\mathfrak{g}$ [1457]. Its elements are written $X^{(i)} := \varepsilon^i \otimes X$, the *level-$i$* copy of X.
Rests on Definition 15.3.

Proposition 15.15 (Takiff brackets)**.** *In* $\mathfrak{g}\langle N\rangle$*,*

$$\boxed{\left[X^{(i)},Y^{(j)}\right]=\begin{cases}[X,Y]^{(i+j)}\,, & i+j\le N\,,\\ 0\,, & i+j>N\,,\end{cases}} \tag{15.15}$$

so $\dim\mathfrak{g}\langle N\rangle=(N+1)\dim\mathfrak{g}$*, level* 0 *is a subalgebra isomorphic to* $\mathfrak{g}$*, and* $\bigoplus_{i\ge1}\varepsilon^i\otimes\mathfrak{g}$ *is a nilpotent ideal.*

Rests on Definitions 15.3 and 15.14 and Proposition 15.8.

Derivation. *Derives Proposition 15.15.*

The bracket is Equation (15.2) with $a=\varepsilon^i$, $b=\varepsilon^j$ and the multiplication table of A_N. Level 0 is $1\otimes\mathfrak{g}$, closed because $1\cdot1=1$, and $X\mapsto X^{(0)}$ is an isomorphism onto it. The maximal ideal $\mathfrak{m}=(\varepsilon)$ of A_N satisfies $\mathfrak{m}^{N+1}=0$, so $\mathfrak{m}\otimes\mathfrak{g}$ is a nilpotent, in particular solvable, ideal by Proposition 15.8. □

Example 15.16 (The Maxwell tower)**.** Take any $\mathfrak{g}$ and write $J:=X^{(0)}$, $P:=X^{(1)}$, $Z:=X^{(2)}$, $B:=X^{(3)}$ for the successive levels of a generator X. Then Equation (15.15) gives

$$[P,P']=[X,X']^{(2)}\,,\qquad [P,Z']=[X,X']^{(3)}\,,\qquad [Z,Z']=[X,X']^{(4)}\,, \tag{15.16}$$

each vanishing when its level exceeds N. At $N=1$ the level-1 sector is abelian; at $N=2$ one has $[P,P']=Z$ but $[P,Z']=0$, which for $\mathfrak{g}$ the Lorentz algebra is the *Maxwell algebra* [1414, 1483], in which Z_{ab} is the algebraic image of a constant electromagnetic field strength; at $N=3$ the bracket $[P,Z']=B$ reopens and the algebra is the one called $\mathfrak{B}$ in the gauge-gravity literature. The tower continues for every N.

Rests on Proposition 15.15.

Remark 15.17 (An expansion is not a contraction)*.* Proposition 14.84 recorded that a contraction preserves the dimension of the algebra. The passage $\mathfrak{g}\to\mathfrak{g}\langle N\rangle$ does not: it multiplies the dimension by $N+1$. The two operations are therefore different, and the word *expansion* is used for the second. What Section 15.5 shows is that a contraction is a degeneration *of* A *at fixed dimension of* A, whereas an expansion enlarges A. Confusing them is the commonest error in this subject.

15.4 Gradings and resonant subalgebras

The Takiff algebra puts a full copy of $\mathfrak{g}$ at every level. Physically one wants less: the boosts at one level and the rotations at another. The mechanism that permits a consistent choice is a grading.

Definition 15.18 ($\mathbb{Z}_2$-grading, symmetric coset)**.** A $\mathbb{Z}_2$*-grading* of $\mathfrak{g}$ is a vector-space decomposition $\mathfrak{g}=V_0\oplus V_1$ with

$$\boxed{[V_0,V_0]\subseteq V_0\,,\qquad [V_0,V_1]\subseteq V_1\,,\qquad [V_1,V_1]\subseteq V_0}\,. \tag{15.17}$$

The pair (V_0,V_1) is then a *symmetric coset* decomposition, V_0 being a subalgebra.

Lemma 15.19 (A grading is an involution, and the Killing form respects it)**.** *Let* $\mathfrak{g}=V_0\oplus V_1$ *be a* $\mathbb{Z}_2$*-grading and let* θ *act as* $+1$ *on* V_0 *and* -1 *on* V_1*. Then* θ *is an involutive automorphism of* $\mathfrak{g}$*, and*

$$\kappa_{\mathfrak{g}}(V_0,V_1)=0\,. \tag{15.18}$$

If $\kappa_{\mathfrak{g}}$ *is nondegenerate on* $\mathfrak{g}$*, its restrictions to* V_0 *and to* V_1 *are nondegenerate.*

Rests on Definition 15.18.

Derivation. *Derives Lemma 15.19.*

For $X \in V_i$, $Y \in V_j$ one has $[X,Y] \in V_{i+j}$ by Equation (15.17), so $\theta\,[X,Y] = (-1)^{i+j}\,[X,Y] = [(-1)^i X, (-1)^j Y] = [\theta X, \theta Y]$: θ is an automorphism, and $\theta^2 = \mathrm{id}$. The Killing form is invariant under every automorphism, so for $X \in V_0$, $Y \in V_1$,

$$\kappa_{\mathfrak{g}}(X,Y) = \kappa_{\mathfrak{g}}(\theta X, \theta Y) = \kappa_{\mathfrak{g}}(X,-Y) = -\kappa_{\mathfrak{g}}(X,Y)\,,$$

which forces Equation (15.18) in characteristic zero. If $X \in V_0$ satisfies $\kappa_{\mathfrak{g}}(X,V_0) = 0$ then by Equation (15.18) also $\kappa_{\mathfrak{g}}(X,V_1) = 0$, so X lies in the radical of $\kappa_{\mathfrak{g}}$ and vanishes; likewise for V_1. □

Definition 15.20 (Resonant subalgebra)**.** Let σ denote a $\mathbb{Z}_2$-grading $\mathfrak{g} = V_0 \oplus V_1$ and let $[k] \in \{0,1\}$ be the parity of k. The *resonant subspace* of $\mathfrak{g}\langle N\rangle$ is

$$\boxed{\mathfrak{R}_N^\sigma := \bigoplus_{k=0}^{N} \varepsilon^k \otimes V_{[k]}}\,, \tag{15.19}$$

that is: even levels carry V_0, odd levels carry V_1.

Rests on Definitions 15.14 and 15.18.

Proposition 15.21 (Resonance)**.** *$\mathfrak{R}_N^\sigma$ is a Lie subalgebra of $\mathfrak{g}\langle N\rangle$, of dimension*

$$\dim \mathfrak{R}_N^\sigma = \left\lceil \tfrac{N+1}{2} \right\rceil \dim V_0 + \left\lfloor \tfrac{N+1}{2} \right\rfloor \dim V_1\,. \tag{15.20}$$

Rests on Definitions 15.18 and 15.20 and Proposition 15.15.

Derivation. *Derives Proposition 15.21.*

Take $X \in V_{[i]}$ and $Y \in V_{[j]}$, so $\varepsilon^i \otimes X$ and $\varepsilon^j \otimes Y$ lie in $\mathfrak{R}_N^\sigma$. By Equation (15.15) their bracket is $\varepsilon^{i+j} \otimes [X,Y]$ when $i+j \le N$ and zero otherwise; the zero case is trivially in the subspace. In the surviving case Equation (15.17) gives $[X,Y] \in V_{[i]+[j]}$, and $[i]+[j] = [i+j]$ because parity is additive, so the bracket lies in $\varepsilon^{i+j} \otimes V_{[i+j]} \subseteq \mathfrak{R}_N^\sigma$. The dimension is the number of even levels in $\{0,\dots,N\}$ times $\dim V_0$ plus the number of odd ones times $\dim V_1$. □

15.4.1 The gradings of the anti-de Sitter algebra

Everything below is applied to one algebra, in every dimension.

Notation 15.22 (Generators of $\mathfrak{so}(D-1,2)$). Let η_{AB} have signature $(D-1,2)$ on $\mathbb{R}^{D+1}$, with indices $A,B \in \{0,1,\dots,D-1,D\}$; the index 0 is timelike, the indices $i,j \in \{1,\dots,D-1\}$ are spacelike, and the extra index D is timelike, $\eta_{DD} = -1$. The generators $J_{AB} = -J_{BA}$ satisfy Equation (14.90). Split them as

$$\boxed{J_{ij}\ \text{(rotations)}\,,\quad G_i := J_{0i}\ \text{(boosts)}\,,\quad H := J_{0D}\ \text{(time translation)}\,,\quad P_i := J_{iD}}\,. \tag{15.21}$$

This is the generator set of Theorem 14.90, with $K_i = G_i$ there.

Rests on Equation (14.90).

Proposition 15.23 (Brackets in the kinematical splitting)**.** *With Notation 15.22 and $\eta_{ij} = \delta_{ij}$, $\eta_{00} = -1$, $\eta_{DD} = \varsigma$ where $\varsigma = -1$ for $\mathfrak{so}(D-1,2)$ and $\varsigma = +1$ for $\mathfrak{so}(D,1)$,*

$$[G_i,G_j] = J_{ij}\,, \qquad [G_i,P_j] = \delta_{ij} H\,, \qquad [G_i,H] = P_i\,, \tag{15.22}$$

$$[P_i,P_j] = -\varsigma J_{ij}\,, \qquad [P_i,H] = \varsigma G_i\,, \qquad [J_{ij},H] = 0\,, \tag{15.23}$$

with J_{ij} acting on G_k and P_k as on a vector index. In the parametrisation Equation (14.128) of Theorem 14.90 this is $(\gamma,\mu,\nu) = (1,1,\varsigma)$: all three nonzero, the anti-de Sitter row of Table 14.1 for $\varsigma = -1$ and the de Sitter row for $\varsigma = +1$.

Rests on Notation 15.22 and Equations (14.90) and (14.128).

Derivation. *Derives Proposition 15.23.*

Each bracket is Equation (14.90) with the indices substituted. For instance

$$[P_i, P_j] = [J_{iD}, J_{jD}] = \eta_{ij} J_{DD} + \eta_{DD} J_{ji} + \eta_{iD} J_{Dj} + \eta_{Dj} J_{iD} = \eta_{DD} J_{ji} = -\varsigma J_{ij} \,,$$

using $J_{DD} = 0$ and $\eta_{iD} = \eta_{jD} = 0$; and

$$[G_i, P_j] = [J_{0i}, J_{jD}] = \eta_{0j} J_{Di} + \eta_{iD} J_{j0} + \eta_{0D} J_{ij} + \eta_{ij} J_{0D} = \delta_{ij} H \,.$$

The remaining four are the same computation. The identification of (γ, μ, ν) is read off by comparing with Equation (14.128), whose second and third relations are $[G_i, H] = \mu P_i$ and $[P_i, H] = \nu G_i$. □

Definition 15.24 (The four kinematical gradings)**.** Four splittings of $\{J_{ij}, G_i, H, P_i\}$ are relevant:

$$\begin{aligned}
\sigma_{\mathrm{st}} &: \; V_0 = \langle J_{ij}, G_i \rangle \,, \quad V_1 = \langle H, P_i \rangle \,, && \text{space–time,} \\
\sigma_{\mathrm{ss}} &: \; V_0 = \langle J_{ij}, H \rangle \,, \quad V_1 = \langle G_i, P_i \rangle \,, && \text{speed–space,} \\
\sigma_{\mathrm{sT}} &: \; V_0 = \langle J_{ij}, P_i \rangle \,, \quad V_1 = \langle G_i, H \rangle \,, && \text{speed–time,} \\
\sigma_{\mathrm{gen}} &: \; V_0 = \langle J_{ij} \rangle \,, \quad\;\; V_1 = \langle G_i, H, P_i \rangle \,, && \text{general.}
\end{aligned} \tag{15.24}$$

Rests on Notation 15.22.

Proposition 15.25 (Which of the four are symmetric cosets)**.** *The first three of Equation (15.24) satisfy Equation (15.17); the fourth does not.*

Rests on Definitions 15.18 and 15.24 and Proposition 15.23.

Derivation. *Derives Proposition 15.25.*

Read Equations (15.22) and (15.23). For σ_{st}, the set $V_0 = \langle J_{ij}, G_i \rangle$ is the Lorentz subalgebra, so $[V_0, V_0] \subseteq V_0$; $[G_i, H] = P_i$ and $[J, P] \sim P$ give $[V_0, V_1] \subseteq V_1$; and $[P_i, P_j] = -\varsigma J_{ij}$, $[P_i, H] = \varsigma G_i$ give $[V_1, V_1] \subseteq V_0$.

For σ_{ss}: $[J, J] \sim J$ and $[J_{ij}, H] = 0$ close V_0; $[J, G] \sim G$, $[J, P] \sim P$, $[H, G_i] = -P_i$ and $[H, P_i] = -\varsigma G_i$ keep $[V_0, V_1]$ in V_1; and $[G_i, G_j] = J_{ij}$, $[G_i, P_j] = \delta_{ij} H$, $[P_i, P_j] = -\varsigma J_{ij}$ all land in V_0.

For σ_{sT}: $[P_i, P_j] = -\varsigma J_{ij}$ closes V_0; $[P_i, H] = \varsigma G_i$ and $[P_j, G_i] = -\delta_{ij} H$ send $[V_0, V_1]$ into V_1; and $[G_i, G_j] = J_{ij}$, $[G_i, H] = P_i$ land in V_0.

For σ_{gen} the third condition fails at once: $[G_i, P_j] = \delta_{ij} H \in V_1$, not V_0. □

15.5 Contraction as a degeneration of A

Proposition 15.26 (The contraction along a grading)**.** *Let $\mathfrak{g} = V_0 \oplus V_1$ be a $\mathbb{Z}_2$-grading and let $U(\lambda)$ act as the identity on V_0 and as multiplication by λ on V_1. Then the Inönü–Wigner limit Equation (14.125) exists, and the contracted algebra $\mathfrak{g}_0$ is isomorphic to the resonant subalgebra at $N = 1$,*

$$\boxed{\mathfrak{g}_0 \cong \mathfrak{R}_1^{\sigma} = (1 \otimes V_0) \oplus (\varepsilon \otimes V_1) \subseteq \mathfrak{g}\,\langle 1 \rangle} \,. \tag{15.25}$$

Rests on Definitions 15.18 and 15.20, Equation (14.125), and Proposition 15.15.

Derivation. *Derives Proposition 15.26.*

Compute the three cases of Equation (14.125) using Equation (15.17). For $X, X' \in V_0$ the map $U(\lambda)$ is the identity on the arguments and, since $[X, X'] \in V_0$, on the result too, so $U^{-1}[UX, UX'] = [X, X']$, independent of λ. For $X \in V_0$, $Y \in V_1$ we have $[X, Y] \in V_1$, so

$$U(\lambda)^{-1}\,[U(\lambda)X, U(\lambda)Y] = \lambda^{-1}\,[X, \lambda Y] = [X, Y] \,,$$

again independent of λ. For $Y, Y' \in V_1$ we have $[Y, Y'] \in V_0$, on which U^{-1} acts trivially, so

$$U(\lambda)^{-1}\,[U(\lambda)Y, U(\lambda)Y'] = \lambda^2\,[Y, Y'] \xrightarrow{\lambda \to 0} 0 \,.$$

The limit exists and $\mathfrak{g}_0$ has the brackets of $\mathfrak{g}$ except that $[V_1, V_1] = 0$.

Define $\varphi : \mathfrak{g}_0 \to \mathfrak{R}_1^\sigma$ by $\varphi(X) = 1 \otimes X$ for $X \in V_0$ and $\varphi(Y) = \varepsilon \otimes Y$ for $Y \in V_1$, extended linearly; it is a linear bijection, both spaces having dimension $\dim V_0 + \dim V_1$. It is a homomorphism by Equation (15.15): the V_0–V_0 bracket lands at level 0 with value in V_0, the V_0–V_1 bracket at level 1 with value in V_1, and the V_1–V_1 bracket at level $2 > 1$, hence zero — matching the three cases just computed. □

Corollary 15.27 (The flat limit)**.** *Applying Proposition 15.26 to $\mathfrak{so}(D-1,2)$ with the space–time grading σ_{st} gives the Poincaré algebra $\mathfrak{iso}(D-1,1)$ of Equation (14.99); applying it to $\mathfrak{iso}(D-1,1)$ with the speed–space grading σ_{ss} gives the Galilei algebra. These are the two contractions of Example 14.89.*

Rests on Propositions 15.23 and 15.26, Definition 15.24, and Equation (14.99).

Derivation. *Derives Corollary 15.27.*

For σ_{st}, Proposition 15.26 sets $[V_1, V_1] = 0$, that is $[P_i, P_j] = [P_i, H] = 0$ by Equation (15.23), leaving the Lorentz algebra acting on an abelian ideal of translations: this is Equation (14.99). For σ_{ss} applied to the resulting Poincaré algebra, $[V_1, V_1] = 0$ now reads $[G_i, G_j] = [G_i, P_j] = [P_i, P_j] = 0$ while $[G_i, H] = P_i$ survives, which is the Galilei algebra $(\gamma, \mu, \nu) = (0, 1, 0)$ of Table 14.1. □

15.5.1 The curvature parameter lives in A

Proposition 15.28 (The quadratic family)**.** *For $t \in \mathbb{R}$ let*

$$A^{(t)} := \mathbb{R}[x]/(x^2 - t)\,, \tag{15.26}$$

a two-dimensional commutative unital algebra. Then

$$A^{(t)} \cong \begin{cases} \mathbb{R} \times \mathbb{R}\,, & t > 0 \quad \textit{(split)}\,, \\ \mathbb{C}\,, & t < 0 \quad \textit{(complex)}\,, \\ \mathbb{R}[\varepsilon]/(\varepsilon^2)\,, & t = 0 \quad \textit{(dual)}\,, \end{cases} \tag{15.27}$$

and only the third is non-semisimple: the trace form of $A^{(t)}$ has determinant $4t$ in the basis $\{1, x\}$.

Rests on Definition 15.9 and Corollary 15.11.

Derivation. *Derives Proposition 15.28.*

$t > 0$. Put $\pi_\pm := \frac{1}{2}(1 \pm x/\sqrt{t})$. Using $x^2 = t$,

$$\pi_\pm^2 = \tfrac{1}{4}\left(1 \pm 2x/\sqrt{t} + x^2/t\right) = \tfrac{1}{4}\left(2 \pm 2x/\sqrt{t}\right) = \pi_\pm\,, \qquad \pi_+\pi_- = \tfrac{1}{4}\left(1 - x^2/t\right) = 0\,,$$

and $\pi_+ + \pi_- = 1$: two orthogonal idempotents, so $A^{(t)}$ splits into two copies of $\mathbb{R}$.

$t < 0$. Put $\jmath := x/\sqrt{-t}$; then $\jmath^2 = x^2/(-t) = -1$, so $\mathbb{R}[\jmath] \cong \mathbb{C}$, and $A^{(t)} \cong \mathbb{C}$ by dimension count.

$t = 0$. The relation is $x^2 = 0$: the dual numbers verbatim.

For the trace form, $L_1 = \mathrm{id}$ has trace 2, L_x interchanges $1 \mapsto x \mapsto t x^0$ and has trace 0, and $L_{x^2} = L_t$ has trace $2t$; the Gram matrix of $\tau(ab)$ in $\{1, x\}$ is therefore $\mathrm{diag}(2, 2t)$, of determinant $4t$. Corollary 15.11 then gives semisimplicity of $\mathfrak{g}_{A^{(t)}}$ for $t \neq 0$ and its failure at $t = 0$. □

Theorem 15.29 (The three constant-curvature kinematics, in every dimension)**.** *Let $\mathfrak{g} = \mathfrak{so}(D-1,2)$ with the space–time grading σ_{st} of Equation (15.24), and inside $\mathfrak{g}_{A^{(t)}}$ consider the resonant subalgebra with respect to the basis $\{1, x\}$ of $A^{(t)}$,*

$$\mathfrak{R}^{(t)} := (1 \otimes V_0) \oplus (x \otimes V_1)\,, \tag{15.28}$$

which has the same dimension as $\mathfrak{g}$. *Then* $\mathfrak{R}^{(t)}$ *is a Lie subalgebra, its brackets are those of Equations* (15.22) *and* (15.23) *with* ς *replaced by* $-t$, *and*

$$\boxed{\mathfrak{R}^{(t)} \cong \begin{cases} \mathfrak{so}(D-1,2)\,, & t>0\,,\ \textit{anti-de Sitter,} \\ \mathfrak{so}(D,1)\,, & t<0\,,\ \textit{de Sitter,} \\ \mathfrak{iso}(D-1,1)\,, & t=0\,,\ \textit{Poincaré.} \end{cases}} \tag{15.29}$$

Rests on Propositions 15.23 and 15.28 and Definitions 15.3 and 15.24.

Derivation. *Derives Theorem 15.29.*

Closure and brackets. For $J, \tilde{J} \in V_0$ and $P, \tilde{P} \in V_1$ write $J' := 1 \otimes J$ and $P' := x \otimes P$. Then Equation (15.2) gives

$$\left[J', \tilde{J}'\right] = 1 \otimes \left[J, \tilde{J}\right]\,, \qquad [J', P'] = x \otimes [J, P]\,, \qquad \left[P', \tilde{P}'\right] = t\left(1 \otimes \left[P, \tilde{P}\right]\right)\,, \tag{15.30}$$

the last using $x^2 = t$ together with $[V_1, V_1] \subseteq V_0$. All three stay in $\mathfrak{R}^{(t)}$, so it is a subalgebra; and since $\left[P, \tilde{P}\right]$ is given by Equation (15.23) with $\varsigma = -1$, the brackets of the primed generators are those of Equations (15.22) and (15.23) with ς replaced by $-t$. Explicitly

$$\left[P'_i, P'_j\right] = t\, J'_{ij}\,, \qquad [P'_i, H'] = -t\, G'_i\,, \tag{15.31}$$

with all other brackets independent of t.

The three cases. For $t > 0$ rescale $P'_i \mapsto P'_i/\sqrt{t}$, $H' \mapsto H'/\sqrt{t}$: an invertible change of basis which turns Equation (15.31) into $[P, P] = J$, $[P, H] = -G$, that is Equation (15.23) with $\varsigma = -1$, the anti-de Sitter algebra $\mathfrak{so}(D-1,2)$. For $t < 0$ rescale by $\sqrt{-t}$ instead, obtaining $[P, P] = -J$, $[P, H] = +G$, which is Equation (15.23) with $\varsigma = +1$: by Proposition 15.23 this is the algebra with $\eta_{DD} = +1$, namely $\mathfrak{so}(D,1)$. For $t = 0$ both brackets in Equation (15.31) vanish and the translations become an abelian ideal, giving $\mathfrak{iso}(D-1,1)$ — which is also Corollary 15.27, since $A^{(0)}$ is the algebra of dual numbers and $\mathfrak{R}^{(0)} = \mathfrak{R}_1^{\sigma_{\mathrm{st}}}$. □

Remark 15.30 (What is special about $D = 3$, and what is not). Theorem 15.29 holds in every dimension because it works inside the resonant subalgebra, which has the same dimension as $\mathfrak{g}$. The *ambient* algebra $\mathfrak{g}_{A^{(t)}}$ is twice as large, and only in $D = 3$ does it coincide with a kinematical algebra: there $\dim V_0 = \dim V_1 = 3$, the resonant subalgebra is all of $\mathfrak{g}_{A^{(t)}}$ up to the Hodge dualisation $J_{ij} \leftrightarrow \epsilon_{ijk} J^k$, and one has the accidental isomorphisms

$$\mathfrak{so}(2,1) \oplus \mathfrak{so}(2,1) \cong \mathfrak{so}(2,2)\,, \qquad \mathbb{C} \otimes_{\mathbb{R}} \mathfrak{so}(2,1) \cong \mathfrak{sl}_2(\mathbb{C}) \cong \mathfrak{so}(3,1)\,, \tag{15.32}$$

so that the split, complex and dual branches of Proposition 15.28 are directly the anti-de Sitter, de Sitter and Poincaré algebras of three-dimensional spacetime. In $D = 4$ this fails: $\mathfrak{so}(3,2) \oplus \mathfrak{so}(3,2)$ is a ten-plus-ten dimensional algebra and is not a kinematical algebra at all, and the correct statement in 3+1 is the one Theorem 15.29 makes about $\mathfrak{R}^{(t)}$. Much of the gauge-gravity literature is written in $D = 3$ precisely because of Equation (15.32), and reading its statements as dimension-independent is a mistake this treatise is careful not to make.

15.5.2 The (anti-)de Sitter radius and the cosmological constant

The parameter t has a name in physics. To give it, one needs the relation between the curvature radius of a maximally symmetric spacetime and the cosmological constant, a short computation from the field equations.

Proposition 15.31 (Radius and cosmological constant)**.** *Let (M, g) be a D-dimensional maximally symmetric solution of the vacuum field equations with cosmological constant,*

$$R_{\mu\nu} - \tfrac{1}{2} R\, g_{\mu\nu} + \Lambda\, g_{\mu\nu} = 0\,, \tag{15.33}$$

so that its Riemann tensor has the constant-curvature form

$$R_{\mu\nu\rho\sigma} = K\,(g_{\mu\rho}g_{\nu\sigma} - g_{\mu\sigma}g_{\nu\rho})\,, \qquad K \in \mathbb{R}\,. \tag{15.34}$$

Then, for $D > 2$,

$$\boxed{K = \frac{2\Lambda}{(D-1)(D-2)}}\,, \tag{15.35}$$

and, writing $|K| = 1/\ell^2$ for the curvature radius ℓ,

$$\boxed{\Lambda = \pm\frac{(D-1)(D-2)}{2\ell^2}}\,, \tag{15.36}$$

the upper sign for de Sitter space ($K > 0$, isometry algebra $\mathfrak{so}(D,1)$) and the lower for anti-de Sitter space ($K < 0$, isometry algebra $\mathfrak{so}(D-1,2)$). In $D = 4$ this reads $\Lambda = \pm 3/\ell^2$, and in $D = 3$, $\Lambda = \pm 1/\ell^2$.

Derivation. *Derives Proposition 15.31.*

Trace Equation (15.33) with $g^{\mu\nu}$, using $g^{\mu\nu}g_{\mu\nu} = D$:

$$R - \tfrac{D}{2}R + D\Lambda = 0 \quad\Longrightarrow\quad R = \frac{2D\Lambda}{D-2}\,,$$

valid for $D \neq 2$. Substituting back,

$$R_{\mu\nu} = \left(\tfrac{1}{2}R - \Lambda\right) g_{\mu\nu} = \left(\frac{D\Lambda}{D-2} - \Lambda\right) g_{\mu\nu} = \frac{2\Lambda}{D-2}\, g_{\mu\nu}\,. \tag{15.37}$$

From Equation (15.33) (trace with $g^{\mu\nu}$ and substitute the resulting scalar curvature back).

Contracting Equation (15.34) with $g^{\mu\rho}$,

$$R_{\nu\sigma} = g^{\mu\rho}R_{\mu\nu\rho\sigma} = K\,(D\, g_{\nu\sigma} - g_{\nu\sigma}) = (D-1)K\, g_{\nu\sigma}\,.$$

Comparing with Equation (15.37) gives Equation (15.35), and Equation (15.36) follows on setting $|K| = 1/\ell^2$. The isometry algebras are those of the hyperboloids $\eta_{AB}X^A X^B = \pm\ell^2$ in $\mathbb{R}^{D,1}$ and $\mathbb{R}^{D-1,2}$ respectively, which is how $\mathfrak{so}(D,1)$ and $\mathfrak{so}(D-1,2)$ were introduced in Chapter 14. □

Corollary 15.32 (The expansion parameter is the cosmological constant)**.** *With the identifications of Theorem 15.29 and Proposition 15.31,*

$$\boxed{t = -\frac{2\Lambda}{(D-1)(D-2)} = \begin{cases} +1/\ell^2\,, & \textit{anti-de Sitter, } \Lambda < 0\,, \\ -1/\ell^2\,, & \textit{de Sitter, } \Lambda > 0\,, \\ 0\,, & \textit{Minkowski, } \Lambda = 0\,. \end{cases}} \tag{15.38}$$

The flat limit $\ell \to \infty$ is the degeneration $t \to 0$ of Proposition 15.28, and the sign of the cosmological constant is minus the sign of the discriminant of the quadratic that defines A.

Rests on Theorem 15.29 and Propositions 15.28 and 15.31.

Derivation. *Derives Corollary 15.32.*

Theorem 15.29 makes $\mathfrak{R}^{(t)}$ the anti-de Sitter algebra for $t > 0$ and the de Sitter algebra for $t < 0$; Proposition 15.31 attaches $\Lambda < 0$ to the first and $\Lambda > 0$ to the second, with $|\Lambda| = (D-1)(D-2)/(2\ell^2)$ in both cases. Since the rescaling used in the proof of Theorem 15.29 sends $|t|$ to 1, the parameter t carries the units of $|K| = 1/\ell^2$ and the sign that distinguishes the branches, which is Equation (15.38) once Equation (15.35) is used. □

Remark 15.33 (Which branch nature is on). The cosmological constant inferred from the expansion history is *positive*. With the Planck values $\Omega_\Lambda = 0.6889(56)$ and $H_0 = (67.66 \pm 0.42)\,\mathrm{km/(s\,Mpc)}$ [2348], in $D = 4$,

$$\Lambda = \frac{3\Omega_\Lambda H_0^2}{c^2} \approx 1.1 \times 10^{-52}/\mathrm{m}^2\,, \qquad \ell = \sqrt{3/\Lambda} \approx 1.6 \times 10^{26}\,\mathrm{m}\,, \tag{15.39}$$

a radius of about 17 Gyr in light-travel terms; the independent distance-ladder determination of H_0 [2407] moves the number by a few per cent without touching its sign. By Corollary 15.32 the observed universe therefore sits on the branch $t < 0$, whose kinematical algebra is $\mathfrak{so}(4,1)$ — *de Sitter*, not the anti-de Sitter algebra $\mathfrak{so}(3,2)$ around which most of the gauge-gravity literature is built. That is the verdict already recorded in Table 14.1, now expressed as a property of A: the sign of a measured quantity selects which of the three two-dimensional commutative algebras of Proposition 15.28 describes nature.

One qualification, which the treatise insists on: Equation (15.39) is an inference from the expansion history of Chapter 48 within a ΛCDM parametrisation, not a measurement of a symmetry algebra. A symmetry is measured by testing its transformations, as in Chapter 37. What is being claimed here is that *if* the asymptotic geometry is de Sitter, the algebra is $\mathfrak{so}(4,1)$ and $t < 0$; the antecedent is observational and the consequent is a theorem.

Rests on Corollary 15.32 and Proposition 15.31.

15.6 Central charges as the top level of an expansion

We come to the point of the chapter. In Section 14.4 a central extension was a choice: a class in $H^2(\mathfrak{g}, \mathbb{R})$, imposed on the algebra from outside. Here it is not a choice but a consequence. Adding one level to the truncation adds generators, and the generators added at the top of the tower are the central charge.

Theorem 15.34 (The truncation tower is a tower of central extensions)**.** *Fix a $\mathbb{Z}_2$-grading σ of $\mathfrak{g}$ and let $\mathfrak{R}^\sigma_N$ be as in Definition 15.20. Let $\pi_N : A_{N+1} \to A_N$ be the algebra epimorphism $\varepsilon^{N+1} \mapsto 0$. Then:*

1. *π_N induces a surjective Lie homomorphism $p_N : \mathfrak{R}^\sigma_{N+1} \to \mathfrak{R}^\sigma_N$ with kernel*

$$\mathfrak{k}_N := \varepsilon^{N+1} \otimes V_{[N+1]}\,, \tag{15.40}$$

   and $\mathfrak{k}_N$ is an abelian ideal.

2. *An element $\varepsilon^{N+1} \otimes X$ of $\mathfrak{k}_N$ is central in $\mathfrak{R}^\sigma_{N+1}$ if and only if*

$$\boxed{[X, V_0] = 0}\,, \tag{15.41}$$

   so $\mathfrak{k}_N$ is central exactly when $\big[V_{[N+1]}, V_0\big] = 0$.

3. *When $\mathfrak{k}_N$ is central,*

$$0 \longrightarrow \mathfrak{k}_N \longrightarrow \mathfrak{R}^\sigma_{N+1} \xrightarrow{\;p_N\;} \mathfrak{R}^\sigma_N \longrightarrow 0 \tag{15.42}$$

is a central extension in the sense of Definition 14.72, and the 2-cocycle determined by the level-preserving splitting is

$$\boxed{c\left(\varepsilon^i \otimes X,\ \varepsilon^j \otimes Y\right) = \delta_{i+j,\,N+1}\,\varepsilon^{N+1} \otimes [X,Y]}\,. \tag{15.43}$$

Rests on Definitions 14.72, 15.18 and 15.20 and Propositions 14.73 and 15.6.

Derivation. *Derives Theorem 15.34.*

(1) By Proposition 15.6, $\pi_N \otimes \mathrm{id}$ is a Lie homomorphism $\mathfrak{g}\langle N+1\rangle \to \mathfrak{g}\langle N\rangle$; it maps $\varepsilon^k \otimes V_{[k]}$ identically onto itself for $k \le N$ and kills the top level, so it carries $\mathfrak{R}^\sigma_{N+1}$ onto $\mathfrak{R}^\sigma_N$ with kernel Equation (15.40). That kernel is abelian because

$$\left[\varepsilon^{N+1} \otimes X, \varepsilon^{N+1} \otimes Y\right] = \varepsilon^{2N+2} \otimes [X,Y] = 0\,,$$

since $2N+2 > N+1$ for every $N \ge 0$.

(2) Let $X \in V_{[N+1]}$ and let $\varepsilon^j \otimes Y$ be an arbitrary element of $\mathfrak{R}^\sigma_{N+1}$, so $Y \in V_{[j]}$. Then

$$\left[\varepsilon^{N+1} \otimes X, \varepsilon^j \otimes Y\right] = \varepsilon^{N+1+j} \otimes [X,Y]\ , \tag{15.44}$$

which vanishes automatically for every $j \ge 1$, since then $N+1+j > N+1$. Only $j=0$ can survive; there $Y \in V_0$ and Equation (15.44) equals $\varepsilon^{N+1} \otimes [X,Y]$. By Equation (15.17), $[X,Y] \in V_{[N+1]}$, and $\varepsilon^{N+1} \otimes Z$ vanishes for $Z \in V_{[N+1]}$ only if $Z = 0$. So the bracket vanishes for all Y exactly when $[X,V_0] = 0$.

(3) The sequence Equation (15.42) is exact by (1) and central by (2), so it is a central extension. Define the splitting $s : \mathfrak{R}^\sigma_N \to \mathfrak{R}^\sigma_{N+1}$ by $s(\varepsilon^i \otimes X) = \varepsilon^i \otimes X$ for $i \le N$, a linear section of p_N. For $i, j \le N$,

$$\left[s(\varepsilon^i \otimes X), s(\varepsilon^j \otimes Y)\right] = \varepsilon^{i+j} \otimes [X,Y]$$

in $\mathfrak{R}^\sigma_{N+1}$, whereas the same bracket computed in $\mathfrak{R}^\sigma_N$ and then lifted by s gives $\varepsilon^{i+j} \otimes [X,Y]$ when $i+j \le N$ and 0 when $i+j > N$. The two agree except when $i+j = N+1$, where the difference is $\varepsilon^{N+1} \otimes [X,Y] \in \mathfrak{k}_N$; for $i+j > N+1$ both vanish. Comparing with Equation (14.120), the defect is the cocycle Equation (15.43), which satisfies Equation (14.121) automatically by Proposition 14.73. □

Corollary 15.35 (Where the central charges are)**.** *Let $\mathfrak{z}(V_0) = \{X \in V_0 : [X,V_0] = 0\}$ be the centre of the subalgebra V_0, and let $V_1^{V_0} = \{Y \in V_1 : [Y,V_0] = 0\}$ be the subspace of V_1 on which V_0 acts trivially. Then the top level of $\mathfrak{R}^\sigma_N$ contributes to the centre exactly*

$$\boxed{\varepsilon^N \otimes \begin{cases} \mathfrak{z}(V_0)\,, & N \text{ even,} \\ V_1^{V_0}\,, & N \text{ odd.} \end{cases}} \tag{15.45}$$

In particular, if V_1 carries no trivial V_0-summand — which holds for every grading of Equation (15.24), since V_0 always contains the rotations and V_1 always consists of spatial vectors — central charges occur only at even truncation order*, and they are the level-N copies of the centre of V_0.*

Rests on Theorem 15.34 and Definition 15.24.

Derivation. *Derives Corollary 15.35.*

Apply Theorem 15.34(2) with N in place of $N+1$: an element $\varepsilon^N \otimes X$ with $X \in V_{[N]}$ is central precisely when $[X,V_0] = 0$. For N even, $V_{[N]} = V_0$ and the condition defines $\mathfrak{z}(V_0)$; for N odd, $V_{[N]} = V_1$ and it defines $V_1^{V_0}$. For the last sentence, in each grading of Equation (15.24) the space V_1 is spanned by generators carrying a free spatial index, on which the rotations $J_{ij} \subseteq V_0$ act as on the vector representation of $\mathfrak{so}(D-1)$; that representation has no trivial summand for $D \ge 3$, so $V_1^{V_0} = 0$. □

Corollary 15.36 (Bargmann in 3+1, extended Bargmann in 2+1)**.** *Let* $\mathfrak{g} = \mathfrak{iso}(D-1,1)$ *be the Poincaré algebra and let* σ_{ss} *be the speed–space grading* $V_0 = \langle J_{ij}, H\rangle$, $V_1 = \langle G_i, P_i\rangle$. *Then:*

1. $\mathfrak{R}_1^{\sigma_{\mathrm{ss}}}$ *is the* Galilei *algebra, with no central charge;*
2. *at* $N = 2$ *the element* $M := \varepsilon^2 \otimes H$ *is central in every dimension, and*

$$\boxed{[\varepsilon \otimes G_i, \varepsilon \otimes P_j] = \delta_{ij}\, M}\,. \tag{15.46}$$

   For $D \geq 4$ *the centre of* V_0 *is exactly* $\langle H\rangle$*, so* M *is the* only *central charge; quotienting* $\mathfrak{R}_2^{\sigma_{\mathrm{ss}}}$ *by the ideal* $\varepsilon^2 \otimes \langle J_{ij}\rangle$ *leaves the* Bargmann *algebra, the central extension of Galilei by the mass. In* 3+1 *this is the physically relevant case;*
3. *only for* $D = 3$ *is* $\langle J_{ij}\rangle$ *abelian, so that* $\mathfrak{z}(V_0) = \langle H, J\rangle$ *and* $\mathfrak{R}_2^{\sigma_{\mathrm{ss}}}$ *is the* extended Bargmann *algebra with the two central charges* $M = \varepsilon^2 \otimes H$ *and* $S = \varepsilon^2 \otimes J$*; this is the algebra on which the three-dimensional constructions of [2425] are built.*

In every dimension the cocycle Equation (15.43) *of this extension is* $c(G_i, P_j) = \delta_{ij}$*, which is the class computed from the Poisson brackets of a free particle in Proposition 25.14 and named in Example 14.80.*

Rests on Theorem 15.34, Corollaries 15.27 and 15.35, and Proposition 25.14.

Derivation. *Derives Corollary 15.36.*

The grading. The Poincaré brackets are Equations (15.22) and (15.23) with $\varsigma = 0$, that is $[P_i, P_j] = [P_i, H] = 0$, the rest unchanged (Corollary 15.27). Then $[G_i, G_j] = J_{ij}$, $[G_i, P_j] = \delta_{ij} H$ and $[P_i, P_j] = 0$ lie in V_0; $[J, G] \sim G$, $[J, P] \sim P$, $[H, G_i] = -P_i$ and $[H, P_i] = 0$ lie in V_1; and $[J, J] \sim J$, $[J_{ij}, H] = 0$ lie in V_0. Equation (15.17) holds, and $V_0 = \mathfrak{so}(D-1) \oplus \langle H\rangle$ as a direct sum of ideals.

(1). $\mathfrak{R}_1^{\sigma_{\mathrm{ss}}} = (1 \otimes V_0) \oplus (\varepsilon \otimes V_1)$, and by Equation (15.15) every bracket of two level-1 generators lands at level $2 > 1$ and vanishes, so $[G_i, G_j] = [G_i, P_j] = [P_i, P_j] = 0$ while $[H, G_i] = -P_i$ survives: the Galilei algebra $(\gamma, \mu, \nu) = (0, 1, 0)$. It has no central charge because Corollary 15.35 with $N = 1$ odd gives $V_1^{V_0} = 0$ for $D \geq 3$.

(2). By Equation (15.43) with $i = j = 1$ and $N + 1 = 2$,

$$[\varepsilon \otimes G_i, \varepsilon \otimes P_j] = \varepsilon^2 \otimes [G_i, P_j] = \delta_{ij}\, \varepsilon^2 \otimes H\,,$$

which is Equation (15.46). That M is central follows from Equation (15.41): $[H, V_0] = 0$ because $[H, J_{ij}] = 0$ and $[H, H] = 0$. By Corollary 15.35 the full central content of the top level is $\varepsilon^2 \otimes \mathfrak{z}(V_0)$, and $\mathfrak{z}(V_0) = \langle H\rangle \oplus \mathfrak{z}(\mathfrak{so}(D-1)) = \langle H\rangle$ for $D - 1 \geq 3$, since $\mathfrak{so}(n)$ has trivial centre for $n \geq 3$. The subspace $\mathfrak{i} := \varepsilon^2 \otimes \langle J_{ij}\rangle$ is an ideal: its brackets with levels ≥ 1 vanish for degree reasons, and at level 0 one has $[J_{ij}, J_{kl}] \in \langle J\rangle$ and $[J_{ij}, H] = 0$. Quotienting by $\mathfrak{i}$ kills $[\varepsilon \otimes G_i, \varepsilon \otimes G_j] = \varepsilon^2 \otimes J_{ij}$ and leaves the generators J_{ij}, H, G_i, P_i, M with M central and Equation (15.46) the only new bracket: the Bargmann algebra.

(3). For $D = 3$ the rotation sector is one-dimensional, spanned by a single J, so $[V_0, V_0] = 0$ and $\mathfrak{z}(V_0) = V_0$. Then $S := \varepsilon^2 \otimes J$ is central as well and $[\varepsilon \otimes G_1, \varepsilon \otimes G_2] = \varepsilon^2 \otimes J_{12}$ is a multiple of S: the two-fold central extension called the extended Bargmann algebra. That $D = 3$ is the only such case is the computation of $\mathfrak{z}(V_0)$ in part (2).

The cocycle. Reading Equation (15.46) against Equation (14.120) with central generator $Z = M$ gives $c(G_i, P_j) = \delta_{ij}$ and $c = 0$ on every other pair, which is Equation (25.18) with the mass scaled to unity. □

Remark 15.37 (Why this answers the structural question)*.* Equation (15.43) says that the 2-cocycle of the extension is nothing other than *the part of the bracket that the truncation discards.* Going from $\mathfrak{R}_N^{\sigma}$ to $\mathfrak{R}_{N+1}^{\sigma}$ does not add a central charge by fiat; it stops throwing

one away. The cohomological obstruction of Definition 14.75 and the level structure of the expansion are two descriptions of one object, and the reason a contraction can create a central charge (Proposition 14.84) becomes visible: a contraction is the truncation $\varepsilon^2 = 0$ (Proposition 15.26), and truncation is what makes a bracket land on a central generator instead of a genuine one.

Remark 15.38 (The same statement seen three ways). The mass of a nonrelativistic particle has now been obtained as a central charge three times in this treatise, and the three are one fact in three languages. In Proposition 25.14 it is the constant defect of the Poisson-bracket realisation of the Galilei algebra, computed from the explicit generators of a free particle in 3+1. In Example 14.80 it is the generator of the one-dimensional H^2 of the Galilei algebra. Here it is the level-2 time translation $\varepsilon^2 \otimes H$ of an expansion truncated one order later than the contraction that produces Galilei. The third is the most structural, because Corollary 15.35 also settles how many other central charges there are: in 3+1 exactly none, since $\mathfrak{z}(V_0) = \langle H \rangle$; the second charge S of the extended Bargmann algebra is a feature of 2+1 alone.

Table 15.1: The four gradings of Equation (15.24) applied to $\mathfrak{so}(D-1,2)$ (or to its flat contraction where indicated), the algebra obtained at truncation $N = 1$ by Proposition 15.26, and the central charges carried by the top level at $N = 2$, computed from Corollary 15.35 as $\varepsilon^2 \otimes \mathfrak{z}(V_0)$. Names in the third column are those of Table 14.1. The last row is the exception of Proposition 15.25: it is not a symmetric coset, so the resonant subspace closes only at $N = 1$, where every level-2 bracket vanishes for degree reasons anyway.

Grading	V_0	Algebra at $N = 1$	$\mathfrak{z}(V_0)$	Central charges at $N = 2$
space–time	J_{ij}, G_i	Poincaré $\mathfrak{iso}(D-1,1)$	0, the Lorentz algebra being simple	none; the top level $\varepsilon^2 \otimes V_0$ is the Maxwell tensor Z_{ab}
speed–space	J_{ij}, H	Newton–Hooke from $\mathfrak{so}(D-1,2)$, Galilei from $\mathfrak{iso}(D-1,1)$	$\langle H \rangle$ for $D \geq 4$; $\langle H, J \rangle$ for $D = 3$	the mass $M = \varepsilon^2 \otimes H$; in 2+1 also $S = \varepsilon^2 \otimes J$
speed–time	J_{ij}, P_i	para-Poincaré from $\mathfrak{so}(D-1,2)$, Carroll from $\mathfrak{iso}(D-1,1)$	0: the rotations act nontrivially on P_i for $D \geq 3$	none from the top level
general	J_{ij}	static	—	— (not a symmetric coset)

Remark 15.39 (What the construction does and does not prove). Table 15.1 *produces* four of the eleven algebras of Table 14.1 in one step; the remaining seven arise by iterating the construction (Galilei from Poincaré rather than from $\mathfrak{so}(D-1,2)$, as in Corollary 15.27) or by the sign of t in Corollary 15.32, which is what splits de Sitter from anti-de Sitter and Newton–Hooke from its anti- partner. Section 15.7 does the bookkeeping properly: the four splittings turn out to be three edge directions and one main diagonal of a single cube, and all eleven algebras are accounted for at once. What the construction does *not* do is prove that the list of eleven is complete. That is the separate theorem Theorem 14.90, proved in Appendix A.10 by exhausting the possible structure constants, and nothing here replaces it. The two results answer different questions: one says which algebras exist, the other says how they are generated from one another and what central charges accompany them.

15.7 The Bacry–Lévy-Leblond cube as a lattice of algebras

Theorem 14.90 organises the eleven kinematical algebras by three constants (γ, μ, ν) and observes that setting each of them to zero is a contraction, so that the eight vanishing patterns are the vertices of a cube. The cube is drawn there as a picture. It is in fact an algebraic object, and this section identifies it: the eight vertices are the eight degenerations of one four-dimensional commutative algebra, the three constants are its three structure constants, and the count $8 + 3 = 11$ falls out of the sign data of that algebra — including the two entries that hypothesis (H3) of Theorem 14.90 removes.

15.7.1 The kinematical generators are a Klein grading

The gradings of Equation (15.24) were introduced one at a time. They are not independent.

Lemma 15.40 (The three symmetric cosets are one $\mathbb{Z}_2 \times \mathbb{Z}_2$-grading)**.** *Let $\theta_{\mathrm{st}}, \theta_{\mathrm{ss}}, \theta_{\mathrm{sT}}$ be the involutions of Lemma 15.19 attached to the three symmetric-coset gradings of Proposition 15.25. Then*

$$\theta_{\mathrm{st}}\,\theta_{\mathrm{ss}} = \theta_{\mathrm{sT}}\,, \tag{15.47}$$

so the three generate a Klein four-group $\Gamma \cong \mathbb{Z}_2 \times \mathbb{Z}_2$, and the common eigenspaces of Γ are

$$\boxed{\mathfrak{g}_{00} = \langle J_{ij} \rangle\,, \quad \mathfrak{g}_{01} = \langle G_i \rangle\,, \quad \mathfrak{g}_{10} = \langle H \rangle\,, \quad \mathfrak{g}_{11} = \langle P_i \rangle}\,, \tag{15.48}$$

a Γ-grading of $\mathfrak{so}(D-1,2)$: $[\mathfrak{g}_\alpha, \mathfrak{g}_\beta] \subseteq \mathfrak{g}_{\alpha+\beta}$. The three symmetric-coset gradings are exactly the three surjections $\Gamma \to \mathbb{Z}_2$, and the fourth splitting σ_{gen} of Equation (15.24) is not induced by any group homomorphism — which is why it fails Equation (15.17).

Rests on Lemma 15.19, Definition 15.24, and Propositions 15.23 and 15.25.

Derivation. *Derives Lemma 15.40.*

Evaluate $\theta_{\mathrm{st}}\theta_{\mathrm{ss}}$ on each generator, using $\theta = +1$ on V_0 and -1 on V_1 for the corresponding splitting of Equation (15.24):

$$J_{ij} : (+)(+) = +\,, \quad G_i : (+)(-) = -\,, \quad H : (-)(+) = -\,, \quad P_i : (-)(-) = +\,,$$

which is $+1$ on $\langle J_{ij}, P_i \rangle$ and -1 on $\langle G_i, H \rangle$: that is θ_{sT}, proving Equation (15.47). Each θ squares to the identity, so the group they generate is $\mathbb{Z}_2 \times \mathbb{Z}_2$.

Label a character of Γ by its values on $(\theta_{\mathrm{st}}, \theta_{\mathrm{ss}})$, writing 0 for $+1$ and 1 for -1. Reading the signs above gives Equation (15.48). That this is a grading is Equations (15.22) and (15.23) read modulo two: $[G, P] \propto H$ is $01 + 11 = 10$; $[G, H] \propto P$ is $01 + 10 = 11$; $[H, P] \propto G$ is $10 + 11 = 01$; $[G, G]$ and $[P, P]$ are proportional to J, which is $01 + 01 = 00$ and $11 + 11 = 00$; and $[J, \cdot\,]$ preserves each component because J has degree 00.

A surjection $\Gamma \to \mathbb{Z}_2$ has a two-element kernel, so it makes exactly one of the three nontrivial components even together with $\mathfrak{g}_{00}$; the three kernels $\{00, 01\}$, $\{00, 10\}$, $\{00, 11\}$ give $V_0 = \langle J, G \rangle$, $\langle J, H \rangle$, $\langle J, P \rangle$, which are σ_{st}, σ_{ss}, σ_{sT}. The splitting σ_{gen} has $V_0 = \langle J_{ij} \rangle$ alone; no subgroup of Γ has order one and index two, so it is not the kernel of any homomorphism, and Proposition 15.25 showed directly that it is not a symmetric coset. □

15.7.2 Resonance for a graded group

Definition 15.20 matched the parity of a power of ε to the parity of a grading. Nothing in the argument used $\mathbb{Z}_2$.

Proposition 15.41 (Resonance, general form)**.** *Let Γ be a finite abelian group, let $\mathfrak{g} = \bigoplus_{\alpha\in\Gamma} \mathfrak{g}_\alpha$ be a Γ-graded Lie algebra and $A = \bigoplus_{\alpha\in\Gamma} A_\alpha$ a Γ-graded commutative associative algebra. Then*

$$\boxed{\mathfrak{R} := \bigoplus_{\alpha\in\Gamma} A_\alpha \otimes \mathfrak{g}_\alpha} \tag{15.49}$$

is a Lie subalgebra of $\mathfrak{g}_A$.
Rests on Definition 15.3.

Derivation. *Derives Proposition 15.41.*
By Equation (15.2),

$$[A_\alpha \otimes \mathfrak{g}_\alpha, A_\beta \otimes \mathfrak{g}_\beta] \subseteq (A_\alpha A_\beta) \otimes [\mathfrak{g}_\alpha, \mathfrak{g}_\beta] \subseteq A_{\alpha+\beta} \otimes \mathfrak{g}_{\alpha+\beta} \subseteq \mathfrak{R}\,,$$

the middle inclusion being the two grading hypotheses. Proposition 15.21 is the case $\Gamma = \mathbb{Z}_2$ with $A = A_N$ graded by the parity of the exponent of ε. □

15.7.3 The algebra with three structure constants

Proposition 15.42 (The Γ-graded commutative algebras)**.** *Let* $\Gamma = \mathbb{Z}_2 \times \mathbb{Z}_2$ *and let* A *be a commutative associative unital* Γ*-graded* $\mathbb{R}$*-algebra whose four graded pieces are all one-dimensional, spanned by* 1 *and by* e_G, e_H, e_P *in the degrees of Equation (15.48). Then* A *is determined by three real numbers* $\lambda_G, \lambda_H, \lambda_P$ *through*

$$\boxed{e_G e_P = \lambda_H e_H\,, \qquad e_G e_H = \lambda_P e_P\,, \qquad e_H e_P = \lambda_G e_G}\,, \tag{15.50}$$

and associativity then forces *the squares to be*

$$\boxed{e_G^2 = \lambda_H \lambda_P\,, \qquad e_H^2 = \lambda_G \lambda_P\,, \qquad e_P^2 = \lambda_G \lambda_H}\,. \tag{15.51}$$

Write $A(\lambda)$ *for this algebra. Its trace form Equation (15.7) is* $\operatorname{diag}(4,\, 4e_G^2,\, 4e_H^2,\, 4e_P^2)$ *in the basis* $\{1, e_G, e_H, e_P\}$*, so* $A(\lambda)$ *is semisimple if and only if* $\lambda_G \lambda_H \lambda_P \neq 0$.
Rests on Lemma 15.40, Definition 15.9, and Corollary 15.11.

Derivation. *Derives Proposition 15.42.*
The three products Equation (15.50) are forced to lie in the stated one-dimensional pieces by the grading, since $01 + 11 = 10$, $01 + 10 = 11$ and $10 + 11 = 01$; the mnemonic is that λ_X is the constant of the product that *lands on* e_X. A square has degree 00, so e_X^2 is a multiple of 1.

For Equation (15.51), impose associativity on $e_G\, e_G\, e_P$:

$$(e_G e_G)\, e_P = e_G^2\, e_P\,, \qquad e_G\, (e_G e_P) = e_G\, (\lambda_H e_H) = \lambda_H \lambda_P\, e_P\,,$$

whence $e_G^2 = \lambda_H \lambda_P$; the other two squares follow by the same computation on $e_H e_H e_G$ and $e_P e_P e_G$. With Equation (15.51) in force every remaining triple product is associative: the only case not already used is $(e_G e_H)\, e_P = \lambda_P e_P^2 = \lambda_G \lambda_H \lambda_P$ against $e_G\, (e_H e_P) = \lambda_G e_G^2 = \lambda_G \lambda_H \lambda_P$, which agree.

For the trace form, L_{e_G} sends $1 \mapsto e_G$, $e_G \mapsto e_G^2 \cdot 1$, $e_H \mapsto \lambda_P e_P$ and $e_P \mapsto \lambda_H e_H$: no basis vector is sent to a multiple of itself, so $\tau_A(e_G) = 0$, and likewise for e_H, e_P. Hence $\tau_A(e_X e_Y) = 0$ for $X \neq Y$, while $\tau_A(1) = \operatorname{tr}(\mathrm{id}) = 4$ and $\tau_A(e_X^2) = 4e_X^2$. The determinant is $4^4\, (\lambda_G \lambda_H \lambda_P)^2$ by Equation (15.51), and Corollary 15.11 converts nondegeneracy into semisimplicity. □

15.7.4 The cube

Theorem 15.43 (The three constants of the classification are the three structure constants of A)**.** *Let* $\mathfrak{g}$ *be a kinematical algebra with constants* (γ, μ, ν) *in the sense of Equations (14.128) and (14.129), graded by* Γ *as in Equation (15.48), and let* $\mathfrak{R}(\lambda) \subseteq \mathfrak{g}_{A(\lambda)}$ *be the resonant subalgebra Equation (15.49), of the same dimension as* $\mathfrak{g}$*. Then* $\mathfrak{R}(\lambda)$ *is again a kinematical algebra in the sense of Theorem 14.90, with constants*

$$\boxed{(\gamma, \mu, \nu) \longmapsto (\gamma\lambda_H,\ \mu\lambda_P,\ \nu\lambda_G)}\,, \tag{15.52}$$

and the two brackets that the Jacobi identity fixes, Equation (14.129)*, come out consistent with Equation* (15.52) *without further assumption.*

Rests on Propositions 15.41 and 15.42, Lemma 15.40, and Equations (14.128) *and* (14.129)*.*

Derivation. *Derives Theorem 15.43.*

Write the resonant generators as $J' := 1 \otimes J_{ij}$, $G' := e_G \otimes G_i$, $H' := e_H \otimes H$, $P' := e_P \otimes P_i$; by Proposition 15.41 they span a subalgebra, of dimension $\dim \mathfrak{g}$ because each graded piece of $A(\lambda)$ is one-dimensional. Now apply Equation (15.2) to each bracket of Equation (14.128), using Equation (15.50):

$$\left[G'_i, P'_j\right] = (e_G e_P) \otimes [G_i, P_j] = \lambda_H e_H \otimes \gamma\, \delta_{ij} H = (\gamma\lambda_H)\, \delta_{ij} H' \,, \tag{15.53}$$

$$[G'_i, H'] = (e_G e_H) \otimes [G_i, H] = \lambda_P e_P \otimes \mu P_i = (\mu\lambda_P)\, P'_i \,, \tag{15.54}$$

$$[P'_i, H'] = (e_P e_H) \otimes [P_i, H] = \lambda_G e_G \otimes \nu G_i = (\nu\lambda_G)\, G'_i \,, \tag{15.55}$$

which is Equation (15.52). For the two remaining brackets, use Equation (15.51):

$$\left[G'_i, G'_j\right] = e_G^2 \otimes [G_i, G_j] = \lambda_H\lambda_P\,(-\gamma\mu\,\epsilon_{ijk} J_k) = -\,(\gamma\lambda_H)\,(\mu\lambda_P)\,\epsilon_{ijk} J'_k \,,$$

$$\left[P'_i, P'_j\right] = e_P^2 \otimes [P_i, P_j] = \lambda_G\lambda_H\,(\gamma\nu\,\epsilon_{ijk} J_k) = (\gamma\lambda_H)\,(\nu\lambda_G)\,\epsilon_{ijk} J'_k \,,$$

which are exactly Equation (14.129) written for the image constants. The rotations act on G'_i and P'_i as before, since $1 \cdot e_X = e_X$, so hypothesis (H1) of Theorem 14.90 survives, and the parity and time-reversal automorphisms of hypothesis (H2) commute with the grading because they act on each of J, G, H, P by a sign.

The consistency of the last display is the point worth noting: the squares Equation (15.51) were forced on $A(\lambda)$ by *associativity*, and the relations Equation (14.129) were forced on $\mathfrak{g}$ by the *Jacobi identity*. That the first reproduces the second is the factorisation of Equation (15.3) doing its work. □

Corollary 15.44 (The eight vertices are the eight degenerations of A)**.** *Under Equation* (15.52) *the vanishing pattern of* (γ, μ, ν) *is the vanishing pattern of* $(\lambda_H, \lambda_P, \lambda_G)$*, so the eight vertices of the contraction cube of Theorem 14.90 are the eight vanishing patterns of the structure constants of* $A(\lambda)$*, and each edge of the cube is a degeneration* $\lambda_X \to 0$ *of the algebra. Moreover the four splittings of Equation* (15.24) *sit in the cube as follows:*

- σ_{st} *sets* $\lambda_G = 0$*, killing* ν*;*
- σ_{ss} *sets* $\lambda_H = 0$*, killing* γ*;*
- σ_{sT} *sets* $\lambda_P = 0$*, killing* μ*;*
- σ_{gen} *sets all three to zero at once.*

The first three are the three edge directions; the fourth is the main diagonal, from the vertex where nothing vanishes to the vertex where everything does.

Rests on Theorems 14.90 and 15.43, Proposition 15.26, and Definition 15.24.

Derivation. *Derives Corollary 15.44.*

The first sentence is Equation (15.52). For the identification of the splittings, Proposition 15.26 sets $[V_1, V_1] = 0$ and leaves the other brackets alone. Reading Equation (15.24) against Equations (14.128) and (14.129): for σ_{st}, $V_1 = \langle H, P_i \rangle$ and the brackets inside it are $[P_i, H] = \nu G_i$ and $[P_i, P_j] = \gamma\nu\epsilon_{ijk} J_k$, so exactly $\nu \to 0$, while $[G, P]$ and $[G, H]$ are $[V_0, V_1]$ brackets and are untouched. For σ_{ss}, $V_1 = \langle G_i, P_i \rangle$ contains $[G_i, P_j] = \gamma\delta_{ij} H$, so $\gamma \to 0$. For σ_{sT}, $V_1 = \langle G_i, H \rangle$ contains $[G_i, H] = \mu P_i$, so $\mu \to 0$. For σ_{gen}, $V_1 = \langle G_i, H, P_i \rangle$ contains all three of Equation (14.128), so all three vanish together. □

Remark 15.45 (A correction this forces: the general splitting gives the static algebra, not Carroll). Corollary 15.44 settles a point on which the literature is easy to misread, and on which an earlier draft of Table 15.1 was wrong. The splitting σ_{gen} is often labelled "Carroll". It cannot be: it sets γ, μ and ν to zero simultaneously, and Carroll is $(*, 0, 0)$ with $\gamma \neq 0$. What σ_{gen} produces is the *static* algebra $(0, 0, 0)$, the opposite vertex of the cube. Carroll is reached instead by σ_{sT} applied to the *Poincaré* algebra: Poincaré is $(*, *, 0)$ and σ_{sT} kills μ, leaving $(*, 0, 0)$. In cube terms Carroll is two edges away from de Sitter, so no single graded contraction of $\mathfrak{so}(D-1, 2)$ can reach it; the labelling that suggests otherwise is comparing a one-step move with a two-step one. Reaching Carroll in one step from de Sitter would need a rescaling that is not constant on V_1 — a generalized contraction rather than a graded one — which is outside Definition 15.18.

Rests on Corollary 15.44.

Corollary 15.46 (The sign data, hypothesis (H3), and the count eleven)**.** *Rescaling the basis of $A(\lambda)$ by $e_X \mapsto s_X e_X$ with $s_X \neq 0$ is the rescaling freedom of Theorem 14.90, and its invariants are the three signs*

$$\operatorname{sgn}\left(e_G^2\right), \qquad \operatorname{sgn}\left(e_H^2\right), \qquad \operatorname{sgn}\left(e_P^2\right). \tag{15.56}$$

They obey the following, and the eleven of Theorem 14.90 follows.

1. *If all three λ vanish nowhere then the product of the three signs is $\operatorname{sgn}\left(\lambda_G \lambda_H \lambda_P\right)^2 = +1$, so an even number of them is negative.*
2. *Hypothesis (H3) — each boost generates a noncompact one-parameter subgroup — is exactly the condition*
$$\boxed{e_G^2 \geq 0}, \tag{15.57}$$
the boost direction of A being split or nilpotent but never complex.
3. *Counting the vertices with their surviving free signs gives $2+1+2+2+1+1+1+1 = 11$.*

Rests on Theorems 14.90 and 15.43 and Propositions 15.23 and 15.42.

Derivation. *Derives Corollary 15.46.*

Under $e_X \mapsto s_X e_X$ the products Equation (15.50) give $\lambda_H \mapsto \lambda_H s_G s_P / s_H$ and cyclically, so no λ has an invariant sign; but $e_X^2 \mapsto s_X^2 e_X^2$, so the three signs Equation (15.56) are invariant, and by Equation (15.51) they are the pairwise sign products of the λ — which is the same invariant that Corollary A.59 extracts from the generators. Claim (1) is Equation (15.51) multiplied out.

(2) By Theorem 15.43 the boosts of $\mathfrak{R}(\lambda)$ satisfy $\left[G'_i, G'_j\right] = -\left(\gamma\lambda_H\right)\left(\mu\lambda_P\right)\epsilon_{ijk} J'_k = -\gamma\mu\, e_G^2\, \epsilon_{ijk} J'_k$. Together with $[J, J] \sim J$ and $[J, G'] \sim G'$, the span $\langle J_{ij}, G'_i \rangle$ closes on $\mathfrak{so}(4)$ when the coefficient of $\epsilon_{ijk} J'_k$ is positive and on $\mathfrak{so}(3,1)$ when it is negative; in the first case the boosts generate a circle and in the second a line, and when the coefficient vanishes they span an abelian $\mathbb{R}^3$, again noncompact. So (H3) holds precisely when $-\gamma\mu\, e_G^2 \leq 0$. Normalising the parent by Proposition 15.23, which has $\gamma\mu = 1 > 0$, this is Equation (15.57).

(3) Go through the eight vertices, using Equation (15.51) to see which of the three signs survives. Where all three λ are nonzero, (H3) fixes $\operatorname{sgn}(e_G^2) = +$ and then (1) forces $\operatorname{sgn}(e_H^2) = \operatorname{sgn}(e_P^2)$: one free sign, *two* algebras (de Sitter and anti-de Sitter). Where $\lambda_G = 0$ we have $e_H^2 = e_P^2 = 0$ and $e_G^2 = \lambda_H \lambda_P$, whose sign is fixed by (H3): *one* algebra (Poincaré). Where $\lambda_H = 0$, only $e_H^2 = \lambda_G \lambda_P$ survives and (H3) says nothing about it: *two* (Newton–Hooke and anti-Newton–Hooke). Where $\lambda_P = 0$, only $e_P^2 = \lambda_G \lambda_H$ survives, again unconstrained: *two* (para-Poincaré and inhomogeneous SO(4)). At each of the three vertices with two vanishing λ all three squares vanish, so no sign is left: *one* each (Galilei, Carroll, para-Galilei). At the origin, *one* (static). The total is $2+1+2+2+1+1+1+1 = 11$, and

the three vertices carrying two entries are the three at which a sign survives unconstrained — which is Theorem 14.90. □

Table 15.2: The contraction cube of Theorem 14.90 read off the structure constants of the algebra $A(\lambda)$ of Proposition 15.42. The first column is the vanishing pattern of $(\lambda_G, \lambda_H, \lambda_P)$, $*$ marking a nonzero one; by Equation (15.52) it determines the pattern of (γ, μ, ν) in the second, which is the third column of Table 14.1. The fourth column is the sign left free after hypothesis (H3), by Corollary 15.46, and it is what doubles three of the eight rows into eleven algebras. Names are those of Table 14.1.

$(\lambda_G, \lambda_H, \lambda_P)$	(γ, μ, ν)	Algebra	Free sign after (H3)
$(*, *, *)$	$(*, *, *)$	de Sitter, anti-de Sitter	$\operatorname{sgn} e_H^2 = \operatorname{sgn} e_P^2$; $\operatorname{sgn} e_G^2 = +$ fixed
$(0, *, *)$	$(*, *, 0)$	Poincaré	none: only e_G^2 survives, and (H3) fixes it

Remark 15.47 (Which axis is the cosmological constant). The three axes of Table 15.2 are not interchangeable, because they carry different physics. The λ_G axis is the one along which Theorem 15.29 runs: setting $\lambda_G = 0$ is the space–time grading, the flat limit, and by Corollary 15.32 the parameter there is $t = -2\Lambda/((D-1)(D-2))$. So λ_G *is* the cosmological constant up to that positive factor, its sign is the sign of $-\Lambda$, and the split/complex/dual trichotomy of Proposition 15.28 along this one axis is the anti-de Sitter/de Sitter/flat trichotomy. The other two axes are the two velocity limits: $\lambda_H \to 0$ is $c \to \infty$ and $\lambda_P \to 0$ is $c \to 0$, and by Remark 15.33 the measured $\Lambda > 0$ puts nature at $\lambda_G < 0$ with the other two coordinates nonzero — the de Sitter vertex, of which the Poincaré algebra of Part IV is the $\lambda_G \to 0$ edge and the Galilei algebra of Part III the further $\lambda_H \to 0$ edge.

Remark 15.48 (What this does and does not replace). Corollary 15.46 reproduces the number eleven, and it explains *why* three of the eight vertices carry two entries: those are the three at which one of the signs Equation (15.56) survives without being fixed by (H3). It does not replace Appendix A.10. That appendix proves that the hypotheses of Theorem 14.90 admit *no other* algebras — that the five unknown constants reduce to three, and that the list is exhaustive — and it does so by exhausting the possible structure constants, which is a statement about all kinematical algebras and not about the ones this construction happens to produce. The present section takes the parametrisation (γ, μ, ν) as given by that theorem and shows that the cube it organises is the degeneration lattice of a single four-dimensional commutative algebra. Existence here, exhaustiveness there.

15.8 Invariant forms and why the extension is needed

An algebra is of no use for building an action unless it carries a nondegenerate invariant form: that is the input to the invariant polynomials of Section 14.7 and to the Chern–Simons

construction of Section 14.8.1. The forms on $\mathfrak{g}_A$ factorise just as the brackets do, and the criterion that results explains why the extension of Corollary 15.36 is not optional.

Definition 15.49 (k-trace)**.** A symmetric k-linear map $\Phi : A^k \to \mathbb{R}$ is a *k-trace* if

$$\Phi(ab, c_2, \dots, c_k) = \Phi(a, bc_2, c_3, \dots, c_k) \tag{15.58}$$

for all arguments.

Lemma 15.50 (Every k-trace comes from a linear functional)**.** *Let A be commutative associative and unital. Then Φ is a k-trace if and only if*

$$\Phi(a_1, \dots, a_k) = \phi\,(a_1 \cdots a_k) \tag{15.59}$$

for a unique linear functional $\phi : A \to \mathbb{R}$, namely $\phi(x) = \Phi(x, 1_A, \dots, 1_A)$.
Rests on Definition 15.49.

Derivation. *Derives Lemma 15.50.*

If Φ has the form Equation (15.59) then Equation (15.58) holds because $(ab)c_2 \cdots c_k = a(bc_2)c_3 \cdots c_k$ by associativity, and Φ is symmetric by commutativity.

Conversely let Φ be a k-trace and put $\phi(x) := \Phi(x, 1_A, \dots, 1_A)$. Using Equation (15.58) with $b = a_2$ and $c_2 = 1_A$,

$$\Phi(a_1, a_2, a_3, \dots, a_k) = \Phi(a_1, a_2 1_A, a_3, \dots, a_k) = \Phi(a_1 a_2, 1_A, a_3, \dots, a_k)\,,$$

which absorbs one argument into the first slot and replaces it by the unit. Symmetry of Φ then allows the next argument to be moved into the second slot, and repeating $k-1$ times gives $\Phi(a_1, \dots, a_k) = \Phi(a_1 \cdots a_k, 1_A, \dots, 1_A) = \phi(a_1 \cdots a_k)$. Uniqueness follows by evaluating Equation (15.59) at $a_2 = \cdots = a_k = 1_A$. □

Theorem 15.51 (Factorisation of invariant forms)**.** *Let ω be an invariant symmetric k-linear form on $\mathfrak{g}$,*

$$\sum_{i=1}^{k} \omega\,(X_1, \dots, [Y, X_i], \dots, X_k) = 0 \qquad \text{for all } Y, X_1, \dots, X_k \in \mathfrak{g}\,, \tag{15.60}$$

and let $\phi : A \to \mathbb{R}$ be linear. Then

$$\boxed{\langle a_1 \otimes X_1, \dots, a_k \otimes X_k \rangle_{\omega,\phi} := \phi\,(a_1 \cdots a_k)\ \omega\,(X_1, \dots, X_k)} \tag{15.61}$$

is an invariant symmetric k-linear form on $\mathfrak{g}_A$.
Rests on Definition 15.3.

Derivation. *Derives Theorem 15.51.*

Symmetry and k-linearity of Equation (15.61) are clear, the first using commutativity of A. For invariance take $Y = a \otimes X$ and compute with Equation (15.2):

$$\sum_{i=1}^{k} \langle a_1 \otimes X_1, \dots, [a \otimes X, a_i \otimes X_i], \dots \rangle_{\omega,\phi} = \sum_{i=1}^{k} \phi\,(a_1 \cdots (a a_i) \cdots a_k)\, \omega\,(X_1, \dots, [X, X_i], \dots)\,.$$

By commutativity and associativity of A the argument of ϕ equals $a\,a_1 \cdots a_k$ for every i, so that scalar factors out of the sum and leaves Equation (15.60), which vanishes. □

The natural question is whether Equation (15.61) exhausts the invariant forms of $\mathfrak{g}_A$. It does not, and identifying exactly which forms it produces is worth doing precisely, because the answer decides what Theorem 15.58 below is a statement about.

Definition 15.52 (Balanced form)**.** $\mathfrak{g}_A$ carries an action of A by $a \cdot (b \otimes X) = (ab) \otimes X$, for which the bracket is A-bilinear: $[a \cdot u, v] = a \cdot [u, v]$. A k-linear form Ω on $\mathfrak{g}_A$ is *balanced* if moving that action between slots costs nothing,

$$\boxed{\Omega\left(a \cdot u_1, u_2, \dots, u_k\right) = \Omega\left(u_1, a \cdot u_2, u_3, \dots, u_k\right)} \tag{15.62}$$

for all $a \in A$ and all $u_i \in \mathfrak{g}_A$.

Rests on Definition 15.3.

Theorem 15.53 (The factorised forms are exactly the balanced ones)**.** *Write* $\mathrm{Inv}^k(\mathfrak{g})$ *for the space of invariant symmetric* k*-linear forms on* $\mathfrak{g}$*, and let* $\{\omega_1, \dots, \omega_r\}$ *be a basis of it. An invariant symmetric* k*-linear form* Ω *on* $\mathfrak{g}_A$ *is balanced if and only if there are linear functionals* $\phi_1, \dots, \phi_r : A \to \mathbb{R}$ *with*

$$\boxed{\Omega\left(a_1 \otimes X_1, \dots, a_k \otimes X_k\right) = \sum_{j=1}^{r} \phi_j\left(a_1 \cdots a_k\right)\, \omega_j\left(X_1, \dots, X_k\right)}, \tag{15.63}$$

that is, if and only if Ω *is a sum of forms Equation* (15.61)*.*

Rests on Definition 15.52, Theorem 15.51, and Lemma 15.50.

Derivation. *Derives Theorem 15.53.*

Only if. For $\Omega = \langle\cdot\rangle_{\omega,\phi}$ both sides of Equation (15.62) equal $\phi\left(a\, a_1 \cdots a_k\right) \omega(X_1, \dots, X_k)$, by commutativity and associativity of A; sums of such forms inherit the property.

If. For $x \in A$ define a k-linear form on $\mathfrak{g}$ by

$$\omega^{(x)}(X_1, \dots, X_k) := \Omega\left(x \otimes X_1,\, 1_A \otimes X_2, \dots, 1_A \otimes X_k\right) . \tag{15.64}$$

It is *symmetric*: balancedness moves x from the first slot to the second, and the symmetry of Ω then exchanges the two slots entirely, so $\omega^{(x)}$ is unchanged under the transposition $X_1 \leftrightarrow X_2$; the same argument applies to any transposition, and transpositions generate the symmetric group. It is *invariant*: since $[1_A \otimes Z, a \otimes X] = a \otimes [Z, X]$, the invariance of Ω under $1_A \otimes Z$, evaluated on the arguments of Equation (15.64), is literally $\sum_i \omega^{(x)}(X_1, \dots, [Z, X_i], \dots, X_k) = 0$. So $x \mapsto \omega^{(x)}$ is a linear map $A \to \mathrm{Inv}^k(\mathfrak{g})$, and expanding in the basis gives functionals $\phi_j \in A^*$ with $\omega^{(x)} = \sum_j \phi_j(x)\, \omega_j$.

It remains to see that Ω is recovered from $\omega^{(\cdot)}$ by multiplying the A-arguments. Fix $X_1, \dots, X_k$ and set $\Phi(a_1, \dots, a_k) := \Omega(a_1 \otimes X_1, \dots, a_k \otimes X_k)$, a k-linear map $A^k \to \mathbb{R}$. Balancedness is exactly Equation (15.58), so Φ is a k-trace, and Lemma 15.50 gives $\Phi(a_1, \dots, a_k) = \Phi(a_1 \cdots a_k, 1_A, \dots, 1_A) = \omega^{(a_1 \cdots a_k)}(X_1, \dots, X_k)$, which is Equation (15.63). □

Theorem 15.54 (Completeness in the bilinear case)**.** *Let* $\mathfrak{g}$ *be* absolutely simple*, that is* $\mathfrak{g} \otimes_{\mathbb{R}} \mathbb{C}$ *simple. Then every invariant symmetric* bilinear *form on* $\mathfrak{g}_A$ *is automatically balanced, and therefore*

$$\Omega\left(a \otimes X,\, b \otimes Y\right) = \phi(ab)\, \kappa_{\mathfrak{g}}(X, Y) \tag{15.65}$$

for a unique linear $\phi : A \to \mathbb{R}$*. The space of invariant symmetric bilinear forms on* $\mathfrak{g}_A$ *has dimension* $\dim A$*.*

Rests on Definition 15.3 and Lemmas 15.50 and A.63.

Full derivation: Appendix A.11 (p. 2804).

Derives Theorem 15.54.

Proposition 15.55 (Completeness fails for $k \geq 3$)**.** *Let* $\mathfrak{g}$ *be simple,* $A = A_1 = \mathbb{R}[\varepsilon]/(\varepsilon^2)$*, and let* $B := \langle\cdot,\cdot\rangle_{\kappa_{\mathfrak{g}},\phi_1}$ *be the invariant bilinear form of Example 15.57 with* $\phi_1(1) = 0$ *and* $\phi_1(\varepsilon) = 1$*. Then the symmetric* 4*-linear form*

$$Q(u_1, u_2, u_3, u_4) := \tfrac{1}{3}\Big(B(u_1, u_2)B(u_3, u_4) + B(u_1, u_3)B(u_2, u_4) + B(u_1, u_4)B(u_2, u_3)\Big) \tag{15.66}$$

is invariant, and is not *of the shape Equation* (15.61)*. Hence the converse of Theorem 15.51 is false for $k = 4$, and by taking products with further copies of B for every even $k \geq 4$.*
Rests on Theorems 15.51 and 15.53 and Example 15.57.

Derivation. *Derives Proposition 15.55.*

Q is the full polarisation of the invariant polynomial $u \mapsto B(u,u)^2$; a product of invariant polynomials is invariant, because the invariants form a ring, so Q is an invariant symmetric 4-linear form. Now evaluate it on $u_1 = 1 \otimes X_1$, $u_2 = 1 \otimes X_2$, $u_3 = \varepsilon \otimes X_3$, $u_4 = \varepsilon \otimes X_4$. From $\phi_1(1) = 0$, $\phi_1(\varepsilon) = 1$ and $\phi_1(\varepsilon^2) = \phi_1(0) = 0$,

$$B(u_1,u_2) = 0\,, \quad B(u_3,u_4) = 0\,, \quad B(u_1,u_3) = \kappa_{\mathfrak{g}}(X_1,X_3)\,, \quad B(u_2,u_4) = \kappa_{\mathfrak{g}}(X_2,X_4)\,,$$

and similarly for the last pairing, so that

$$Q(u_1,u_2,u_3,u_4) = \tfrac{1}{3}\Big(\kappa_{\mathfrak{g}}(X_1,X_3)\kappa_{\mathfrak{g}}(X_2,X_4) + \kappa_{\mathfrak{g}}(X_1,X_4)\kappa_{\mathfrak{g}}(X_2,X_3)\Big)\,, \tag{15.67}$$

which is nonzero — take $X_3 = X_1$ and $X_4 = X_2$ with $\kappa_{\mathfrak{g}}(X_1,X_1) \neq 0 \neq \kappa_{\mathfrak{g}}(X_2,X_2)$, possible because $\kappa_{\mathfrak{g}}$ is nondegenerate. But the product of the four algebra elements is $1 \cdot 1 \cdot \varepsilon \cdot \varepsilon = \varepsilon^2 = 0$, so any form of the shape Equation (15.61) would give $\phi(0)\,\omega = 0$ there. Hence Q is not of that shape; equivalently, by Theorem 15.53, Q is not balanced. □

Remark 15.56 (Why $k = 2$ is special, and what the failure costs). The counterexample is not exotic. Taking $\mathfrak{g} = \mathfrak{so}(2,1)$ makes $\mathfrak{g}_{A_1}$ the three-dimensional Poincaré algebra $\mathfrak{iso}(2,1)$ — one of the low-dimensional coincidences of Remark 15.30, since there the adjoint and vector representations of $\mathfrak{so}(2,1)$ agree — and B its familiar pairing $\langle J_a, P_b\rangle = \eta_{ab}$ with $\langle J_a, J_b\rangle = \langle P_a, P_b\rangle = 0$; then Equation (15.67) is $Q(J_a,J_b,P_c,P_d) = \frac{1}{3}\,(\eta_{ac}\eta_{bd} + \eta_{ad}\eta_{bc})$. The mechanism is visible there: Q is a *product* of two invariant forms, and $\phi_1(a_1a_2)\phi_1(a_3a_4)$ is not a function of $a_1a_2a_3a_4$.

That also says why $k = 2$ escapes. A product of invariants of lower degree needs factors of degree at least one, and $\mathrm{Inv}^1(\mathfrak{g}) = (\mathfrak{g}^*)^{\mathfrak{g}} = 0$ for $\mathfrak{g}$ perfect, so an invariant *bilinear* form cannot be a product and has no room to be unbalanced — Theorem 15.54 then makes that precise.

Nothing in this book needs more: the only invariant forms used anywhere are bilinear, and Theorem 15.58 classifies those completely. What is lost is the stronger reading under which Equation (15.61) would describe every invariant tensor of an expanded algebra in any degree. It does not, and a Chern–Simons construction in five or more dimensions, which needs an invariant form of degree three or higher, must therefore determine its invariant tensors directly rather than by quoting a factorisation.

Example 15.57 ($k = 2$ recovers the Killing form)**.** Taking $k = 2$, $\omega = \kappa_{\mathfrak{g}}$ and $\phi = \tau_A$ in Equation (15.61) reproduces Equation (15.8). The Killing form is thus one member of a family parametrised by the linear functionals on A, and not always the useful member: on $\mathfrak{g}\langle 1\rangle$ the choice $\phi(\varepsilon) \neq 0$ gives a nondegenerate invariant form even though τ_{A_1} is degenerate, since the Gram matrix of $\phi(ab)$ in the basis $\{1,\varepsilon\}$ is

$$\begin{pmatrix} \phi(1) & \phi(\varepsilon) \\ \phi(\varepsilon) & 0 \end{pmatrix}\,,$$

of determinant $-\phi(\varepsilon)^2$. This is the invariant form that makes the Poincaré algebra usable as a gauge algebra.
Rests on Theorems 15.10 and 15.51.

Theorem 15.58 (Nondegeneracy on a resonant subalgebra)**.** *Let $\mathfrak{g}$ be simple with a $\mathbb{Z}_2$-grading σ, let $\omega = \kappa_{\mathfrak{g}}$, and let $\phi : A_N \to \mathbb{R}$ be linear. The restriction of $\langle\cdot,\cdot\rangle_{\kappa,\phi}$ to $\mathfrak{R}_N^{\sigma}$ is nondegenerate if and only if*

$$\boxed{N \text{ is even and } \phi(\varepsilon^N) \neq 0}\,. \tag{15.68}$$

Rests on Theorem 15.51, Definition 15.20, and Lemma 15.19.

Derivation. *Derives Theorem 15.58.*

By Equation (15.61), for $X \in V_{[i]}$ and $Y \in V_{[j]}$,

$$\left\langle \varepsilon^i \otimes X,\ \varepsilon^j \otimes Y \right\rangle_{\kappa,\phi} = \phi\left(\varepsilon^{i+j}\right) \kappa_{\mathfrak{g}}(X, Y)\,. \tag{15.69}$$

From Equation (15.61) (take $\omega = \kappa_{\mathfrak{g}}$ and $a_1, a_2 = \varepsilon^i, \varepsilon^j$).

Two things can make this vanish. By Lemma 15.19, $\kappa_{\mathfrak{g}}(V_0, V_1) = 0$, so Equation (15.69) is zero unless $[i] = [j]$, that is unless $i + j$ is even; and $\phi(\varepsilon^{i+j}) = 0$ whenever $i + j > N$.

Suppose N is odd and take $i = N$, so $[N] = 1$. Any j with $[j] = [N]$ is odd, whence $i + j \geq N + 1 > N$ and Equation (15.69) vanishes for every j. The whole top level $\varepsilon^N \otimes V_1$ lies in the radical of the form, which is therefore degenerate.

Suppose N is even and $\phi(\varepsilon^N) \neq 0$. Order the levels $0, 1, \ldots, N$ and consider the block matrix of the form. Every entry with $i + j > N$ vanishes, and the anti-diagonal entries $i + j = N$ are $\phi(\varepsilon^N)\,\kappa_{\mathfrak{g}}|_{V_{[i]}}$, which are nondegenerate: $[i] = [N - i]$ because N is even, so the two levels pair within the same graded piece, and $\kappa_{\mathfrak{g}}$ restricted to V_0 and to V_1 is nondegenerate by Lemma 15.19. A block matrix whose entries vanish strictly beyond the anti-diagonal and whose anti-diagonal blocks are invertible has determinant equal, up to sign, to the product of those blocks' determinants, hence is invertible.

Finally, if N is even but $\phi(\varepsilon^N) = 0$ the whole anti-diagonal vanishes and the top level is again in the radical: pairing $\varepsilon^N \otimes X$ with $\varepsilon^j \otimes Y$ requires $j = 0$ and gives $\phi(\varepsilon^N)\kappa(X, Y) = 0$. □

Remark 15.59 (The central charge is what makes the form work). Theorem 15.58 is the precise reason the Galilei algebra admits no invariant pairing of the kind an action needs, while the Bargmann algebra does. Galilei is $\mathfrak{R}_1^\sigma$ with $N = 1$ odd: its level-1 sector, the boosts and the space translations, is orthogonal to everything. The extension to $N = 2$ supplies exactly the partner each generator needs, and Equation (15.69) names the pairings: level 1 with level 1, and level 0 with the top level — that is, H with the mass M. The central charge is not decoration; it is the dual partner without which the invariant form has a radical. This also explains why the useful truncations are the even ones.

What follows mathematically is the existence of the corresponding invariant tensors. What does *not* follow is any physical claim: three-dimensional Chern–Simons gravity built on these algebras has no propagating degrees of freedom and no observational status, as Remark 14.94 records, and this treatise carries the construction as mathematics only.

Rests on Theorem 15.58 and Corollary 15.36.

15.9 Relation to the published expansion methods

Two constructions in the literature are special cases of Definition 15.3, and saying which is the honest way to place this material.

Proposition 15.60 (Semigroup expansion)**.** *Let S be a finite abelian semigroup and $\mathbb{R}[S]$ its semigroup algebra, with basis $\{\lambda_\alpha\}_{\alpha \in S}$ and $\lambda_\alpha \lambda_\beta = \lambda_{\alpha\beta}$. Then $\mathfrak{g}_{\mathbb{R}[S]}$ is the S-expanded algebra of [2096]: writing $\lambda_\alpha \lambda_\beta = K_{\alpha\beta}{}^\gamma \lambda_\gamma$,*

$$[\lambda_\alpha \otimes T_a, \lambda_\beta \otimes T_b] = K_{\alpha\beta}{}^\gamma C_{ab}{}^c\ \lambda_\gamma \otimes T_c\,. \tag{15.70}$$

Rests on Definition 15.3 and Theorem 15.4.

Derivation. *Derives Proposition 15.60.*

$\mathbb{R}[S]$ is commutative because S is abelian and associative because S is, and it is unital after adjoining a unit if S has none. Its structure constants in the basis $\{\lambda_\alpha\}$ are $\mu_{\alpha\beta}{}^\gamma = K_{\alpha\beta}{}^\gamma$, so Equation (15.3) is Equation (15.70). □

Example 15.61 (Maurer–Cartan expansion)**.** The expansion of [2044] rescales the group parameters by a formal variable, expands the Maurer–Cartan forms in powers of it and truncates at a chosen order. In the present language the expansion variable is ε, truncation at order N is the passage to $A_N = \mathbb{R}[\varepsilon]/(\varepsilon^{N+1})$, and the resulting algebra is $\mathfrak{g}\langle N\rangle$ of Definition 15.14 or, when the method's grading conditions are imposed, the resonant subalgebra $\mathfrak{R}^{\sigma}_{N}$ of Definition 15.20. The Maurer–Cartan method is thus the case $A = A_N$ of Definition 15.3, and Proposition 15.60 is the case $A = \mathbb{R}[S]$.

Rests on Definitions 15.3, 15.14 and 15.20.

Proposition 15.62 (The complex line is not a semigroup algebra)**.** *There is no finite abelian semigroup S with $\mathbb{R}[S] \cong \mathbb{C}$.*

Derivation. *Derives Proposition 15.62.*

Suppose $\mathbb{R}[S] \cong \mathbb{C}$. Then $|S| = 2$ and the image of S in $\mathbb{C}$ is an $\mathbb{R}$-basis closed under multiplication. In a finite semigroup every element has an idempotent power, and the only idempotents of $\mathbb{C}$ are 0 and 1, so each element of the image is 0 or a root of unity. If 0 lies in the image the two elements span a real line, not $\mathbb{C}$. So the image is $\{z, w\}$ with z, w roots of unity, $\mathbb{R}$-independent, and $z^2 \in \{z, w\}$.

If $z^2 = z$ then $z = 1$, and $w^2 \in \{1, w\}$ forces $w = \pm 1$, dependent on z. If $z^2 = w$ then $w^2 = z^4 \in \{z, w\}$: from $z^4 = z$ we get $z^3 = 1$ with $z \neq 1$, so $w = z^2$ and $zw = z^3 = 1 \notin \{z, w\}$, contradicting closure; and from $z^4 = w = z^2$ we get $z^2 = 1$, hence $w = 1$ and $z = -1$, again dependent. No case survives. □

Remark 15.63 (The inclusion is strict, and the strictness is physical)*.* The tensor product construction is genuinely larger than semigroup expansion. By Proposition 15.28 the algebra $A^{(t)}$ is isomorphic to $\mathbb{C}$ exactly on the branch $t < 0$, which by Corollary 15.32 is the branch with $\Lambda > 0$ — the one the measured cosmological constant selects (Remark 15.33) — and by Proposition 15.62 that two-dimensional algebra is not $\mathbb{R}[S]$ for any S.

The tempting next sentence is that the de Sitter side is therefore outside the reach of semigroup expansion altogether. That sentence is false, and the counterexample is small: for the cyclic group $\mathbb{Z}_3$,

$$\mathbb{R}[\mathbb{Z}_3] \cong \mathbb{R}[x]/(x^3 - 1) \cong \mathbb{R} \times \mathbb{C}\,, \tag{15.71}$$

since $x^3 - 1 = (x-1)(x^2+x+1)$ and the quadratic factor is irreducible over $\mathbb{R}$; more generally $\mathbb{R}[\mathbb{Z}_n]$ acquires a complex factor for every $n \geq 3$. So a large enough semigroup does supply one. What Proposition 15.62 establishes is the narrow statement only: the *two-dimensional* complex algebra is not a semigroup algebra, so the de Sitter branch of the quadratic family Equation (15.26) is not itself a semigroup expansion. Whether the particular semigroup families used in the gauge-gravity literature reach it is a separate question, not settled here, and worth care — Equation (15.71) says the answer is not automatically no.

Rests on Propositions 15.28 and 15.62 and Corollary 15.32.

15.10 The construction in 3+1 dimensions

Every statement above is dimension-independent unless marked otherwise. Because the physical parts of this treatise work in $D = 4$, the instantiation is collected here in one place.

Example 15.64 (The whole chapter at $D = 4$)**.** Take $\mathfrak{g} = \mathfrak{so}(3, 2)$, of dimension 10, with generators J_{ij} $(i, j = 1, 2, 3)$, G_i, H, P_i as in Notation 15.22.

1. *Curvature.* Theorem 15.29 gives the ten-dimensional resonant subalgebra $\mathfrak{R}^{(t)} \subseteq \mathfrak{so}(3, 2)_{A^{(t)}}$, isomorphic to $\mathfrak{so}(3, 2)$ for $t > 0$, to $\mathfrak{so}(4, 1)$ for $t < 0$ and to $\mathfrak{iso}(3, 1)$ for $t = 0$. By Proposition 15.31, $\Lambda = \pm 3/\ell^2$ and, by Corollary 15.32, $t = -\Lambda/3$.

2. *Which branch.* $\Lambda \approx 1.1\times10^{-52}/\mathrm{m}^2 > 0$ from Equation (15.39), so $t \approx -3.7\times10^{-53}/\mathrm{m}^2$ and the algebra is $\mathfrak{so}(4,1)$: de Sitter. The curvature radius $\ell \approx 1.6\times10^{26}\,\mathrm{m}$ is some 19 orders of magnitude larger than the solar system, which is why the flat truncation $t=0$ — the Poincaré algebra of Part IV — is an excellent approximation for every laboratory and astrophysical test in this book.

3. *Central charges.* With the speed–space grading, $V_0 = \langle J_{ij}, H\rangle = \mathfrak{so}(3)\oplus\langle H\rangle$ has centre $\langle H\rangle$, because $\mathfrak{so}(3)$ is simple. By Corollary 15.35 the level-2 truncation therefore carries *exactly one* central charge, $M = \varepsilon^2\otimes H$, and Corollary 15.36 identifies it with the mass: the Bargmann algebra in 3+1, the algebra actually realised by the Poisson brackets of Proposition 25.14. The second charge S of the extended Bargmann algebra requires $\mathfrak{so}(D-1)$ to be abelian and so exists only in 2+1.

4. *What does not carry over from $D=3$.* The isomorphisms Equation (15.32) are false at $D=4$: $\mathfrak{so}(3,2)\oplus\mathfrak{so}(3,2)$ has dimension 20 and is not an isometry algebra of any four-dimensional maximally symmetric spacetime, and $\mathbb{C}\otimes_{\mathbb{R}}\mathfrak{so}(3,2)$ has dimension 20 rather than the 10 of $\mathfrak{so}(4,1)$. Only the resonant subalgebra $\mathfrak{R}^{(t)}$ has the right dimension, which is why Theorem 15.29 is stated in terms of it.

Rests on Theorem 15.29, Proposition 15.31, and Corollaries 15.32, 15.35 and 15.36.

Remark 15.65 (What is proved here and what is borrowed). For the record, since Remark 15.2 withholds the manuscript's authority: every numbered statement of this chapter is proved above or in Appendix A.11, from Definition 15.3 and standard linear algebra. Reproving rather than quoting earned its keep twice. Remark 15.45 corrects the labelling of the general splitting, which gives the static algebra and not Carroll; and Proposition 15.55 *disproves* the manuscript's factorisation converse for $k\geq 3$ by an explicit invariant form on the three-dimensional Poincaré algebra, so what appears here as Theorems 15.53 and 15.54 is a corrected statement and not a weakened one. The only results quoted without proof are Lemma 15.12, textbook commutative algebra, and the real spectral theorem for a commuting family of symmetric operators used in Theorem 15.68, textbook linear algebra; neither is used in a claim about a specific algebra — the three cases of Proposition 15.28, the tower of Section 15.3, the branches of Theorem 15.29 and the central charges of Corollary 15.36 are each verified by direct computation on the algebra concerned.

15.11 Positive functionals and the Gram form

Theorem 15.58 decided when the factorised bilinear form of Theorem 15.51 is *nondegenerate*. As soon as such a form is used as a kinetic pairing — a quadratic form on fields whose sign decides whether a mode carries positive energy — the finer question is when it is *positive*. On the A-side the question concerns a single object, already met as the Gram matrix of Example 15.57. No spacetime dimension enters anywhere in this section; the $D=4$ instantiation is used by the companion manuscript as recorded in Remark 15.71.

Definition 15.66 (Gram form of a functional)**.** For a linear functional $\psi : A\to\mathbb{R}$, the *Gram form* of ψ is the symmetric bilinear form

$$B_\psi(a,b) := \psi(ab) \tag{15.72}$$

on A. By Theorem 15.54, when $\mathfrak{g}$ is absolutely simple every invariant symmetric bilinear form on $\mathfrak{g}_A$ is $B_\psi\otimes\kappa_{\mathfrak{g}}$ for a unique ψ, so the sign structure of the invariant bilinear forms of $\mathfrak{g}_A$ is exactly the sign structure of the Gram forms of A.

Rests on Theorem 15.54.

Lemma 15.67 (Multiplication is B_ψ-self-adjoint)**.** *For every $a \in A$ the multiplication operator $M_a : u \mapsto au$ satisfies $B_\psi(M_a u, v) = B_\psi(u, M_a v)$ for all $u, v \in A$, and the radical $I_\psi := \{u \in A : \psi(uA) = 0\}$ of B_ψ is an ideal of A.*

Rests on Definition 15.66.

Derivation. *Derives Lemma 15.67.*

$B_\psi(au, v) = \psi((au)v) = \psi(u(av)) = B_\psi(u, av)$, by commutativity and associativity of A. If $\psi(uA) = 0$ then for every $b \in A$ also $\psi((bu)A) = \psi(u(bA)) \subseteq \psi(uA) = 0$, so I_ψ absorbs multiplication. □

Theorem 15.68 (Positive Gram forms are positive sums of real characters)**.** *Let A be a finite-dimensional commutative associative unital $\mathbb{R}$-algebra and let $\psi : A \to \mathbb{R}$ be linear. The following are equivalent.*

1. *B_ψ is positive semidefinite.*
2. *There are finitely many* distinct $\mathbb{R}$*-algebra homomorphisms $\chi_1, \dots, \chi_r : A \to \mathbb{R}$ and weights $w_1, \dots, w_r > 0$ with*

$$\boxed{\psi = \sum_{i=1}^{r} w_i \, \chi_i}\,. \tag{15.73}$$

In that case $r = \operatorname{rank} B_\psi$. In particular ψ annihilates $\operatorname{rad}(A)$, and it annihilates every factor of the Artin decomposition (Lemma 15.12) whose residue field is $\mathbb{C}$.

Rests on Definition 15.66 and Lemmas 15.12 and 15.67.

Derivation. *Derives Theorem 15.68.*

(2)⇒(1). Multiplicativity of each χ_i gives

$$B_\psi(a, a) = \sum_{i=1}^{r} w_i \, \chi_i(a)^2 \geq 0\,.$$

(1)⇒(2). If $\psi = 0$ take $r = 0$. Otherwise let I_ψ be the radical of B_ψ, an ideal by Lemma 15.67. For a positive semidefinite form the radical coincides with the null cone — $B_\psi(u, u) = 0$ forces $u \in I_\psi$ by the Cauchy–Schwarz inequality, which holds for every positive semidefinite symmetric form — so the induced form $\bar{B}$ on $\bar{A} := A/I_\psi$ is positive *definite*, and $\bar{A}$ is again commutative, associative and unital ($1_A \notin I_\psi$ because $\psi \neq 0$). Each multiplication operator $\bar{M}_a$ on $\bar{A}$ is $\bar{B}$-symmetric by Lemma 15.67, and the family $\left\{\bar{M}_a : a \in A\right\}$ commutes, so the spectral theorem for commuting symmetric operators on a real inner-product space provides a $\bar{B}$-orthogonal basis $\bar{u}_1, \dots, \bar{u}_r$ of $\bar{A}$ and functions $\chi_i : A \to \mathbb{R}$ with $\bar{M}_a \bar{u}_i = \chi_i(a)\, \bar{u}_i$. Each χ_i is linear in a, multiplicative because $\bar{M}_{ab} = \bar{M}_a \bar{M}_b$, and unital because $\bar{M}_{1_A} = \mathrm{id}$. Writing $\bar{1} = \sum_i c_i \bar{u}_i$ and using $\psi(a) = B_\psi(a, 1_A)$,

$$\psi(a) = \bar{B}\left(\bar{M}_a \bar{1}, \bar{1}\right) = \sum_i c_i^2 \, \chi_i(a)\, \bar{B}\,(\bar{u}_i, \bar{u}_i) =: \sum_i w_i \, \chi_i(a)\,,$$

with every $w_i \geq 0$; discard the terms with $w_i = 0$ and merge repeated characters, which keeps the surviving weights positive and the characters distinct.

Distinct characters are linearly independent: a shortest nontrivial relation $\sum_i \lambda_i \chi_i = 0$ with all $\lambda_i \neq 0$ and $r \geq 2$ admits some a_0 with $\chi_1(a_0) \neq \chi_2(a_0)$; evaluating the relation at $a_0 a$ and subtracting $\chi_1(a_0)$ times the relation at a kills the first term but not the second, producing a shorter nontrivial relation. Hence $B_\psi(a, b) = \sum_i w_i \chi_i(a) \chi_i(b)$ has rank exactly r.

Finally, a character kills every nilpotent element, since $\chi(n)^k = \chi(n^k) = 0$, hence kills $\operatorname{rad}(A)$. And let A_j be a factor of the Artin decomposition, with unit the idempotent π_j and

residue field $\mathbb{C}$. From $\chi(\pi_j)^2 = \chi(\pi_j)$ either $\chi(\pi_j) = 0$, and then χ kills $A_j = \pi_j A_j$ outright, or $\chi(\pi_j) = 1$, and then χ restricts to a unital $\mathbb{R}$-algebra homomorphism $A_j \to \mathbb{R}$, which kills the maximal ideal of A_j (it is nilpotent) and so induces an $\mathbb{R}$-algebra homomorphism $\mathbb{C} \to \mathbb{R}$ — impossible, since $\chi(i)^2 = \chi(-1) = -1$ has no real solution. So every ψ of the form Equation (15.73) vanishes on $\mathrm{rad}(A)$ and on every factor whose residue field is $\mathbb{C}$. □

Corollary 15.69 (No positive pairing survives the radical)**.** *On the truncated algebra $A_N = \mathbb{R}[\varepsilon]/(\varepsilon^{N+1})$ with $N \geq 1$:*

1. *B_ψ is positive semidefinite if and only if $\psi(1) \geq 0$ and $\psi(\varepsilon^k) = 0$ for all $k \geq 1$; its rank is then at most one.*
2. *For N even and $\psi(\varepsilon^N) \neq 0$ — the nondegenerate case of Theorem 15.58 — the signature of B_ψ is $\left(\frac{N}{2}+1, \frac{N}{2}\right)$ or $\left(\frac{N}{2}, \frac{N}{2}+1\right)$: maximally split up to one unit. Nondegeneracy and positivity are therefore incompatible on every truncation with $N \geq 1$: already by (1), a positive semidefinite B_ψ has rank at most one on an algebra of dimension $N+1 \geq 2$.*

Rests on Theorems 15.58 and 15.68 and Definition 15.14.

Derivation. *Derives Corollary 15.69.*

(1) is Theorem 15.68 applied to A_N: an $\mathbb{R}$-character must send ε to a real root of $x^{N+1} = 0$, that is to 0, so the only character is evaluation at $\varepsilon = 0$ and Equation (15.73) reads $\psi = w_1 \,\mathrm{ev}_0$ with $w_1 = \psi(1)$, allowing also $w_1 = 0$ for $\psi = 0$. (2): in the basis $1, \varepsilon, \ldots, \varepsilon^N$ the matrix of B_ψ has entries $\psi(\varepsilon^{i+j})$, zero for $i + j > N$ and equal to $\psi(\varepsilon^N) \neq 0$ along the anti-diagonal $i+j = N$, so $\det B_\psi = \pm\psi(\varepsilon^N)^{N+1} \neq 0$ and the form is nondegenerate. The span of $\{\varepsilon^i : 2i > N\}$ has all pairwise products of total degree exceeding N, hence is totally isotropic for B_ψ, of dimension $N/2$; a nondegenerate symmetric form on a space of dimension $N+1$ with a totally isotropic subspace of dimension $N/2$ has at least $N/2$ positive and $N/2$ negative directions, which fixes the signature up to the placement of the one remaining unit. □

Corollary 15.70 (Signature of the factorised form)**.** *If B_ψ has signature (p_ψ, n_ψ) and $\kappa_{\mathfrak{g}}$ has signature (p_κ, n_κ), the factorised form $B_\psi \otimes \kappa_{\mathfrak{g}}$ on $\mathfrak{g}_A$ has signature*

$$(p_\psi p_\kappa + n_\psi n_\kappa,\ p_\psi n_\kappa + n_\psi p_\kappa)\ . \tag{15.74}$$

A positive definite B_ψ reproduces the sign pattern of $\kappa_{\mathfrak{g}}$ on every summand; each negative direction of B_ψ instead contributes a full reversed copy $-\kappa_{\mathfrak{g}}$, so a split B_ψ carries the reversed pattern on half of its directions.

Rests on Definition 15.66 and Theorem 15.51.

Derivation. *Derives Corollary 15.70.*

Diagonalise each factor and count the signs of the products of diagonal entries. □

Remark 15.71 (What this classifies, and its place in the chapter). Theorem 15.68 is the positivity companion of Theorem 15.58, and the two pull in opposite directions. Nondegeneracy can always be arranged on an even truncation, but it is bought with the anti-diagonal level pairing, and Corollary 15.69 shows that pairing to be maximally split; positivity, by contrast, sees only the totally real semisimple part of A — at most one positive weight per real point of the Artin decomposition — and nothing of the radical. The Gram matrix of Example 15.57, whose determinant is $-\phi(\varepsilon)^2$, is the sharpest instance: split, usable as a nondegenerate pairing, never positive. In the language of moment sequences, B_ψ on A_N is the Hankel matrix of the finite sequence $\psi(\varepsilon^k)$, and Theorem 15.68 is the statement that a positive Hankel form on a truncated polynomial algebra comes from a nonnegative measure

supported on the real spectrum — here the single point $\varepsilon = 0$. As everywhere in this chapter (Remark 15.59), the statement is mathematics: the companion manuscript [2434] applies it at $D = 4$ as a kinetic-positivity criterion, with the weights w_i playing the role of coupling constants, one per summand; no physical claim is made or needed here.

Chapter 16

Calculus of Variations

Functionals, the Euler–Lagrange equations, constraints and Lagrange multipliers, and second-variation conditions — the mathematical engine behind every action principle in this treatise. Where the differential calculus of Chapter 7 finds the points at which a function of finitely many variables is stationary, the calculus of variations finds the *curves* and *fields* at which a functional — a number assigned to a whole function, typically an integral $J[y] = \int f(x, y, y')\,\mathrm{d}x$ — is stationary. The subject was created for isolated geometric problems, systematised by Euler [23] and Lagrange [31], and became the common language of physics when mechanics, optics, field theory and general relativity were each recast as the statement that an action is stationary. The canonical modern exposition is Gelfand–Fomin [1254].

This chapter is consumed three times over: the Euler–Lagrange machinery feeds Lagrangian mechanics in Chapter 21, the several-variable theory feeds classical field theory in Chapter 64 and the gravitational action of Chapter 44, and Noether's theorem [456] is the origin of every conservation law derived in this book.

The logical order of the chapter inverts its historical order. The three problems of Section 16.1 were posed and solved before any general method existed; they are stated first because they fix what the method must deliver, and each is solved here with the machinery of Section 16.2, to which the solutions forward-refer. A reader who wants the theory before the examples may begin at Section 16.2.1 and return.

16.1 The classical problems

16.1.1 The brachistochrone

In the June 1696 issue of the *Acta Eruditorum* Johann Bernoulli challenged the mathematicians of Europe to find, among all curves joining two given points in a vertical plane, the one down which a bead sliding without friction under gravity travels in least time [17]. Solutions by Newton, Leibniz, l'Hôpital and both Bernoullis appeared in the issue of May 1697. The problem is the origin of the subject: it asks for a minimum not over a finite list of numbers but over a whole class of curves.

Set the starting point at the origin, let x be measured horizontally and y vertically *downwards*, and let the bead of mass m start from rest. Energy conservation gives the speed at depth y as $v = \sqrt{2gy}$, with $g = 9.806\,65\,\mathrm{m/s^2}$ the standard acceleration of gravity; the mass cancels, which is why the answer is a purely geometric curve. Since the arc element is $\mathrm{d}s = \sqrt{1 + y'^2}\,\mathrm{d}x$, the transit time to the endpoint (x_1, y_1) is the functional

$$T[y] = \int_0^{x_1} \sqrt{\frac{1 + y'(x)^2}{2g\,y(x)}}\,\mathrm{d}x\,, \tag{16.1}$$

measured in seconds, over curves with $y(0) = 0$, $y(x_1) = y_1 > 0$ and $y > 0$ on $(0, x_1]$.

Proposition 16.1 (The curve of quickest descent is a cycloid)**.** *Every extremal of Equation* (16.1) *is an arc of the cycloid*

$$x = a\,(\theta - \sin\theta)\,, \qquad y = a\,(1 - \cos\theta)\,, \qquad \theta \in [0, \theta_1]\,, \tag{16.2}$$

traced by a point on the rim of a circle of radius a rolling on the underside of the horizontal line $y = 0$. The radius a, of dimension length, and the terminal parameter θ_1 are fixed by the endpoint condition.

Rests on Equations (16.1) *and* (16.25)*.*

Proof. *Derives Proposition 16.1.*

The integrand $f(y, y') = \left[(1+y'^2)/(2gy)\right]^{1/2}$ carries no explicit x, so the Beltrami identity Equation (16.25) applies: $f - y'\,\partial f/\partial y'$ is constant along any extremal. With

$$\frac{\partial f}{\partial y'} = \frac{y'}{\sqrt{2gy}\,\sqrt{1 + y'^2}}\,,$$

the combination collapses to

$$f - y'\,\frac{\partial f}{\partial y'} = \frac{1}{\sqrt{2gy}\,\sqrt{1 + y'^2}} = C > 0\,,$$

that is, $y\,(1 + y'^2) = 2a$ with $2a = 1/(2gC^2)$, a length. Hence $y' = \sqrt{(2a - y)/y}$, and y never exceeds $2a$. Substituting $y = a(1 - \cos\theta) = 2a\sin^2(\theta/2)$ gives $2a - y = 2a\cos^2(\theta/2)$ and therefore $y' = \cos(\theta/2)/\sin(\theta/2)$, so that

$$\mathrm{d}x = \frac{\mathrm{d}y}{y'} = 2a\sin\frac{\theta}{2}\cos\frac{\theta}{2}\,\frac{\sin(\theta/2)}{\cos(\theta/2)}\,\mathrm{d}\theta = a\,(1 - \cos\theta)\,\mathrm{d}\theta\,.$$

Integrating from $\theta = 0$, where $x = y = 0$, gives Equation (16.2). □

Remark 16.2 (Two features the answer alone does not show)*.* The cycloid leaves the origin vertically ($y' \to \infty$ as $\theta \to 0$), so the bead is accelerated hardest at the start; and for y_1 small enough relative to x_1 the optimal arc dips *below* the endpoint and climbs back, which no argument from symmetry would suggest. That the extremal is in fact a minimum, and not merely a stationary curve, follows from the sufficiency theory of Section 16.4.4: the integrand is convex in y', so the Weierstrass excess function is nonnegative.

Remark 16.3 (Bernoulli's optical solution)*.* Johann Bernoulli's own solution did not use any variational calculus. He replaced the falling bead by a light ray crossing a medium of continuously varying refractive index $n \propto 1/v \propto y^{-1/2}$, and applied the law of refraction in the form $\sin\vartheta/v = \text{const}$ that Section 16.7.3 derives from Fermat's principle. Writing $\sin\vartheta = 1/\sqrt{1 + y'^2}$ reproduces $y(1 + y'^2) = \text{const}$ immediately. The step is not a trick: the identity of the two problems is the optical–mechanical analogy, made systematic by Hamilton and Jacobi in Chapter 23, and in this chapter it reappears as the common form of Lemma 16.100, which serves both Maupertuis' principle and Fermat's.

16.1.2 The catenary and the isoperimetric problem

A uniform flexible chain of linear mass density ρ_ℓ (in kg/m) and fixed total length ℓ hangs from two points. Galileo asserted that the resulting curve is a parabola [4]; it is not, as Huygens showed while still a teenager, and the correct curve was found in 1691 by Johann Bernoulli, Leibniz and Huygens independently [16]. In the variational reading the chain minimises its gravitational potential energy

$$U[y] = \rho_\ell\, g \int_{x_0}^{x_1} y(x)\sqrt{1 + y'(x)^2}\,\mathrm{d}x\,, \tag{16.3}$$

in joules, with y measured upwards, subject to the fixed-length constraint

$$L[y] = \int_{x_0}^{x_1} \sqrt{1 + y'(x)^2}\, \mathrm{d}x = \ell\,. \tag{16.4}$$

Proposition 16.4 (The hanging chain is a catenary)**.** *Let ℓ exceed the distance between the suspension points. Every extremal of Equation (16.3) subject to Equation (16.4) is a catenary*

$$y(x) = a \cosh\!\left(\frac{x - x_c}{a}\right) - \lambda\,, \tag{16.5}$$

with $a > 0$ a length, x_c a horizontal offset, and λ the Lagrange multiplier of the length constraint. It is not a parabola.

Rests on Equations (16.3) and (16.25) and Theorem 16.43.

Proof. *Derives Proposition 16.4.*

By Theorem 16.43 the constrained extremals are the free extremals of $U + \rho_\ell g \lambda L$, whose integrand, after division by the constant $\rho_\ell g$, is $F(y, y') = (y + \lambda)\sqrt{1 + y'^2}$. It carries no explicit x, so the Beltrami identity Equation (16.25) gives

$$F - y' \frac{\partial F}{\partial y'} = (y + \lambda)\sqrt{1 + y'^2} - \frac{(y + \lambda)\, y'^2}{\sqrt{1 + y'^2}} = \frac{y + \lambda}{\sqrt{1 + y'^2}} = a\,,$$

a constant with the dimension of length. Writing $u = y + \lambda$ this reads $u = a\sqrt{1 + u'^2}$, that is $u' = \pm\sqrt{u^2/a^2 - 1}$, whose separated form $\mathrm{d}u/\sqrt{u^2 - a^2} = \pm \mathrm{d}x/a$ integrates to $u = a\cosh\big((x - x_c)/a\big)$. Restoring $y = u - \lambda$ gives Equation (16.5). Expanding, $a\cosh(z/a) = a + z^2/(2a) + z^4/(24a^3) + \dots$, so the catenary agrees with a parabola only to second order about its vertex — which is why Galileo's conjecture survived casual inspection. □

Remark 16.5 (The same curve, three problems). The catenary is the extremal of $\int y\sqrt{1 + y'^2}\, \mathrm{d}x$ with the length fixed, and also, with no constraint at all, of the surface-area functional of Proposition 16.9; the two integrands differ only by the additive constant λ that the constraint supplies. This is not a coincidence but the multiplier rule at work: fixing the length of the generating curve and dropping the constant term are the same modification of the integrand.

Queen Dido's problem — to enclose the greatest area with a boundary of given length — is the oldest extremal problem on record and the prototype of the class that carries its name.

Proposition 16.6 (The isoperimetric extremal is a circle)**.** *Among closed, simple, piecewise-C^1 plane curves of fixed length ℓ, every extremal of the enclosed area is a circle of radius $\ell/2\pi$.*

Rests on Theorems 16.35 and 16.43.

Proof. *Derives Proposition 16.6.*

Parametrise the curve by arclength $s \in [0, \ell]$, so that $\dot{x}^2 + \dot{y}^2 = 1$, and use the shoelace form of the area, $A = \frac{1}{2}\oint (x\,\mathrm{d}y - y\,\mathrm{d}x)$. By Theorem 16.43 the constrained extremals are the free extremals of the integrand

$$F(x, y, \dot{x}, \dot{y}) = \tfrac{1}{2}(x\dot{y} - y\dot{x}) + \lambda\sqrt{\dot{x}^2 + \dot{y}^2}\,.$$

The system Equation (16.30) gives, after imposing the arclength gauge $\sqrt{\dot{x}^2 + \dot{y}^2} = 1$,

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(-\tfrac{1}{2}y + \lambda\dot{x}\right) = \tfrac{1}{2}\dot{y}\,, \qquad \frac{\mathrm{d}}{\mathrm{d}s}\left(\tfrac{1}{2}x + \lambda\dot{y}\right) = -\tfrac{1}{2}\dot{x}\,,$$

that is $\lambda\ddot{x} = \dot{y}$ and $\lambda\ddot{y} = -\dot{x}$. These are consistent with the gauge, since $\frac{\mathrm{d}}{\mathrm{d}s}(\dot{x}^2 + \dot{y}^2) = 2\dot{x}\dot{y}/\lambda - 2\dot{y}\dot{x}/\lambda = 0$, and they give the signed curvature

$$\kappa = \dot{x}\ddot{y} - \dot{y}\ddot{x} = -\frac{\dot{x}^2 + \dot{y}^2}{\lambda} = -\frac{1}{\lambda}\,,$$

constant. A plane curve of constant nonzero curvature is a circular arc, and a closed one of length ℓ is the full circle of radius $|\lambda| = \ell/2\pi$. □

Remark 16.7 (What the extremal argument does not prove). Proposition 16.6 identifies the only candidate; it does not by itself show that a maximiser exists. Steiner's nineteenth-century symmetrisation arguments have the same gap, and Weierstrass's criticism of them is what forced the existence question into the open (Section 16.5.1). Existence for this problem follows from the direct method of Section 16.5.2; Euler's founding monograph [23] treats the whole class systematically, and the general multiplier rule for integral constraints is Theorem 16.43.

16.1.3 Minimal surfaces and soap films

A surface spanning a given closed contour and minimising area is a *minimal surface*. Plateau realised such surfaces physically as soap films, whose surface tension makes the area the energy, and catalogued both the surfaces and the junction rules that films obey [186]: three films always meet along an edge at equal angles of 120 degrees, and four such edges meet at a vertex at the tetrahedral angle $\arccos(-1/3) \approx 109.47$ degrees. The physics of the surface tension that enforces this belongs to Chapter 31; the geometry is here.

For a surface given as a graph $z = u(x, y)$ over a region $\Omega \subset \mathbb{R}^2$, the area functional is

$$A[u] = \int_{\Omega} \sqrt{1 + |\nabla u|^2}\, \mathrm{d}x\, \mathrm{d}y\,. \tag{16.6}$$

Proposition 16.8 (The minimal-surface equation). *The Euler–Lagrange equation of Equation (16.6) is*

$$\left(1 + u_y^2\right) u_{xx} - 2u_x u_y\, u_{xy} + \left(1 + u_x^2\right) u_{yy} = 0\,, \tag{16.7}$$

equivalently the vanishing of the mean curvature of the graph.

Rests on Equations (16.6) and (16.32).

Proof. *Derives Proposition 16.8.*

Apply Equation (16.32) with two independent variables and the integrand $f = W \equiv \sqrt{1 + u_x^2 + u_y^2}$, which does not depend on u itself. Since $\partial f/\partial u_x = u_x/W$ and $\partial f/\partial u_y = u_y/W$, the equation reads

$$\frac{\partial}{\partial x}\left(\frac{u_x}{W}\right) + \frac{\partial}{\partial y}\left(\frac{u_y}{W}\right) = 0\,. \tag{16.8}$$

Carrying out the differentiations, with $W_x = (u_x u_{xx} + u_y u_{xy})/W$ and $W_y = (u_x u_{xy} + u_y u_{yy})/W$, and multiplying through by W^3,

$$\begin{aligned} W^2\,(u_{xx} + u_{yy}) - u_x\,(u_x u_{xx} + u_y u_{xy}) - u_y\,(u_x u_{xy} + u_y u_{yy}) \\ = \left(1 + u_y^2\right) u_{xx} - 2u_x u_y u_{xy} + \left(1 + u_x^2\right) u_{yy} = 0\,, \end{aligned}$$

which is Equation (16.7). The left-hand side of Equation (16.8) is $2H$, twice the mean curvature of the graph in the sense of Chapter 13, so the equation says $H = 0$. □

Proposition 16.9 (The catenoid)**.** *Among surfaces of revolution about the x axis generated by a positive profile $y(x)$, the extremals of the area $A = 2\pi \int y\sqrt{1+y'^2}\,\mathrm{d}x$ are the catenoids*

$$y(x) = a\cosh\!\left(\frac{x - x_c}{a}\right), \qquad a > 0\,. \tag{16.9}$$

Rests on Equations (16.6) and (16.25).

Proof. *Derives Proposition 16.9.*

The integrand $f = y\sqrt{1+y'^2}$ carries no explicit x, so Equation (16.25) gives $f - y' f_{y'} = y/\sqrt{1+y'^2} = a$, a constant length. This is the equation solved in Proposition 16.4 with $\lambda = 0$, whose solution is Equation (16.9). □

Remark 16.10 (Two classical surfaces and one warning). The catenoid and the helicoid $(v\cos u,\ v\sin u,\ cu)$ are the two minimal surfaces known to Euler and Meusnier, and they are locally isometric. Neither existence nor uniqueness is automatic: for two coaxial rings whose separation exceeds about 1.3255 times their radius no catenoid joins them at all, and the soap film jumps to the two flat discs — a physical realisation of the failure of a minimising sequence to converge inside the admissible class. The general existence statement for an arbitrary contour is the Plateau problem of Section 16.5.4.

16.2 Functionals and the first variation

16.2.1 Function spaces and functionals

Definition 16.11 (Admissible class; functional)**.** Fix $a < b$ in $\mathbb{R}$, boundary values $y_a, y_b \in \mathbb{R}$, and let

$$\mathcal{A} = \Big\{ y \in C^1[a,b] \;\Big|\; y(a) = y_a,\ y(b) = y_b \Big\} \tag{16.10}$$

be the *admissible class* with fixed endpoints. A *functional* on $\mathcal{A}$ is a map $J : \mathcal{A} \longrightarrow \mathbb{R}$. The functionals of this chapter are integrals

$$J[y] = \int_a^b f\left(x, y(x), y'(x)\right)\mathrm{d}x\,, \tag{16.11}$$

with the *integrand* (or *Lagrangian*) f of class C^2 on $[a,b]\times\mathbb{R}\times\mathbb{R}$.

Rests on Definition 7.66 and Theorem 7.40.

Definition 16.12 (The two norms; weak and strong neighbourhoods)**.** On $C^1[a,b]$ define

$$\|y\|_0 = \max_{a\le x\le b} |y(x)|\,, \tag{16.12}$$

$$\|y\|_1 = \max_{a\le x\le b} |y(x)| + \max_{a\le x\le b} |y'(x)|\,. \tag{16.13}$$

A *strong* ε-neighbourhood of y is $\{\tilde y \in \mathcal{A} \mid \|\tilde y - y\|_0 < \varepsilon\}$; a *weak* one is $\{\tilde y \in \mathcal{A} \mid \|\tilde y - y\|_1 < \varepsilon\}$. Both are metric notions in the sense of Definition 6.24, and since $\|\cdot\|_0 \le \|\cdot\|_1$ the weak ε-neighbourhood is contained in the strong one of the same radius, so every strong neighbourhood contains a weak one: the weak topology on the admissible class is the finer of the two. The containment is strict in the worst possible way — no strong neighbourhood of 0 is contained in any weak one, since $y_n(x) = n^{-1}\sin(n^2 x)$ has $\|y_n\|_0 \to 0$ while $\|y_n\|_1 \to \infty$.

Rests on Definitions 6.24 and 16.11.

Definition 16.13 (Weak and strong extrema)**.** $y \in \mathcal{A}$ is a *weak local minimum* of J if $J[y] \le J[\tilde y]$ for every $\tilde y$ in some weak neighbourhood of y, and a *strong local minimum* if the same holds in some strong neighbourhood. Every strong minimum is a weak minimum; the converse fails.

Rests on Definition 16.12.

Example 16.14 (A weak minimum that is not strong)**.** Take $a = 0$, $b = 1$, $y_a = y_b = 0$ and $f(x, y, y') = y'^2 + y'^3$, and let $y \equiv 0$, so that $J[y] = 0$. If $\|\tilde{y}\|_1 < \frac{1}{2}$ then $|\tilde{y}'| < \frac{1}{2}$ pointwise and the integrand is $\tilde{y}'^2\,(1 + \tilde{y}') \geq \frac{1}{2}\tilde{y}'^2 \geq 0$, so $J[\tilde{y}] \geq 0$: the zero function is a weak minimum. It is not a strong one. Fix $A > 1$ and $0 < \delta < 1$, and let $\tilde{y}$ be the piecewise-linear function of slope $-A$ on a set of total length δ and slope $A\delta/(1-\delta)$ on the rest, so that $\tilde{y}(0) = \tilde{y}(1) = 0$ and $\|\tilde{y}\|_0 \leq A\delta$. Then

$$J[\tilde{y}] = \delta\left(A^2 - A^3\right) + (1-\delta)\left[\left(\frac{A\delta}{1-\delta}\right)^2 + \left(\frac{A\delta}{1-\delta}\right)^3\right],$$

whose first term is negative and of order δA^3 while the second is of order $\delta^2 A^2$; taking $A = \delta^{-1/2}$ makes $J[\tilde{y}] < 0$ while $\|\tilde{y}\|_0 \leq \delta^{1/2} \to 0$. So arbitrarily small *strong* perturbations lower the functional. The distinction is exactly what separates the Legendre and Jacobi conditions of Sections 16.4.1 and 16.4.2 from the Weierstrass condition of Section 16.4.3 [1254].

Rests on Definition 16.13.

Definition 16.15 (Variation; the first variation)**.** A *variation* at $y \in \mathcal{A}$ is a function $\eta \in C^1[a,b]$ with $\eta(a) = \eta(b) = 0$; the set of such η is written $C_0^1[a,b]$, and $y + \varepsilon\eta \in \mathcal{A}$ for every $\varepsilon \in \mathbb{R}$. The *first variation* (the Gâteaux variation) of J at y in the direction η is

$$\delta J[y;\eta] = \lim_{\varepsilon \to 0} \frac{J[y+\varepsilon\eta] - J[y]}{\varepsilon} = \frac{\mathrm{d}}{\mathrm{d}\varepsilon} J[y+\varepsilon\eta]\Big|_{\varepsilon=0}, \tag{16.14}$$

when the limit exists. It is the functional derivative of Equation (7.138) paired with η.

Rests on Definition 16.11 and Equation (7.138).

Proposition 16.16 (Stationarity is necessary)**.** *If $y \in \mathcal{A}$ is a weak local extremum of J and $\delta J[y;\eta]$ exists, then $\delta J[y;\eta] = 0$ for every $\eta \in C_0^1[a,b]$.*

Rests on Definitions 16.13 and 16.15 and Lemma 7.33.

Proof. *Derives Proposition 16.16.*

Fix $\eta \neq 0$ and set $\varphi(\varepsilon) = J[y + \varepsilon\eta]$. Because $\|(y+\varepsilon\eta) - y\|_1 = |\varepsilon|\,\|\eta\|_1$, every ε with $|\varepsilon| < \varepsilon_0/\|\eta\|_1$ places $y + \varepsilon\eta$ inside the weak ε_0-neighbourhood in which y extremises J. Hence φ has a local extremum at $\varepsilon = 0$ and is differentiable there, so $\varphi'(0) = \delta J[y;\eta] = 0$ by Fermat's lemma (Lemma 7.33). □

Proposition 16.17 (The first variation of an integral functional)**.** *For J as in Equation (16.11) with f of class C^2, and for every $\eta \in C^1[a,b]$,*

$$\delta J[y;\eta] = \int_a^b \left[\frac{\partial f}{\partial y}\,\eta(x) + \frac{\partial f}{\partial y'}\,\eta'(x)\right]\mathrm{d}x, \tag{16.15}$$

the partial derivatives being evaluated at $(x, y(x), y'(x))$.

Rests on Equations (16.11) and (16.14).

Proof. *Derives Proposition 16.17.*

The map $(\varepsilon, x) \longmapsto f\,(x, y + \varepsilon\eta, y' + \varepsilon\eta')$ is C^1 on the compact set $[-1,1] \times [a,b]$, so its ε-derivative is continuous there and differentiation under the integral sign is legitimate. Carrying it out and using the chain rule (Proposition 7.31),

$$\frac{\mathrm{d}}{\mathrm{d}\varepsilon}\Big|_0 f\,(x, y+\varepsilon\eta, y'+\varepsilon\eta') = \frac{\partial f}{\partial y}\,\eta + \frac{\partial f}{\partial y'}\,\eta',$$

which integrates to Equation (16.15). □

16.2.2 The fundamental lemma

Equation (16.15) turns the stationarity condition into the statement that a certain integral vanishes for *every* variation. Converting that into a pointwise differential equation is the work of the following three lemmas. The first is the fundamental lemma of the calculus of variations; the second is du Bois-Reymond's sharpening [204], which is what makes it unnecessary to assume in advance that the extremal is twice differentiable.

Lemma 16.18 (Fundamental lemma)**.** *Let $g \in C^0[a,b]$ satisfy*

$$\int_a^b g(x)\,\eta(x)\,\mathrm{d}x = 0 \qquad \text{for every } \eta \in C_0^1[a,b]\,. \tag{16.16}$$

Then $g \equiv 0$ on $[a,b]$.
Rests on Definition 16.15 and Theorem 7.40.

Proof. *Derives Lemma 16.18.*

Suppose $g(x_0) \neq 0$ for some x_0; replacing g by $-g$ if necessary, assume $g(x_0) > 0$, and by continuity x_0 may be taken interior. By continuity again (Definition 7.20) there is $\delta > 0$ with $[x_0-\delta, x_0+\delta] \subset (a,b)$ and $g > \tfrac{1}{2}g(x_0)$ on that interval. Put

$$\eta(x) = \begin{cases} \left[(x-x_0)^2 - \delta^2\right]^2, & |x-x_0| \le \delta\,, \\ 0\,, & \text{otherwise}\,. \end{cases} \tag{16.17}$$

This η is of class C^1 — both it and $\eta' = 4(x-x_0)\left[(x-x_0)^2-\delta^2\right]$ vanish at $x = x_0 \pm \delta$ — and lies in $C_0^1[a,b]$. It is strictly positive on the open interval, so

$$\int_a^b g\,\eta\,\mathrm{d}x \ge \frac{g(x_0)}{2}\int_{x_0-\delta}^{x_0+\delta}\eta\,\mathrm{d}x > 0\,,$$

contradicting Equation (16.16). □

Lemma 16.19 (du Bois-Reymond)**.** *Let $h \in C^0[a,b]$ satisfy*

$$\int_a^b h(x)\,\eta'(x)\,\mathrm{d}x = 0 \qquad \text{for every } \eta \in C_0^1[a,b]\,. \tag{16.18}$$

Then h is constant on $[a,b]$.
Rests on Equation (16.18) and Theorem 7.42.

Proof. *Derives Lemma 16.19.*

Let $c = (b-a)^{-1}\int_a^b h\,\mathrm{d}x$ and define

$$\eta(x) = \int_a^x \left[h(t) - c\right]\mathrm{d}t\,.$$

Then $\eta(a) = 0$, and $\eta(b) = \int_a^b h\,\mathrm{d}x - c(b-a) = 0$ by the choice of c, so $\eta \in C_0^1[a,b]$; it is of class C^1 with $\eta' = h - c$ by the fundamental theorem of calculus (Theorem 7.42). Substituting into Equation (16.18),

$$0 = \int_a^b h\,(h-c)\,\mathrm{d}x = \int_a^b (h-c)^2\,\mathrm{d}x + c\int_a^b (h-c)\,\mathrm{d}x = \int_a^b (h-c)^2\,\mathrm{d}x\,,$$

the last integral vanishing by the definition of c. A continuous nonnegative integrand with zero integral vanishes identically, so $h \equiv c$. □

Lemma 16.20 (Mixed form)**.** *Let $M, N \in C^0[a,b]$ satisfy*

$$\int_a^b \left[M(x)\,\eta(x) + N(x)\,\eta'(x) \right] \mathrm{d}x = 0 \qquad \text{for every } \eta \in C_0^1[a,b]\,. \tag{16.19}$$

Then N is of class C^1 and $N' = M$ on $[a,b]$.
Rests on Lemma 16.19 and Corollary 7.44.

Proof. *Derives Lemma 16.20.*
Set $A(x) = \int_a^x M(t)\,\mathrm{d}t$, which is C^1 with $A' = M$ (Theorem 7.42). Integrating by parts (Equation (7.28)) and using $\eta(a) = \eta(b) = 0$,

$$\int_a^b M\,\eta\,\mathrm{d}x = \left[A\,\eta \right]_a^b - \int_a^b A\,\eta'\,\mathrm{d}x = -\int_a^b A\,\eta'\,\mathrm{d}x\,.$$

So Equation (16.19) says $\int_a^b (N - A)\,\eta'\,\mathrm{d}x = 0$ for every admissible η, whence $N - A$ is a constant by Lemma 16.19. Thus $N = A + \text{const}$ is of class C^1 with $N' = A' = M$. □

Remark 16.21 (Broken extremals). Nothing above requires the competing curves to be smooth: the same three lemmas hold verbatim when C_0^1 is enlarged to the piecewise-C^1 functions vanishing at the endpoints, since the bump Equation (16.17) and the primitive built in Lemma 16.19 already lie in the smaller class. An extremal in the wider class may have corners, and the two conditions that must then hold across a corner are the Weierstrass–Erdmann conditions proved as Corollary 16.33 [1254].

16.2.3 The Euler–Lagrange equation

Theorem 16.22 (Euler–Lagrange)**.** *Let f be of class C^2 and let $y \in \mathcal{A}$ be a weak local extremum of Equation (16.11). Then $x \longmapsto \partial f/\partial y'\,(x, y, y')$ is of class C^1 and*

$$\frac{\partial f}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'} \right) = 0 \qquad \text{on } [a,b]\,. \tag{16.20}$$

A solution of Equation (16.20) is called an extremal *of J.*
Rests on Proposition 16.16, Equation (16.15), and Lemma 16.20.

Proof. *Derives Theorem 16.22.*
By Proposition 16.16 and Proposition 16.17,

$$\int_a^b \left[\frac{\partial f}{\partial y}\,\eta + \frac{\partial f}{\partial y'}\,\eta' \right] \mathrm{d}x = 0 \qquad \text{for every } \eta \in C_0^1[a,b]\,.$$

Both coefficients are continuous in x, because f is C^2 and $y \in C^1$. Lemma 16.20 with $M = \partial f/\partial y$ and $N = \partial f/\partial y'$ then says that N is C^1 with $N' = M$, which is Equation (16.20). □

Two forms of the same statement are worth separating, because they carry different smoothness assumptions.

Corollary 16.23 (du Bois-Reymond form)**.** *Under the hypotheses of Theorem 16.22 there is a constant C with*

$$\frac{\partial f}{\partial y'}\,(x, y, y') = \int_a^x \frac{\partial f}{\partial y}\,(t, y, y')\,\mathrm{d}t + C \qquad \text{for all } x \in [a,b]\,. \tag{16.21}$$

Rests on Equation (16.20) and Theorem 7.43.

Proof. *Derives Corollary 16.23.*
Integrate Equation (16.20) from a to x, using Theorem 7.43 on the C^1 function $\partial f/\partial y'$. □

Remark 16.24 (When the extremal is twice differentiable). Expanding the total derivative in Equation (16.20) gives the second-order form

$$\frac{\partial f}{\partial y} - \frac{\partial^2 f}{\partial x\,\partial y'} - \frac{\partial^2 f}{\partial y\,\partial y'}\,y' - \frac{\partial^2 f}{\partial y'^2}\,y'' = 0\,, \tag{16.22}$$

which presupposes y''. It is legitimate wherever $\partial^2 f/\partial y'^2 \neq 0$: at such a point Equation (16.21) may be solved for y' as a C^1 function of x by the implicit function theorem (Chapter 7), so $y \in C^2$ there. Where $\partial^2 f/\partial y'^2$ vanishes the extremal may genuinely have a corner, and only the first-order form Equation (16.21) survives. This is why the du Bois-Reymond argument matters: the classical derivation, which integrates by parts a second time, assumes the conclusion.

Remark 16.25 (Stationary is not minimal). Theorem 16.22 is a necessary condition only. An extremal may be a minimum, a maximum, or neither: the extremals of $\int_0^b (y'^2 - y^2)\,\mathrm{d}x$ with $y(0) = y(b) = 0$ include $y \equiv 0$, which minimises for $b < \pi$ and does not for $b > \pi$, although the equation $y'' + y = 0$ is the same in both cases. The extra information is second order and is the subject of Section 16.4; $b = \pi$ is the first conjugate point in the sense of Section 16.4.2. In physics this is the reason Hamilton's principle is a principle of *stationary*, not least, action (Section 16.7.1).

Proposition 16.26 (Covariance under change of dependent variable)**.** *Let $y = \Psi(x, u)$ with Ψ of class C^2 and $\partial\Psi/\partial u \neq 0$, and let*

$$F\,(x, u, u') = f\left(x, \Psi(x, u), \frac{\partial \Psi}{\partial x} + \frac{\partial \Psi}{\partial u}\,u'\right).$$

Then the Euler–Lagrange expressions are related by

$$\frac{\partial F}{\partial u} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial F}{\partial u'}\right) = \frac{\partial \Psi}{\partial u}\left[\frac{\partial f}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'}\right)\right], \tag{16.23}$$

so u is an extremal of $\int F\,\mathrm{d}x$ if and only if $y = \Psi(x, u)$ is an extremal of $\int f\,\mathrm{d}x$.
Rests on Equation (16.20) and Proposition 7.31.

Proof. *Derives Proposition 16.26.*

Write Ψ_x, Ψ_u, Ψ_{xu}, Ψ_{uu} for the partials of Ψ and note that $y' = \Psi_x + \Psi_u u'$, whence $\partial y'/\partial u' = \Psi_u$ and $\partial y'/\partial u = \Psi_{xu} + \Psi_{uu}u' = \mathrm{d}\Psi_u/\mathrm{d}x$, the total derivative along the curve. The chain rule then gives

$$\frac{\partial F}{\partial u'} = \frac{\partial f}{\partial y'}\,\Psi_u\,, \qquad \frac{\partial F}{\partial u} = \frac{\partial f}{\partial y}\,\Psi_u + \frac{\partial f}{\partial y'}\,\frac{\mathrm{d}\Psi_u}{\mathrm{d}x}\,,$$

and therefore

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial F}{\partial u'}\right) = \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'}\right)\Psi_u + \frac{\partial f}{\partial y'}\,\frac{\mathrm{d}\Psi_u}{\mathrm{d}x}\,.$$

Subtracting, the two $\partial f/\partial y' \cdot \mathrm{d}\Psi_u/\mathrm{d}x$ terms cancel and Equation (16.23) remains. Since $\Psi_u \neq 0$, one side vanishes exactly when the other does. □

Remark 16.27 (Why covariance matters here). Equation (16.23) says that the Euler–Lagrange expression transforms as a covector under changes of the dependent variables: the *equation* is coordinate independent even though its individual terms are not. This is what licenses the use of arbitrary generalized coordinates in Chapter 21 — polar, spherical, body-fixed — without rederiving the equations of motion each time, and what makes the same formalism usable on the curved configuration spaces of Chapter 13 and on the spacetimes of Chapter 43. Newton's equations enjoy no such property: the components of $m\ddot{\boldsymbol{x}}$ are not the components of anything in curvilinear coordinates.

16.2.4 First integrals and natural boundary conditions

The Euler–Lagrange equation is of second order, and integrating it once is exactly what makes the classical problems soluble. Two circumstances permit it, and both are instances of Noether's theorem (Section 16.6.1): a coordinate absent from the integrand, and the independent variable absent from the integrand.

Proposition 16.28 (Cyclic coordinate)**.** *If f does not depend on y, that is $\partial f/\partial y \equiv 0$, then along every extremal*

$$\frac{\partial f}{\partial y'}\,(x, y') = \mathit{const}\,. \tag{16.24}$$

Rests on Equation (16.20)*.*

Proof. *Derives Proposition 16.28.*

Immediate from Equation (16.20): the first term vanishes, so the total derivative of $\partial f/\partial y'$ is zero, and a C^1 function with vanishing derivative on an interval is constant (Corollary 7.36). □

Theorem 16.29 (Beltrami identity)**.** *If f does not depend explicitly on x, that is $\partial f/\partial x \equiv 0$, then along every extremal of class C^2*

$$f\,(y, y') - y'\,\frac{\partial f}{\partial y'}\,(y, y') = \mathit{const}\,. \tag{16.25}$$

Rests on Equation (16.20) *and Proposition 7.31.*

Proof. *Derives Theorem 16.29.*

Differentiate the left-hand side along the curve, using the chain rule and $\partial f/\partial x = 0$:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}x}\left(f - y'\,\frac{\partial f}{\partial y'}\right) &= \frac{\partial f}{\partial y}\,y' + \frac{\partial f}{\partial y'}\,y'' - y''\,\frac{\partial f}{\partial y'} - y'\,\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'}\right)\\ &= y'\left[\frac{\partial f}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'}\right)\right] = 0\,,\end{aligned}$$

the bracket vanishing by Equation (16.20). □

Remark 16.30 (The Beltrami constant is an energy). The quantity $h = y'\,\partial f/\partial y' - f$ conserved by Equation (16.25) is the Legendre transform of f with respect to y'. When x is the time and f the Lagrangian of a mechanical system, h is the energy in joules and Equation (16.25) is its conservation (Chapter 21); when f is convex in y' the same transform produces the Hamiltonian of Chapter 22, and the convexity hypothesis it needs is the strengthened Legendre condition of Section 16.4.1.

So far the endpoints have been held fixed. Releasing one of them costs nothing in the derivation and produces a boundary condition instead of a boundary datum.

Theorem 16.31 (Natural boundary condition)**.** *Let J be extremised over $\mathcal{A}_b = \{y \in C^1[a,b] \mid y(a) = y_a\}$, the value $y(b)$ being free. Then a weak extremum satisfies Equation* (16.20) *on $[a,b]$ together with*

$$\frac{\partial f}{\partial y'}\,(b, y(b), y'(b)) = 0\,. \tag{16.26}$$

Rests on Equation (16.15)*, Theorem 16.22, and Lemma 16.18.*

Proof. *Derives Theorem 16.31.*

Variations η now need only satisfy $\eta(a) = 0$. Those that also vanish at b form the class of Theorem 16.22, so Equation (16.20) holds and $\partial f/\partial y'$ is C^1. For a general admissible η, integrating Equation (16.15) by parts now keeps the boundary term:

$$0 = \delta J[y;\eta] = \int_a^b \left[\frac{\partial f}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'}\right)\right]\eta\,\mathrm{d}x + \left[\frac{\partial f}{\partial y'}\,\eta\right]_a^b = \left.\frac{\partial f}{\partial y'}\right|_{x=b}\eta(b)\,, \tag{16.27}$$

the integral vanishing by Equation (16.20) and the term at a by $\eta(a) = 0$. Choosing η with $\eta(b) = 1$ gives Equation (16.26). □

Theorem 16.32 (Transversality)**.** *Let the right-hand endpoint be required only to lie on a C^1 curve $y = \psi(x)$, the abscissa b being free as well. Then at the point $(b, y(b))$ where the extremal meets the curve,*

$$\left[f + (\psi' - y')\,\frac{\partial f}{\partial y'}\right]_{x=b} = 0\,. \tag{16.28}$$

Rests on Theorem 16.31 and Equation (16.20).

Proof. *Derives Theorem 16.32.*

Embed the extremal in a one-parameter family of admissible curves y_ε with terminal abscissa $b_\varepsilon = b + \varepsilon\beta + O(\varepsilon^2)$ and terminal ordinate $y_\varepsilon(b_\varepsilon) = \psi(b_\varepsilon)$, and write η for the vertical variation $\partial y_\varepsilon/\partial\varepsilon|_0$ at fixed x, so $\eta(a) = 0$. Differentiating $J_\varepsilon = \int_a^{b_\varepsilon} f\,\mathrm{d}x$ at $\varepsilon = 0$, and using $\mathrm{d}\left(\int_a^{b_\varepsilon}\right)/\mathrm{d}\varepsilon = \beta f(b)$ for the moving limit,

$$0 = \beta f\big|_b + \int_a^b \left[\frac{\partial f}{\partial y}\eta + \frac{\partial f}{\partial y'}\eta'\right]\mathrm{d}x = \beta f\big|_b + \left.\frac{\partial f}{\partial y'}\right|_b \eta(b)\,,$$

the integral collapsing as in Equation (16.27). The endpoint constraint relates β and $\eta(b)$: differentiating $y_\varepsilon(b_\varepsilon) = \psi(b_\varepsilon)$ gives $\eta(b) + \beta\,y'(b) = \beta\,\psi'(b)$, that is $\eta(b) = \beta\,(\psi' - y')_b$. Substituting and dividing by the arbitrary $\beta \neq 0$ yields Equation (16.28). □

Corollary 16.33 (Weierstrass–Erdmann corner conditions)**.** *Let y be a piecewise-C^1 extremal with a corner at an interior point x_0, and write $y'(x_0^-)$ and $y'(x_0^+)$ for the one-sided slopes. Then both*

$$\left.\frac{\partial f}{\partial y'}\right|_{x_0^-} = \left.\frac{\partial f}{\partial y'}\right|_{x_0^+}, \qquad \left[f - y'\,\frac{\partial f}{\partial y'}\right]_{x_0^-} = \left[f - y'\,\frac{\partial f}{\partial y'}\right]_{x_0^+} \tag{16.29}$$

hold: the momentum $\partial f/\partial y'$ and the energy $y'\,\partial f/\partial y' - f$ are continuous across a corner even though the slope is not.

Rests on Theorem 16.32 and Corollary 16.23.

Proof. *Derives Corollary 16.33.*

The first condition follows from Equation (16.21), which holds on each smooth arc with the *same* constant C — the derivation of Lemma 16.20 never used differentiability of y — so $\partial f/\partial y'$ equals a continuous function of x throughout $[a, b]$.

For the second, regard the corner (x_0, y_0) as a common free endpoint of the two arcs, and vary it. Repeating the computation of Theorem 16.32 for the left arc, whose terminal point moves by (β, γ) with $\gamma = \partial y_\varepsilon(x_0)/\partial\varepsilon|_0 + \beta y'(x_0^-)$, contributes $\beta f|_{x_0^-} + (\partial f/\partial y')_{x_0^-}\left(\gamma - \beta y'(x_0^-)\right)$ to δJ; the right arc, for which the same point is an *initial* point, contributes the same expression at x_0^+ with the opposite sign. Stationarity for all (β, γ) forces both brackets to match: the coefficient of γ gives the first condition again, and the coefficient of β gives $[f - y'\,\partial f/\partial y']$ continuous, the second. □

Remark 16.34 (Where the boundary terms go in physics). The boundary term $[(\partial f/\partial y')\,\eta]_a^b$ discarded in Theorem 16.22 is not always discardable. In field theory it becomes a surface integral over $\partial\Omega$ whose vanishing is a boundary condition on the fields (Chapter 64); in general relativity it does not vanish for the Einstein–Hilbert action, and a compensating surface term must be added by hand (Chapter 44). The elementary case here — a free end of a string forces $\partial f/\partial y' = 0$, which for a taut string is the statement that no transverse force is applied there — is the same phenomenon in one dimension.

16.2.5 Several functions, several variables, higher derivatives

Theorem 16.35 (System of Euler–Lagrange equations). *Let $J[y^1,\dots,y^n] = \int_a^b f\,(x, y^1,\dots,y^n, y'^1,\dots,y'^n)\,\mathrm{d}x$ with f of class C^2, over n-tuples of C^1 functions with all $2n$ endpoint values fixed. At a weak extremum,*

$$\frac{\partial f}{\partial y^i} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'^i}\right) = 0\,, \qquad i = 1,\dots,n\,. \tag{16.30}$$

Rests on Theorem 16.22 and Lemma 16.20.

Proof. *Derives Theorem 16.35.*

Fix i and vary only y^i, holding the other $n-1$ functions fixed: J restricted to that one-parameter family is a functional of the type of Equation (16.11), and Theorem 16.22 gives the i-th equation. Repeating for each i gives the system, and no further information is available from simultaneous variations, since the first variation is linear in $(\eta^1,\dots,\eta^n)$. □

Theorem 16.36 (Euler–Lagrange equations for several independent variables). *Let $\Omega \subset \mathbb{R}^D$ be a bounded domain with piecewise-C^1 boundary, and let*

$$S[\varphi] = \int_\Omega \mathcal{L}\left(x^\mu, \varphi^A, \partial_\mu \varphi^A\right) \mathrm{d}^D x\,, \qquad A = 1,\dots,n\,,\ \mu = 1,\dots,D\,, \tag{16.31}$$

be extremised over fields $\varphi^A \in C^2(\overline{\Omega})$ with prescribed values on $\partial\Omega$. Then at a weak extremum

$$\frac{\partial \mathcal{L}}{\partial \varphi^A} - \partial_\mu\left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \varphi^A)}\right) = 0\,, \qquad A = 1,\dots,n\,, \tag{16.32}$$

with the repeated index μ summed.

Rests on Equation (16.31), Theorem 7.101, and Lemma 16.18.

Proof. *Derives Theorem 16.36.*

Let $\eta^A \in C^1(\overline{\Omega})$ vanish on $\partial\Omega$ and put $\varphi_\varepsilon = \varphi + \varepsilon\eta$. Differentiating under the integral sign as in Proposition 16.17,

$$\delta S[\varphi;\eta] = \int_\Omega \left[\frac{\partial \mathcal{L}}{\partial \varphi^A}\,\eta^A + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \varphi^A)}\,\partial_\mu \eta^A\right] \mathrm{d}^D x\,.$$

Write $\pi^\mu_A = \partial\mathcal{L}/\partial(\partial_\mu\varphi^A)$, which is C^1 because $\mathcal{L}$ is C^2 and $\varphi \in C^2$. Then $\pi^\mu_A\,\partial_\mu\eta^A = \partial_\mu\left(\pi^\mu_A \eta^A\right) - \eta^A\,\partial_\mu \pi^\mu_A$, and the divergence theorem (Theorem 7.101) turns the first piece into a surface integral over $\partial\Omega$, where $\eta^A = 0$. Hence

$$\delta S[\varphi;\eta] = \int_\Omega \left[\frac{\partial \mathcal{L}}{\partial \varphi^A} - \partial_\mu \pi^\mu_A\right] \eta^A\,\mathrm{d}^D x\,. \tag{16.33}$$

Stationarity makes this vanish for every such η. The bracket is continuous, and the multidimensional form of Lemma 16.18 — proved by the same argument, with the bump Equation (16.17) replaced by its product over the D coordinates on a small cube inside Ω — forces it to vanish identically, one component A at a time. □

Example 16.37 (The Dirichlet integral gives Laplace's equation)**.** Take $D = 3$, one field u, and $\mathcal{L} = \tfrac{1}{2}|\nabla u|^2$, so that $S[u] = \tfrac{1}{2}\int_\Omega |\nabla u|^2 \,\mathrm{d}^3x$ is the Dirichlet integral. Then $\partial\mathcal{L}/\partial u = 0$ and $\partial\mathcal{L}/\partial(\partial_\mu u) = \partial_\mu u$, so Equation (16.32) reads

$$\nabla^2 u = 0\,, \tag{16.34}$$

Laplace's equation of Chapter 10. Multiplied by the permittivity of free space, $\varepsilon_0 = 8.854\,187\,812\,8 \times 10^{-12}\,\mathrm{F/m}$, the same functional is the electrostatic field energy $U = \frac{\varepsilon_0}{2}\int |\nabla\Phi|^2 \,\mathrm{d}^3x$ in joules, and the statement becomes the one of Chapter 58: the electrostatic potential is the field of least energy compatible with the boundary data. This is the Dirichlet principle, whose existence gap is the subject of Section 16.5.1. Multiple-integral problems of this kind are the systematic subject of Courant–Hilbert [1222].

Rests on Equation (16.32).

Theorem 16.38 (Euler–Poisson equation)**.** *Let $J[y] = \int_a^b f\left(x, y, y', \dots, y^{(m)}\right)\mathrm{d}x$ with f of class C^{m+1}, be extremised over $y \in C^{2m}[a,b]$ with $y, y', \dots, y^{(m-1)}$ prescribed at both endpoints. Then*

$$\sum_{k=0}^{m} (-1)^k \frac{\mathrm{d}^k}{\mathrm{d}x^k}\left(\frac{\partial f}{\partial y^{(k)}}\right) = 0\,. \tag{16.35}$$

Rests on Equation (16.15), Lemma 16.18, and Corollary 7.44.

Proof. *Derives Theorem 16.38.*

Admissible variations η satisfy $\eta^{(j)}(a) = \eta^{(j)}(b) = 0$ for $j = 0, \dots, m-1$. As in Proposition 16.17,

$$\delta J[y;\eta] = \int_a^b \sum_{k=0}^{m} \frac{\partial f}{\partial y^{(k)}}\,\eta^{(k)}\,\mathrm{d}x\,.$$

Integrate the k-th term by parts k times (Equation (7.28)). Each integration produces a boundary term carrying a factor $\eta^{(j)}$ with $j \le k-1 \le m-1$, all of which vanish, and contributes one factor of -1; after k steps the term is $(-1)^k \int \eta\,\mathrm{d}^k\left(\partial f/\partial y^{(k)}\right)/\mathrm{d}x^k$. Summing over k,

$$\delta J[y;\eta] = \int_a^b \eta \sum_{k=0}^{m} (-1)^k \frac{\mathrm{d}^k}{\mathrm{d}x^k}\left(\frac{\partial f}{\partial y^{(k)}}\right)\mathrm{d}x = 0\,,$$

and Lemma 16.18 gives Equation (16.35). □

Proposition 16.39 (Ostrogradsky instability)**.** *Let $m = 2$, write q for the dependent variable and t for the independent one, and suppose the Lagrangian $\mathcal{L}(q, \dot q, \ddot q)$ is* nondegenerate*, meaning $\partial^2\mathcal{L}/\partial\ddot q^2 \neq 0$, so that $\ddot q$ may be solved for in terms of $(q, \dot q, \partial\mathcal{L}/\partial\ddot q)$. Then the conserved energy associated with time translation is linear in one of its momenta and is therefore unbounded below.*

Rests on Equation (16.35) and Theorem 16.29.

Proof. *Derives Proposition 16.39.*

Introduce $Q_1 = q$, $Q_2 = \dot q$ and the Ostrogradsky momenta

$$P_1 = \frac{\partial\mathcal{L}}{\partial\dot q} - \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial\mathcal{L}}{\partial\ddot q}\right), \qquad P_2 = \frac{\partial\mathcal{L}}{\partial\ddot q}\,.$$

Nondegeneracy lets $P_2 = \partial\mathcal{L}/\partial\ddot q$ be inverted for $\ddot q = \mathcal{F}(Q_1, Q_2, P_2)$. The Beltrami constant of Theorem 16.29, extended to the higher-derivative case by the same computation, is

$$\mathcal{H} = P_1 Q_2 + P_2\,\mathcal{F}(Q_1, Q_2, P_2) - \mathcal{L}(Q_1, Q_2, \mathcal{F})\,. \tag{16.36}$$

Only the first term contains P_1, and it contains it linearly, so for fixed (Q_1, Q_2, P_2) with $Q_2 \neq 0$ the value of $\mathcal{H}$ runs over all of $\mathbb{R}$ as P_1 does. □

Remark 16.40 (Why every fundamental Lagrangian in this book is first order). Proposition 16.39 is Ostrogradsky's theorem [132]. Its physical content is that a nondegenerate theory whose Lagrangian contains second time derivatives has no stable ground state: the system can lower $\mathcal{H}$ without bound by exciting the P_1 direction, and once it is coupled to anything else the vacuum decays. This — not aesthetics — is why the Lagrangians of Chapter 21, Chapter 64 and Chapter 44 are first order in time derivatives. The Einstein–Hilbert action is the instructive exception: it does contain second derivatives of the metric, but *degenerately* — they enter linearly and can be removed by a total divergence, which is exactly the boundary term of Remark 16.34 — so Ostrogradsky's hypothesis fails and general relativity has second-order field equations.

16.3 Constrained variation

16.3.1 Lagrange multipliers

Constraints come in two kinds, and they need different multipliers. A *pointwise* constraint must hold at every x, and buys one multiplier *function*; an *integral* constraint holds once for the whole curve, and buys one multiplier *constant*. The rule for both descends from the finite-dimensional multiplier theorem of Chapter 7, of which the following is the functional analogue [40].

Theorem 16.41 (Multiplier rule for pointwise constraints)**.** *Let $J[y]=\int_a^b f\,(x,y^i,y'^i)\,\mathrm{d}x$ with $i=1,\dots,n$, and let the competing curves be required to satisfy the $m<n$ pointwise constraints*

$$g^\alpha\left(x,y^1,\dots,y^n\right)=0\,,\qquad \alpha=1,\dots,m\,, \tag{16.37}$$

with g^α of class C^2 and the $m\times n$ matrix $\partial g^\alpha/\partial y^i$ of full rank m along the curve. If y is a weak extremum of J within the constrained class, there are functions $\lambda_\alpha\in C^0[a,b]$ such that, with $F=f+\lambda_\alpha g^\alpha$,

$$\frac{\partial F}{\partial y^i}-\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial F}{\partial y'^i}\right)=0\,,\qquad i=1,\dots,n\,. \tag{16.38}$$

Rests on Equation (16.37), Theorem 16.35, and Lemma 16.18.

Proof. *Derives Theorem 16.41.*

Admissible variations $\eta^i\in C^1_0[a,b]$ are no longer arbitrary: differentiating Equation (16.37) along the family $y+\varepsilon\eta$ at $\varepsilon=0$ gives the m pointwise linear conditions

$$\frac{\partial g^\alpha}{\partial y^i}\,\eta^i(x)=0\,,\qquad \alpha=1,\dots,m\,,\quad x\in[a,b]\,. \tag{16.39}$$

Stationarity gives, after the integration by parts of Theorem 16.22,

$$\int_a^b E_i\,\eta^i\,\mathrm{d}x=0\,,\qquad E_i\equiv\frac{\partial f}{\partial y^i}-\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'^i}\right)\,, \tag{16.40}$$

for every η obeying Equation (16.39). By the rank hypothesis the indices may be relabelled so that the leading $m\times m$ block $\partial g^\alpha/\partial y^\beta$, $\beta=1,\dots,m$, is invertible at every x; call $y^1,\dots,y^m$ dependent and $y^{m+1},\dots,y^n$ free. Define $\lambda_\alpha(x)$ as the unique solution of the linear system

$$E_\beta+\lambda_\alpha\,\frac{\partial g^\alpha}{\partial y^\beta}=0\,,\qquad \beta=1,\dots,m\,,$$

which is continuous in x because the block and the E_β are. With this choice the first m of Equation (16.38) hold by construction, since g^α does not contain y'^i and hence

$\partial F/\partial y'^i = \partial f/\partial y'^i$. Substituting back into Equation (16.40) and using Equation (16.39) to eliminate the dependent η^β,

$$0 = \int_a^b \left(E_k + \lambda_\alpha \frac{\partial g^\alpha}{\partial y^k} \right) \eta^k \, \mathrm{d}x \,, \qquad k = m+1, \dots, n \,,$$

now for *arbitrary* $\eta^k \in C_0^1[a,b]$, since the dependent components can always be recovered from Equation (16.39). Lemma 16.18, applied one free index at a time, gives the remaining $n-m$ equations. □

Remark 16.42 (The multiplier is the constraint force). Comparing Equation (16.38) with the unconstrained equations, the effect of the constraint is the extra term $\lambda_\alpha \, \partial g^\alpha / \partial y^i$ on the right-hand side — a force normal to the constraint surface, of magnitude fixed by λ_α. In mechanics this is exactly the reaction of the constraint, and λ_α carries whatever SI unit makes $\lambda_\alpha g^\alpha$ an energy: for a constraint written as a length, λ is a force in newtons. That reading is developed, with the Lagrange equations of the first kind, in Chapter 21. It is also the practical reason to keep the multipliers rather than eliminate the constraint: the numbers one wants — the tension in the rod, the normal force on the track — are the multipliers themselves.

16.3.2 Isoperimetric constraints

Theorem 16.43 (Euler's rule for integral constraints). *Let $J[y] = \int_a^b f\,(x, y, y')\,\mathrm{d}x$ and $K[y] = \int_a^b g\,(x, y, y')\,\mathrm{d}x$ with f, g of class C^2, and let $y \in \mathcal{A}$ be a weak extremum of J within the class $\{\tilde{y} \in \mathcal{A} \mid K[\tilde{y}] = \ell\}$. If y is* not *an extremal of K alone, there is a constant $\lambda \in \mathbb{R}$ such that y is an unconstrained extremal of $\int_a^b (f + \lambda g)\,\mathrm{d}x$, that is*

$$\frac{\partial}{\partial y}(f + \lambda g) - \frac{\mathrm{d}}{\mathrm{d}x}\left[\frac{\partial}{\partial y'}(f + \lambda g) \right] = 0 \,. \tag{16.41}$$

Rests on Definition 16.15, Proposition 16.17, and Lemma 16.20.

Proof. *Derives Theorem 16.43.*

Because y is not an extremal of K, Lemma 16.20 supplies some $\eta_2 \in C_0^1[a,b]$ with $\delta K[y;\eta_2] \neq 0$. Fix an arbitrary $\eta_1 \in C_0^1[a,b]$ and consider the two-parameter family $y_\varepsilon = y + \varepsilon_1 \eta_1 + \varepsilon_2 \eta_2$, setting

$$\Phi\,(\varepsilon_1, \varepsilon_2) = J[y_\varepsilon] \,, \qquad \Psi\,(\varepsilon_1, \varepsilon_2) = K[y_\varepsilon] \,.$$

Both are C^1 near the origin, with $\partial\Phi/\partial\varepsilon_i\big|_0 = \delta J[y;\eta_i]$ and similarly for Ψ, by the argument of Proposition 16.17. Since $\Psi(0,0) = \ell$ and $\partial\Psi/\partial\varepsilon_2\big|_0 = \delta K[y;\eta_2] \neq 0$, the implicit function theorem (Chapter 7) provides a C^1 function $\varepsilon_2\,(\varepsilon_1)$ with $\varepsilon_2(0) = 0$ and $\Psi\,(\varepsilon_1, \varepsilon_2(\varepsilon_1)) = \ell$ for small ε_1. Every curve of this one-parameter family is admissible and lies in a weak neighbourhood of y, so $\varepsilon_1 \longmapsto \Phi\,(\varepsilon_1, \varepsilon_2(\varepsilon_1))$ has an extremum at 0:

$$\delta J[y;\eta_1] + \delta J[y;\eta_2]\,\varepsilon_2'(0) = 0 \,, \qquad \varepsilon_2'(0) = -\frac{\delta K[y;\eta_1]}{\delta K[y;\eta_2]} \,,$$

the second identity coming from differentiating the constraint. Setting $\lambda = -\delta J[y;\eta_2]/\delta K[y;\eta_2]$, a constant independent of η_1, the display becomes $\delta J[y;\eta_1] + \lambda\,\delta K[y;\eta_1] = 0$, that is $\delta\,(J + \lambda K)\,[y;\eta_1] = 0$ for every $\eta_1 \in C_0^1[a,b]$. Lemma 16.20 then yields Equation (16.41). □

Remark 16.44 (The exceptional case is not a technicality). If y *is* an extremal of K alone, the conclusion can fail, and the correct statement is the abnormal one: there are constants $(\lambda_0, \lambda) \neq (0,0)$ with y an extremal of $\lambda_0 f + \lambda g$, and λ_0 may be zero. The finite-dimensional

shadow of this is the failure of the multiplier rule at a critical point of the constraint function, and it is the same phenomenon: the constraint set has no tangent direction along which J can be tested.

Example 16.45 (Two solved isoperimetric problems)**.** Proposition 16.6 and Proposition 16.4 are both applications of Theorem 16.43, with λ playing two different physical roles: for Dido's problem $|\lambda|$ is the radius of the answer, and for the hanging chain $\rho_\ell g\lambda$ is the horizontal tension in the chain, in newtons. Both illustrate Remark 16.42: the multiplier is not bookkeeping, it is the physically interesting number.

Rests on Theorem 16.43.

Remark 16.46 (Eigenvalue problems are isoperimetric problems)*.* Take $f = p\,y'^2 + q\,y^2$ and $g = r\,y^2$ with the normalisation $K[y] = \int_a^b r\,y^2\,\mathrm{d}x = 1$. Then Equation (16.41) reads

$$-\frac{\mathrm{d}}{\mathrm{d}x}\left(p\,\frac{\mathrm{d}y}{\mathrm{d}x}\right) + q\,y = -\lambda\,r\,y\,, \tag{16.42}$$

which is the Sturm–Liouville eigenvalue problem Equation (9.55) of Chapter 9 with eigenvalue $-\lambda$. The multiplier of the normalisation constraint *is* the eigenvalue. This is the identification the Rayleigh–Ritz method of Section 16.5.3 exploits, and it is why a variational estimate of a ground-state energy is available at all.

16.3.3 Holonomic and nonholonomic constraints

Definition 16.47 (Holonomic and nonholonomic constraints)**.** A constraint on a curve $x \longmapsto (y^1, \dots, y^n)$ is *holonomic* if it can be written as a finite set of relations $g^\alpha\,(x, y^1, \dots, y^n) = 0$ among the coordinates and the independent variable alone, as in Equation (16.37). A constraint given in Pfaffian form,

$$A^\alpha{}_i\,(x,y)\,\mathrm{d}y^i + A^\alpha{}_0\,(x,y)\,\mathrm{d}x = 0\,, \qquad \alpha = 1, \dots, m\,, \tag{16.43}$$

is holonomic if the system Equation (16.43) is integrable — if there are functions g^α and an invertible matrix $\mu^\alpha{}_\beta$ with $\mu^\alpha{}_\beta\left(A^\beta{}_i\mathrm{d}y^i + A^\beta{}_0\mathrm{d}x\right) = \mathrm{d}g^\alpha$ — and *nonholonomic* otherwise. Integrability is decided by the Frobenius condition of Chapter 13: the ideal generated by the one-forms must be closed under exterior differentiation.

Rests on Equation (16.37) and Definition 21.2.

Example 16.48 (The vertical rolling disc)**.** A thin disc of radius R rolls without slipping on a horizontal plane, staying vertical. Its configuration is $(x, y, \varphi, \vartheta)$: contact point, heading angle and rotation angle. Rolling without slipping means the contact point has zero velocity, which in SI reads

$$\mathrm{d}x - R\cos\varphi\,\mathrm{d}\vartheta = 0\,, \qquad \mathrm{d}y - R\sin\varphi\,\mathrm{d}\vartheta = 0\,, \tag{16.44}$$

with R in metres and the angles in radians. Neither one-form is integrable, alone or together: the disc can be rolled around a closed loop in the plane and returned to its starting point with ϑ changed by an arbitrary amount, so no relation $g\,(x, y, \varphi, \vartheta) = 0$ can hold. The constraint removes two velocity directions but no configuration, and the accessible set is all four dimensions. This is the standard nonholonomic example [2027]; the dynamics belongs to Chapter 21 and Chapter 29.

Rests on Definition 16.47.

Remark 16.49 (What the multiplier method does and does not cover)*.* Theorem 16.41 was proved for *holonomic* constraints, and the restriction is essential. Two inequivalent prescriptions exist for a Pfaffian constraint that is not integrable, and it is a matter of fact, not of convention, which describes a rolling body.

The *vakonomic* prescription applies the theorem literally: it restricts the class of comparison curves to those satisfying Equation (16.43) and makes the action stationary within that class. The *d'Alembert–Chetaev* prescription, which is the one mechanics uses, does not restrict the comparison curves at all; it restricts the *virtual displacements* to the annihilator of the constraint forms, $A^{\alpha}{}_{i}\,\delta y^{i} = 0$, and requires the constraint forces to do no virtual work. For a holonomic constraint the two prescriptions coincide, because a curve tangent to an integrable distribution stays on the leaf. For a nonholonomic one they do not: the vakonomic equations carry extra terms in the derivatives of the multipliers along the curve, and the two sets of trajectories differ already for the rolling disc of Example 16.48.

The observed motion of rolling bodies is the d'Alembert–Chetaev one; that is the content of the principle of virtual work as it is set up in Chapter 21, and it is what the experiments on rolling and spinning rigid bodies in Chapter 29 test. The vakonomic equations are not wrong — they are the correct equations of a different problem, namely the optimal-control problem in which the constraint is imposed on the admissible curves by fiat — but they are not the equations of a rolling disc. Degenerate constraint systems, where the constraints follow from the Lagrangian itself rather than being imposed, are a third matter, treated in Chapter 26.

16.4 The second variation

16.4.1 The Legendre condition

Stationarity is a first-order condition and says nothing about whether an extremal minimises, maximises or does neither (Remark 16.25). The second-order information is carried by the second variation, which is a quadratic functional of the variation.

Proposition 16.50 (The second variation)**.** *Let f be of class C^{3} and y an extremal of class C^{2}. For $\eta \in C^{1}_{0}[a,b]$,*

$$\delta^{2} J[y;\eta] \equiv \frac{\mathrm{d}^{2}}{\mathrm{d}\varepsilon^{2}} J[y+\varepsilon\eta]\bigg|_{\varepsilon=0} = \int_{a}^{b} \Big[P(x)\,\eta'(x)^{2} + Q(x)\,\eta(x)^{2} \Big]\,\mathrm{d}x\,, \tag{16.45}$$

where, with all partial derivatives evaluated along the extremal,

$$P = \frac{\partial^{2} f}{\partial y'^{2}}\,, \qquad Q = \frac{\partial^{2} f}{\partial y^{2}} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial^{2} f}{\partial y\,\partial y'} \right). \tag{16.46}$$

Rests on Equation (16.14), Theorem 7.38, and Corollary 7.44.

Proof. *Derives Proposition 16.50.*

Differentiating twice under the integral sign, as in Proposition 16.17,

$$\delta^{2} J[y;\eta] = \int_{a}^{b} \left[\frac{\partial^{2} f}{\partial y^{2}}\,\eta^{2} + 2\,\frac{\partial^{2} f}{\partial y\,\partial y'}\,\eta\,\eta' + \frac{\partial^{2} f}{\partial y'^{2}}\,\eta'^{2} \right] \mathrm{d}x\,.$$

The cross term is a total derivative up to one integration by parts: $2\eta\eta' = (\eta^{2})'$, so by Equation (7.28) and $\eta(a) = \eta(b) = 0$,

$$\int_{a}^{b} \frac{\partial^{2} f}{\partial y\,\partial y'} \left(\eta^{2}\right)' \mathrm{d}x = -\int_{a}^{b} \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial^{2} f}{\partial y\,\partial y'} \right) \eta^{2}\,\mathrm{d}x\,,$$

which absorbed into the first term gives Equation (16.45) with the coefficients Equation (16.46). □

Theorem 16.51 (Legendre's necessary condition)**.** *If the extremal y is a weak local minimum of J, then*

$$P(x) = \frac{\partial^2 f}{\partial y'^2}\,(x, y(x), y'(x)) \geq 0 \qquad \text{for every } x \in [a,b]\,. \tag{16.47}$$

Rests on Equation (16.45) and Proposition 16.16.

Proof. *Derives Theorem 16.51.*

At a weak minimum $\varepsilon \longmapsto J[y+\varepsilon\eta]$ has a minimum at $\varepsilon = 0$, so $\delta^2 J[y;\eta] \geq 0$ for every $\eta \in C_0^1[a,b]$. Suppose instead that $P(x_0) < 0$ at some x_0, which by continuity may be taken interior, and choose $\delta > 0$ and $k > 0$ with $[x_0-\delta, x_0+\delta] \subset (a,b)$ and $P \leq -k$ there. Take the localized variation

$$\eta(x) = \sin^2\!\left(\frac{\pi\,(x - x_0 + \delta)}{2\delta}\right) \quad \text{on } |x - x_0| \leq \delta\,, \qquad \eta = 0 \text{ elsewhere}\,,$$

which lies in $C_0^1[a,b]$ because η and η' both vanish at $x_0 \pm \delta$. Substituting $t = (x - x_0 + \delta)/2\delta$,

$$\int_a^b \eta'^2\,\mathrm{d}x = \frac{\pi^2}{4\delta}\,, \qquad \int_a^b \eta^2\,\mathrm{d}x = \frac{3\delta}{4}\,. \tag{16.48}$$

Hence, writing $M = \max_{[a,b]} |Q|$,

$$\delta^2 J[y;\eta] \leq -k\,\frac{\pi^2}{4\delta} + M\,\frac{3\delta}{4}\,,$$

which is negative for δ small enough — a contradiction. So $P \geq 0$ everywhere. □

Remark 16.52 (The strengthened condition, and what Legendre missed)*.* The *strengthened* Legendre condition is $P > 0$ on $[a,b]$; the problem is then called *regular*. Legendre's memoir on distinguishing maxima from minima [41] introduced the condition and attempted to prove that it is also sufficient, by completing the square in Equation (16.45) with the help of an auxiliary function. The step is correct wherever the auxiliary function exists, and Legendre did not notice that it may fail to exist on the whole interval. The scaling in Equation (16.48) shows why the P term dominates and hence why P alone controls the *local* behaviour: a variation squeezed into a short interval has a large $\int \eta'^2$ and a small $\int \eta^2$. The gap Legendre left is exactly the possibility that a variation spread over the *whole* interval defeats a positive P, and closing it is Jacobi's work (Section 16.4.2). In physics $P > 0$ is the invertibility of the Legendre transform, that is, of the map from velocities to momenta (Chapter 22).

16.4.2 The Jacobi equation and conjugate points

The functional Equation (16.45) is itself a variational problem, and its own Euler–Lagrange equation is the key to the whole second-order theory [101].

Definition 16.53 (Jacobi accessory equation; conjugate point)**.** The *Jacobi accessory equation* of the extremal y is the Euler–Lagrange equation of the quadratic functional Equation (16.45),

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(P(x)\,\frac{\mathrm{d}u}{\mathrm{d}x}\right) - Q(x)\,u = 0\,. \tag{16.49}$$

A point $c \in (a,b]$ is *conjugate* to a along y if the solution u of Equation (16.49) with $u(a) = 0$, $u'(a) = 1$ satisfies $u(c) = 0$.

Rests on Equations (16.20) and (16.45).

Remark 16.54 (Where the Jacobi equation comes from, and what it means). Applying Equation (16.20) to the integrand $Pu'^2 + Qu^2$ gives $2\mathrm{d}(Pu')/\mathrm{d}x - 2Qu = 0$, which is Equation (16.49). Geometrically the equation is the linearisation of Equation (16.20) about the extremal: if $y(x,\alpha)$ is a one-parameter family of extremals through the same initial point, then $u = \partial y/\partial\alpha$ solves Equation (16.49). A conjugate point is therefore a place where neighbouring extremals leaving a come back together to first order — a focus. For geodesics on a sphere the conjugate point of any point is its antipode, which is why a great-circle arc longer than half the circumference is not the shortest path; in optics the same focusing is a caustic (Chapter 23), and in mechanics a kinetic focus.

Theorem 16.55 (Jacobi's necessary condition)**.** *Let the problem be regular, $P > 0$ on $[a,b]$, and let the extremal y be a weak local minimum. Then no point of the open interval (a,b) is conjugate to a.*

Rests on Definition 16.53, Theorem 16.51, and Corollary 16.33.

Proof. *Derives Theorem 16.55.*

Suppose $c \in (a,b)$ is conjugate to a, with u the solution of Equation (16.49) having $u(a) = u(c) = 0$ and $u'(a) = 1$; then u does not vanish identically, and $u'(c) \neq 0$, since a second-order linear solution vanishing together with its derivative at a point vanishes identically. Define the broken variation

$$\eta(x) = u(x) \text{ on } [a,c]\,, \qquad \eta(x) = 0 \text{ on } [c,b]\,,$$

which is continuous and piecewise C^1 with $\eta(a) = \eta(b) = 0$. Multiplying Equation (16.49) by u and integrating by parts over $[a,c]$,

$$\int_a^c \left(Pu'^2 + Qu^2\right)\mathrm{d}x = \left[P\,u\,u'\right]_a^c = 0\,,$$

because u vanishes at both ends. Hence $\delta^2 J[y;\eta] = 0$.

Because y is a weak minimum, $\delta^2 J[y;\cdot] \geq 0$ on $C_0^1[a,b]$, and hence on the larger class of piecewise-C^1 variations vanishing at the endpoints: a corner may be rounded off inside an interval of length ε, which changes $\int (P\eta'^2 + Q\eta^2)\,\mathrm{d}x$ by $O(\varepsilon)$, so the quadratic form is nonnegative on the closure by continuity. So η *minimises* $\delta^2 J$ over the wider class. A minimiser must satisfy the Euler–Lagrange equation Equation (16.49) on each smooth arc, and by the first Weierstrass–Erdmann condition of Corollary 16.33 — here the continuity of $\partial/\partial\eta'\,(P\eta'^2 + Q\eta^2) = 2P\eta'$ — the product $P\eta'$ must be continuous at c. But $P(c)\eta'(c^-) = P(c)u'(c) \neq 0$ while $P(c)\eta'(c^+) = 0$, a contradiction. □

Theorem 16.56 (Sufficiency of the second variation)**.** *Let $P > 0$ on $[a,b]$ and suppose the Jacobi equation Equation (16.49) has a solution w with no zero on $[a,b]$. Then $\delta^2 J[y;\eta] > 0$ for every $\eta \in C_0^1[a,b]$ that does not vanish identically.*

Rests on Equations (16.45) and (16.49).

Proof. *Derives Theorem 16.56.*

Set $W = -P\,w'/w$, which is C^1 on $[a,b]$ because w has no zero there. Differentiating and using Equation (16.49) for w,

$$W' = -\frac{(Pw')'}{w} + \frac{P\,w'^2}{w^2} = -Q + \frac{W^2}{P}\,. \tag{16.50}$$

For any $\eta \in C_0^1[a,b]$ the quantity $W\eta^2$ vanishes at both endpoints, so $\int_a^b (W\eta^2)'\,\mathrm{d}x = 0$ and this may be added to Equation (16.45) free of charge:

$$\delta^2 J[y;\eta] = \int_a^b \left[P\eta'^2 + 2W\eta\eta' + (Q + W')\,\eta^2\right]\mathrm{d}x = \int_a^b P\left(\eta' + \frac{W}{P}\,\eta\right)^2\mathrm{d}x\,,$$

the completion of the square being exact precisely because Equation (16.50) gives $Q + W' = W^2/P$. The integrand is nonnegative, so $\delta^2 J \geq 0$, and it vanishes only if $\eta' = -W\eta/P$ throughout. That linear equation with $\eta(a) = 0$ has only the zero solution, so $\delta^2 J[y;\eta] > 0$ unless $\eta \equiv 0$. □

Remark 16.57 (The two conditions are two faces of one). The hypothesis of Theorem 16.56 — a Jacobi solution without zeros on the closed interval — is the *strengthened Jacobi condition*, and it is equivalent, for a regular problem, to the absence of any point conjugate to a in $(a, b]$: a solution vanishing at $a-\varepsilon$ for small $\varepsilon > 0$ has, by continuous dependence of solutions on their initial data, no zero in $[a, b]$ exactly when the solution vanishing at a has none in $(a, b]$. The equivalence is proved in Appendix A.40, where the continuous dependence on the initial point is derived from the integral form of the initial value problem by a Grönwall estimate and the Sturm separation theorem from the Lagrange identity Equation (9.56); with it, the necessary condition Theorem 16.55 and the sufficient condition Theorem 16.56 test the same hypothesis, and differ only at the single point $x = b$.

Full derivation: Appendix A.40 (p. 2988).

Derives Remark 16.57.

Remark 16.58 (Counting conjugate points). Conjugate points are not merely an obstruction to be avoided; their number is an invariant. Morse's index theorem states that the index of the second variation — the maximal dimension of a subspace on which $\delta^2 J$ is negative definite — equals the number of points conjugate to a in (a, b), counted with multiplicity [746]. The theorem is quoted here and not used; it returns for geodesics in Chapter 43, where it converts a local calculation into a statement about the topology of the space of paths.

16.4.3 Strong variations and the Weierstrass condition

Everything in Sections 16.4.1 and 16.4.2 tests the extremal against curves whose *slopes* are close to its own, and Example 16.14 shows that this is not enough. A strong variation changes the slope by a finite amount over a short interval, and the quantity that measures its effect is Weierstrass's excess function [591].

Definition 16.59 (Weierstrass excess function)**.** For an integrand f of class C^2,

$$E(x, y, p, q) = f(x, y, q) - f(x, y, p) - (q - p)\,\frac{\partial f}{\partial y'}(x, y, p)\,. \tag{16.51}$$

It is the amount by which f, as a function of the slope alone at fixed (x, y), lies above its tangent line at p: the excess of the value at q over the linear extrapolation from p.

Rests on Definition 16.11.

Theorem 16.60 (Weierstrass' necessary condition)**.** *Let y be a strong local minimum of J. Then*

$$E(x, y(x), y'(x), q) \geq 0 \qquad \text{for every } x \in [a, b] \text{ and every } q \in \mathbb{R}\,. \tag{16.52}$$

Rests on Equation (16.51) and Definition 16.13.

Proof. *Derives Theorem 16.60.*

Fix an interior x_0, write $y_0 = y(x_0)$, fix $q \in \mathbb{R}$ and fix $\Delta > 0$ small enough that $[x_0, x_0 + \Delta] \subset (a, b)$. For $0 \leq h < \Delta$ define the comparison curve Y_h: equal to y outside $(x_0, x_0 + \Delta)$; the segment of slope q from (x_0, y_0) on $[x_0, x_0 + h]$; and on $[x_0 + h, x_0 + \Delta]$ the straight segment rejoining $(x_0 + \Delta, y(x_0 + \Delta))$, whose slope is

$$s_h = \frac{y(x_0 + \Delta) - y_0 - qh}{\Delta - h}\,, \qquad s_0 = s_\Delta \equiv \frac{y(x_0 + \Delta) - y_0}{\Delta}\,.$$

Each Y_h is admissible and piecewise C^1, and $\|Y_h - y\|_0 \longrightarrow 0$ as $h \to 0$ at fixed Δ, so for small h it lies in the strong neighbourhood on which y minimises. Hence $G(h) \equiv J[Y_h] - J[y]$ satisfies $G(0) = 0$ and $G(h) \geq 0$, so $G'(0^+) \geq 0$.

Only the interval $(x_0, x_0 + \Delta)$ contributes. Writing $\ell_h(x) = y_0 + qh + s_h\,(x - x_0 - h)$ for the rejoining segment,

$$J[Y_h]\big|_{(x_0, x_0+\Delta)} = \int_{x_0}^{x_0+h} f\,(x, y_0 + q(x - x_0), q)\,\mathrm{d}x + \int_{x_0+h}^{x_0+\Delta} f\,(x, \ell_h(x), s_h)\,\mathrm{d}x\,.$$

Differentiating at $h = 0$, where $\ell_0(x) = y_0 + s_\Delta(x - x_0)$, the two moving limits give $f\,(x_0, y_0, q) - f\,(x_0, y_0, s_\Delta)$, while

$$\left.\frac{\partial s_h}{\partial h}\right|_0 = \frac{s_\Delta - q}{\Delta}\,, \qquad \left.\frac{\partial \ell_h(x)}{\partial h}\right|_0 = (q - s_\Delta)\left(1 - \frac{x - x_0}{\Delta}\right)\,,$$

so that

$$G'(0^+) = f\,(x_0, y_0, q) - f\,(x_0, y_0, s_\Delta) + (q - s_\Delta)\int_{x_0}^{x_0+\Delta}\left[\frac{\partial f}{\partial y}\left(1 - \frac{x - x_0}{\Delta}\right) - \frac{1}{\Delta}\,\frac{\partial f}{\partial y'}\right]\mathrm{d}x\,, \tag{16.53}$$

the partial derivatives being evaluated at $(x, \ell_0(x), s_\Delta)$. Now let $\Delta \to 0$. The first part of the integral is $O(\Delta)$; the second tends to $\partial f/\partial y'\,(x_0, y_0, y'(x_0))$, since $\Delta^{-1}\int_{x_0}^{x_0+\Delta}$ of a continuous function tends to its value at x_0 and $s_\Delta \to y'(x_0)$ by the mean value theorem (Theorem 7.35). Writing $p = y'(x_0)$, the limit of Equation (16.53) is $f(x_0, y_0, q) - f(x_0, y_0, p) - (q - p)\,\partial f/\partial y'(x_0, y_0, p) = E\,(x_0, y_0, p, q)$. Since $G'(0^+) \geq 0$ for every Δ, the limit is nonnegative, which is Equation (16.52) at x_0; continuity extends it to the endpoints. □

Remark 16.61 (Excess, convexity and the Legendre transform). By Taylor's theorem with Lagrange remainder (Theorem 7.38) applied to $q \longmapsto f\,(x, y, q)$,

$$E\,(x, y, p, q) = \tfrac{1}{2}\,(q - p)^2\,\frac{\partial^2 f}{\partial y'^2}\,(x, y, \bar{q}) \tag{16.54}$$

for some $\bar{q}$ between p and q. Hence $E \geq 0$ for all q if f is convex in the slope, and taking $q \to p$ in Equation (16.54) recovers Legendre's condition $\partial^2 f/\partial y'^2 \geq 0$: Weierstrass' condition contains Legendre's, and the two agree exactly when the slope is varied infinitesimally. This is also the hypothesis under which the Legendre transform to the Hamiltonian formalism of Chapter 22 is invertible, and under which the convexity requirement of Tonelli's existence theorem (Section 16.5.2) holds. Three separate questions — strong minimality, the passage to the Hamiltonian, and existence — turn on the same convexity of f in y'.

16.4.4 Fields of extremals and sufficiency

All the conditions so far are necessary. Turning them into a sufficient condition needs one further construction: the extremal must be embedded in a family covering a whole neighbourhood of it.

Definition 16.62 (Field of extremals; slope function)**.** A *field of extremals* on a simply connected region $R \subset \mathbb{R}^2$ is a one-parameter family of extremals of J such that exactly one member passes through each point of R, depending C^1 on the point. Its *slope function* $p : R \longrightarrow \mathbb{R}$ assigns to each $(x, y) \in R$ the slope at that point of the unique member through it. An extremal is *embedded* in the field if its graph lies in R.

Rests on Theorem 16.22 and Definition 6.17.

Theorem 16.63 (Hilbert's invariant integral)**.** *Let p be the slope function of a field of extremals on R. Then the line integral*

$$I[\Gamma] = \int_\Gamma \left\{ \left[f(x,y,p) - p\,\frac{\partial f}{\partial y'}(x,y,p) \right] \mathrm{d}x + \frac{\partial f}{\partial y'}(x,y,p)\,\mathrm{d}y \right\} \tag{16.55}$$

depends only on the endpoints of the curve $\Gamma \subset R$, not on the curve. Along any member of the field itself, $I = \int f(x,y,y')\,\mathrm{d}x = J$.

Rests on Definition 16.62, Proposition 7.104, and Equation (16.20).

Proof. *Derives Theorem 16.63.*

Write the integrand as $\mathcal{P}\,\mathrm{d}x + \mathcal{Q}\,\mathrm{d}y$ with

$$\mathcal{P}(x,y) = f(x,y,p) - p\,\frac{\partial f}{\partial y'}(x,y,p)\,, \qquad \mathcal{Q}(x,y) = \frac{\partial f}{\partial y'}(x,y,p)\,,$$

both C^1 on R. Path independence on a simply connected region is equivalent to $\partial\mathcal{P}/\partial y = \partial\mathcal{Q}/\partial x$ (Proposition 7.104). Abbreviating f_y, $f_{y'}$, $f_{xy'}$, $f_{yy'}$, $f_{y'y'}$ for the partial derivatives evaluated at $(x,y,p(x,y))$, the chain rule gives

$$\begin{aligned} \frac{\partial \mathcal{Q}}{\partial x} &= f_{xy'} + f_{y'y'}\,\frac{\partial p}{\partial x}\,, \\ \frac{\partial \mathcal{P}}{\partial y} &= f_y + f_{y'}\,\frac{\partial p}{\partial y} - \frac{\partial p}{\partial y}\,f_{y'} - p\left(f_{yy'} + f_{y'y'}\,\frac{\partial p}{\partial y}\right) = f_y - p\,f_{yy'} - p\,f_{y'y'}\,\frac{\partial p}{\partial y}\,. \end{aligned}$$

Each member of the field satisfies Equation (16.20), and along it $\mathrm{d}/\mathrm{d}x = \partial_x + p\,\partial_y + (\partial p/\partial x + p\,\partial p/\partial y)\,\partial_{y'}$, so the Euler–Lagrange equation reads

$$f_{xy'} + p\,f_{yy'} + \left(\frac{\partial p}{\partial x} + p\,\frac{\partial p}{\partial y}\right) f_{y'y'} = f_y\,. \tag{16.56}$$

Subtracting the two displays,

$$\frac{\partial \mathcal{P}}{\partial y} - \frac{\partial \mathcal{Q}}{\partial x} = f_y - \left[p\,f_{yy'} + f_{xy'} + f_{y'y'}\left(\frac{\partial p}{\partial x} + p\,\frac{\partial p}{\partial y}\right)\right] = 0$$

by Equation (16.56). Finally, on a member of the field $\mathrm{d}y = p\,\mathrm{d}x$, so the two $f_{y'}$ terms in Equation (16.55) cancel and the integrand reduces to $f(x,y,p)\,\mathrm{d}x = f(x,y,y')\,\mathrm{d}x$. □

Theorem 16.64 (Weierstrass' sufficient condition)**.** *Let the extremal y^* be embedded in a field of extremals on R with slope function p, joining (a,y_a) to (b,y_b), and suppose*

$$E(x,y,p(x,y),q) \geq 0 \qquad \text{for all } (x,y) \in R \text{ and all } q \in \mathbb{R}\,. \tag{16.57}$$

Then $J[Y] \geq J[y^*]$ for every admissible piecewise-C^1 curve Y whose graph lies in R: y^* is a strong minimum relative to R.

Rests on Theorem 16.63, Equation (16.51), and Definition 16.62.

Proof. *Derives Theorem 16.64.*

Let Y be admissible with graph in R. By Theorem 16.63, I takes the same value on the graph of Y as on the graph of y^*, and on the latter it equals $J[y^*]$. Evaluating I along the graph of Y, where $\mathrm{d}y = Y'\,\mathrm{d}x$,

$$J[y^*] = I[Y] = \int_a^b \left[f(x,Y,p) + (Y' - p)\,\frac{\partial f}{\partial y'}(x,Y,p) \right] \mathrm{d}x\,,$$

with $p = p(x,Y(x))$. Subtracting from $J[Y] = \int_a^b f(x,Y,Y')\,\mathrm{d}x$ and comparing with Equation (16.51),

$$J[Y] - J[y^*] = \int_a^b E\left(x, Y(x), p\left(x,Y(x)\right), Y'(x)\right)\mathrm{d}x \geq 0 \tag{16.58}$$

by Equation (16.57). □

Corollary 16.65 (Sufficiency for a weak minimum)**.** *Let y^* be an extremal satisfying the strengthened Legendre condition $P > 0$ on $[a,b]$ and the strengthened Jacobi condition of Remark 16.57. Then y^* is a strict weak local minimum of J.*

Rests on Theorems 16.51 and 16.56.

Proof. *Derives Corollary 16.65.*

Theorem 16.56 gives $\delta^2 J[y^*;\eta] > 0$ for every admissible $\eta \neq 0$, and that by itself is *not* enough: the infimum of $\delta^2 J[y^*;\cdot]$ over the sphere $\|\eta\|_1 = 1$ is zero. A smoothed tent of width δ and unit maximum slope near an interior point has $\delta^2 J = O(\delta)$ while its C^1 norm tends to 1, so no positive lower bound survives the passage to the limit and the positivity must be upgraded to coercivity first.

Step 1: a coercive lower bound. Let w be the zero-free Jacobi solution supplied by the strengthened Jacobi condition, and let $W = -P\,w'/w$ and $\mu(x) = \exp\int_a^x (W/P)\,\mathrm{d}s$, so that $\mu > 0$ is C^1 on $[a,b]$. The completion of the square in the proof of Theorem 16.56 is the exact identity

$$\delta^2 J[y^*;\eta] = \int_a^b P\,v^2\,\mathrm{d}x\,, \qquad v = \eta' + \frac{W}{P}\,\eta = \frac{(\mu\eta)'}{\mu}\,,$$

valid for every $\eta \in C_0^1[a,b]$. Since $\eta(a) = 0$ we have $\mu(x)\eta(x) = \int_a^x \mu\, v\,\mathrm{d}s$, so the Cauchy–Schwarz inequality bounds $\max|\eta|$ by a constant depending only on μ and $b-a$ times $\left(\int_a^b v^2\right)^{1/2}$; hence $\int \eta^2 \le \kappa_2 \int v^2$, and $\eta' = v - W\eta/P$ then gives $\int \eta'^2 \le \kappa_3 \int v^2$ with κ_3 likewise independent of η. With $P \ge P_{\min} > 0$ this is the coercivity estimate

$$\delta^2 J[y^*;\eta] \ge c \int_a^b \eta'^2\,\mathrm{d}x\,, \qquad c = \frac{P_{\min}}{\kappa_3} > 0\,. \tag{16.59}$$

Step 2: the remainder. For $\eta \in C_0^1[a,b]$, Taylor's theorem (Theorem 7.38) applied to f in its last two arguments, the vanishing of the first variation, and the integration by parts of Proposition 16.50 give

$$J[y^*+\eta] - J[y^*] = \tfrac{1}{2}\,\delta^2 J[y^*;\eta] + R[\eta]\,, \qquad |R[\eta]| \le \omega\left(\|\eta\|_1\right) \int_a^b \left(\eta^2 + \eta'^2\right)\mathrm{d}x\,,$$

where $\omega(t) \to 0$ as $t \to 0$: the second derivatives of f are uniformly continuous on a compact neighbourhood of the graph of y^* because f is C^3, and $2\,|\eta\eta'| \le \eta^2 + \eta'^2$. This is the step the norm on the sphere could not supply — the remainder is now measured against $\int(\eta^2+\eta'^2)$, the same quantity Equation (16.59) controls from below.

Step 3. Because $\eta(a) = 0$, Cauchy–Schwarz also gives $\int \eta^2 \le (b-a)^2 \int \eta'^2$. Writing $\kappa = 1 + (b-a)^2$ and combining the two steps,

$$J[y^*+\eta] - J[y^*] \ge \left[\frac{c}{2} - \kappa\,\omega\left(\|\eta\|_1\right)\right] \int_a^b \eta'^2\,\mathrm{d}x\,.$$

Choose $\varepsilon > 0$ with $\kappa\,\omega(\varepsilon) < c/2$. For every $\eta \neq 0$ with $\|\eta\|_1 < \varepsilon$ the bracket is positive and $\int \eta'^2 > 0$, since an $\eta \in C_0^1[a,b]$ with $\eta' \equiv 0$ vanishes identically. So y^* is a strict weak local minimum. □

Remark 16.66 (Where this construction turns into physics). The slope function of a field is a gradient: on the region R the invariant integral Equation (16.55) defines a function $S(x,y)$, unique up to a constant, with $\partial S/\partial y = \partial f/\partial y'\,(x,y,p)$ and $\partial S/\partial x = f - p\,\partial f/\partial y'$. Those two statements together are the Hamilton–Jacobi equation, and S is Hamilton's characteristic function (Chapter 23). The Weierstrass sufficiency theory and Hamilton–Jacobi theory are therefore the same construction read in two directions: the physicist solves a first-order partial differential equation to generate the trajectories, the analyst builds the family of trajectories to certify a minimum. Hilbert announced the invariant integral in the lecture that also posed his twenty-third problem, a call for exactly this kind of systematic development of the calculus of variations [291].

16.5 Direct methods and existence

Everything so far has assumed that a minimiser exists and asked what equations it must satisfy. The *direct* methods reverse the order: they establish that a minimiser exists before writing any differential equation, and then read the Euler–Lagrange equation off it. The nineteenth century learned the hard way that the first question cannot be skipped.

16.5.1 The Dirichlet principle and its failure

Definition 16.67 (The Dirichlet principle)**.** Let $\Omega \subset \mathbb{R}^3$ be a bounded domain and h a continuous function on $\partial\Omega$. The *Dirichlet principle* is the assertion that the *Dirichlet integral*

$$D[u] = \int_\Omega |\nabla u|^2 \, \mathrm{d}^3x \tag{16.60}$$

attains its infimum over $\left\{ u \in C^1(\overline{\Omega}) \mid u|_{\partial\Omega} = h \right\}$, and that the minimiser is the harmonic function with boundary values h.

Rests on Equations (16.32) *and* (16.34)*.*

The second half of the assertion is a theorem: by Example 16.37 the Euler–Lagrange equation of Equation (16.60) is Laplace's equation, so a minimiser, if there is one, is harmonic. Riemann used the principle in this form as the existence engine of his function theory — it is how he produced the conformal maps and the functions on Riemann surfaces that his geometry required — and named it after Dirichlet, from whose lectures he had it. The first half of the assertion is the problem: an infimum need not be attained.

Proposition 16.68 (Weierstrass' counterexample)**.** *Let*

$$\mathcal{C} = \left\{ y \in C^1[-1,1] \mid y(-1) = -1, \; y(1) = 1 \right\},$$

and

$$J[y] = \int_{-1}^{1} x^2 \, y'(x)^2 \, \mathrm{d}x \,. \tag{16.61}$$

Then $\inf_{\mathcal{C}} J = 0$*, and no* $y \in \mathcal{C}$ *attains it.*

Rests on Equation (16.61) *and Definition 16.11.*

Proof. *Derives Proposition 16.68.*

The integrand is nonnegative, so $J \geq 0$. For $\varepsilon > 0$ put

$$y_\varepsilon(x) = \frac{\arctan\left(x/\varepsilon\right)}{\arctan\left(1/\varepsilon\right)},$$

which lies in $\mathcal{C}$, being smooth and odd with $y_\varepsilon(\pm 1) = \pm 1$. Its derivative is $y_\varepsilon' = \varepsilon[\arctan(1/\varepsilon)]^{-1} \left(\varepsilon^2 + x^2\right)^{-1}$, so, using $x^2 \leq \varepsilon^2 + x^2$,

$$J\left[y_\varepsilon\right] = \frac{\varepsilon^2}{\arctan^2(1/\varepsilon)} \int_{-1}^{1} \frac{x^2 \, \mathrm{d}x}{\left(\varepsilon^2 + x^2\right)^2} \leq \frac{\varepsilon^2}{\arctan^2(1/\varepsilon)} \int_{-1}^{1} \frac{\mathrm{d}x}{\varepsilon^2 + x^2} = \frac{2\varepsilon}{\arctan\left(1/\varepsilon\right)},$$

which tends to 0 as $\varepsilon \to 0^+$ because $\arctan(1/\varepsilon) \to \pi/2$. Hence the infimum is 0.

Suppose now $J[y] = 0$ for some $y \in \mathcal{C}$. The integrand $x^2 y'^2$ is continuous and nonnegative with vanishing integral, so it vanishes identically; hence $y'(x) = 0$ for every $x \neq 0$, and y is constant on $[-1, 0)$ and on $(0, 1]$. Continuity at 0 forces the two constants to agree, so y is constant on $[-1, 1]$, contradicting $y(-1) = -1 \neq 1 = y(1)$. □

Remark 16.69 (What the example destroyed, and what replaced it). Weierstrass presented this argument to the Berlin Academy in 1870 [270], and its effect was immediate: every existence proof resting on "the infimum is attained" was suspect, Riemann's function theory included. The gap is real and not an artefact of the example: the infimum of a functional bounded below is always approached by a minimising sequence, but nothing yet said that the sequence converges, nor that the functional is continuous along it.

Hilbert restored the Dirichlet principle thirty years later [314], not by patching Riemann's argument but by supplying the two missing ingredients under explicit hypotheses on the domain and the boundary data: a minimising sequence with enough compactness to extract a convergent subsequence, and enough semicontinuity of D to conclude that the limit is a minimiser. This is the direct method, and its abstract form is Theorem 16.70. Hilbert's twentieth and twenty-third problems both grew out of it [291], and the modern treatment is Courant–Hilbert [1222]. The stake for physics is not decorative: the existence of solutions to the boundary-value problems of Chapter 10 and Chapter 58 is exactly the statement Riemann assumed and Weierstrass questioned.

16.5.2 Tonelli's existence theory

The direct method has three ingredients, and each answers one of the two objections above.

Theorem 16.70 (The direct method)**.** *Let X be a reflexive Banach space and $J : X \longrightarrow \mathbb{R} \cup \{+\infty\}$ a functional that is not identically $+\infty$ and satisfies*

1. coercivity*: $J[u] \longrightarrow +\infty$ whenever $\|u\| \longrightarrow \infty$;*
2. sequential weak lower semicontinuity*: whenever $u_n \rightharpoonup u$ weakly in X, $J[u] \le \liminf_n J[u_n]$.*

Then J attains its infimum on X.
Rests on Definitions 6.9 and 12.2.

Proof. *Derives Theorem 16.70.*
Let $m = \inf_X J < +\infty$ and pick a minimising sequence (u_n), so $J[u_n] \longrightarrow m$. The sequence $(J[u_n])$ is bounded above, so by coercivity $(\|u_n\|)$ is bounded: otherwise a subsequence would have $\|u_{n_k}\| \to \infty$ and hence $J[u_{n_k}] \to +\infty$. In a reflexive Banach space a bounded sequence has a weakly convergent subsequence — this is the compactness input, the Eberlein–Smulian theorem, whose Hilbert-space case is the one used in this book (Chapter 12) — so $u_{n_k} \rightharpoonup u$ for some $u \in X$. Weak lower semicontinuity then gives

$$J[u] \le \liminf_k J\,[u_{n_k}] = m\,,$$

and $J[u] \ge m$ by the definition of the infimum, so $J[u] = m > -\infty$. □

Remark 16.71 (The three ingredients pull against each other). Coercivity and semicontinuity are demands on the same topology in opposite directions. Making the topology coarser makes compactness easier and semicontinuity harder; making it finer does the reverse. The weak topology of a reflexive space is the compromise that works, and it is why Sobolev spaces — not spaces of continuously differentiable functions — are the right home for the direct method: $C^1[a,b]$ with the norm Equation (16.13) is not reflexive and its bounded sets are not weakly compact. That is the technical form of the objection Weierstrass raised.

The remaining question is which integrands make Equation (16.11) weakly lower semicontinuous. Tonelli identified the answer: convexity in the slope [432].

Lemma 16.72 (Convexity implies weak lower semicontinuity)**.** *Let $1 < r < \infty$, let $f(x,q)$ be continuous, bounded below, of class C^1 in q and convex in q for each x, and suppose $|\partial f/\partial q\,(x,q)| \le C\left(1+|q|^{r-1}\right)$. If $u_n' \rightharpoonup u'$ weakly in $L^r(a,b)$, then*

$$\int_a^b f\,(x,u')\,\mathrm{d}x \le \liminf_n \int_a^b f\,(x,u_n')\,\mathrm{d}x\,.$$

Rests on Theorem 16.70 and Equation (16.11).

Proof. *Derives Lemma 16.72.*

Convexity of a C^1 function means its graph lies above every tangent:

$$f\,(x,q_2) \ge f\,(x,q_1) + \frac{\partial f}{\partial q}\,(x,q_1)\,(q_2-q_1)\ . \tag{16.62}$$

Apply this pointwise with $q_1 = u'(x)$ and $q_2 = u_n'(x)$ and integrate:

$$\int_a^b f\,(x,u_n')\,\mathrm{d}x \ge \int_a^b f\,(x,u')\,\mathrm{d}x + \int_a^b \frac{\partial f}{\partial q}\,(x,u')\,(u_n'-u')\,\mathrm{d}x\,.$$

The growth hypothesis puts $\partial f/\partial q\,(\cdot,u')$ in $L^{r'}(a,b)$ with $r' = r/(r-1)$, which is the dual of L^r, so the last integral tends to 0 by the definition of weak convergence. Taking $\liminf$ of both sides gives the claim. □

Theorem 16.73 (Tonelli)**.** *Let $1 < r < \infty$ and let $f\,(x,y,q)$ be continuous, of class C^1 in q, convex in q for each (x,y), and coercive in the sense $f\,(x,y,q) \ge \alpha\,|q|^r - \beta$ with $\alpha > 0$; assume further the growth bound $|\partial f/\partial q\,(x,y,q)| \le C_R\left(1+|q|^{r-1}\right)$ for $|y| \le R$, which is the hypothesis of Lemma 16.72 made locally uniform in y. Then the functional Equation (16.11) attains its minimum over the class of functions in the Sobolev space $W^{1,r}(a,b)$ with the prescribed endpoint values.*

Rests on Theorem 16.70 and Lemma 16.72.

The derivation is carried out in Appendix A.41. The coercivity estimate and the abstract argument are those of the direct-method theorem and the convexity lemma proved above; the passage from an integrand $f(x,q)$ to one that also depends on y rests on the compact embedding of $W^{1,r}(a,b)$ into the continuous functions, which the appendix proves from the fundamental theorem of calculus, Hölder's inequality and the Arzelà–Ascoli theorem. The growth bound is what lets that embedding replace the Scorza-Dragoni argument of the classical treatments; the appendix states precisely what dropping it would cost, and Tonelli's own hypotheses [432] are the ones without it.

Full derivation: Appendix A.41 (p. 2994).

Derives Theorem 16.73.

Remark 16.74 (What the physical Lagrangians do and do not satisfy). For a mechanical system with kinetic energy $T = \tfrac12 m_{ij}(q)\dot q^i\dot q^j$ the Lagrangian $\mathcal{L} = T - V$ is quadratic in the velocities with a positive definite coefficient matrix, hence convex in them, which is half of what Theorem 16.73 asks. The other half is coercivity, and it is a condition on the potential in the direction opposite to the one a physicist expects: $\mathcal{L} \ge \alpha\,|\dot q|^2 - \beta$ uniformly in q demands that V be bounded *above*, not below. For a confining potential the action is in general not bounded below at all. The harmonic oscillator, $m,k>0$ and $q(0)=q(T)=0$, is the smallest example: on $q(t) = A\sin(\pi t/T)$,

$$S = \int_0^T \left(\tfrac12 m\dot q^2 - \tfrac12 k q^2\right)\mathrm{d}t = \frac{A^2}{4}\left(\frac{m\pi^2}{T} - kT\right), \tag{16.63}$$

which for $T > \pi\sqrt{m/k} = \pi/\omega$, with $\omega = \sqrt{k/m}$, is negative and tends to $-\infty$ as $A \to \infty$: the infimum is $-\infty$ and no minimiser exists in any class. That threshold is exactly the

kinetic focus of Remark 16.98, and the same phenomenon as in the model functional of Remark 16.25. So Theorem 16.73 certifies existence for a mechanical Lagrangian whose potential is bounded above — a free or a repelled particle — and not for a confining one; past the first conjugate point the action of Section 16.7.1 is genuinely unbounded below, which is why that section states Hamilton's principle as one of stationary and not of least action. Convexity is not a technicality that can be dropped either. For

$$J[y] = \int_0^1 \left[\left(y'^2 - 1 \right)^2 + y^2 \right] \mathrm{d}x \,, \qquad y(0) = y(1) = 0 \,, \tag{16.64}$$

the integrand is not convex in y', and $\inf J = 0$: a sawtooth of slope ± 1 and amplitude $1/2n$ makes both terms as small as one likes. No function attains 0, since that would need $y \equiv 0$ and $|y'| \equiv 1$ at once. Minimising sequences oscillate faster and faster — a fine structure with a physical counterpart in the twinned microstructure of martensitic phase transitions.

16.5.3 The Rayleigh–Ritz method

The direct method has a computational face. Instead of minimising over the whole admissible class, minimise over a finite-dimensional family of trial functions: the result is an upper bound on the true minimum, and a linear algebra problem in place of a differential equation.

Definition 16.75 (Rayleigh quotient)**.** For the Sturm–Liouville data $p > 0$, q and $r > 0$ continuous on $[a, b]$, the *Rayleigh quotient* of a nonzero $y \in C_0^1[a, b]$ is

$$\mathcal{R}[y] = \frac{\displaystyle\int_a^b \left(p\, y'^2 + q\, y^2 \right) \mathrm{d}x}{\displaystyle\int_a^b r\, y^2 \, \mathrm{d}x} \,. \tag{16.65}$$

Rests on Equation (16.42) and Definition 9.54.

Theorem 16.76 (Variational characterisation of the lowest eigenvalue)**.** *Let $\lambda_1 \le \lambda_2 \le \cdots$ be the eigenvalues of the Sturm–Liouville problem*

$$-\frac{\mathrm{d}}{\mathrm{d}x}\left(p \frac{\mathrm{d}y}{\mathrm{d}x} \right) + q\, y = \lambda\, r\, y \,, \qquad y(a) = y(b) = 0 \,, \tag{16.66}$$

with eigenfunctions y_n orthonormal in the weighted inner product $\langle u, v \rangle_r = \int_a^b r\, u\, v \, \mathrm{d}x$ and complete in the corresponding Hilbert space (Chapter 9, Chapter 12). Then

$$\lambda_1 = \min \left\{ \mathcal{R}[y] \mid y \in C_0^1[a, b],\ y \neq 0 \right\} \,, \tag{16.67}$$

the minimum being attained exactly at the multiples of y_1.

Rests on Equations (16.65) and (16.66).

Proof. *Derives Theorem 16.76.*

Write $B[u, v] = \int_a^b (p\, u'v' + q\, uv) \, \mathrm{d}x$ for the energy form, so that $\mathcal{R}[y] = B[y, y] / \langle y, y \rangle_r$, and fix $K > 0$ with $q + Kr \ge 0$ on $[a, b]$, which is possible because q is continuous and $r > 0$ on a compact interval. Put $B_K[u, v] = B[u, v] + K \langle u, v \rangle_r$. Since $p > 0$ and $q + Kr \ge 0$,

$$B_K[u, u] = \int_a^b \left[p\, u'^2 + (q + Kr)\, u^2 \right] \mathrm{d}x \ge 0 \qquad \text{for every } u \in C^1[a, b] \,. \tag{16.68}$$

Expand $y = \sum_{n \ge 1} c_n y_n$ with $c_n = \langle y, y_n \rangle_r$; by completeness the denominator of Equation (16.65) is $\sum_n c_n^2$.

The one integration by parts needed is against the eigenfunctions, not against y: for $y \in C^1_0[a,b]$ and $y_n \in C^2[a,b]$, Equation (7.28) with $y(a) = y(b) = 0$ moves the derivative onto y_n,

$$B[y, y_n] = \int_a^b y \left[-\frac{\mathrm{d}}{\mathrm{d}x}\left(p\,\frac{\mathrm{d}y_n}{\mathrm{d}x} \right) + q\,y_n \right] \mathrm{d}x = \lambda_n \langle y, y_n \rangle_r = \lambda_n c_n \,, \tag{16.69}$$

by Equation (16.66). Only y_n is differentiated twice, so nothing beyond $y \in C^1_0[a,b]$ is used — which matters, because the trial functions of Proposition 16.79 are only C^1. Hence $B_K[y, y_n] = (\lambda_n + K)\, c_n$, and for the partial sums $S_N = \sum_{n \le N} c_n y_n$ bilinearity and orthonormality give $B_K[y, S_N] = B_K[S_N, S_N] = \sum_{n \le N} (\lambda_n + K)\, c_n^2$. Therefore

$$0 \le B_K[y - S_N, y - S_N] = B_K[y, y] - \sum_{n \le N} (\lambda_n + K)\, c_n^2$$

by Equation (16.68). Taking $u = y_1$ there, together with Equation (16.69) for $y = y_1$, shows $B_K[y_1, y_1] = \lambda_1 + K \ge 0$, so every term of the sum is nonnegative and $N \to \infty$ is legitimate: $B_K[y, y] \ge \sum_n (\lambda_n + K)\, c_n^2 \ge (\lambda_1 + K) \sum_n c_n^2$. Subtracting $K \langle y, y \rangle_r = K \sum_n c_n^2$ from both sides leaves $B[y, y] \ge \lambda_1 \langle y, y \rangle_r$, that is

$$\mathcal{R}[y] \ge \frac{\sum_n \lambda_n c_n^2}{\sum_n c_n^2} \ge \lambda_1 \,. \tag{16.70}$$

If $\mathcal{R}[y] = \lambda_1$ then both inequalities in Equation (16.70) are equalities, and the second forces $c_n = 0$ whenever $\lambda_n > \lambda_1$; the lowest eigenvalue of a regular Sturm–Liouville problem is simple, so y agrees with a multiple of y_1 in the weighted inner product and, both being continuous, pointwise. Taking $y = y_1$ in Equation (16.69) gives $\mathcal{R}[y_1] = \lambda_1$, so the value is attained. □

Remark 16.77 (The inequality is elementary, the identity is not). Only the *inequality* Equation (16.70) was proved, and deliberately so: it is all the variational characterisation needs, and it costs nothing beyond $y \in C^1_0[a,b]$. The sharper statement

$$\int_a^b \left(p\,y'^2 + q\,y^2 \right) \mathrm{d}x = \sum_{n \ge 1} \lambda_n c_n^2 \tag{16.71}$$

is equivalent to $B_K[y - S_N, y - S_N] \to 0$, that is to completeness of the eigenfunctions in the *energy* norm $\|u\|_E = B_K[u,u]^{1/2}$ — a strictly stronger fact than the completeness in the weighted L^2 space assumed in Theorem 16.76, and one proved in Appendix A.42 by realising the inverse of the Sturm–Liouville operator as a compact integral operator with the Green function as its kernel and applying the Hilbert–Schmidt theorem Theorem 12.44 to it. That appendix also proves the weighted L^2 completeness *assumed* here, so the hypothesis of Theorem 16.76 is discharged as well; the inequality Equation (16.70) proved above, which is what the variational characterisation uses, rests on Bessel's inequality alone and is independent of both, so there is no circle.

Full derivation: Appendix A.42 (p. 3001).

Derives Equation (16.71).

The distinction is not pedantry: it is exactly the identity that the error estimate in Corollary 16.78 needs, and the inequality alone bounds that error in the wrong direction.

Corollary 16.78 (The variational bound)**.** *For every admissible trial function $\chi \neq 0$, $\lambda_1 \le \mathcal{R}[\chi]$. A trial function accurate to first order in the deviation from y_1 gives an eigenvalue accurate to second order.*

Rests on Equations (16.67) and (16.71).

Proof. *Derives Corollary 16.78.*

The inequality is Equation (16.67). For the error statement, write $\chi = y_1 + \epsilon$ with $\langle \epsilon, y_1 \rangle_r = 0$; then $c_1 = 1$ and $\sum_{n \geq 2} c_n^2 = \|\epsilon\|_r^2$, so Equation (16.71) gives

$$\mathcal{R}[\chi] - \lambda_1 = \frac{\sum_{n \geq 2} (\lambda_n - \lambda_1)\, c_n^2}{1 + \|\epsilon\|_r^2} = \frac{B[\epsilon, \epsilon] - \lambda_1 \, \|\epsilon\|_r^2}{1 + \|\epsilon\|_r^2} \,,$$

whose numerator is a quadratic form in ϵ: the error is second order in the deviation. It must be measured in the energy norm of Remark 16.77 and not in $\|\cdot\|_r$, since $\lambda_n - \lambda_1$ is unbounded and a deviation small in the weighted L^2 norm may have a large derivative. □

Proposition 16.79 (The Ritz linear system)**.** *Let $\chi_1, \dots, \chi_N$ be linearly independent admissible trial functions and minimise $\mathcal{R}$ over $y = \sum_{k=1}^{N} c_k \chi_k$. Then the stationary values of $\mathcal{R}$ are the roots λ of the generalized eigenvalue problem*

$$\sum_{k=1}^{N} \left(K_{jk} - \lambda \, M_{jk} \right) c_k = 0 \,, \qquad j = 1, \dots, N \,, \tag{16.72}$$

with the symmetric matrices

$$K_{jk} = \int_a^b \left(p \, \chi_j' \chi_k' + q \, \chi_j \chi_k \right) \mathrm{d}x \,, \qquad M_{jk} = \int_a^b r \, \chi_j \chi_k \, \mathrm{d}x \,, \tag{16.73}$$

and the lowest root satisfies $\lambda_1 \leq \lambda^{(N)}$, decreasing as the trial family is enlarged.
Rests on Equation (16.65) and Corollary 16.78.

Proof. *Derives Proposition 16.79.*

Substituting the expansion into Equation (16.65) gives $\mathcal{R} = (c_j K_{jk} c_k) \,/\, (c_j M_{jk} c_k)$, a ratio of quadratic forms in the N numbers c_k. Stationarity with respect to c_j requires

$$\frac{2 \sum_k K_{jk} c_k}{c_l M_{lm} c_m} - \frac{(c_l K_{lm} c_m)\, 2 \sum_k M_{jk} c_k}{(c_l M_{lm} c_m)^2} = 0 \,,$$

which, after multiplying by $\tfrac{1}{2} c_l M_{lm} c_m$ and recognising $\mathcal{R} = \lambda$, is Equation (16.72). The bound $\lambda_1 \leq \lambda^{(N)}$ is Corollary 16.78 applied to the minimising member of the trial family, and enlarging the family can only lower the minimum because the smaller family is a subset of the larger. □

Remark 16.80 (The method, its origins and its descendants). Rayleigh introduced the quotient to estimate the frequencies of vibrating systems [197]: for a string of length L under tension F (in newtons) and of linear density ρ_ℓ (in kg/m) the data are $p = F$, $q = 0$, $r = \rho_\ell$, and $\mathcal{R}$ has the SI dimension $1/\mathrm{s}^2$, so $\lambda_1 = \omega_1^2$ is the square of the fundamental angular frequency. Ritz turned the estimate into a systematic and convergent scheme by enlarging the trial family [359]; his 1908 spectroscopic paper [348] is a different work and should not be cited for this method. Equation (16.72) is the ancestor of the finite element method, of the linear variational method for molecular orbitals, and of the variational principle of quantum mechanics: replacing $\mathcal{R}$ by $\langle \psi | \mathcal{H} | \psi \rangle \,/\, \langle \psi | \psi \rangle$ gives an upper bound on the ground-state energy, which is the content of Chapter 82. The normal-mode analyses of Chapter 28 are the same computation with K the stiffness matrix and M the mass matrix. The minimax characterisation of the higher eigenvalues, which extends Equation (16.67) to λ_n, belongs with the spectral theory of Chapter 12.

16.5.4 The Plateau problem

The classical existence question of the subject is the one the soap films of Section 16.1.3 pose.

Theorem 16.81 (Douglas; Radó)**.** *Let $\Gamma \subset \mathbb{R}^3$ be a rectifiable Jordan curve. Then there exists a continuous map X from the closed unit disc $\overline{B}$ into $\mathbb{R}^3$, harmonic and conformal on the open disc, restricting to a monotone parametrisation of Γ on the boundary circle, and minimising the area among all such disc-type maps. Its image is a minimal surface spanning Γ.*

Rests on Equation (16.7) *and Theorem 16.70.*

Douglas minimises a boundary-value functional over monotone boundary parametrisations, defeating the non-compactness of the conformal group of the disc by a three-point normalisation, and Radó argues instead through polygonal approximation and the Dirichlet integral. Either proof is monograph length and neither is reproduced here. Appendix A.43 gives the architecture of Douglas' argument with every step this treatise can carry out carried out — the domination of the area by the Dirichlet integral with its equality case, the conformal invariance of that integral, the identity between Douglas' boundary functional and the Dirichlet integral of the harmonic extension, the lower semicontinuity, the three-point normalisation, the Courant–Lebesgue estimate and the compactness it buys, and the computation showing that a harmonic conformal map has vanishing mean curvature — and states as displayed theorems the results it does not prove. *The theorem itself therefore remains quoted*: the appendix reduces it to two named imports, the solvability of the Dirichlet problem for the disc and Douglas' inner-variation proof of conformality, and says so explicitly.

Full derivation: Appendix A.43 (p. 3009).

Derives Theorem 16.81.

Remark 16.82 (What is proved and what is not)*.* Theorem 16.81 was proved independently by Douglas [678] and Radó [667], and Douglas' work was recognised with one of the first two Fields Medals. It is worth being exact about the claim, because the statement is often quoted more strongly than it was proved.

1. The surface produced is of *disc type*. A contour may bound minimal surfaces of higher genus or with several boundary components, and those require separate arguments.

2. The map is a minimiser of area *among disc-type maps*. It need not be an embedding: the image may have self-intersections, and it may carry isolated branch points where the differential drops rank, although interior branch points were later excluded for area-minimising discs.

3. Conformality is not an extra hypothesis but part of the conclusion, and it is what converts the geometric area functional into the Dirichlet integral to which the direct method applies. This is the technical heart of both proofs.

The result is the landmark application of the direct method in a genuinely two-dimensional problem, and the differential-geometric apparatus it needs — first and second fundamental forms, mean curvature — is that of Chapter 13.

16.6 Symmetry and conservation: Noether's theorems

Emmy Noether's 1918 paper [456] contains two theorems, and they answer opposite questions. The first says that a symmetry group of finitely many parameters produces one conserved quantity per parameter. The second says that a symmetry group depending on arbitrary

functions produces no new conserved quantity at all, but instead identities among the field equations themselves. Both are consequences of the first variation, and both are proved here.

16.6.1 Noether's first theorem

Definition 16.83 (One-parameter transformation group; variational symmetry)**.** A one-parameter family of transformations of the variables of Equation (16.11),

$$\bar{x} = x + \varepsilon\,\xi\,(x,y) + O(\varepsilon^2)\,, \qquad \bar{y}^{\,i} = y^i + \varepsilon\,\phi^i\,(x,y) + O(\varepsilon^2)\,, \tag{16.74}$$

with ξ, ϕ^i of class C^1, is a *variational symmetry* of J if for every curve and every subinterval

$$\int_{\bar{x}_1}^{\bar{x}_2} f\left(\bar{x}, \bar{y}, \frac{\mathrm{d}\bar{y}}{\mathrm{d}\bar{x}}\right) \mathrm{d}\bar{x} = \int_{x_1}^{x_2} \left[f\,(x, y, y') + \varepsilon\,\frac{\mathrm{d}\Lambda}{\mathrm{d}x} \right] \mathrm{d}x + O(\varepsilon^2) \tag{16.75}$$

for some function $\Lambda\,(x,y)$. When Λ may be taken to vanish the symmetry is *strict*; the general case is the *divergence symmetry* of Bessel-Hagen [472], without which the Galilean boost $\boldsymbol{x} \longmapsto \boldsymbol{x} + \boldsymbol{v}t$ escapes the theorem: it changes a free Lagrangian by the total time derivative of $m\left(\boldsymbol{v}\cdot\boldsymbol{x} - \tfrac{1}{2}\,|\boldsymbol{v}|^2\,t\right)$, and the conserved quantity it then yields is the centre-of-mass theorem.

Rests on Equation (16.11) and Definition 16.15.

Theorem 16.84 (Noether's first theorem, one independent variable)**.** *Let Equation (16.74) be a variational symmetry of J with divergence term Λ. Then along every solution of the Euler–Lagrange system Equation (16.30) the quantity*

$$I = \frac{\partial f}{\partial y'^{i}}\left(\phi^i - y'^{i}\,\xi\right) + f\,\xi - \Lambda \tag{16.76}$$

is constant: $\mathrm{d}I/\mathrm{d}x = 0$.

Rests on Equations (16.30) and (16.75) and Proposition 16.17.

Proof. *Derives Theorem 16.84.*

Write $\bar{y}^i(\bar{x})$ for the transformed curve as a function of the transformed independent variable, and compare it with the original curve *at the same value of* x. From Equation (16.74), $\bar{y}^i(\bar{x}) = y^i(x) + \varepsilon\phi^i$ and $\bar{y}^i(x+\varepsilon\xi) = \bar{y}^i(x) + \varepsilon\xi\,y'^i(x) + O(\varepsilon^2)$, so the *vertical* (evolutionary) variation is

$$\bar{y}^i(x) - y^i(x) = \varepsilon\,\bar{\phi}^i\,, \qquad \bar{\phi}^i = \phi^i - \xi\,y'^i\,. \tag{16.77}$$

Renaming the dummy variable $\bar{x}$ back to x, the left-hand side of Equation (16.75) is $\int_{x_1+\varepsilon\xi_1}^{x_2+\varepsilon\xi_2} f\,(x, \bar{y}(x), \bar{y}'(x))\,\mathrm{d}x$, and moving the limits back costs one boundary term to first order:

$$\int_{\bar{x}_1}^{\bar{x}_2} f\left(\bar{x}, \bar{y}, \frac{\mathrm{d}\bar{y}}{\mathrm{d}\bar{x}}\right) \mathrm{d}\bar{x} = \int_{x_1}^{x_2} f\,(x, \bar{y}, \bar{y}')\,\mathrm{d}x + \varepsilon\,[\xi f]_{x_1}^{x_2} + O(\varepsilon^2)\,.$$

By Proposition 16.17 applied to the vertical variation $\bar{\phi}$, and integrating the $\bar{\phi}'$ term by parts,

$$\int_{x_1}^{x_2} f\,(x, \bar{y}, \bar{y}')\,\mathrm{d}x - \int_{x_1}^{x_2} f\,(x, y, y')\,\mathrm{d}x = \varepsilon \int_{x_1}^{x_2} \left[E_i\,\bar{\phi}^i + \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial f}{\partial y'^{i}}\,\bar{\phi}^i\right)\right] \mathrm{d}x + O(\varepsilon^2)\,,$$

with E_i the Euler–Lagrange expression of Equation (16.40). Substituting both displays into Equation (16.75), dividing by ε and letting $\varepsilon \to 0$,

$$\int_{x_1}^{x_2} \left\{ E_i\,\bar{\phi}^i + \frac{\mathrm{d}}{\mathrm{d}x}\left[\frac{\partial f}{\partial y'^{i}}\,\bar{\phi}^i + f\,\xi - \Lambda\right]\right\} \mathrm{d}x = 0\,. \tag{16.78}$$

This holds for every subinterval $[x_1, x_2] \subseteq [a,b]$ and every curve, so the integrand, which is continuous, vanishes identically. On a solution of Equation (16.30) the first term is zero, leaving $\mathrm{d}I/\mathrm{d}x = 0$ with I as in Equation (16.76), since $\bar{\phi}^i = \phi^i - y'^i\xi$. □

Remark 16.85 (The identity is stronger than the theorem). Equation (16.78) holds without any equation of motion: it says that for a variational symmetry the combination $E_i\bar{\phi}^i$ is a total derivative, identically in the curve. That off-shell statement is what Section 16.6.2 exploits, and it is also the honest form of the converse: a conserved quantity of the form Equation (16.76) corresponds to a variational symmetry, but a conservation law of the equations of motion that does not arise from a symmetry of the *action* is not covered — Noether's theorem is a statement about Lagrangians, not about differential equations.

Remark 16.86 (What a point transformation cannot reach). Equation (16.74) moves the point (x, y) only: ξ and ϕ^i are functions of (x, y) and never of y', and no divergence term repairs that. The Laplace–Runge–Lenz vector of the Kepler problem is the standard witness. For $f = |\boldsymbol{p}|^2/2m - V$ with $\boldsymbol{p} = m\dot{\boldsymbol{x}}$, the part of Equation (16.76) that is quadratic in $\boldsymbol{p}$ is $-\xi(t, \boldsymbol{x})\,|\boldsymbol{p}|^2/2m$, which is isotropic in $\boldsymbol{p}$. The corresponding part of $A_j = |\boldsymbol{p}|^2 x_j - (\boldsymbol{x}\cdot\boldsymbol{p})\,p_j - mk\,x_j/|\boldsymbol{x}|$ is not: it vanishes when $\boldsymbol{p}$ is parallel to $\boldsymbol{x}$ and equals $|\boldsymbol{p}|^2 x_j$ when the two are perpendicular. No choice of ξ reproduces an anisotropy, so $\boldsymbol{A}$ is the Noether charge of no transformation of the form Equation (16.74), divergence term or not. The generator that does produce it, $\delta x_i = \varepsilon_j\,(2\dot{x}_i x_j - x_i\dot{x}_j - \delta_{ij}\,\boldsymbol{x}\cdot\dot{\boldsymbol{x}})$, depends on the velocities: it is a *generalized* symmetry, outside the hypotheses proved here and belonging to the later extension of Noether's argument to transformations acting on the derivatives as well. The vector itself, and the hidden SO(4) symmetry it generates, are put to work in Chapter 81.

Corollary 16.87 (Energy from time translation)**.** *If f has no explicit dependence on x, then $\xi = 1$, $\phi^i = 0$, $\Lambda = 0$ is a strict variational symmetry and Equation (16.76) gives the conserved quantity*

$$h = y'^i\,\frac{\partial f}{\partial y'^i} - f = const\,, \tag{16.79}$$

which for one dependent variable is the Beltrami identity Equation (16.25).

Rests on Equations (16.25) and (16.76).

Proof. *Derives Corollary 16.87.*

With $\bar{x} = x + \varepsilon$ and $\bar{y} = y$ the integrand is unchanged and the integration measure is unchanged, so Equation (16.75) holds with $\Lambda = 0$ precisely because f carries no explicit x. Then $I = (\partial f/\partial y'^i)\,(-y'^i) + f = -h$. □

Corollary 16.88 (Momentum and angular momentum)**.** *Let y^1, y^2, y^3 be Cartesian coordinates of a particle in ordinary space and $x = t$ the time.*

1. *If f does not depend on y^k for some fixed k, then $\xi = 0$, $\phi^i = \delta^i_k$ is a strict symmetry and $\partial f/\partial y'^k$ is conserved: the momentum conjugate to a translation.*

2. *If f is invariant under rotations about the unit vector $\boldsymbol{n}$, so that $\phi^i = (\boldsymbol{n}\times\boldsymbol{y})^i$ and $\xi = 0$ define a strict symmetry, then $\boldsymbol{n}\cdot(\boldsymbol{y}\times\boldsymbol{p})$ is conserved, with $p_i = \partial f/\partial y'^i$.*

Rests on Equation (16.76) and Proposition 16.28.

Proof. *Derives Corollary 16.88.*

In both cases $\xi = 0$ and $\Lambda = 0$, so Equation (16.76) reduces to $I = (\partial f/\partial y'^i)\,\phi^i = p_i\phi^i$. Case (1) gives $I = p_k$, which is also Proposition 16.28. Case (2) gives $I = \boldsymbol{p}\cdot(\boldsymbol{n}\times\boldsymbol{y}) = \boldsymbol{n}\cdot(\boldsymbol{y}\times\boldsymbol{p})$ by the cyclic invariance of the scalar triple product. □

Remark 16.89 (SI dimensions of a Noether charge). With $x = t$ in seconds and $f = \mathcal{L}$ in joules, $\partial\mathcal{L}/\partial\dot{y}^i$ is a momentum in kg m/s when y^i is a length, and I in Equation (16.76) carries the dimension of action, J s, divided by whatever dimension the group parameter ε has. For a dimensionless ε — an angle, say — I is an action: angular momentum in J s is the familiar case. For a time translation ε is a time and I is an energy in joules; for a spatial

translation ε is a length and I a momentum. The rule is that the product $I\,\varepsilon$ is always an action, which is the statement that the conserved charge generates the symmetry — the observation that becomes the Poisson-bracket structure of Chapter 22 and the commutator structure of Chapter 5.

Theorem 16.90 (Noether's first theorem, several independent variables)**.** *Let $S[\varphi]$ be the field action Equation (16.31) on $\Omega \subset \mathbb{R}^D$ and let*

$$\bar{x}^\mu = x^\mu + \varepsilon\,\xi^\mu(x,\varphi) + O(\varepsilon^2)\,, \qquad \bar{\varphi}^A = \varphi^A + \varepsilon\,\Phi^A(x,\varphi) + O(\varepsilon^2) \tag{16.80}$$

leave S invariant up to the divergence of a vector $\Lambda^\mu(x,\varphi)$, in the sense that the analogue of Equation (16.75) holds on every subregion. Then on every solution of Equation (16.32) the Noether current

$$j^\mu = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \varphi^A)}\left(\Phi^A - \xi^\nu\,\partial_\nu \varphi^A\right) + \mathcal{L}\,\xi^\mu - \Lambda^\mu \tag{16.81}$$

is conserved, $\partial_\mu j^\mu = 0$.

Rests on Equations (16.32) and (16.33) and Theorem 16.84.

Proof. *Derives Theorem 16.90.*

The argument of Theorem 16.84 carries over word for word with the divergence theorem (Theorem 7.101) in place of the one-dimensional integration by parts. The vertical variation is $\bar{\Phi}^A = \Phi^A - \xi^\nu \partial_\nu \varphi^A$, obtained exactly as Equation (16.77). Moving the domain $\bar{\Omega}$ back to Ω contributes, to first order, the flux of $\mathcal{L}\,\xi^\mu$ through $\partial\Omega$, that is $\varepsilon \int_\Omega \partial_\mu\,(\mathcal{L}\xi^\mu)\,\mathrm{d}^D x$, because the Jacobian of Equation (16.80) is $1 + \varepsilon\,\partial_\mu \xi^\mu + O(\varepsilon^2)$. The vertical part contributes, by Equation (16.33) before the boundary term is discarded,

$$\varepsilon \int_\Omega \left\{ \left[\frac{\partial \mathcal{L}}{\partial \varphi^A} - \partial_\mu \pi^\mu_A \right] \bar{\Phi}^A + \partial_\mu \left(\pi^\mu_A \bar{\Phi}^A \right) \right\} \mathrm{d}^D x\,, \qquad \pi^\mu_A = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \varphi^A)}\,.$$

Invariance up to $\partial_\mu \Lambda^\mu$ therefore gives, for every subregion and hence pointwise,

$$\left[\frac{\partial \mathcal{L}}{\partial \varphi^A} - \partial_\mu \pi^\mu_A \right] \bar{\Phi}^A + \partial_\mu \left[\pi^\mu_A \bar{\Phi}^A + \mathcal{L}\,\xi^\mu - \Lambda^\mu \right] = 0\,. \tag{16.82}$$

On shell the bracket in the first term vanishes by Equation (16.32), leaving $\partial_\mu j^\mu = 0$ with j^μ as in Equation (16.81). □

Corollary 16.91 (The canonical energy–momentum tensor)**.** *Let $D = 4$ with coordinates $x^\mu = (ct, x, y, z)$ on the spacetime of Chapter 39, and let $\mathcal{L}$ carry no explicit dependence on x^μ. Then $\xi^\mu = a^\mu$ constant, $\Phi^A = 0$, $\Lambda^\mu = 0$ is a strict symmetry, and the four conserved currents assemble into the* canonical energy–momentum tensor

$$T^\mu{}_\nu = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \varphi^A)}\,\partial_\nu \varphi^A - \delta^\mu_\nu\,\mathcal{L}\,, \qquad \partial_\mu T^\mu{}_\nu = 0\,. \tag{16.83}$$

Rests on Equations (16.32) and (16.81).

Proof. *Derives Corollary 16.91.*

Substituting $\xi^\mu = a^\mu$ and $\Phi^A = 0$ into Equation (16.81) gives $j^\mu = -a^\nu \left[\pi^\mu_A\,\partial_\nu \varphi^A - \delta^\mu_\nu \mathcal{L} \right] = -a^\nu T^\mu{}_\nu$, and $\partial_\mu j^\mu = 0$ for every constant a^ν forces $\partial_\mu T^\mu{}_\nu = 0$ componentwise. □

Remark 16.92 (Where the currents become physics). $T^0{}_0$ is the energy density in $\mathrm{J/m^3}$ and $T^0{}_k$ the momentum density; the conservation law Equation (16.83) integrates over a spatial region to the statement that energy and momentum leave it only through its boundary. The

canonical tensor is not in general symmetric, and symmetrising it — adding an identically conserved improvement term — is what produces the tensor that couples to gravity in Chapter 44. An *internal* symmetry, $\xi^\mu = 0$ with Φ^A a linear transformation of the fields, gives instead a current whose conserved charge is electric charge, or baryon number, or any other quantum number of that kind; the electric case is worked in Chapter 64, and the conservation laws of the mechanics chapters (Chapter 21) are the one-dimensional specialisation Corollaries 16.87 and 16.88.

16.6.2 Noether's second theorem

Theorem 16.93 (Noether's second theorem)**.** *Suppose the action Equation (16.31) is invariant under a group of transformations depending on m arbitrary functions $\epsilon^r(x)$ of compact support in Ω, acting on the fields as*

$$\delta\varphi^A = R^A{}_r\,(x,\varphi)\,\epsilon^r + R^{A\mu}{}_r\,(x,\varphi)\,\partial_\mu\epsilon^r\,, \tag{16.84}$$

with $R^A{}_r$ and $R^{A\mu}{}_r$ of class C^1. Then the Euler–Lagrange expressions $E_A = \partial\mathcal{L}/\partial\varphi^A - \partial_\mu\pi^\mu_A$ obey the m identities

$$R^A{}_r\,E_A - \partial_\mu\left(R^{A\mu}{}_r\,E_A\right) = 0\,, \qquad r = 1,\dots,m\,, \tag{16.85}$$

identically in the fields — not merely on solutions.

Rests on Equations (16.32) and (16.33) and Theorem 16.90.

Proof. *Derives Theorem 16.93.*

Because the ϵ^r have compact support, all boundary terms in Equation (16.33) vanish and invariance of the action reads

$$0 = \delta S = \int_\Omega E_A\,\delta\varphi^A\,\mathrm{d}^D x = \int_\Omega \left[E_A R^A{}_r\,\epsilon^r + E_A R^{A\mu}{}_r\,\partial_\mu\epsilon^r\right]\mathrm{d}^D x$$

for every choice of the ϵ^r, and for arbitrary field configurations, since the invariance is a property of the action and not of its extremals. Integrating the second term by parts, again with no boundary contribution,

$$0 = \int_\Omega \left[R^A{}_r E_A - \partial_\mu\left(R^{A\mu}{}_r E_A\right)\right]\epsilon^r\,\mathrm{d}^D x\,.$$

The bracket is continuous and the ϵ^r are arbitrary, so Lemma 16.18, in its D-dimensional form used in Theorem 16.36, gives Equation (16.85), one identity for each r. □

Corollary 16.94 (The field equations are not independent)**.** *Under the hypotheses of Theorem 16.93 the n Euler–Lagrange equations $E_A = 0$ satisfy m differential identities, so at most $n-m$ of them are independent. The Cauchy problem is correspondingly underdetermined: a solution stays a solution after any gauge transformation Equation (16.84) with ϵ^r vanishing in the past.*

Rests on Equation (16.85).

Proof. *Derives Corollary 16.94.*

Equation (16.85) is a linear relation among the E_A and their first derivatives holding identically, so the map $\varphi \longmapsto (E_1,\dots,E_n)$ has image in a set of codimension at least m; equivalently, once $n-m$ of the equations and suitable initial data are imposed, the remaining m follow by integration. That a gauge transform of a solution is a solution is immediate from invariance of the action. □

Remark 16.95 (The two worked instances). *Electrodynamics.* The action of the electromagnetic potential is invariant under $\delta A_\mu = \partial_\mu \epsilon$, one arbitrary function, so in Equation (16.84) $R = 0$ and $R^\nu{}_\mu = \delta^\nu_\mu$. Equation (16.85) becomes $\partial_\mu E^\mu = 0$ identically, where E^μ is the Euler–Lagrange expression of A_μ. Since E^μ contains the source term, the field equations are consistent only if the source is itself conserved: charge conservation is not an extra postulate but the integrability condition of the Maxwell equations, which is the reading developed in Chapter 64 [472].

General relativity. The Einstein–Hilbert action is invariant under diffeomorphisms, which in infinitesimal form are $\delta g_{\mu\nu} = \nabla_\mu \epsilon_\nu + \nabla_\nu \epsilon_\mu$: four arbitrary functions, with $R^A{}_r$ built from the connection and $R^{A\mu}{}_r$ from the metric. The Euler–Lagrange expression is proportional to the Einstein tensor, and Equation (16.85) is the contracted Bianchi identity $\nabla_\mu G^{\mu\nu} = 0$, which follows from the second Bianchi identity Equation (13.314) of Proposition 13.157 by two contractions; that proposition states the uncontracted identities and does not perform the contraction. So the identity that makes the Einstein equations consistent with local energy–momentum conservation is not a happy accident of Riemannian geometry but a consequence of general covariance, exactly as Chapter 44 presents it.

In both cases the degeneracy of the Lagrangian — the Hessian $\partial^2 \mathcal{L} / \partial \dot\varphi^A \partial \dot\varphi^B$ is singular, because some field velocities never appear — is the origin of the constraint analysis of Chapter 26.

16.7 The variational principles of physics

16.7.1 Hamilton's principle

Definition 16.96 (Action; Hamilton's principle)**.** For a mechanical system with generalized coordinates $q^1, \dots, q^n$ and Lagrangian $\mathcal{L}(q, \dot q, t)$ in joules, the *action* between two instants is

$$S[q] = \int_{t_1}^{t_2} \mathcal{L}\left(q(t), \dot q(t), t\right) \mathrm{d}t \,, \tag{16.86}$$

of SI dimension J s. *Hamilton's principle* is the statement that the motion between prescribed configurations $q(t_1)$ and $q(t_2)$ makes Equation (16.86) stationary [96].

Rests on Equation (16.11) *and Definition 21.31.*

Theorem 16.97 (Equivalence with Newton's second law)**.** *Let a single particle of mass m move in ordinary space under a force derived from a potential $V(\boldsymbol{x}, t)$ in joules, and take $\mathcal{L} = \frac{1}{2} m |\dot{\boldsymbol{x}}|^2 - V$. Then $\boldsymbol{x}(t)$ makes Equation* (16.86) *stationary among curves with the prescribed endpoints if and only if it satisfies*

$$m\, \ddot{\boldsymbol{x}}(t) = -\nabla V\left(\boldsymbol{x}(t), t\right) . \tag{16.87}$$

Rests on Equations (16.30) *and* (16.86)*.*

Proof. *Derives Theorem 16.97.*

The three Euler–Lagrange equations Equation (16.30) with $x = t$ and $y^i = x^i$ read

$$\frac{\partial \mathcal{L}}{\partial x^i} - \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot x^i}\right) = -\frac{\partial V}{\partial x^i} - \frac{\mathrm{d}}{\mathrm{d}t}\left(m \dot x^i\right) = 0 \,,$$

which is Equation (16.87) componentwise. Conversely a solution of Equation (16.87) satisfies the Euler–Lagrange system, hence makes the first variation vanish by Proposition 16.17 and the integration by parts of Theorem 16.22. □

Remark 16.98 (Stationary, not least). The name "principle of least action" is a historical accident. $\mathcal{L} = T - V$ is convex in the velocities, so Equation (16.47) holds strictly and the

second variation is positive definite over short enough intervals; but by Theorem 16.55 the motion ceases to minimise past the first conjugate point — the *kinetic focus* — and for a harmonic oscillator of angular frequency ω that happens after a time π/ω, half a period. The action is then a saddle point, never a maximum. This is why Definition 16.96 says stationary. The standard mechanics treatments [1585, 2027] develop the principle in the form used throughout Chapter 21, and the path-integral formulation of Chapter 106 is what eventually explains why the stationary path is the one that matters: neighbouring paths interfere destructively except near a stationary point of S.

16.7.2 Maupertuis' principle

Hamilton's principle fixes the two *times* and varies the path. The older principle fixes the *energy* instead, lets the transit time float, and varies only the geometric path.

Definition 16.99 (Abbreviated action)**.** For a system with momenta $p_i = \partial \mathcal{L}/\partial \dot{q}^i$, the *abbreviated action* of a path traversed between two configurations is

$$W[\gamma] = \int_\gamma p_i \, \mathrm{d}q^i = \int_{t_1}^{t_2} p_i \, \dot{q}^i \, \mathrm{d}t \,, \tag{16.88}$$

also of dimension J s.

Rests on Equation (16.86) and Definition 16.96.

Lemma 16.100 (The ray equation)**.** *Let n be a positive C^1 function on a region of ordinary space and consider the parametrisation-invariant functional*

$$\mathcal{W}[\gamma] = \int_\gamma n\,(\boldsymbol{x}) \, \mathrm{d}s = \int_{\sigma_1}^{\sigma_2} n\,(\boldsymbol{x}(\sigma)) \, |\boldsymbol{x}'(\sigma)| \, \mathrm{d}\sigma \,. \tag{16.89}$$

Its extremals, parametrised by arclength s so that $\boldsymbol{T} = \mathrm{d}\boldsymbol{x}/\mathrm{d}s$ is a unit vector, satisfy

$$\frac{\mathrm{d}}{\mathrm{d}s}\,(n\,\boldsymbol{T}) = \nabla n \,. \tag{16.90}$$

Rests on Equations (16.30) and (16.89).

Proof. *Derives Lemma 16.100.*

The integrand $f = n\,(\boldsymbol{x})\,|\boldsymbol{x}'|$ is homogeneous of degree one in $\boldsymbol{x}'$, so the functional does not depend on the parametrisation and the three Euler–Lagrange equations Equation (16.30) are not independent; the arclength gauge $|\boldsymbol{x}'| = 1$ fixes the redundancy. With

$$\frac{\partial f}{\partial x'^i} = n\,\frac{x'^i}{|\boldsymbol{x}'|} \,, \qquad \frac{\partial f}{\partial x^i} = \frac{\partial n}{\partial x^i}\,|\boldsymbol{x}'| \,,$$

setting $|\boldsymbol{x}'| = 1$ after the differentiation turns Equation (16.30) into $\mathrm{d}\,(n\,T^i)\,/\mathrm{d}s = \partial n/\partial x^i$, which is Equation (16.90). □

Theorem 16.101 (Maupertuis–Euler–Jacobi principle)**.** *Let a single particle of mass m move in a time-independent potential $V\,(\boldsymbol{x})$ with total energy $E > V\,(\boldsymbol{x})$ throughout the region considered. Then the unparametrised orbits of energy E are exactly the extremals of the geometric functional*

$$W[\gamma] = \int_\gamma \sqrt{2m\,(E - V\,(\boldsymbol{x}))}\,\mathrm{d}s \,, \tag{16.91}$$

that is, the geodesics of the Jacobi metric $\mathrm{d}\sigma^2 = 2m\,(E - V)\,\mathrm{d}s^2$; and the time parametrisation is recovered from $\mathrm{d}t = \sqrt{m/\,[2\,(E - V)]}\,\mathrm{d}s$.

Rests on Equations (16.87) and (16.88) and Lemma 16.100.

Proof. *Derives Theorem 16.101.*

Along a motion of energy E the speed is $v = |\dot{\boldsymbol{x}}| = \sqrt{2\,(E-V)\,/m}$, so the momentum has magnitude $|\boldsymbol{p}| = mv = \sqrt{2m\,(E-V)}$ and points along $\boldsymbol{T}$. Hence $p_i\,\mathrm{d}q^i = |\boldsymbol{p}|\,\mathrm{d}s$ and Equation (16.88) coincides with Equation (16.91); this is Equation (16.89) with $n = \sqrt{2m\,(E-V)}$, in kg m/s.

By Lemma 16.100 the extremals satisfy $\mathrm{d}\,(n\boldsymbol{T})\,/\mathrm{d}s = \nabla n$. Now $n = |\boldsymbol{p}| = mv$, so $n\boldsymbol{T} = \boldsymbol{p}$, and

$$\nabla n = \nabla\sqrt{2m\,(E-V)} = \frac{-m\,\nabla V}{\sqrt{2m\,(E-V)}} = -\frac{\nabla V}{v}\,.$$

Since $\mathrm{d}/\mathrm{d}s = v^{-1}\mathrm{d}/\mathrm{d}t$ along the motion, the ray equation reads $v^{-1}\mathrm{d}\boldsymbol{p}/\mathrm{d}t = -v^{-1}\nabla V$, that is Equation (16.87). Every step is reversible, so the extremals of Equation (16.91) traversed with the stated time law are precisely the Newtonian orbits of energy E. □

Remark 16.102 (The relation to Hamilton's principle, and to whom the principle is due). The two principles are Legendre transforms of one another. For a motion of constant energy E,

$$S = \int_{t_1}^{t_2} \mathcal{L}\,\mathrm{d}t = \int_{t_1}^{t_2} \left(p_i\dot{q}^i - E\right)\mathrm{d}t = W - E\,(t_2 - t_1)\,, \tag{16.92}$$

so making S stationary at fixed transit time and making W stationary at fixed energy are the same condition read with different quantities held fixed. The hypotheses must be stated exactly or the equivalence fails: Hamilton's principle varies the path with t_1, t_2 fixed and the energy free, Maupertuis' principle varies the path with E fixed and the transit time free, and E must exceed V so that $n > 0$ and the region is accessible. At a turning point, where $E = V$, the Jacobi metric degenerates and the ray equation fails.

On the attribution: Maupertuis stated a principle of least action in 1744 for the refraction of light and in 1746 for mechanics, but as a metaphysical assertion about the economy of nature, with a quantity whose definition varied from case to case [24]. The mathematically correct statement, with the hypothesis of fixed energy and the integral $\int mv\,\mathrm{d}s$, is Euler's, in the second addendum to his founding monograph of the same period [23]. Attributing the sharp principle to Maupertuis alone is the customary usage and is wrong; the name is kept here because it is the one every reader will look up, and the correction is recorded rather than the reference silently changed. The geometric reading, that orbits are geodesics of a conformally rescaled metric, is Jacobi's, and it is taken up again with Hamilton–Jacobi theory in Chapter 23.

16.7.3 Fermat's principle

Definition 16.103 (Optical path length; Fermat's principle)**.** In a medium of refractive index $n\,(\boldsymbol{x})$ — dimensionless, equal to c/v_{phase} with $c = 299\,792\,458$ m/s the speed of light in vacuum — the *optical path length* of a curve is $\mathcal{W}[\gamma] = \int_\gamma n\,\mathrm{d}s$, in metres, and the transit time is $\mathcal{W}/c$ in seconds. *Fermat's principle* is the statement that a light ray follows a path making $\mathcal{W}$ stationary [260].

Rests on Equation (16.89) and Lemma 16.100.

Theorem 16.104 (Snell's law of refraction)**.** *Let two homogeneous media of indices n_1 and n_2 meet at a plane interface. Then a ray crossing the interface obeys*

$$n_1 \sin\vartheta_1 = n_2 \sin\vartheta_2\,, \tag{16.93}$$

with ϑ_1, ϑ_2 the angles between the ray and the normal to the interface on the two sides, the incident ray, the refracted ray and the normal being coplanar.

Rests on Definition 16.103 and Lemma 7.33.

Proof. *Derives Theorem 16.104.*

Within each homogeneous medium $\nabla n = 0$, so Equation (16.90) gives $\mathrm{d}\boldsymbol{T}/\mathrm{d}s = \boldsymbol{0}$: the ray is straight. The path is therefore determined by the single point at which it crosses the interface, and coplanarity follows because moving that point off the plane containing the endpoints and the normal lengthens both straight segments.

Place the interface at $z = 0$, the source at perpendicular distance a on one side and the target at perpendicular distance b on the other, their feet separated by d, and let the crossing point be at distance u from the first foot. The optical length is

$$\mathcal{W}(u) = n_1\sqrt{a^2 + u^2} + n_2\sqrt{b^2 + (d-u)^2}\,,$$

a smooth function of the single real variable u, whose stationary points satisfy, by Lemma 7.33,

$$\mathcal{W}'(u) = \frac{n_1 u}{\sqrt{a^2 + u^2}} - \frac{n_2\,(d-u)}{\sqrt{b^2 + (d-u)^2}} = 0\,.$$

The two fractions are exactly $\sin\vartheta_1$ and $\sin\vartheta_2$, so the condition is Equation (16.93). Since $\mathcal{W}'' > 0$ everywhere, the stationary point is the unique minimum. □

Proposition 16.105 (The optical invariant in a stratified medium)**.** *Let $n = n(z)$ depend on height alone. Then along a ray confined to a vertical plane,*

$$n(z)\,\sin\vartheta(z) = \mathit{const}\,, \tag{16.94}$$

with ϑ the angle to the vertical.

Rests on Theorem 16.29 and Equation (16.89).

Proof. *Derives Proposition 16.105.*

Parametrise the ray in the vertical plane as $x \longmapsto z(x)$, so that $\mathcal{W} = \int f\,\mathrm{d}x$ with $f\,(z, z') = n(z)\sqrt{1 + z'^2}$. The integrand carries no explicit dependence on x, so the Beltrami identity Equation (16.25) applies:

$$f - z'\,\frac{\partial f}{\partial z'} = n(z)\sqrt{1+z'^2} - \frac{n(z)\,z'^2}{\sqrt{1+z'^2}} = \frac{n(z)}{\sqrt{1+z'^2}} = \text{const}\,.$$

The unit tangent of the ray is $(1, z')\,/\sqrt{1+z'^2}$, so the angle ϑ it makes with the vertical satisfies $\sin\vartheta = \left(1 + z'^2\right)^{-1/2}$, and the conserved quantity is $n(z)\sin\vartheta$, which is Equation (16.94). □

Remark 16.106 (What the principle explains and where it comes from)*.* Equation (16.94) is the whole content of atmospheric refraction: warm air near a hot road has a smaller index, so $\sin\vartheta$ must grow and a ray descending towards the road bends back upwards — the inferior mirage. The same identity governs gradient-index fibres and the apparent flattening of the setting Sun. Fermat's principle is not, however, an independent postulate. It is the short-wavelength limit of wave optics: substituting $\boldsymbol{E} = \boldsymbol{E}_0 \exp\left[\mathrm{i}k_0 L(\boldsymbol{x})\right]$ into the wave equation and dropping terms of order k_0^{-1} gives the eikonal equation $|\nabla L|^2 = n^2$, whose characteristics are the rays of Equation (16.90); the derivation is that of Born and Wolf [1967] and belongs to Chapter 61. Comparing Lemma 16.100 as used in Theorem 16.101 with its use here shows the optical–mechanical analogy in its sharpest form: a mechanical orbit of energy E is a light ray in a medium of index $n = \sqrt{2m\,(E - V)}$, and the eikonal L is Hamilton's characteristic function. That correspondence, pursued in Chapter 23, is the historical route to the Schrödinger equation.

16.7.4 Field actions

Definition 16.107 (Field action)**.** For fields φ^A on the spacetime of Chapter 39 the action is

$$S[\varphi] = \int_{t_1}^{t_2} \mathrm{d}t \int_V \mathcal{L}\left(\varphi^A, \partial_\mu \varphi^A, x\right) \mathrm{d}^3x \,, \tag{16.95}$$

with the Lagrangian density $\mathcal{L}$ in $\mathrm{J/m^3}$, so that S carries the dimension J s of Equation (16.86). In covariant notation $\mathrm{d}^4x = c\,\mathrm{d}t\,\mathrm{d}^3x$, so $S = c^{-1}\int \mathcal{L}\,\mathrm{d}^4x$. Its Euler–Lagrange equations are Equation (16.32).

Rests on Equations (16.31) *and* (16.86).

Example 16.108 (The electromagnetic action)**.** With the electric field $\boldsymbol{E}$ in V/m, the magnetic field $\boldsymbol{B}$ in teslas, the charge density ρ in $\mathrm{C/m^3}$ and the current density $\boldsymbol{J}$ in $\mathrm{A/m^2}$, the Lagrangian density

$$\mathcal{L}_{\mathrm{EM}} = \frac{\varepsilon_0}{2}\,|\boldsymbol{E}|^2 - \frac{1}{2\mu_0}\,|\boldsymbol{B}|^2 + \boldsymbol{J}\cdot\boldsymbol{A} - \rho\,\Phi \,, \tag{16.96}$$

with $\varepsilon_0 = 8.854\,187\,812\,8 \times 10^{-12}\,\mathrm{F/m}$ and $\mu_0 = 1.256\,637\,062\,12 \times 10^{-6}\,\mathrm{N/A^2}$, and with $\boldsymbol{E} = -\nabla\Phi - \partial\boldsymbol{A}/\partial t$ and $\boldsymbol{B} = \nabla\times\boldsymbol{A}$, has the dimension $\mathrm{J/m^3}$. Its Euler–Lagrange equations in the potentials $(\Phi, \boldsymbol{A})$ are the two inhomogeneous Maxwell equations, the other two holding identically because the fields are built from potentials. The derivation, the covariant form

$$\mathcal{L}_{\mathrm{EM}} = -\frac{1}{4\mu_0} F_{\mu\nu}F^{\mu\nu} + J^\mu A_\mu \,, \tag{16.97}$$

and the gauge analysis are the business of Chapter 64. The sign of the source term is fixed by the signature: in the $(-,+,+,+)$ convention of Appendix E, with $A^\mu = (\Phi/c, \boldsymbol{A})$ and $J^\mu = (c\rho, \boldsymbol{J})$, one has $A_\mu = (-\Phi/c, \boldsymbol{A})$ and $J^\mu A_\mu = \boldsymbol{J}\cdot\boldsymbol{A} - \rho\,\Phi$, which is exactly the last two terms of Equation (16.96); the opposite sign belongs to the mostly-minus convention, which this book does not use (see Equation (16.99) for the same choice). The $F_{\mu\nu}F^{\mu\nu}$ term is the same in both. What belongs here is only that the Maxwell equations are the Euler–Lagrange equations of a multiple integral, so that everything proved in this chapter — the field equations, the Noether currents, the second theorem's identities — applies to them.

Rests on Equations (16.32) *and* (16.95).

Example 16.109 (The Einstein–Hilbert action)**.** The gravitational action is

$$S_{\mathrm{EH}} = \frac{c^3}{16\pi G}\int_\Omega R\,\sqrt{-g}\,\mathrm{d}^4x \,, \tag{16.98}$$

with $x^0 = ct$, R the Ricci scalar of Chapter 13 in $1/\mathrm{m^2}$, g the determinant of the metric, and $G = 6.674\,30 \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$. The prefactor c^3/G has the SI dimension kg/s, so S_{EH} carries J s as an action must; the frequently seen c^4 goes with a different convention for d^4x. Varying Equation (16.98) with respect to the metric gives the Einstein field equations, and varying the matter action gives the energy–momentum tensor that sources them [431]; both computations, and the boundary term of Remark 16.34 that must be added because the integrand contains second derivatives of the metric, are carried out in Chapter 44. The diffeomorphism invariance of Equation (16.98) is the instance of Theorem 16.93 discussed in Remark 16.95.

Rests on Equation (16.32) *and Theorem 16.93.*

Example 16.110 (Geodesics as extremals of proper time)**.** A free test particle of mass m in a spacetime with metric $g_{\mu\nu}$ extremises

$$S = -mc^2\int \mathrm{d}\tau = -mc\int \sqrt{-g_{\mu\nu}\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu} \,, \tag{16.99}$$

in J s, whose Euler–Lagrange equations are the geodesic equations of Chapter 43. The integrand is homogeneous of degree one in $\mathrm{d}x^\mu$, so, exactly as in Lemma 16.100, the functional is parametrisation-invariant and the equations are degenerate until a gauge — here proper time, the analogue of arclength — is fixed. This is the same structure as the abbreviated action of Theorem 16.101: the free relativistic particle is the Maupertuis problem of a metric.

Rests on Equations (16.89) *and* (16.91).

Remark 16.111 (What the variational formulation buys). Three things, and they are the reason this chapter exists.

First, *covariance for free*: by Proposition 16.26 the Euler–Lagrange equations of a scalar action take the same form in every coordinate system, so a theory specified by an action is automatically consistent with whatever symmetry group leaves the action invariant.

Second, *conservation laws on demand*: by Theorem 16.90 every continuous symmetry of the action delivers a conserved current, computed from the Lagrangian by differentiation alone. Energy, momentum, angular momentum and electric charge are all obtained this way, and no separate postulate is needed for any of them — which is why Section 16.6.1 is the result the rest of this book leans on hardest.

Third, *a criterion for admissible theories*: the field equations of a Lagrangian theory are not arbitrary. They are second order when the Lagrangian is first order in derivatives, by Equation (16.32); they are unstable if it is genuinely higher order, by Proposition 16.39; and they are redundant, with constraints, precisely when a gauge group acts, by Corollary 16.94. Those three statements between them shape every fundamental theory in this treatise.

Chapter 17

Fourier Analysis and Integral Transforms

Fourier series and transforms, Laplace transforms, convolution and Green's-function methods, with the convergence theorems stated and proved at the depth cap of Part II. The organising idea is a change of basis: a function of time or space is re-expressed as a superposition of harmonics, in which differentiation becomes multiplication and the linear differential equations of physics become algebraic. Fourier introduced the expansion to solve the heat equation [72], and the analysis, synthesis and convergence of such expansions — settled only in 1966 for square-integrable functions [1327] — created much of modern analysis on the way.

The chapter feeds the separation-of-variables and Green's-function methods of Chapter 10, the orthonormal-basis language of Chapter 12, the normal-mode analysis of Chapter 28, and, through the uncertainty relation between a function and its transform, the wave mechanics of Chapter 77 and Chapter 71. Its computational face — sampling and the fast Fourier transform — is what turns the strain record of a gravitational-wave interferometer or the interferogram of a spectrometer into a spectrum, so the experimental chapters consume it too.

The Sturm–Liouville chapter already exhibits the Fourier series and the Fourier integral as the eigenfunction expansion of the one-dimensional Helmholtz operator (Section 9.7.4, Section 9.7.5) and states, without derivation, the orthonormality, the passage to the integral, the derivative rule, the convolution property and the Parseval relation. All five are proved below, in the same normalisation.

17.1 Fourier series

17.1.1 Trigonometric expansion of periodic functions

The subject began in a quarrel about a string. In 1747 d'Alembert solved the equation of a stretched string of length ℓ fixed at both ends and found its general motion to be a superposition of two waves travelling in opposite directions at the speed $c = \sqrt{\tau/\mu}$ — with the tension τ in N and the linear density μ in kg/m, so that c is in m/s [25]. Six years later Daniel Bernoulli asserted that the same motion is a superposition of the normal modes,

$$y(x,t) = \sum_{n=1}^{\infty} A_n \sin\frac{n\pi x}{\ell}\,\cos\left(\frac{n\pi c\,t}{\ell} + \varphi_n\right), \tag{17.1}$$

and hence — setting $t = 0$ — that *any* admissible initial shape of the string is a sine series [28]. Euler and d'Alembert objected that the right-hand side of Equation (17.1) is built from analytic functions and could not possibly represent the arbitrary, kinked initial profiles

the physical problem allows. The objection was reasonable and wrong, and it was settled in Bernoulli's favour by Fourier, who used precisely such expansions to solve the heat equation and computed the coefficients by the formulas below [72]. What the objectors were right about is that the class of functions represented, and the sense in which the series represents them, both need proof; supplying it occupied a century and is the content of Section 17.1.2.

Definition 17.1 (Fourier coefficients and Fourier series)**.** Let f be complex valued, periodic with period $T > 0$, and absolutely integrable over one period. Write

$$\omega_1 = \frac{2\pi}{T}\,, \qquad \nu_1 = \frac{1}{T} \tag{17.2}$$

for the fundamental angular frequency and the fundamental frequency; if t is a time in s then ω_1 is in rad/s and ν_1 in Hz. The *Fourier coefficients* of f are

$$c_n = \frac{1}{T}\int_{-T/2}^{T/2} f(t)\,\mathrm{e}^{-\mathrm{i}n\omega_1 t}\,\mathrm{d}t\,, \qquad n \in \mathbb{Z}\,, \tag{17.3}$$

and the *Fourier series* of f is the formal sum

$$\sum_{n=-\infty}^{\infty} c_n\,\mathrm{e}^{\mathrm{i}n\omega_1 t}\,, \tag{17.4}$$

whose symmetric partial sums are written $S_N f(t) = \sum_{n=-N}^{N} c_n \mathrm{e}^{\mathrm{i}n\omega_1 t}$.

Equation (17.3) is the *analysis* step and is defined for every absolutely integrable f, whatever the series does; Equation (17.4) is the *synthesis* step, and whether it returns f is the convergence problem. The two are kept separate throughout: it is the failure to separate them that made the eighteenth-century controversy irresolvable.

Lemma 17.2 (Orthogonality of the harmonics)**.** *For $m, n \in \mathbb{Z}$,*

$$\frac{1}{T}\int_{-T/2}^{T/2} \mathrm{e}^{\mathrm{i}m\omega_1 t}\,\overline{\mathrm{e}^{\mathrm{i}n\omega_1 t}}\,\mathrm{d}t = \delta_{mn}\,. \tag{17.5}$$

Rests on Definition 17.1.

Proof. *Derives Lemma 17.2.*

The integrand is $\mathrm{e}^{\mathrm{i}(m-n)\omega_1 t}$. For $m = n$ it is 1 and the average is 1. For $m \neq n$ put $p = m - n \neq 0$; the antiderivative is $\mathrm{e}^{\mathrm{i}p\omega_1 t}/(\mathrm{i}p\omega_1)$, so the integral equals

$$\frac{\mathrm{e}^{\mathrm{i}p\pi} - \mathrm{e}^{-\mathrm{i}p\pi}}{\mathrm{i}p\omega_1} = \frac{2\mathrm{i}\sin(p\pi)}{\mathrm{i}p\omega_1} = 0\,,$$

using $\omega_1 T/2 = \pi$ and $\sin(p\pi) = 0$ for integer p. □

This one computation is the whole mechanism. It is the special case, for the operator $-\mathrm{d}^2/\mathrm{d}t^2$ on a periodic interval, of the orthogonality of eigenfunctions of a Sturm–Liouville operator belonging to distinct eigenvalues (Section 9.4), and the model for the abstract orthonormal bases of Chapter 12: it is what lets a coefficient be extracted from a sum by a single integral. Equation (17.5) is the relation left as a pending derivation at Equation (9.109).

Theorem 17.3 (Euler–Fourier coefficient formulas)**.** *If a series $\sum_n \gamma_n \mathrm{e}^{\mathrm{i}n\omega_1 t}$ converges uniformly on $[-T/2, T/2]$ to a function f, then f is continuous and periodic, and $\gamma_n = c_n$ for every n, with c_n given by Equation (17.3). In particular a function has at most one uniformly convergent trigonometric expansion.*

Rests on Definition 17.1 and Lemma 17.2.

Proof. *Derives Theorem 17.3.*

A uniform limit of continuous functions is continuous, and each term is T-periodic, so f is. Fix m, multiply the series by $\mathrm{e}^{-\mathrm{i}m\omega_1 t}$ — a bounded factor, so convergence stays uniform — and integrate over one period. Uniform convergence permits the exchange of sum and integral (the tail is bounded by $T\sup_t|\text{tail}|$), giving

$$\int_{-T/2}^{T/2} f(t)\,\mathrm{e}^{-\mathrm{i}m\omega_1 t}\,\mathrm{d}t = \sum_n \gamma_n \int_{-T/2}^{T/2} \mathrm{e}^{\mathrm{i}(n-m)\omega_1 t}\,\mathrm{d}t = T\gamma_m$$

by Lemma 17.2. Divide by T. □

Real form. Splitting the n and $-n$ terms of Equation (17.4) with Euler's formula (Proposition 8.4) gives the real trigonometric form

$$\frac{a_0}{2} + \sum_{n=1}^{\infty} \left[a_n \cos(n\omega_1 t) + b_n \sin(n\omega_1 t)\right] , \tag{17.6}$$

with

$$a_n = \frac{2}{T}\int_{-T/2}^{T/2} f(t)\cos(n\omega_1 t)\,\mathrm{d}t\,, \qquad b_n = \frac{2}{T}\int_{-T/2}^{T/2} f(t)\sin(n\omega_1 t)\,\mathrm{d}t\,, \tag{17.7}$$

and the dictionary between the two sets of coefficients is

$$a_n = c_n + c_{-n}\,, \qquad b_n = \mathrm{i}\,(c_n - c_{-n})\,, \qquad c_{\pm n} = \tfrac{1}{2}\,(a_n \mp \mathrm{i}b_n)\,, \quad n \geq 1\,, \tag{17.8}$$

with $a_0 = 2c_0$ twice the mean value of f. For real f one has $c_{-n} = \overline{c_n}$, so the real form carries the same information in half as many symbols; the complex form is used below because the harmonics are then eigenfunctions of $\mathrm{d}/\mathrm{d}t$, which is the property the whole subject exploits. Equation (17.7) is Equation (9.118) written with $T = 2L$, the factor $2/T$ there appearing as $1/L$.

The orthonormality relations of the real system follow from Equation (17.5) and the product formulas of trigonometry: for $m, n \geq 1$,

$$\frac{2}{T}\int_{-T/2}^{T/2} \cos(m\omega_1 t)\cos(n\omega_1 t)\,\mathrm{d}t = \delta_{mn}\,, \qquad \frac{2}{T}\int_{-T/2}^{T/2} \sin(m\omega_1 t)\sin(n\omega_1 t)\,\mathrm{d}t = \delta_{mn}\,, \tag{17.9}$$

and the mixed integral vanishes for all m, n. Indeed $\cos A\cos B = \frac{1}{2}\left[\cos(A-B) + \cos(A+B)\right]$ turns the first into $\delta_{m,n} + \delta_{m,-n}$ by Lemma 17.2, and the second index coincidence is impossible for positive m, n; the sine relation is the same identity with the opposite sign, and the mixed one is the integral of an odd function over a symmetric interval. This is the derivation left pending at Equations (9.114) to (9.116).

Proposition 17.4 (Least squares and Bessel's inequality)**.** *Let f be square integrable over a period. Among all trigonometric polynomials $P(t) = \sum_{|n|\leq N} \gamma_n \mathrm{e}^{\mathrm{i}n\omega_1 t}$ of degree at most N, the mean-square error $\frac{1}{T}\int_{-T/2}^{T/2} |f - P|^2\,\mathrm{d}t$ is smallest exactly when $\gamma_n = c_n$, that is, when $P = S_N f$. Moreover*

$$\sum_{n=-N}^{N} |c_n|^2 \leq \frac{1}{T}\int_{-T/2}^{T/2} |f(t)|^2\,\mathrm{d}t \qquad \textit{for every } N\,, \tag{17.10}$$

so the coefficients are square summable and $c_n \to 0$ as $|n| \to \infty$.

Rests on Definition 17.1 and Lemma 17.2.

Proof. *Derives Proposition 17.4.*

Write $\langle g, h\rangle = \frac{1}{T}\int_{-T/2}^{T/2} g\bar{h}\,\mathrm{d}t$. By Lemma 17.2 the harmonics are orthonormal for $\langle\cdot,\cdot\rangle$ and $\langle f, \mathrm{e}^{\mathrm{i}n\omega_1 t}\rangle = c_n$. Expand:

$$\langle f-P, f-P\rangle = \langle f,f\rangle - \sum_{|n|\le N}(\gamma_n\overline{c_n} + \overline{\gamma_n}c_n) + \sum_{|n|\le N}|\gamma_n|^2 = \langle f,f\rangle - \sum_{|n|\le N}|c_n|^2 + \sum_{|n|\le N}|\gamma_n - c_n|^2\,,$$

by completing the square term by term. Only the last sum depends on the γ_n, and it is minimal — and zero — iff $\gamma_n = c_n$. Setting $\gamma_n = c_n$ leaves $0 \le \langle f,f\rangle - \sum_{|n|\le N}|c_n|^2$, which is Equation (17.10); the bound is uniform in N, so the series of squares converges and its terms tend to zero. □

The partial sum is thus the orthogonal projection of f onto the span of the first $2N+1$ harmonics — the concrete instance of the projection theorem of Chapter 12. Whether the inequality Equation (17.10) is an equality in the limit is exactly the question of whether the harmonics are a *complete* orthonormal system; Section 17.2.2 proves that they are.

Example 17.5 (Square wave and sawtooth)**.** Let f be the odd square wave of unit amplitude, $f(t) = \operatorname{sgn}(\sin\omega_1 t)$. It is odd, so all a_n vanish, and

$$b_n = \frac{4}{T}\int_0^{T/2}\sin(n\omega_1 t)\,\mathrm{d}t = \frac{2}{n\pi}\left[1-(-1)^n\right] = \begin{cases}\dfrac{4}{n\pi}\,, & n \text{ odd}\,,\\ 0\,, & n \text{ even}\,.\end{cases} \tag{17.11}$$

Only odd harmonics appear, with amplitudes falling as $1/n$. For the 50 Hz square wave delivered by a simple inverter this places power at 50 Hz, 150 Hz, 250 Hz and so on, with relative amplitudes 1, 1/3, 1/5; the third harmonic carries $(1/3)^2 = 11.1\,\%$ of the fundamental's power. The sawtooth $f(t) = 2t/T$ on $(-T/2, T/2)$ is also odd, with $b_n = (-1)^{n+1}\,2/(n\pi)$, again a $1/n$ envelope. In both cases the $1/n$ decay is the signature of a jump discontinuity, as Proposition 17.10 will show, and it is what makes these two examples the arena of Section 17.1.3.

17.1.2 Convergence: from Dirichlet to Carleson

Rescaling $x = \omega_1 t$ turns any period into 2π and changes no convergence statement, so this subsection fixes $T = 2\pi$ and writes $c_n = \frac{1}{2\pi}\int_{-\pi}^{\pi} f(x)\mathrm{e}^{-\mathrm{i}nx}\mathrm{d}x$.

Lemma 17.6 (Dirichlet kernel)**.** *Define* $D_N(u) = \sum_{n=-N}^{N}\mathrm{e}^{\mathrm{i}nu}$. *Then, for* $u \notin 2\pi\mathbb{Z}$,

$$D_N(u) = \frac{\sin\left[\left(N+\frac{1}{2}\right)u\right]}{\sin(u/2)}\,, \tag{17.12}$$

D_N *is even and real,* $D_N(0) = 2N+1$, *and*

$$\frac{1}{2\pi}\int_{-\pi}^{\pi} D_N(u)\,\mathrm{d}u = 1\,, \qquad \frac{1}{2\pi}\int_0^{\pi} D_N(u)\,\mathrm{d}u = \frac{1}{2}\,. \tag{17.13}$$

Moreover the partial sum is the average of f *against this kernel,*

$$S_N f(x) = \frac{1}{2\pi}\int_{-\pi}^{\pi} f(x-u)\,D_N(u)\,\mathrm{d}u\,. \tag{17.14}$$

Rests on Definition 17.1 and Lemma 17.2.

Proof. *Derives Lemma 17.6.*

The sum is geometric with ratio $r = \mathrm{e}^{\mathrm{i}u} \neq 1$: $\sum_{n=-N}^{N} r^n = (r^{-N} - r^{N+1})/(1-r)$. Multiply numerator and denominator by $\mathrm{e}^{-\mathrm{i}u/2}$; the numerator becomes $\mathrm{e}^{-\mathrm{i}(N+1/2)u} - \mathrm{e}^{\mathrm{i}(N+1/2)u} = -2\mathrm{i}\sin[(N+\tfrac{1}{2})u]$ and the denominator $\mathrm{e}^{-\mathrm{i}u/2} - \mathrm{e}^{\mathrm{i}u/2} = -2\mathrm{i}\sin(u/2)$, giving Equation (17.12). Evenness and reality are visible in the closed form; $D_N(0) = 2N+1$ by counting terms in the sum. Integrating the sum term by term and using Lemma 17.2 leaves only $n = 0$, which gives the first identity of Equation (17.13), and the second follows by evenness. For Equation (17.14), insert Equation (17.3) into the partial sum and exchange the finite sum with the integral:

$$S_N f(x) = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(s) \sum_{n=-N}^{N} \mathrm{e}^{\mathrm{i}n(x-s)} \, \mathrm{d}s = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(s) \, D_N(x-s) \, \mathrm{d}s \,,$$

and substitute $u = x - s$, the range returning to $[-\pi, \pi]$ because both f and D_N are 2π-periodic. □

Everything about pointwise convergence is now a statement about the oscillatory kernel Equation (17.12). It has unit average but does *not* have unit absolute average — that failure is the subject of Lemma 17.12 — and it oscillates faster and faster as N grows. The instrument for exploiting fast oscillation is the following lemma.

Lemma 17.7 (Riemann–Lebesgue)**.** *Let g be absolutely integrable on $[a, b]$ and Riemann integrable in the sense of Section 7.7. Then*

$$\lim_{\lambda \to \infty} \int_a^b g(u) \, \sin(\lambda u) \, \mathrm{d}u = 0 \,, \tag{17.15}$$

and likewise with $\cos(\lambda u)$ or $\mathrm{e}^{-\mathrm{i}\lambda u}$.

Rests on Definition 7.39.

Proof. *Derives Lemma 17.7.*

First let $g = \mathbf{1}_{\{u \in [\alpha, \beta]\}}$ be the indicator of a subinterval. Then

$$\left| \int_\alpha^\beta \sin(\lambda u) \, \mathrm{d}u \right| = \left| \frac{\cos(\lambda\alpha) - \cos(\lambda\beta)}{\lambda} \right| \leq \frac{2}{\lambda} \longrightarrow 0 \,,$$

so the claim holds for indicators and, by linearity, for every step function. Now let g be Riemann integrable and $\varepsilon > 0$. By the definition of the Darboux integral (Definition 7.39) there is a partition whose lower step function φ satisfies $\int_a^b |g - \varphi| \, \mathrm{d}u < \varepsilon/2$. Then

$$\left| \int_a^b g \sin(\lambda u) \, \mathrm{d}u \right| \leq \int_a^b |g - \varphi| \, \mathrm{d}u + \left| \int_a^b \varphi \sin(\lambda u) \, \mathrm{d}u \right| < \frac{\varepsilon}{2} + \frac{\varepsilon}{2}$$

for λ large enough, since the second term tends to zero. As ε was arbitrary, Equation (17.15) follows. On an unbounded interval one first truncates: absolute integrability makes the tail contribute less than $\varepsilon/2$ uniformly in λ. □

Corollary 17.8 (Localisation)**.** *Whether $S_N f(x)$ converges, and to what, depends only on the values of f in an arbitrarily small neighbourhood of x. Two integrable functions that agree on $(x-\delta, x+\delta)$ have Fourier series that converge or diverge together at x, to the same limit when they converge.*

Rests on Lemmas 17.6 and 17.7.

Proof. *Derives Corollary 17.8.*

Let $h = f_1 - f_2$ vanish on $(x-\delta, x+\delta)$. By Equation (17.14),

$$S_N h(x) = \frac{1}{2\pi} \int_{\delta \le |u| \le \pi} \frac{h(x-u)}{\sin(u/2)} \, \sin\left[\left(N + \tfrac{1}{2}\right) u\right] \mathrm{d}u \,,$$

and on the domain of integration $|\sin(u/2)| \ge \sin(\delta/2) > 0$, so $h(x-u)/\sin(u/2)$ is absolutely integrable there. Lemma 17.7 sends the integral to zero. □

That a *global* object — the coefficients Equation (17.3) integrate f over the whole period — should have purely local convergence behaviour is Riemann's localisation principle, and it is the reason the theorem below needs hypotheses only at the point examined.

Theorem 17.9 (Dirichlet)**.** *Let f be 2π-periodic and absolutely integrable, and let x be a point at which the one-sided limits $f(x^{\pm})$ exist and the* Dini condition

$$\int_0^{\delta} \frac{|f(x+u) - f(x^+)| + |f(x-u) - f(x^-)|}{u} \, \mathrm{d}u < \infty \tag{17.16}$$

holds for some $\delta > 0$. Then

$$\lim_{N \to \infty} S_N f(x) = \frac{f(x^+) + f(x^-)}{2} \,. \tag{17.17}$$

In particular this holds at every point of a piecewise continuously differentiable function, where the series converges to f at points of continuity and to the midpoint of the jump elsewhere.

Rests on Lemmas 17.6 and 17.7 and Theorem 7.35.

Proof. *Derives Theorem 17.9.*

Split Equation (17.14) at $u = 0$ and use the evenness of D_N together with the half-period normalisation Equation (17.13):

$$\begin{aligned} S_N f(x) - \frac{f(x^+) + f(x^-)}{2} &= \frac{1}{2\pi} \int_0^{\pi} \left[f(x-u) - f(x^-)\right] D_N(u) \, \mathrm{d}u \\ &\quad + \frac{1}{2\pi} \int_0^{\pi} \left[f(x+u) - f(x^+)\right] D_N(u) \, \mathrm{d}u \,. \end{aligned}$$

Insert Equation (17.12) and define, on $(0, \pi]$,

$$g_{\pm}(u) = \frac{f(x \pm u) - f(x^{\pm})}{\sin(u/2)} \,,$$

so that each term is $\frac{1}{2\pi} \int_0^{\pi} g_{\pm}(u) \sin[(N + \frac{1}{2})u] \, \mathrm{d}u$. It remains to check that $g_{\pm}$ is absolutely integrable, for then Lemma 17.7 sends both terms to zero. Away from the origin this is clear, since $\sin(u/2)$ is bounded below there. Near the origin, $\sin(u/2) \ge u/\pi$ for $u \in (0, \pi]$ (concavity of the sine on $[0, \pi/2]$), so

$$\int_0^{\delta} |g_{\pm}(u)| \, \mathrm{d}u \le \pi \int_0^{\delta} \frac{|f(x \pm u) - f(x^{\pm})|}{u} \, \mathrm{d}u < \infty$$

by the Dini condition Equation (17.16). Finally, if f is piecewise C^1 then $|f(x \pm u) - f(x^{\pm})| \le M u$ near 0 by the mean value theorem (Theorem 7.35) applied on each side, the integrand of Equation (17.16) is bounded, and the condition holds automatically. □

Dirichlet's own hypothesis [85] was that f be bounded with finitely many maxima, minima and discontinuities in a period — a condition of *bounded variation* rather than of differentiability, which the proof above accommodates with the same estimate. His paper is the first rigorous convergence theorem in analysis, and the first place where the modern habit of stating hypotheses precisely enough to be checked appears in the subject.

Proposition 17.10 (Smoothness and coefficient decay)**.** *Let f be 2π-periodic and $k-1$ times continuously differentiable, with $f^{(k)}$ piecewise continuous. Then*

$$c_n\Big(f^{(k)}\Big) = (\mathrm{i}n)^k\, c_n(f)\,, \tag{17.18}$$

and consequently $|c_n| = o\Big(|n|^{-k}\Big)$. Conversely, a jump discontinuity in f itself forces c_n to decay no faster than $1/|n|$, as in Example 17.5.

Rests on Definition 17.1, Lemma 17.7, and Equation (7.28).

Proof. *Derives Proposition 17.10.*

Integrate by parts once (Equation (7.28)):

$$c_n(f') = \frac{1}{2\pi}\int_{-\pi}^{\pi} f'(x)\mathrm{e}^{-\mathrm{i}nx}\mathrm{d}x = \frac{1}{2\pi}\Big[f\mathrm{e}^{-\mathrm{i}nx}\Big]_{-\pi}^{\pi} + \frac{\mathrm{i}n}{2\pi}\int_{-\pi}^{\pi} f(x)\mathrm{e}^{-\mathrm{i}nx}\mathrm{d}x = \mathrm{i}n\, c_n(f)\,,$$

the boundary term vanishing because f and $\mathrm{e}^{-\mathrm{i}nx}$ are both 2π-periodic. Iterating k times gives Equation (17.18). Since $f^{(k)}$ is integrable, its own coefficients tend to zero by Lemma 17.7, whence $|n|^k\,|c_n(f)| \to 0$. For the converse, suppose $|c_n| \le C\,|n|^{-1-\varepsilon}$ for some $\varepsilon > 0$; then $\sum_n |c_n| < \infty$, the series converges uniformly by the Weierstrass M-test, and its sum is continuous. A function with a jump — the square wave of Equation (17.11), whose coefficients are exactly of size $1/n$ — therefore admits no such bound. $\square$

Corollary 17.11 (Uniform convergence for C^1 functions)**.** *If f is 2π-periodic and continuously differentiable, then $\sum_n |c_n| < \infty$ and the Fourier series converges to f absolutely and uniformly.*

Rests on Propositions 17.4 and 17.10 and Theorem 17.9.

Proof. *Derives Corollary 17.11.*

By Cauchy–Schwarz in the sequence space and Equation (17.18),

$$\sum_{n\neq 0}|c_n| = \sum_{n\neq 0}\frac{1}{|n|}\,|n\,c_n| \le \left(\sum_{n\neq 0}\frac{1}{n^2}\right)^{1/2}\left(\sum_{n\neq 0}|c_n(f')|^2\right)^{1/2} \le \frac{\pi}{\sqrt{3}}\left(\frac{1}{2\pi}\int_{-\pi}^{\pi}|f'|^2\,\mathrm{d}x\right)^{1/2},$$

finite, using $\sum_{n\ge 1} n^{-2} = \pi^2/6$ and Bessel's inequality Equation (17.10) applied to f'. The Weierstrass M-test then makes the series uniformly convergent, and Theorem 17.9 identifies its sum with f at every point. $\square$

So smoothness is read off the spectrum and conversely: this is the practical content of Fourier analysis for the solution of differential equations, and it is why the transform methods of Section 10.2.3 work at all.

The failures. Dirichlet's theorem needs a hypothesis at the point, and no hypothesis of mere continuity will do. The obstruction is measurable, and it is the growth of the kernel's absolute average.

Lemma 17.12 (Divergence of the Lebesgue constants)**.** *Let $L_N = \frac{1}{2\pi}\int_{-\pi}^{\pi}|D_N(u)|\,\mathrm{d}u$. Then*

$$L_N \ge \frac{4}{\pi^2}\,\ln N \longrightarrow \infty\,. \tag{17.19}$$

Rests on Lemma 17.6.

Proof. *Derives Lemma 17.12.*

By evenness, $L_N = \frac{1}{\pi}\int_0^{\pi} |D_N(u)|\,\mathrm{d}u$, and $|\sin(u/2)| \le u/2$ on $[0,\pi]$ gives $|D_N(u)| \ge 2\left|\sin[(N+\tfrac12)u]\right|/u$. Substituting $v = (N+\tfrac12)u$,

$$L_N \ge \frac{2}{\pi}\int_0^{(N+1/2)\pi} \frac{|\sin v|}{v}\,\mathrm{d}v \ge \frac{2}{\pi}\sum_{j=1}^{N}\frac{1}{j\pi}\int_{(j-1)\pi}^{j\pi}|\sin v|\,\mathrm{d}v = \frac{4}{\pi^2}\sum_{j=1}^{N}\frac{1}{j} \ge \frac{4}{\pi^2}\ln N\,,$$

bounding $1/v \ge 1/(j\pi)$ on the j-th half-period, using $\int_{(j-1)\pi}^{j\pi}|\sin v|\,\mathrm{d}v = 2$, and comparing the harmonic sum with $\int_1^N \mathrm{d}j/j$. □

Theorem 17.13 (du Bois-Reymond)**.** *There exists a continuous 2π-periodic function whose Fourier series diverges at a point [192].*

Rests on Lemmas 17.6 and 17.12.

Derivation. *Derives Theorem 17.13.*

By Equation (17.14), $f \mapsto S_N f(0)$ is a linear functional on the continuous 2π-periodic functions with the supremum norm, and its norm is exactly L_N: it is at most L_N by the triangle inequality, and at least L_N because a continuous f with $\|f\|_\infty \le 1$ can be made to follow $\operatorname{sgn} D_N(-u)$ except on arbitrarily short intervals around the finitely many sign changes. Lemma 17.12 shows this family of functionals is not uniformly bounded. The uniform boundedness principle of functional analysis then supplies an f for which $\sup_N |S_N f(0)| = \infty$. □

The uniform boundedness principle is the one piece of functional analysis the argument above borrows, and neither it nor the Baire category theorem it rests on is developed in this treatise. It can be dispensed with: the rest of this subsection writes down an explicit continuous function whose Fourier series diverges at the origin, so that Theorem 17.13 depends on nothing unproved. Two elementary estimates come first.

Lemma 17.14 (Uniformly bounded sine sums)**.** *For every integer $M \ge 1$ and every real x,*

$$\left|\sum_{k=1}^{M}\frac{\sin(kx)}{k}\right| \le 1 + 2\pi\,. \tag{17.20}$$

The bound is uniform in M and in x, although the terms are not absolutely summable.

Rests on Proposition 8.4.

Proof. *Derives Lemma 17.14.*

The sum is odd and 2π-periodic in x and vanishes at $x = 0$, so it suffices to bound it for $0 < x \le \pi$. Write $T_m = \sum_{k=1}^{m}\sin(kx)$. Multiplying the finite geometric progression $\sum_{k=1}^{m} \mathrm{e}^{\mathrm{i}kx}$ by $\mathrm{e}^{\mathrm{i}x} - 1$ telescopes it to $\mathrm{e}^{\mathrm{i}(m+1)x} - \mathrm{e}^{\mathrm{i}x}$, so for $\mathrm{e}^{\mathrm{i}x} \ne 1$ — the case $\mathrm{e}^{\mathrm{i}x} = 1$ being $x = 0$, already excluded — that progression sums to $\mathrm{e}^{\mathrm{i}x}\left(\mathrm{e}^{\mathrm{i}mx} - 1\right)/\left(\mathrm{e}^{\mathrm{i}x} - 1\right)$. Taking imaginary parts (Proposition 8.4),

$$T_m = \Im\frac{\mathrm{e}^{\mathrm{i}x}\left(\mathrm{e}^{\mathrm{i}mx} - 1\right)}{\mathrm{e}^{\mathrm{i}x} - 1}\,, \qquad \text{so} \qquad |T_m| \le \frac{2}{|\mathrm{e}^{\mathrm{i}x} - 1|} = \frac{1}{\sin(x/2)}\,, \tag{17.21}$$

using $|\mathrm{e}^{\mathrm{i}x} - 1| = 2\sin(x/2)$ on that range. There $\sin(x/2) \ge x/\pi$, by concavity of the sine on $[0,\pi/2]$, so $|T_m| \le \pi/x$ for every m.

Let $K = \lfloor 1/x \rfloor$. For $k \le K$ use $|\sin(kx)| \le kx$, which gives

$$\sum_{k=1}^{\min(K,M)}\frac{|\sin(kx)|}{k} \le Kx \le 1\,.$$

For $k > K$, and assuming $M > K$ since otherwise there is nothing left, summation by parts against $T_k - T_{k-1} = \sin(kx)$ gives

$$\sum_{k=K+1}^{M} \frac{\sin(kx)}{k} = \frac{T_M}{M} - \frac{T_K}{K+1} + \sum_{k=K+1}^{M-1} T_k \left(\frac{1}{k} - \frac{1}{k+1} \right) ,$$

in which the coefficients $1/k - 1/(k+1)$ are positive and telescope to $1/(K+1) - 1/M$. Bounding every $|T_k|$ by π/x, the modulus of the right-hand side is at most

$$\frac{\pi}{x} \left(\frac{1}{M} + \frac{1}{K+1} + \frac{1}{K+1} - \frac{1}{M} \right) = \frac{2\pi}{x\,(K+1)} < 2\pi ,$$

the last step because $K + 1 > 1/x$. Adding the two ranges gives Equation (17.20). □

Lemma 17.15 (A polynomial whose partial sum spikes at the origin)**.** *For integers $1 \le N < n$ put*

$$Q_{N,n}(x) := 2\sin(nx) \sum_{k=1}^{N} \frac{\sin(kx)}{k} = \sum_{k=1}^{N} \frac{\cos\left[(n-k)x\right] - \cos\left[(n+k)x\right]}{k} . \tag{17.22}$$

Then $Q_{N,n}$ is a real 2π-periodic trigonometric polynomial, and every frequency m occurring in it satisfies $n - N \le |m| \le n + N$. Moreover

$$|Q_{N,n}(x)| \le 2\,(1 + 2\pi) , \qquad Q_{N,n}(0) = 0 , \qquad S_n Q_{N,n}(0) = \sum_{k=1}^{N} \frac{1}{k} \ge \ln N , \tag{17.23}$$

the first for every real x.

Rests on Lemma 17.14 and Definition 17.1.

Proof. *Derives Lemma 17.15.*

The second expression in Equation (17.22) is the first, term by term, by $2\sin(nx)\sin(kx) = \cos\left[(n-k)x\right] - \cos\left[(n+k)x\right]$. It writes $Q_{N,n}$ as a combination of $\cos(mx)$ for $m \in \{n-N, \dots, n-1\} \cup \{n+1, \dots, n+N\}$, all positive because $N < n$; since $\cos(mx) = \frac{1}{2}\left(\mathrm{e}^{\mathrm{i}mx} + \mathrm{e}^{-\mathrm{i}mx}\right)$, the frequencies present are $\pm m$ for those m, and each satisfies $n - N \le |m| \le n + N$.

The bound in Equation (17.23) is Equation (17.20) multiplied by $|2\sin(nx)| \le 2$, and $Q_{N,n}(0) = 0$ because every $\sin(kx)$ vanishes there. Finally the symmetric partial sum S_n of Definition 17.1 retains exactly the frequencies with $|m| \le n$: of the terms just listed it keeps those with $m = n - k$ and discards those with $m = n + k$, so

$$S_n Q_{N,n}(x) = \sum_{k=1}^{N} \frac{\cos\left[(n-k)x\right]}{k} ,$$

which at $x = 0$ is the harmonic sum $\sum_{k=1}^{N} 1/k$; comparison with $\int_1^{N+1} \mathrm{d}t/t$ bounds it below by $\ln(N+1) > \ln N$. □

Proposition 17.16 (An explicit continuous function with a divergent Fourier series)**.** *Put $N_j = 2^{j^3}$ and $n_j = 2N_j$ for $j \ge 1$, and*

$$f(x) := \sum_{j=1}^{\infty} \frac{1}{j^2}\, Q_{N_j,n_j}(x) \tag{17.24}$$

with $Q_{N,n}$ as in Equation (17.22). Then f is continuous and 2π-periodic, and

$$S_{n_j} f(0) = \frac{1}{j^2} \sum_{k=1}^{N_j} \frac{1}{k} \ge j \ln 2 \longrightarrow \infty , \tag{17.25}$$

so its Fourier series diverges at the origin. This proves Theorem 17.13 without appeal to the uniform boundedness principle.

Rests on Lemma 17.15 and Definition 17.1.

Proof. *Derives Proposition 17.16.*

Continuity. Each term of Equation (17.24) is a trigonometric polynomial, hence continuous and 2π-periodic, and by Equation (17.23) it is bounded in modulus by $2(1+2\pi)/j^2$. Since $\sum_j j^{-2}$ converges, the Weierstrass M-test makes the convergence uniform, and a uniform limit of continuous periodic functions is continuous and periodic.

The coefficients are the termwise ones. Write f_J for the J-th partial sum of Equation (17.24). For any $m \in \mathbb{Z}$, Equation (17.3) gives

$$|c_m(f) - c_m(f_J)| = \left| \frac{1}{2\pi} \int_{-\pi}^{\pi} [f(x) - f_J(x)]\, \mathrm{e}^{-\mathrm{i}mx}\, \mathrm{d}x \right| \le \sup_x |f - f_J| \longrightarrow 0\,,$$

so $c_m(f) = \sum_j j^{-2} c_m\big(Q_{N_j,n_j}\big)$. No rearrangement is involved, because the next paragraph shows at most one summand is nonzero for each m.

The blocks occupy disjoint frequency bands. By Lemma 17.15 the j-th term occupies the frequencies m with $N_j \le |m| \le 3N_j$, since $n_j - N_j = N_j$ and $n_j + N_j = 3N_j$. For $i > j$,

$$\frac{N_i}{N_j} \ge \frac{N_{j+1}}{N_j} = 2^{(j+1)^3 - j^3} = 2^{3j^2+3j+1} \ge 2^7 > 3\,,$$

so the bands are pairwise disjoint and move upward with j.

The partial sum at the origin. Fix j and apply S_{n_j}, which keeps the frequencies with $|m| \le n_j = 2N_j$. A block $i < j$ lies entirely below the cut, since $3N_i \le 3N_{j-1} < N_j < 2N_j$, and contributes $i^{-2} Q_{N_i,n_i}(0) = 0$ by Equation (17.23). A block $i > j$ lies entirely above it, since $N_i > 3N_j > 2N_j$, and contributes nothing. The block $i = j$ contributes $j^{-2} S_{n_j} Q_{N_j,n_j}(0) = j^{-2} \sum_{k=1}^{N_j} k^{-1}$, again by Equation (17.23), and that sum is at least $\ln N_j = j^3 \ln 2$. This is Equation (17.25). Since $\sup_N |S_N f(0)| = \infty$, the series cannot converge at $x = 0$. □

Remark 17.17 (What the explicit example costs and buys). The soft proof of Theorem 17.13 is shorter and says more: it shows that *most* continuous functions, in the sense of Baire category, have divergent Fourier series somewhere, whereas Proposition 17.16 exhibits one. What the explicit construction buys is independence: the treatise nowhere proves the uniform boundedness principle, and a chapter that leaned on it would be resting a stated theorem on an unstated one. The two arguments share their mechanism — the harmonic sum $\sum_{k \le N} 1/k$ of Equation (17.23) is the same logarithm that Equation (17.19) produces — which is why the size of the Lebesgue constants is the real content of the theorem either way.

Two further results mark the boundary of the subject and are stated without proof, at the depth cap of Part II. Kolmogorov constructed an absolutely integrable function whose Fourier series diverges at *every* point [548] — so integrability alone guarantees nothing pointwise. Carleson proved that for square-integrable functions the series converges at almost every point [1327], which settles the case relevant to physics, since the states of Chapter 12 and the finite-energy signals of Section 17.2.2 are square integrable. The theorem was extended shortly afterwards to L^p for every $p > 1$; the endpoint $p = 1$ is Kolmogorov's counterexample, so the classification is complete.

Remark 17.18 (Two theorems quoted, and not proved). Carleson's theorem [1327] and Kolmogorov's example [548] are the only statements of this chapter that carry no derivation, and the omission is a decision rather than a debt. Carleson's argument, and every later proof of the same theorem, turns on the boundedness of a maximal operator obtained by decomposing the partial-sum operator over dyadic families in frequency and discarding

an exceptional set in time; the estimates that control it are the subject matter of a course in harmonic analysis, none of that machinery appears anywhere in this treatise, and introducing it to serve one statement would unbalance Part II. Kolmogorov's counterexample is a construction of the same explicit kind as Proposition 17.16, but far more delicate: the function must be arranged so that the partial sums are unbounded at every point at once. Both are quoted because they fix the boundary of the subject, and a reader needs to know where it lies. Nothing in this chapter, and nothing in the physical parts that consume it, uses either: the working statements are Theorem 17.9, Corollary 17.11, Theorem 17.22 and the mean-square convergence of Section 17.2.2, each proved in full here.

Remark 17.19 (What physics actually needs). None of the pathology touches the working use of Fourier series. The signals of the experimental chapters are square integrable, so Proposition 17.4 and Section 17.2.2 give convergence in the mean — which is the sense in which energies, spectra and expectation values are computed — and the pieces of them that are piecewise smooth converge pointwise by Theorem 17.9. The counterexamples matter because they say what may *not* be assumed: that a continuous waveform is reconstructed pointwise by its harmonics is false, and any argument that needs it needs a hypothesis.

17.1.3 The Gibbs phenomenon and summability

At a jump, Theorem 17.9 promises convergence to the midpoint at each fixed point, but says nothing uniform. Something specific and permanent goes wrong nearby.

Theorem 17.20 (Overshoot at a jump)**.** *Let $f(x) = \operatorname{sgn}(\sin x)$, the odd square wave of Example 17.5 with $T = 2\pi$, whose jump at the origin has height 2. Then the partial sum $S_{2N+1}f$ attains its first maximum to the right of the origin at $x_N = \pi/(2N+2)$, and*

$$\lim_{N\to\infty} S_{2N+1}f(x_N) = \frac{2}{\pi}\int_0^{\pi} \frac{\sin v}{v}\,\mathrm{d}v = \frac{2}{\pi}\,\mathrm{Si}(\pi) = 1.178979\ldots \tag{17.26}$$

The partial sums therefore overshoot the limiting value 1 by $0.178979\ldots$, that is by $8.949\,\%$ of the jump height, and the overshoot does not diminish with N: it merely migrates toward the discontinuity, since $x_N \to 0$.

Rests on Equation (17.11) and Theorem 7.38.

Derivation. Derives Theorem 17.20.

By Equation (17.11) the partial sum through the $(2N+1)$-th harmonic is

$$S_{2N+1}f(x) = \frac{4}{\pi}\sum_{k=0}^{N}\frac{\sin\left[(2k+1)x\right]}{2k+1}, \qquad \text{so} \qquad \frac{\mathrm{d}}{\mathrm{d}x}S_{2N+1}f(x) = \frac{4}{\pi}\sum_{k=0}^{N}\cos\left[(2k+1)x\right].$$

The finite sum is geometric: $\sum_{k=0}^{N} \mathrm{e}^{\mathrm{i}(2k+1)x} = \mathrm{e}^{\mathrm{i}x}\left(1-\mathrm{e}^{2\mathrm{i}(N+1)x}\right)/\left(1-\mathrm{e}^{2\mathrm{i}x}\right) = \mathrm{e}^{\mathrm{i}(N+1)x}\sin\left[(N+1)x\right]/\sin x$, whose real part is $\sin\left[2(N+1)x\right]/(2\sin x)$. Hence

$$\frac{\mathrm{d}}{\mathrm{d}x}S_{2N+1}f(x) = \frac{2}{\pi}\,\frac{\sin\left[2(N+1)x\right]}{\sin x}. \tag{17.27}$$

For $0 < x < \pi/(2N+2)$ the right-hand side is positive and it changes sign at $x_N = \pi/(2N+2)$, so that point is the first maximum. Integrating Equation (17.27) from 0, where the partial sum vanishes, and substituting $v = 2(N+1)x$,

$$S_{2N+1}f(x_N) = \frac{2}{\pi}\int_0^{x_N}\frac{\sin\left[2(N+1)x\right]}{\sin x}\,\mathrm{d}x = \frac{2}{\pi}\int_0^{\pi}\frac{\sin v}{2(N+1)\sin\left[v/(2(N+1))\right]}\,\mathrm{d}v\,.$$

As $N\to\infty$ the denominator tends to v uniformly on $[0,\pi]$ — indeed $0 \le v - 2(N+1)\sin[v/(2(N+1))] \le v^3/(24(N+1)^2)$ from the alternating Taylor bound for the sine (Theorem 7.38) — so the integrand converges uniformly to $\sin v/v$, and the limit is Equation (17.26). Numerically $\mathrm{Si}(\pi) = 1.851937\ldots$, giving $1.178979\ldots$, and the excess over 1 divided by the jump height 2 is $8.949\,\%$. □

Remark 17.21 (The name is wrong, and the record says so). The overshoot was described, computed and published by Henry Wilbraham in 1848 [124], half a century before the exchange in *Nature* in which Josiah Willard Gibbs — correcting his own earlier letter — gave the value quoted above [283]. The customary name "Gibbs phenomenon" therefore misattributes the discovery. This treatise keeps the customary name, because a reader searching the literature needs it, and records the misattribution here rather than passing it on silently.

The overshoot is not a defect of the coefficients, which are exactly right, but of the *summation method*: the sharp truncation $\sum_{|n|\le N}$ multiplies the spectrum by a rectangular window, and Lemma 17.6 shows this is equivalent to smoothing f with an oscillating, sign-changing kernel. Change the window and the pathology goes away.

Theorem 17.22 (Fejér). *Let $\sigma_N f = \frac{1}{N+1}\sum_{n=0}^{N} S_n f$ be the Cesàro average of the partial sums. Then*

$$\sigma_N f(x) = \frac{1}{2\pi}\int_{-\pi}^{\pi} f(x-u)\,K_N(u)\,\mathrm{d}u\,, \qquad K_N(u) = \frac{1}{N+1}\left(\frac{\sin\left[(N+1)u/2\right]}{\sin(u/2)}\right)^2, \tag{17.28}$$

and if f is continuous and 2π-periodic then $\sigma_N f \to f$ uniformly [310].

Rests on Lemma 17.6 and Theorem 7.25.

Proof. *Derives Theorem 17.22.*

Averaging Equation (17.14) gives Equation (17.28) with $K_N = \frac{1}{N+1}\sum_{n=0}^{N} D_n$. For the closed form multiply by $\sin^2(u/2)$ and use $\sin\left[(n+\frac12)u\right]\sin(u/2) = \frac12\left[\cos(nu) - \cos((n+1)u)\right]$; the sum telescopes to $\frac12\left[1-\cos((N+1)u)\right] = \sin^2\left[(N+1)u/2\right]$, which is the assertion.

The closed form exhibits three properties. (i) $K_N \ge 0$, being a square. (ii) $\frac{1}{2\pi}\int_{-\pi}^{\pi} K_N = 1$, by averaging Equation (17.13). (iii) For $\delta \le |u| \le \pi$, $K_N(u) \le \left[(N+1)\sin^2(\delta/2)\right]^{-1}$, which tends to 0 uniformly on that set. A family with these three properties is an *approximate identity*, and the standard argument now applies: given $\varepsilon > 0$, uniform continuity of f on the compact circle (Theorem 7.25) gives δ with $|f(x-u) - f(x)| < \varepsilon/2$ for $|u| < \delta$, uniformly in x. Then, using (ii) to write $f(x) = \frac{1}{2\pi}\int K_N(u) f(x)\,\mathrm{d}u$,

$$|\sigma_N f(x) - f(x)| \le \frac{1}{2\pi}\int_{|u|<\delta} |f(x-u)-f(x)|\,K_N(u)\mathrm{d}u + \frac{1}{2\pi}\int_{\delta\le|u|\le\pi} 2\,\|f\|_\infty\,K_N(u)\,\mathrm{d}u\,,$$

where (i) was used to drop the absolute value on K_N. The first term is below $\varepsilon/2$ by (ii); the second is below $\varepsilon/2$ for N large by (iii). The bound is uniform in x. □

Corollary 17.23 (Density, uniqueness, and no overshoot). *(a) Every continuous periodic function is a uniform limit of trigonometric polynomials. (b) If all Fourier coefficients of a continuous periodic f vanish, then $f \equiv 0$; hence the coefficients determine the function. (c) $\min f \le \sigma_N f \le \max f$ pointwise, so the Cesàro means exhibit no overshoot whatever at a jump.*

Rests on Theorem 17.22.

Proof. *Derives Corollary 17.23.*

(a) $\sigma_N f$ is a trigonometric polynomial of degree N. (b) If every $c_n = 0$ then every $S_n f = 0$, so $\sigma_N f = 0$, and Theorem 17.22 gives $f = \lim \sigma_N f = 0$. (c) $K_N \ge 0$ with unit average, so Equation (17.28) exhibits $\sigma_N f(x)$ as a weighted average of values of f, which cannot leave the range of f. □

Part (b) is what closes Theorem 17.3 into a genuine one-to-one correspondence, and it is used in Section 17.2.2 to prove completeness. Part (c) is the practical lesson: the overshoot belongs to the rectangular window and not to the data.

Example 17.24 (Ringing in a band-limited reproduction)**.** A 1.0 kHz square wave passed through a system with a sharp cutoff at 20 kHz retains harmonics up to the nineteenth, i.e. $N = 9$ in Theorem 17.20. Its reconstruction still overshoots by 9 % of the step, in a ripple whose first peak sits $x_N/\omega_1 = 1/\left[4(N+1)\nu_1\right] = 25\,\mu\text{s}$ after the edge. Increasing the cutoff moves the ripple closer to the edge and makes it narrower; it never makes it smaller. Tapering the cutoff instead — which is what a window function does, and what Theorem 17.22 does in its extreme form — trades the ripple for a slower edge. The same trade reappears as spectral leakage in Section 17.5.2 and as the choice of apodisation in every Fourier-transform spectrometer.

17.1.4 Series in several variables

Everything above concerns a function of one variable. A field periodic in space, a motion on a torus, a crystal potential: each is periodic with respect to a lattice in $\mathbb{R}^n$, and the expansion it admits is indexed by the reciprocal lattice. Nothing new has to be proved for it, which is exactly the point of stating it.

Definition 17.25 (Multiple Fourier series)**.** Let $\Lambda \subset \mathbb{R}^n$ be a lattice with primitive vectors $\boldsymbol{a}_1, \dots, \boldsymbol{a}_n$, let C be a primitive cell of volume $|C|$, and let Λ^* be the reciprocal lattice generated by the $\boldsymbol{b}_j$ with $\boldsymbol{a}_i \cdot \boldsymbol{b}_j = 2\pi\delta_{ij}$. For f square integrable on C and Λ-periodic, the *multiple Fourier coefficients* are

$$c_{\boldsymbol{G}} = \frac{1}{|C|}\int_C f(\boldsymbol{x})\, \mathrm{e}^{-\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{x}}\, \mathrm{d}^n x\,, \qquad \boldsymbol{G} \in \Lambda^*\,, \tag{17.29}$$

and the associated series is $\sum_{\boldsymbol{G}\in\Lambda^*} c_{\boldsymbol{G}}\, \mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{x}}$. If f carries an SI unit, so does every $c_{\boldsymbol{G}}$; the exponent is a pure number because $\boldsymbol{G}$ carries $1/\mathrm{m}$.

Rests on Definition 17.1 and Corollary 17.49.

Proposition 17.26 (The lattice harmonics are an orthonormal basis)**.** *The functions $e_{\boldsymbol{G}}(\boldsymbol{x}) = |C|^{-1/2}\, \mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{x}}$, $\boldsymbol{G}$ running over Λ^*, form an orthonormal basis of $L^2(C)$. Consequently, for Λ-periodic square-integrable f: the coefficients Equation (17.29) determine f up to a null set; the series converges to f in the mean square; and Parseval's identity holds,*

$$\frac{1}{|C|}\int_C |f|^2\, \mathrm{d}^n x = \sum_{\boldsymbol{G}\in\Lambda^*} |c_{\boldsymbol{G}}|^2\,. \tag{17.30}$$

If in addition $\sum_{\boldsymbol{G}} |c_{\boldsymbol{G}}| < \infty$, the series converges absolutely and uniformly, and its sum is continuous and equal to f.

Rests on Definition 17.25 and Theorems 12.30 and 17.22.

Proof. *Derives Proposition 17.26.*

Change variables to the lattice coordinates $\boldsymbol{x} = u^i \boldsymbol{a}_i$ with $u^i \in [0,1)$, in which C is the unit cube and $\boldsymbol{G}\cdot\boldsymbol{x} = 2\pi\,\ell_i u^i$ for $\boldsymbol{G} = \ell_i \boldsymbol{b}_i$ with integer ℓ_i. The substitution is linear, so its Jacobian is the constant $|C|$ and cancels the prefactor of Equation (17.29); no change-of-variables theorem beyond the scaling of a volume by a determinant is used. The integral Equation (17.29) then factorises into n copies of the one-dimensional integral of Lemma 17.2, so that

$$\frac{1}{|C|}\int_C \mathrm{e}^{\mathrm{i}(\boldsymbol{G}-\boldsymbol{G}')\cdot\boldsymbol{x}}\, \mathrm{d}^n x = \prod_{i=1}^{n} \delta_{\ell_i \ell'_i}\,, \tag{17.31}$$

and the family $\{e_{\boldsymbol{G}}\}$ is orthonormal in $L^2(C)$.

For completeness, take the product of n copies of the Fejér kernel of Equation (17.28), one in each coordinate u^i, and let $\sigma_N f$ be the corresponding average of f. The product kernel inherits the three properties established in the proof of Theorem 17.22: it is non-negative, its

average over the cube is 1, and outside a cube of side 2δ it is bounded by a quantity tending to zero, because at least one factor is then evaluated at an argument of modulus at least δ while the others integrate to at most 1. It is therefore an approximate identity, and the argument of that proof, run with the cube in place of the circle and with uniform continuity supplied by Theorem 7.25 on the compact torus, gives $\sigma_N f \to f$ uniformly for continuous Λ-periodic f. Each $\sigma_N f$ is a finite combination of the $e_{\boldsymbol{G}}$, so their span is dense in the continuous periodic functions for the supremum norm and hence, C having finite volume, in $L^2(C)$ (Remark 17.28). So the orthonormal family is total, which by Theorem 12.30 makes it a basis, and that theorem supplies the mean-square convergence and Equation (17.30); the uniqueness statement is Equation (17.30) applied to a difference.

The last claim is the Weierstrass criterion: each term has modulus $|c_{\boldsymbol{G}}|$, so an absolutely convergent sum of the moduli forces uniform convergence of a series of continuous functions. Its sum is therefore continuous, and it agrees with f outside a null set because it also converges in the mean square; if f is itself continuous the two agree at every point. □

Remark 17.27 (Where the several-variable case is used). Three places, and in each the value of Proposition 17.26 is that it costs nothing. A quasiperiodic motion with n incommensurate frequencies is by construction a function on an n-torus evaluated along a straight line, so its time dependence is a multiple Fourier series and its power sits on the countable set of integer combinations of the frequencies — which is what Chapter 32 needs when it distinguishes quasiperiodicity from chaos by the presence of a continuous spectral component. A one-electron potential in a crystal is Λ-periodic, and Equation (17.29) defines its structure factors (Chapter 126). And Corollary 17.49 is the Poisson-summation counterpart of the same statement, relating a lattice sum to a sum over Λ^*.

17.2 The Fourier transform

Remark 17.28 (Analytical inputs quoted, not proved). From here on three standard tools of integration theory are used freely and are *not* developed in this treatise, whose integral is the Riemann–Darboux integral of Section 7.7: the Fubini–Tonelli theorem on exchanging the order of a double integral, the dominated convergence theorem, and the density of smooth rapidly decreasing functions in the absolutely integrable and square-integrable classes. Each is quoted explicitly at the point of use rather than absorbed silently. Everything else in this chapter is proved.

17.2.1 Definition and inversion

Let f be absolutely integrable on the whole line and, for the moment, supported in $[-T/2, T/2]$. Its Fourier series on that interval, with $\omega_1 = 2\pi/T$ and $\omega_n = n\omega_1$, is built from the coefficients Equation (17.3). Introduce

$$\hat f(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(t)\, \mathrm{e}^{-\mathrm{i}\omega t}\, \mathrm{d}t\,, \tag{17.32}$$

so that $c_n = \sqrt{2\pi}\, \hat f(\omega_n)/T$, and note that $\sqrt{2\pi}/T = \Delta\omega/\sqrt{2\pi}$ with $\Delta\omega = \omega_{n+1} - \omega_n = \omega_1$. The synthesis formula Equation (17.4) then reads

$$f(t) = \frac{1}{\sqrt{2\pi}} \sum_{n=-\infty}^{\infty} \hat f(\omega_n)\, \mathrm{e}^{\mathrm{i}\omega_n t}\, \Delta\omega\,, \tag{17.33}$$

which is a Riemann sum for $\frac{1}{\sqrt{2\pi}} \int \hat f(\omega) \mathrm{e}^{\mathrm{i}\omega t} \mathrm{d}\omega$ with mesh $\Delta\omega = 2\pi/T \to 0$ as the interval is enlarged. This is the passage left as a pending derivation at Equation (9.121); as an argument it is only heuristic, because the summand depends on T as well as on the mesh,

and Theorem 17.32 below supplies the proof. The discrete spectrum of a periodic function becomes a continuous spectrum, and the spacing $\Delta\nu = 1/T$ of the harmonics — in Hz for a signal in time — becomes the resolution of the transform, a fact that returns quantitatively in Section 17.5.2.

Definition 17.29 (Fourier transform; the treatise convention)**.** For absolutely integrable f the *Fourier transform* is Equation (17.32), also written $\mathcal{F}f = \hat{f}$, with the *inverse transform*

$$\left(\mathcal{F}^{-1}g\right)(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} g(\omega)\, \mathrm{e}^{+\mathrm{i}\omega t}\, \mathrm{d}\omega\,. \tag{17.34}$$

The symmetric factor $1/\sqrt{2\pi}$ and the sign $\mathrm{e}^{-\mathrm{i}\omega t}$ in the analysis kernel are fixed for the whole treatise, matching Equation (9.121). For a function of position the pair is written with the wavenumber k in place of ω and $\mathrm{e}^{-\mathrm{i}kx}$ in place of $\mathrm{e}^{-\mathrm{i}\omega t}$; if x is in m then k is in 1/m, and if t is in s then ω is in rad/s and $\nu = \omega/2\pi$ in Hz. The transform carries the SI unit of f multiplied by that of t: the transform of a voltage record in V is in V s.

Other normalisations are in use and none is wrong; what is fatal is mixing them, since the factors of 2π move between the transform, the inverse and the convolution theorem. Table 17.1 is the dictionary.

Table 17.1: The three conventions in common use, and the translation between them. Writing $\hat{f}$ for the symmetric transform of Equation (17.32), F for the asymmetric one and $\tilde{f}$ for the ordinary-frequency one, the dictionary is $\hat{f}(\omega) = F(\omega)/\sqrt{2\pi} = \tilde{f}(\omega/2\pi)/\sqrt{2\pi}$. Only the first and third are unitary, so only they make Plancherel's theorem (Theorem 17.36) free of stray factors.

Convention	Analysis	Synthesis	Used by
Symmetric, angular frequency (this treatise)	$\dfrac{1}{\sqrt{2\pi}}\int f\,\mathrm{e}^{-\mathrm{i}\omega t}\mathrm{d}t$	$\dfrac{1}{\sqrt{2\pi}}\int \hat{f}\,\mathrm{e}^{\mathrm{i}\omega t}\mathrm{d}\omega$	mathematical physics
Asymmetric, angular frequency	$\displaystyle\int f\,\mathrm{e}^{-\mathrm{i}\omega t}\mathrm{d}t$	$\dfrac{1}{2\pi}\int F\,\mathrm{e}^{\mathrm{i}\omega t}\mathrm{d}\omega$	field theory, solid state
Ordinary frequency	$\displaystyle\int f\,\mathrm{e}^{-2\pi\mathrm{i}\nu t}\mathrm{d}t$	$\displaystyle\int \tilde{f}\,\mathrm{e}^{2\pi\mathrm{i}\nu t}\mathrm{d}\nu$	signal processing

Proposition 17.30 (Elementary properties)**.** *Let f, g be absolutely integrable, $a \in \mathbb{R}$, $\lambda \neq 0$. Then $\hat{f}$ is bounded, with $\left\|\hat{f}\right\|_\infty \le \|f\|_1/\sqrt{2\pi}$, uniformly continuous, and $\hat{f}(\omega) \to 0$ as $|\omega| \to \infty$. Moreover*

$$\widehat{f(\cdot - a)}(\omega) = \mathrm{e}^{-\mathrm{i}\omega a}\,\hat{f}(\omega) \qquad \textit{(translation)}\,, \tag{17.35}$$

$$\widehat{\mathrm{e}^{\mathrm{i}\omega_0 \cdot} f}(\omega) = \hat{f}(\omega - \omega_0) \qquad \textit{(modulation)}\,, \tag{17.36}$$

$$\widehat{f(\lambda\,\cdot)}(\omega) = \frac{1}{|\lambda|}\,\hat{f}\!\left(\frac{\omega}{\lambda}\right) \qquad \textit{(scaling)}\,, \tag{17.37}$$

$$\widehat{f'}(\omega) = \mathrm{i}\omega\,\hat{f}(\omega) \qquad \textit{(differentiation)}\,, \tag{17.38}$$

$$\widehat{tf}(\omega) = \mathrm{i}\,\frac{\mathrm{d}\hat{f}}{\mathrm{d}\omega}(\omega) \qquad \textit{(multiplication by } t)\,. \tag{17.39}$$

the last two under the hypotheses that f', respectively $tf(t)$, is itself absolutely integrable and that f vanishes at infinity.

Rests on Definition 17.29, Lemma 17.7, and Equation (7.28).

Proof. *Derives Proposition 17.30.*

The bound is immediate from $\left|\hat f\right| \le \frac{1}{\sqrt{2\pi}}\int|f|$. Uniform continuity: $\left|\hat f(\omega+h)-\hat f(\omega)\right| \le \frac{1}{\sqrt{2\pi}}\int|f(t)|\left|\mathrm{e}^{-\mathrm{i}ht}-1\right|\mathrm{d}t$, which tends to zero with h by dominated convergence, independently of ω. The decay is Lemma 17.7 extended to the line as noted in its proof. Equation (17.35) and Equation (17.36) are the substitutions $t\mapsto t+a$ and a regrouping of exponentials; Equation (17.37) is the substitution $s=\lambda t$, the modulus arising because the limits reverse when $\lambda<0$. For Equation (17.38), integrate by parts (Equation (7.28)); the boundary term $\left[f\mathrm{e}^{-\mathrm{i}\omega t}\right]_{-\infty}^{\infty}$ vanishes because $f\to 0$. For Equation (17.39), differentiate Equation (17.32) under the integral sign, legitimate by dominated convergence when $tf(t)$ is absolutely integrable, which brings down a factor $-\mathrm{i}t$. □

Equation (17.38) is the reason the transform exists as a tool: it converts $\mathrm{d}/\mathrm{d}t$ into multiplication by $\mathrm{i}\omega$, hence a constant-coefficient linear differential operator into a polynomial, and a linear partial differential equation into an algebraic one in the transformed variable. That is precisely the manoeuvre of Section 10.2.3, and it is the pending derivative rule Equation (9.122), now proved.

Example 17.31 (The three standard pairs)**.** *(i) Rectangle and sinc.* For the rectangular pulse $f=\mathbf{1}_{\{|t|\le\tau/2\}}$ of duration τ,

$$\hat f(\omega)=\frac{1}{\sqrt{2\pi}}\int_{-\tau/2}^{\tau/2}\mathrm{e}^{-\mathrm{i}\omega t}\,\mathrm{d}t=\frac{\tau}{\sqrt{2\pi}}\,\operatorname{sinc}\!\left(\frac{\omega\tau}{2}\right),\qquad \operatorname{sinc}x=\frac{\sin x}{x}. \tag{17.40}$$

The first zero sits at $\omega=2\pi/\tau$, i.e. at $\nu=1/\tau$: a pulse of duration $1.0\,\mu\mathrm{s}$ has its first spectral null at $1.0\,\mathrm{MHz}$.

(ii) Exponential and Lorentzian. For the causal decay $f(t)=\mathrm{e}^{-\alpha t}$ for $t>0$ and 0 for $t<0$, with $\alpha>0$ in $1/\mathrm{s}$,

$$\hat f(\omega)=\frac{1}{\sqrt{2\pi}}\,\frac{1}{\alpha+\mathrm{i}\omega},\qquad \left|\hat f(\omega)\right|^2=\frac{1}{2\pi}\,\frac{1}{\alpha^2+\omega^2}, \tag{17.41}$$

a Lorentzian of full width at half maximum $\Delta\omega=2\alpha$, i.e. $\Delta\nu=\alpha/\pi$. This is the natural line shape of a decaying emitter and the origin of the linewidths measured in Chapter 90.

(iii) Gaussian and Gaussian. For $f(t)=\mathrm{e}^{-t^2/(2a^2)}$, Equation (17.38) and Equation (17.39) give $\mathrm{i}\omega\hat f=\widehat{f'}=-a^{-2}\widehat{tf}=-\mathrm{i}a^{-2}\hat f'$, i.e. the first-order equation $\hat f'=-a^2\omega\hat f$ with $\hat f(0)=a$ from the Gauss integral. Hence

$$\widehat{\mathrm{e}^{-t^2/(2a^2)}}(\omega)=a\,\mathrm{e}^{-a^2\omega^2/2}, \tag{17.42}$$

a Gaussian of width $1/a$ in ω for a Gaussian of width a in t. The Gaussian is thus an eigenfunction of the transform up to scaling, and Theorem 17.43 will show it is the unique minimiser of the bandwidth product.

Rests on Definition 17.29 and Proposition 17.30.

Theorem 17.32 (Fourier inversion)**.** *Let f be absolutely integrable and continuous, and suppose $\hat f$ is also absolutely integrable. Then for every t*

$$f(t)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\hat f(\omega)\,\mathrm{e}^{\mathrm{i}\omega t}\,\mathrm{d}\omega. \tag{17.43}$$

Rests on Definition 17.29 and Equation (17.42).

Proof. *Derives Theorem 17.32.*

Fourier stated the integral theorem in 1822 [72]; the proof below is the Gaussian-regularisation argument of Titchmarsh's monograph [802]. For $\varepsilon > 0$ set

$$I_\varepsilon(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \hat f(\omega)\, \mathrm{e}^{-\varepsilon\omega^2/2}\, \mathrm{e}^{\mathrm{i}\omega t}\, \mathrm{d}\omega\,.$$

Insert Equation (17.32). The double integral converges absolutely, because $|f(s)|\,\mathrm{e}^{-\varepsilon\omega^2/2}$ is integrable over the (s,ω) plane, so Fubini's theorem permits doing the ω integral first:

$$I_\varepsilon(t) = \int_{-\infty}^{\infty} f(s)\, \left[\frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{-\varepsilon\omega^2/2}\mathrm{e}^{\mathrm{i}\omega(t-s)}\mathrm{d}\omega\right] \mathrm{d}s = \int_{-\infty}^{\infty} f(s)\, g_\varepsilon(t-s)\, \mathrm{d}s\,,$$

where, by the Gaussian pair Equation (17.42) read with $a^2 = 1/\varepsilon$,

$$g_\varepsilon(u) = \frac{1}{\sqrt{2\pi\varepsilon}}\, \mathrm{e}^{-u^2/(2\varepsilon)}\,, \qquad \int_{-\infty}^{\infty} g_\varepsilon(u)\,\mathrm{d}u = 1\,, \qquad g_\varepsilon \ge 0\,.$$

The family g_ε is an approximate identity exactly as in Theorem 17.22: non-negative, of unit mass, and concentrating on $|u| < \delta$ as $\varepsilon \to 0$, since $\int_{|u|\ge\delta} g_\varepsilon \to 0$. Continuity and boundedness of f therefore give $I_\varepsilon(t) \to f(t)$. On the other hand $\left|\hat f(\omega)\mathrm{e}^{-\varepsilon\omega^2/2}\right| \le \left|\hat f(\omega)\right|$, which is integrable by hypothesis, so dominated convergence gives $I_\varepsilon(t) \to \frac{1}{\sqrt{2\pi}}\int \hat f(\omega)\mathrm{e}^{\mathrm{i}\omega t}\mathrm{d}\omega$. Two limits of one sequence, hence Equation (17.43). □

Corollary 17.33 (The transform is injective)**.** *Two continuous absolutely integrable functions with the same transform are equal. Hence a spectrum determines its signal.*
Rests on Theorem 17.32.

Proof. *Derives Corollary 17.33.*

Apply Theorem 17.32 to the difference, whose transform vanishes identically and is trivially integrable. □

17.2.2 Parseval and Plancherel

Theorem 17.34 (Parseval's identity for series)**.** *Let f be T-periodic and square integrable over a period. Then the harmonics are a* complete *orthonormal system: $S_N f \to f$ in mean square, and*

$$\frac{1}{T}\int_{-T/2}^{T/2} |f(t)|^2\,\mathrm{d}t = \sum_{n=-\infty}^{\infty} |c_n|^2 = \frac{|a_0|^2}{4} + \frac{1}{2}\sum_{n=1}^{\infty}\left(|a_n|^2 + |b_n|^2\right)\,. \tag{17.44}$$

More generally $\frac{1}{T}\int f\bar g = \sum_n c_n\overline{d_n}$ for the coefficients c_n of f and d_n of g.
Rests on Lemma 17.2, Proposition 17.4, and Theorem 17.22.

Proof. *Derives Theorem 17.34.*

Suppose first that f is continuous. By Theorem 17.22 the Cesàro means converge uniformly, hence in mean square, and $\sigma_N f$ is a trigonometric polynomial of degree N; by the least-squares property of Proposition 17.4 the partial sum does at least as well,

$$\frac{1}{T}\int |f - S_N f|^2 \le \frac{1}{T}\int |f - \sigma_N f|^2 \le \|f - \sigma_N f\|_\infty^2 \longrightarrow 0\,.$$

Expanding the left-hand side with Lemma 17.2 gives $\frac{1}{T}\int|f|^2 - \sum_{|n|\le N}|c_n|^2 \to 0$, which is Equation (17.44). For general square-integrable f, pick continuous $f_j \to f$ in mean square (density, quoted in Remark 17.28); both sides of Equation (17.44) are continuous in that norm — the right side because $|c_n(f) - c_n(f_j)|$ is controlled by Bessel's inequality Equation (17.10) applied to $f - f_j$ — so the identity passes to the limit. The bilinear form follows by polarisation, replacing f by $f+g$, $f-g$, $f+\mathrm{i}g$, $f-\mathrm{i}g$ in turn. The real form is Equation (17.8) substituted term by term. □

Parseval stated the identity in 1806 for power series, as a formal consequence of multiplying two series and integrating [51]; its reading as the Pythagorean theorem for an orthonormal system — the length of a vector is the root of the sum of the squares of its components — came later, and is the statement completed in the abstract in Chapter 12. It is the relation left pending at Section 9.4.4.

Lemma 17.35 (Multiplication formula)**.** *If f and g are absolutely integrable then*

$$\int_{-\infty}^{\infty} \hat{f}(\omega)\, g(\omega)\, \mathrm{d}\omega = \int_{-\infty}^{\infty} f(t)\, \hat{g}(t)\, \mathrm{d}t\,. \tag{17.45}$$

Rests on Definition 17.29.

Proof. *Derives Lemma 17.35.*

Both sides equal $\frac{1}{\sqrt{2\pi}} \iint f(t) g(\omega) \mathrm{e}^{-\mathrm{i}\omega t} \mathrm{d}t\, \mathrm{d}\omega$, and the double integral converges absolutely since $|f(t)g(\omega)|$ is integrable on the plane; Fubini's theorem exchanges the order. □

Theorem 17.36 (Plancherel)**.** *The Fourier transform, defined by Equation (17.32) on functions that are both absolutely and square integrable, satisfies*

$$\int_{-\infty}^{\infty} |f(t)|^2 \, \mathrm{d}t = \int_{-\infty}^{\infty} \left|\hat{f}(\omega)\right|^2 \, \mathrm{d}\omega\,, \qquad \text{and} \qquad \int f \bar{g}\, \mathrm{d}t = \int \hat{f}\bar{\hat{g}}\, \mathrm{d}\omega\,, \tag{17.46}$$

and extends uniquely to a unitary map of the square-integrable functions onto themselves, whose inverse is the extension of Equation (17.34) [363].

Rests on Definition 17.29 and Theorem 17.32.

Proof. *Derives Theorem 17.36.*

Take first f smooth and rapidly decreasing, so that f and $\hat{f}$ are both absolutely integrable and Theorem 17.32 applies. Then, inserting Equation (17.43) and exchanging the order of integration (Fubini, the double integral converging absolutely),

$$\int |f(t)|^2 \, \mathrm{d}t = \int \overline{f(t)} \left[\frac{1}{\sqrt{2\pi}} \int \hat{f}(\omega) \mathrm{e}^{\mathrm{i}\omega t} \mathrm{d}\omega\right] \mathrm{d}t = \int \hat{f}(\omega) \overline{\left[\frac{1}{\sqrt{2\pi}} \int f(t) \mathrm{e}^{-\mathrm{i}\omega t} \mathrm{d}t\right]}\, \mathrm{d}\omega = \int \left|\hat{f}(\omega)\right|^2 \mathrm{d}\omega\,.$$

So $\mathcal{F}$ is norm preserving on a dense subspace of the square-integrable functions (density quoted in Remark 17.28). A norm-preserving linear map on a dense subspace of a complete space extends uniquely and continuously: if $f_j \to f$ then (f_j) is Cauchy, hence so is $(\hat{f}_j)$ by isometry, hence it converges, and the limit is independent of the approximating sequence because the isometry controls the difference. The extension is again an isometry, and Equation (17.34) extends the same way to a two-sided inverse, since $\mathcal{F}^{-1}\mathcal{F} = \mathrm{id}$ holds on the dense subspace by Theorem 17.32 and passes to the limit. An invertible isometry of a complex inner-product space is unitary, and the polarisation identity turns the norm statement into the inner-product statement. □

The theorem is the relation left pending at Equation (9.123), and it is the single most useful statement in the chapter for physics, because it says that a change to the frequency description conserves the quadratic quantity — energy, probability, power — that the physics is about.

Example 17.37 (Energy spectral density in SI)**.** Let $u(t)$, in V, be the voltage across a resistance R in Ω. The total energy dissipated is

$$E = \int_{-\infty}^{\infty} \frac{u(t)^2}{R}\, \mathrm{d}t = \frac{1}{R} \int_{-\infty}^{\infty} |\hat{u}(\omega)|^2 \, \mathrm{d}\omega = \frac{2}{R} \int_{0}^{\infty} |\hat{u}(\omega)|^2 \, \mathrm{d}\omega\,, \tag{17.47}$$

the last step for real u, where $\hat{u}(-\omega) = \overline{\hat{u}(\omega)}$. Dimensionally $\hat{u}$ is in V s, so $|\hat{u}|^2/R$ is in J s/rad and its integral over rad/s is in J: the quantity $2\,|\hat{u}(\omega)|^2/R$ is the *energy spectral density*, telling how many joules sit in each interval of angular frequency. The one-sided form is why laboratory instruments report positive frequencies only, and the factor 2 is the commonest bookkeeping error in noise budgets.

17.2.3 Tempered distributions

Equation (17.32) needs f to be absolutely integrable, and the functions physics most wants to transform are not: a constant, a plane wave $\mathrm{e}^{\mathrm{i}k_0 x}$, a periodic signal, the Heaviside step. Each has a perfectly definite spectrum in practice — a plane wave is one sharp line — but the integral defining it diverges. Dirac introduced the object that the answer requires, a "function" δ with $\int \delta(x)\varphi(x)\mathrm{d}x = \varphi(0)$, and used it exactly so [646]; Schwartz supplied the theory in which the object is legitimate [971]. The idea is to stop asking what the value of δ is at a point and to define it by what it does to test functions.

Definition 17.38 (Schwartz space and tempered distributions)**.** The *Schwartz space* $\mathcal{S}$ consists of the infinitely differentiable $\varphi : \mathbb{R} \to \mathbb{C}$ such that

$$p_{m,k}(\varphi) = \sup_{t\in\mathbb{R}} |t|^m \left|\varphi^{(k)}(t)\right| < \infty \qquad \text{for all } m, k \geq 0\,, \tag{17.48}$$

that is, functions decreasing faster than any power together with all their derivatives. A *tempered distribution* T is a linear map $\mathcal{S} \to \mathbb{C}$, written $\langle T, \varphi\rangle$, continuous in the sense that $|\langle T,\varphi\rangle| \leq C \sum_{m,k\leq M} p_{m,k}(\varphi)$ for some C and M. Every function of at most polynomial growth defines one by $\langle T_f, \varphi\rangle = \int f\varphi\,\mathrm{d}t$, and $\langle \delta, \varphi\rangle = \varphi(0)$ defines the Dirac distribution.

Proposition 17.39 (The transform preserves $\mathcal{S}$)**.** *If $\varphi \in \mathcal{S}$ then $\hat\varphi \in \mathcal{S}$, and $\mathcal{F}$ is a bijection of $\mathcal{S}$ with inverse Equation (17.34).*

Rests on Definition 17.38, Proposition 17.30, and Theorem 17.32.

Proof. *Derives Proposition 17.39.*

Iterating Equation (17.38) and Equation (17.39), both of which apply because every $t^m\varphi^{(k)}$ is absolutely integrable, gives

$$\omega^k \frac{\mathrm{d}^m\hat\varphi}{\mathrm{d}\omega^m}(\omega) = \frac{(-\mathrm{i})^m}{\mathrm{i}^{\,k}} \left[\widehat{\frac{\mathrm{d}^k}{\mathrm{d}t^k}\,(t^m\varphi)}\right](\omega)\,, \tag{17.49}$$

each application of Equation (17.39) contributing one factor $-\mathrm{i}$ and each application of Equation (17.38) one factor i. The right-hand side is the transform of an absolutely integrable function, hence bounded by Proposition 17.30; so every seminorm Equation (17.48) of $\hat\varphi$ is finite and $\hat\varphi \in \mathcal{S}$. Since φ and $\hat\varphi$ are both absolutely integrable, Theorem 17.32 applies and exhibits Equation (17.34) as a two-sided inverse. □

Definition 17.40 (Transform and derivative of a distribution)**.** For $T \in \mathcal{S}'$ define

$$\left\langle \hat T, \varphi\right\rangle = \langle T, \hat\varphi\rangle\,, \qquad \langle T', \varphi\rangle = -\langle T, \varphi'\rangle\,, \qquad \varphi \in \mathcal{S}\,. \tag{17.50}$$

Both right-hand sides are defined by Proposition 17.39 and by $\varphi' \in \mathcal{S}$, and both are continuous, so $\hat T$ and T' are again tempered distributions.

Rests on Definition 17.38 and Proposition 17.39.

The definition is forced, not chosen: for an ordinary absolutely integrable f, Lemma 17.35 says exactly $\int \hat f\varphi = \int f\hat\varphi$, so Equation (17.50) is the unique extension of the classical transform. The same holds for the derivative, where integration by parts with vanishing boundary terms gives $\int f'\varphi = -\int f\varphi'$.

Proposition 17.41 (The identities physics uses)**.** *In the sense of Definition 17.40,*

$$\hat\delta = \frac{1}{\sqrt{2\pi}}\,, \qquad \hat 1 = \sqrt{2\pi}\,\delta\,, \tag{17.51}$$

$$\widehat{\mathrm{e}^{\mathrm{i}\omega_0 t}} = \sqrt{2\pi}\,\delta(\omega-\omega_0)\,, \qquad \widehat{\cos\omega_0 t} = \sqrt{\frac{\pi}{2}}\,[\delta(\omega-\omega_0)+\delta(\omega+\omega_0)]\,, \tag{17.52}$$

and, as an identity between distributions in $t - t'$,

$$\frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{\mathrm{i}\omega(t-t')}\,\mathrm{d}\omega = \delta(t-t')\,. \tag{17.53}$$

Furthermore $\theta' = \delta$ for the Heaviside step θ, and $\widehat{T'} = \mathrm{i}\omega\hat{T}$ for every tempered T.
Rests on Definition 17.40 and Theorems 7.43 and 17.32.

Proof. *Derives Proposition 17.41.*
$\left\langle \hat{\delta}, \varphi \right\rangle = \langle \delta, \hat{\varphi}\rangle = \hat{\varphi}(0) = \frac{1}{\sqrt{2\pi}}\int \varphi(t)\mathrm{d}t$, which is the action of the constant $1/\sqrt{2\pi}$. Next, $\left\langle \hat{1}, \varphi \right\rangle = \int \hat{\varphi}(\omega)\mathrm{d}\omega = \sqrt{2\pi}\,\varphi(0)$ by Equation (17.43) evaluated at $t = 0$, which is the action of $\sqrt{2\pi}\delta$; this is Equation (17.53) rewritten, since the left side of Equation (17.53) is $\frac{1}{\sqrt{2\pi}}\hat{1}$ evaluated on the difference variable. Equation (17.52) follows by applying the modulation rule Equation (17.36), valid verbatim in the dual pairing, to $\hat{1}$, and the cosine case by $\cos = \frac{1}{2}(\mathrm{e}^{\mathrm{i}\omega_0 t} + \mathrm{e}^{-\mathrm{i}\omega_0 t})$. For the step, $\langle \theta', \varphi\rangle = -\int_0^\infty \varphi'(t)\mathrm{d}t = \varphi(0)$ by the fundamental theorem of calculus (Theorem 7.43) and $\varphi(\infty) = 0$. Finally $\left\langle \widehat{T'}, \varphi \right\rangle = \langle T', \hat{\varphi}\rangle = -\langle T, (\hat{\varphi})'\rangle = -\left\langle T, \widehat{-\mathrm{i}t\varphi} \right\rangle = \left\langle \hat{T}, \mathrm{i}\omega\varphi \right\rangle$, using Equation (17.39). □

Equation (17.53) is the completeness relation of the continuous plane-wave basis. It is what makes the Green's-function constructions of Section 10.3 legitimate — the fundamental solution of a constant-coefficient operator $P(\partial_t)$ is $G(t) = \frac{1}{2\pi}\int \mathrm{e}^{\mathrm{i}\omega t}/P(\mathrm{i}\omega)\,\mathrm{d}\omega$ precisely because $P(\partial_t)G = \delta$ reduces to Equation (17.53) — and it is the normalisation of the non-normalisable scattering states of Chapter 86, whose rigorous home is the rigged triple of Section 12.6.3. Distributional derivatives are likewise what allows a solution of a partial differential equation to have a kink or a shock: that is the weak formulation of Section 10.6, and $\theta' = \delta$ is its smallest example.

Proposition 17.42 (Sokhotski–Plemelj)**.** *As tempered distributions,*

$$\lim_{\varepsilon\to 0^+} \frac{1}{x \pm \mathrm{i}\varepsilon} = \mathrm{PV}\,\frac{1}{x} \mp \mathrm{i}\pi\,\delta(x)\,, \tag{17.54}$$

where the principal value is $\left\langle \mathrm{PV}\,\frac{1}{x}, \varphi \right\rangle = \lim_{\eta\to 0^+}\int_{|x|>\eta} \varphi(x)\,\mathrm{d}x/x$.
Rests on Definition 17.38 and Theorem 17.32.

Proof. *Derives Proposition 17.42.*
Separate real and imaginary parts, $\frac{1}{x\pm\mathrm{i}\varepsilon} = \frac{x}{x^2+\varepsilon^2} \mp \mathrm{i}\frac{\varepsilon}{x^2+\varepsilon^2}$. The imaginary part is π times the Poisson kernel $\frac{1}{\pi}\frac{\varepsilon}{x^2+\varepsilon^2}$, which is non-negative, has unit integral — the substitution $x = \varepsilon s$ gives $\frac{1}{\pi}\int \mathrm{d}s/(1+s^2) = 1$ — and concentrates at the origin, hence is an approximate identity and converges to δ as in Theorem 17.32. For the real part, use oddness to write

$$\int \frac{x\,\varphi(x)}{x^2+\varepsilon^2}\,\mathrm{d}x = \int_0^\infty \frac{x\,[\varphi(x) - \varphi(-x)]}{x^2+\varepsilon^2}\,\mathrm{d}x\,,$$

whose integrand is bounded near 0 by $2\,\|\varphi'\|_\infty\, x^2/(x^2+\varepsilon^2) \le 2\,\|\varphi'\|_\infty$, uniformly in ε; dominated convergence lets $\varepsilon \to 0$ inside, giving $\int_0^\infty [\varphi(x) - \varphi(-x)]\,\mathrm{d}x/x$, which is the principal value. □

Equation (17.54) is the identity behind the causal "$+\mathrm{i}\epsilon$" prescriptions of propagator theory and behind the dispersion relations of Section 17.4.2; it is stated here because it is a statement about distributions and nothing else.

17.2.4 The uncertainty principle

A function and its transform cannot both be sharply localised: this is a theorem about integrals, provable in a page, and it acquires physical content only when the transform variable is given a physical meaning. Both halves are given below, in that order, because conflating them is the commonest confusion in the subject.

Theorem 17.43 (Bandwidth theorem)**.** *Let f be square integrable with $\|f\|_2^2 = \int |f|^2 \,\mathrm{d}t = 1$, and suppose $tf(t)$ and f' are square integrable. Define the centroids and dispersions*

$$\langle t \rangle = \int t\,|f(t)|^2 \,\mathrm{d}t\,, \quad \sigma_t^2 = \int (t-\langle t\rangle)^2\,|f(t)|^2\,\mathrm{d}t\,, \quad \sigma_\omega^2 = \int (\omega - \langle\omega\rangle)^2 \left|\hat f(\omega)\right|^2 \mathrm{d}\omega\,, \tag{17.55}$$

with $\langle\omega\rangle$ defined from $\left|\hat f\right|^2$ in the same way. Then

$$\sigma_t\,\sigma_\omega \geq \frac{1}{2}\,, \tag{17.56}$$

with equality if and only if f is a Gaussian, $f(t) = C\mathrm{e}^{\mathrm{i}\langle\omega\rangle t}\mathrm{e}^{-(t-\langle t\rangle)^2/(4\sigma_t^2)}$.

Rests on Proposition 17.30, Theorem 17.36, and Equation (17.42).

Derivation. *Derives Theorem 17.43.*

Translating t and modulating by $\mathrm{e}^{-\mathrm{i}\langle\omega\rangle t}$ changes neither σ_t nor σ_ω, by Equation (17.35) and Equation (17.36), so assume $\langle t\rangle = \langle\omega\rangle = 0$. By Equation (17.38) and Plancherel Equation (17.46),

$$\sigma_\omega^2 = \int \omega^2 \left|\hat f\right|^2 \mathrm{d}\omega = \int \left|\widehat{f'}\right|^2 \mathrm{d}\omega = \int |f'(t)|^2 \,\mathrm{d}t\,.$$

Now integrate $\frac{\mathrm{d}}{\mathrm{d}t}\left(t\,|f|^2\right) = |f|^2 + t\left(\bar f f' + f\bar f'\right) = |f|^2 + 2t\,\Re\left(\bar f f'\right)$ over the line. The left-hand side integrates to zero, because $t\,|f(t)|^2 \to 0$ at infinity when tf and f are square integrable, so

$$1 = \int |f|^2 \,\mathrm{d}t = -2\int t\,\Re\left(\bar f(t) f'(t)\right)\mathrm{d}t \leq 2\int |tf(t)|\;|f'(t)|\;\mathrm{d}t \leq 2\,\sigma_t\,\sigma_\omega\,,$$

the last step by the Cauchy–Schwarz inequality applied to tf and f'. That is Equation (17.56).

Equality requires equality in Cauchy–Schwarz, i.e. $f'(t) = \lambda\, t\, f(t)$ for a constant λ, and equality in $\Re(\bar f f') \geq -\left|\bar f f'\right|$, which forces λ real and negative. Integrating the first-order equation gives $f(t) = C\mathrm{e}^{\lambda t^2/2}$, a Gaussian; matching $\sigma_t^2 = -1/(2\lambda)$ from Equation (17.42) and undoing the translation and modulation yields the stated form. □

Corollary 17.44 (Duration and bandwidth in SI)**.** *With t in* s *and $\nu = \omega/2\pi$ in* Hz*, Equation (17.56) reads*

$$\sigma_t\,\sigma_\nu \geq \frac{1}{4\pi} \approx 0.0796\,. \tag{17.57}$$

A transform-limited optical pulse of $\sigma_t = 10\,\mathrm{fs}$ therefore has a spectral width of at least $\sigma_\nu = 7.96\,\mathrm{THz}$; at a centre wavelength of $800\,\mathrm{nm}$, where $\nu_0 = c/\lambda_0 = 375\,\mathrm{THz}$, that is about $2\,\%$ of the carrier frequency, so such a pulse cannot be called monochromatic.

Rests on Theorem 17.43 and Equation (17.37).

Proof. *Derives Corollary 17.44.*

$\sigma_\omega = 2\pi\sigma_\nu$ by Equation (17.37) with $\lambda = 2\pi$; substitute in Equation (17.56). The numbers are $1/(4\pi \times 1 \times 10^{-14}\,\mathrm{s}) = 7.96 \times 10^{12}\,\mathrm{Hz}$ and $c/\lambda_0 = 2.998 \times 10^8\,\mathrm{m/s}/800 \times 10^{-9}\,\mathrm{m}$. □

Example 17.45 (Two purely classical consequences)**.** *Natural linewidth.* An emitter whose amplitude decays as $\mathrm{e}^{-t/(2\tau)}$ has, by Equation (17.41) with $\alpha = 1/(2\tau)$, a Lorentzian spectral profile of full width $\Delta\nu = 1/(2\pi\tau)$. For an excited state of lifetime $\tau = 16\,\mathrm{ns}$ — the order of an allowed optical transition — this is $\Delta\nu = 9.9\,\mathrm{MHz}$, the irreducible floor under every measurement in Chapter 90.

Diffraction. A slit of width a multiplies an incident plane wave by a rectangle, so by Equation (17.40) the transmitted amplitude as a function of transverse wavenumber k_x is a sinc with first zero at $k_x = 2\pi/a$. Since $k_x = k\sin\theta$ with $k = 2\pi/\lambda$, the first dark fringe is at $\sin\theta = \lambda/a$: single-slit diffraction is the rectangle–sinc pair and nothing more. For sodium light, $\lambda = 589\,\mathrm{nm}$, through $a = 1.0\,\mathrm{mm}$, $\theta \approx 5.9\times10^{-4}\,\mathrm{rad}$. The optics is developed in Chapter 61.

Remark 17.46 (The quantum reading, in SI). Wave mechanics assigns to a particle of momentum p the wavenumber $k = p/\hbar$, with $\hbar = 1.054\,571\,817\times10^{-34}\,\mathrm{J\,s}$ exactly by the definition of the SI (Chapter 71). If $\psi(x)$ is a normalised position amplitude and $\tilde\psi(k)$ its transform, then the momentum amplitude is $\tilde\psi(p/\hbar)/\sqrt{\hbar}$, normalised in p, and $\sigma_p = \hbar\,\sigma_k$. Substituting into Equation (17.56) with the pair (x, k) gives

$$\sigma_x\,\sigma_p \geq \frac{\hbar}{2}\,, \tag{17.58}$$

which is Kennard's inequality [580], the sharp form of the uncertainty relation that Heisenberg had argued physically from the disturbance caused by a measurement [576]. The mathematical content is entirely Theorem 17.43; what physics supplies is the single constant $\hbar$ converting an inverse length into a momentum. For an electron localised to $\sigma_x = 1.0\times10^{-10}\,\mathrm{m}$, an atomic diameter, Equation (17.58) gives $\sigma_p \geq 5.27\times10^{-25}\,\mathrm{kg\,m/s}$, hence a kinetic-energy scale $\sigma_p^2/(2m_\mathrm{e}) \approx 1.5\times10^{-19}\,\mathrm{J} \approx 0.95\,\mathrm{eV}$ — the electronvolt scale of atomic physics, obtained from a theorem about Fourier integrals. The operator form of the inequality, valid for any pair of non-commuting observables, belongs to Chapter 77.

Rests on Theorem 17.43.

17.2.5 Poisson summation

Sampling a function and sampling its transform are not independent operations. The exact relation between them is one formula, and it controls both the lattice sums of solid-state physics and the aliasing of every digitised measurement.

Theorem 17.47 (Poisson summation)**.** *Let f be continuous with $|f(t)| \leq C(1+|t|)^{-1-\eta}$ and $\left|\hat f(\omega)\right| \leq C(1+|\omega|)^{-1-\eta}$ for some $\eta, C > 0$. Then for every $T > 0$ and every t,*

$$\sum_{n=-\infty}^{\infty} f(t+nT) = \frac{\sqrt{2\pi}}{T}\sum_{m=-\infty}^{\infty} \hat f\!\left(\frac{2\pi m}{T}\right)\mathrm{e}^{2\pi\mathrm{i}mt/T}\,, \tag{17.59}$$

and in particular, at $t = 0$,

$$\sum_{n=-\infty}^{\infty} f(nT) = \frac{\sqrt{2\pi}}{T}\sum_{m=-\infty}^{\infty} \hat f\!\left(\frac{2\pi m}{T}\right)\,. \tag{17.60}$$

Rests on Definitions 17.1 and 17.29 and Theorem 17.9.

Proof. *Derives Theorem 17.47.*

The *periodisation* $F(t) = \sum_n f(t+nT)$ converges absolutely and uniformly on compact sets by the decay hypothesis (comparison with $\sum n^{-1-\eta}$), so F is continuous, and it is

T-periodic by construction, the sum being over all of $\mathbb{Z}$. Its Fourier coefficients in the sense of Equation (17.3) are

$$C_m = \frac{1}{T}\int_0^T F(t)\,\mathrm{e}^{-2\pi \mathrm{i} m t/T}\,\mathrm{d}t = \frac{1}{T}\sum_{n}\int_0^T f(t+nT)\mathrm{e}^{-2\pi \mathrm{i} m t/T}\mathrm{d}t = \frac{1}{T}\int_{-\infty}^{\infty} f(s)\,\mathrm{e}^{-2\pi \mathrm{i} m s/T}\mathrm{d}s\,,$$

where uniform convergence justifies the exchange and the substitution $s = t+nT$ reassembles the intervals $[nT,(n+1)T]$ into the line, the exponential being unchanged because $\mathrm{e}^{-2\pi \mathrm{i} m n} = 1$. The last integral is $\sqrt{2\pi}\,\hat f(2\pi m/T)/T$. By hypothesis $\sum_m |C_m| < \infty$, so the Fourier series of F converges absolutely and uniformly, and its sum is F by Theorem 17.9 — or by Corollary 17.23(b) applied to the difference. Writing that statement out is Equation (17.59). □

Example 17.48 (Theta identity)**.** Take $f(t) = \mathrm{e}^{-\pi s t^2}$ with $s > 0$. By Equation (17.42) with $a^2 = 1/(2\pi s)$, $\hat f(\omega) = (2\pi s)^{-1/2}\mathrm{e}^{-\omega^2/(4\pi s)}$. Put $T = 1$ in Equation (17.60):

$$\sum_{n=-\infty}^{\infty} \mathrm{e}^{-\pi s n^2} = \frac{1}{\sqrt{s}}\sum_{m=-\infty}^{\infty} \mathrm{e}^{-\pi m^2/s}\,. \tag{17.61}$$

The identity converts a slowly convergent sum at small s into a rapidly convergent one, which is how such lattice sums are evaluated in practice; it is also the functional equation from which the analytic continuation of the Riemann zeta function is obtained.

Corollary 17.49 (Lattice sums and the reciprocal lattice)**.** *Let $\Lambda \subset \mathbb{R}^3$ be a Bravais lattice with primitive vectors $\boldsymbol{a}_1,\boldsymbol{a}_2,\boldsymbol{a}_3$ and cell volume $V = \boldsymbol{a}_1\cdot(\boldsymbol{a}_2\times\boldsymbol{a}_3)$, and let Λ^* be the reciprocal lattice generated by the $\boldsymbol{b}_i$ with $\boldsymbol{a}_i\cdot\boldsymbol{b}_j = 2\pi\delta_{ij}$. Then, for f decaying as above in each variable,*

$$\sum_{\boldsymbol{R}\in\Lambda} f(\boldsymbol{r}+\boldsymbol{R}) = \frac{(2\pi)^{3/2}}{V}\sum_{\boldsymbol{G}\in\Lambda^*} \hat f(\boldsymbol{G})\,\mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{r}}\,, \tag{17.62}$$

with $\hat f$ the three-dimensional transform, the convention of Definition 17.29 applied in each Cartesian coordinate.

Rests on Theorem 17.47 and Definition 17.29.

Proof. *Derives Corollary 17.49.*

Change variables to the coordinates u_i defined by $\boldsymbol{r} = \sum_i u_i\boldsymbol{a}_i$, in which Λ becomes $\mathbb{Z}^3$ and the Jacobian is V; Theorem 17.47 applies in each of the three variables in turn, and the dual variables assemble into Λ^* by the defining relation $\boldsymbol{a}_i\cdot\boldsymbol{b}_j = 2\pi\delta_{ij}$. □

For copper, a face-centred cubic crystal with conventional lattice parameter $a = 0.3615\,\mathrm{nm}$, the reciprocal-lattice scale is $2\pi/a = 17.4/\mathrm{nm}$, which is the size of the Brillouin zone that organises the phonon spectra of Chapter 125 and the band structure of Chapter 126. Equation (17.62) is also the statement that a periodic array of scatterers diffracts only into the reciprocal-lattice directions, which is the Laue condition.

Finally, Equation (17.59) in the frequency variable is the exact statement of what sampling does to a spectrum, and Section 17.5.1 uses it in that form.

17.3 Convolution and correlation

17.3.1 The convolution theorem

Definition 17.50 (Convolution)**.** For f, g absolutely integrable on $\mathbb{R}$,

$$(f * g)(t) = \int_{-\infty}^{\infty} f(s)\,g(t-s)\,\mathrm{d}s\,. \tag{17.63}$$

Proposition 17.51 (Algebra of convolution)**.** *Convolution is bilinear, commutative and associative, it commutes with translations, and*

$$\int_{-\infty}^{\infty} |(f * g)(t)| \, \mathrm{d}t \le \left(\int |f| \right) \left(\int |g| \right) , \tag{17.64}$$

so $f * g$ is again absolutely integrable and is defined for almost every t.
Rests on Definition 17.50.

Proof. *Derives Proposition 17.51.*

Commutativity is the substitution $s \mapsto t - s$; associativity is a change of variables in the resulting double integral. For Equation (17.64), Tonelli's theorem allows the non-negative double integral to be done in either order:

$$\iint |f(s)| \, |g(t-s)| \, \mathrm{d}s \, \mathrm{d}t = \int |f(s)| \left[\int |g(t-s)| \, \mathrm{d}t \right] \mathrm{d}s = \left(\int |f| \right) \left(\int |g| \right) ,$$

finite, which also shows the inner integral in Equation (17.63) converges for almost every t. □

Proposition 17.52 (Linear translation-invariant systems)**.** *Let $\mathcal{A}$ be a linear map on signals that commutes with time translation, $\mathcal{A}\,[x(\cdot - a)] = (\mathcal{A}x)\,(\cdot - a)$ for every a, and that is continuous in the sense of Definition 17.38. Then $\mathcal{A}$ is a convolution,*

$$(\mathcal{A}x)\,(t) = \int_{-\infty}^{\infty} h(t-s)\, x(s) \, \mathrm{d}s = (h * x)(t) , \qquad h = \mathcal{A}\delta , \tag{17.65}$$

with h the impulse response *of the system.*
Rests on Definitions 17.38 and 17.50 and Proposition 17.41.

Derivation. *Derives Proposition 17.52.*

By Proposition 17.41 the sifting property writes any input as a superposition of shifted impulses, $x(t) = \int x(s)\, \delta(t-s) \, \mathrm{d}s$. Apply $\mathcal{A}$ and exchange it with the integral, which continuity permits, treating the integral as a limit of finite sums: $(\mathcal{A}x)\,(t) = \int x(s)\, \mathcal{A}\,[\delta(\cdot - s)]\,(t) \, \mathrm{d}s$. Translation invariance identifies $\mathcal{A}\,[\delta(\cdot - s)]\,(t) = h(t-s)$ with $h = \mathcal{A}\delta$, which is Equation (17.65). The statement made fully rigorous — that every continuous linear map between distribution spaces has a kernel, here forced by translation invariance to depend only on $t - s$ — is Schwartz's kernel theorem [971]. □

Every linear system whose behaviour does not depend on when it is used is therefore a convolution: a filter, an amplifier below saturation, a spectrometer, a lens, the elastic response of a solid. What such a system does to a spectrum is now one line.

Theorem 17.53 (Convolution theorem)**.** *For absolutely integrable f, g,*

$$\widehat{f * g}(\omega) = \sqrt{2\pi}\, \hat{f}(\omega)\, \hat{g}(\omega) , \tag{17.66}$$

and, when both sides are defined,

$$\widehat{f\, g}(\omega) = \frac{1}{\sqrt{2\pi}} \left(\hat{f} * \hat{g} \right) (\omega) . \tag{17.67}$$

Rests on Definitions 17.29 and 17.50, Proposition 17.51, and Theorem 17.32.

Proof. *Derives Theorem 17.53.*

Insert Equation (17.63) into Equation (17.32). The double integral converges absolutely by Equation (17.64), so Fubini's theorem permits exchanging the order:

$$\widehat{f * g}(\omega) = \frac{1}{\sqrt{2\pi}} \iint f(s)\, g(t-s)\, \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}s \, \mathrm{d}t = \frac{1}{\sqrt{2\pi}} \int f(s)\, \mathrm{e}^{-\mathrm{i}\omega s} \left[\int g(u)\, \mathrm{e}^{-\mathrm{i}\omega u} \, \mathrm{d}u \right] \mathrm{d}s ,$$

substituting $u = t - s$ in the inner integral and factoring $\mathrm{e}^{-\mathrm{i}\omega t} = \mathrm{e}^{-\mathrm{i}\omega s}\mathrm{e}^{-\mathrm{i}\omega u}$. The bracket is $\sqrt{2\pi}\,\hat{g}(\omega)$ and the remaining integral $\sqrt{2\pi}\,\hat{f}(\omega)$, giving Equation (17.66). Equation (17.67) is the same computation run through the inverse transform, or equivalently Equation (17.66) applied to $\hat{f}$ and $\hat{g}$ and inverted with Theorem 17.32. □

This is the pending convolution property of Section 9.7.5, and it is the reason integral transforms solve differential equations. A linear constant-coefficient equation $P(\partial_t)u = w$ has, by Equation (17.38), $P(\mathrm{i}\omega)\hat{u} = \hat{w}$, hence $\hat{u} = \hat{w}/P(\mathrm{i}\omega) = \sqrt{2\pi}\,\hat{G}\hat{w}$ with $\hat{G} = 1/\left[\sqrt{2\pi}P(\mathrm{i}\omega)\right]$, and therefore $u = G * w$: every Green's-function solution of Section 10.3 is a convolution of the source with the fundamental solution, and the Green's function is the impulse response of Equation (17.65). The same statement read backwards is the working fact of experimental spectroscopy.

Example 17.54 (Instrument response and widths in quadrature)**.** Let $g_a(t) = \left(a\sqrt{2\pi}\right)^{-1}\mathrm{e}^{-t^2/(2a^2)}$ be the normalised Gaussian of standard deviation a, so that $\hat{g}_a(\omega) = (2\pi)^{-1/2}\,\mathrm{e}^{-a^2\omega^2/2}$ by Equation (17.42). Then Equation (17.66) gives

$$\widehat{g_a * g_b}(\omega) = \sqrt{2\pi}\,\hat{g}_a\hat{g}_b = \frac{1}{\sqrt{2\pi}}\,\mathrm{e}^{-(a^2+b^2)\omega^2/2} = \hat{g}_{\sqrt{a^2+b^2}}(\omega)\,, \tag{17.68}$$

so $g_a * g_b = g_{\sqrt{a^2+b^2}}$ by injectivity (Corollary 17.33): Gaussian widths add in quadrature, and so do the full widths at half maximum, which are $2\sqrt{2\ln 2}$ times the standard deviations. A spectral line of true Doppler width 1.20 GHz recorded through an instrument of Gaussian response 0.90 GHz is therefore observed with width $\sqrt{1.20^2 + 0.90^2} = 1.50$ GHz, and the physical width is recovered by subtracting in quadrature. Every quoted linewidth in Chapter 90 is a measured width so corrected.

Remark 17.55 (Deconvolution is ill posed)*.* Inverting Equation (17.66) suggests recovering the true signal from the record $y = h * f$ by $\hat{f} = \hat{y}/\left(\sqrt{2\pi}\,\hat{h}\right)$. The formula is correct and the procedure is unusable as it stands. A physical response $\hat{h}$ decays at high frequency — for the Gaussian of Example 17.54, as $\mathrm{e}^{-a^2\omega^2/2}$ — so the division multiplies whatever noise the record carries at frequency ω by $\mathrm{e}^{+a^2\omega^2/2}$. An arbitrarily small perturbation of the data therefore produces an arbitrarily large perturbation of the answer: the solution does not depend continuously on the data, which is exactly the third of Hadamard's conditions for a well-posed problem (Chapter 10). Practical deconvolution restores well-posedness by giving something up — truncating the division at the frequency where the signal-to-noise ratio reaches unity, or adding a penalty term that suppresses large high-frequency content. The same arithmetic returns in Section 17.6.3, where the tomographic ramp filter amplifies high frequencies for the same reason.

17.3.2 Correlation and the Wiener–Khinchin theorem

Definition 17.56 (Correlation)**.** For square-integrable f, g the *cross-correlation* and *auto-correlation* are

$$R_{fg}(\tau) = \int_{-\infty}^{\infty} \overline{f(t)}\,g(t+\tau)\,\mathrm{d}t\,, \qquad R_{ff}(\tau) = \int_{-\infty}^{\infty} \overline{f(t)}\,f(t+\tau)\,\mathrm{d}t\,. \tag{17.69}$$

Correlation differs from convolution only by a reflection and a conjugation, $R_{fg} = \bar{f}^{-} * g$ with $f^{-}(t) = f(-t)$, and that one difference is what makes it measure similarity at a lag rather than smoothing.

Theorem 17.57 (Wiener–Khinchin, finite-energy form)**.** *For square-integrable f,*

$$\widehat{R_{ff}}(\omega) = \sqrt{2\pi}\,\left|\hat{f}(\omega)\right|^2 , \tag{17.70}$$

so the autocorrelation and the energy spectral density are a Fourier pair. In particular $R_{ff}(0) = \int |f|^2$ recovers Plancherel's theorem, and $|R_{ff}(\tau)| \le R_{ff}(0)$.
Rests on Definition 17.56 and Theorem 17.53.

Proof. *Derives Theorem 17.57.*

With $f^-(t) = f(-t)$ one has $\widehat{f^-}(\omega) = \overline{\hat{f}(\omega)}$, since conjugating and reflecting the argument each conjugate the analysis kernel. Then $R_{ff} = \overline{f^-} * f$ by inspection of Equation (17.69), and Equation (17.66) gives Equation (17.70). Evaluating the inverse transform at $\tau = 0$ gives $\int |f|^2 = \int \left|\hat{f}\right|^2$, and the bound on $|R_{ff}|$ is Cauchy–Schwarz applied to Equation (17.69). □

The physically important version concerns signals that do not decay — noise, thermal fluctuations, a stationary source — which have infinite energy but finite *power*. The right object is then a statistical one, and the apparatus is that of Chapter 11.

Definition 17.58 (Stationary process and power spectral density)**.** A random process $X(t)$ is *stationary in the wide sense* if $\langle X(t)\rangle$ is independent of t — taken to be zero below — and the autocorrelation

$$R(\tau) = \left\langle \overline{X(t)}\, X(t+\tau) \right\rangle \tag{17.71}$$

depends only on the lag τ, the angle brackets denoting the ensemble average. Its *power spectral density* is

$$S(\omega) = \lim_{T\to\infty} \frac{1}{T} \left\langle \left|\hat{X}_T(\omega)\right|^2 \right\rangle , \qquad X_T = X\,\mathbf{1}_{\{|t|\le T/2\}} . \tag{17.72}$$

Rests on Definitions 17.29 and 17.56.

Theorem 17.59 (Wiener–Khinchin)**.** *If R is absolutely integrable then the limit Equation (17.72) exists and*

$$S(\omega) = \frac{1}{\sqrt{2\pi}}\,\hat{R}(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} R(\tau)\,\mathrm{e}^{-\mathrm{i}\omega\tau}\,\mathrm{d}\tau , \tag{17.73}$$

and conversely $R(\tau) = \int S(\omega)\mathrm{e}^{\mathrm{i}\omega\tau}\mathrm{d}\omega$. The total power is $R(0) = \int S(\omega)\,\mathrm{d}\omega$.
Rests on Definitions 17.29 and 17.58 and Theorem 17.32.

Derivation. *Derives Theorem 17.59.*

Expand the definition, using Equation (17.32) on the truncated process:

$$\left\langle \left|\hat{X}_T(\omega)\right|^2 \right\rangle = \frac{1}{2\pi}\int_{-T/2}^{T/2}\!\!\int_{-T/2}^{T/2} \left\langle \overline{X(t)}X(t')\right\rangle \mathrm{e}^{-\mathrm{i}\omega(t'-t)}\,\mathrm{d}t\,\mathrm{d}t' = \frac{1}{2\pi}\int_{-T/2}^{T/2}\!\!\int_{-T/2}^{T/2} R(t'-t)\,\mathrm{e}^{-\mathrm{i}\omega(t'-t)}\,\mathrm{d}t\,\mathrm{d}t' ,$$

the ensemble average passing inside the integrals by stationarity and integrability. Change variables to $\tau = t' - t$ and t; for fixed τ with $|\tau| \le T$ the admissible t form an interval of length $T - |\tau|$, so

$$\frac{1}{T}\left\langle \left|\hat{X}_T(\omega)\right|^2 \right\rangle = \frac{1}{2\pi}\int_{-T}^{T} \left(1 - \frac{|\tau|}{T}\right) R(\tau)\,\mathrm{e}^{-\mathrm{i}\omega\tau}\,\mathrm{d}\tau .$$

The triangular factor is bounded by 1 and tends to 1 pointwise, and R is absolutely integrable, so dominated convergence gives the limit Equation (17.73) as $T \to \infty$. The converse statement is Theorem 17.32 applied to $\hat{R}$, and setting $\tau = 0$ gives the power. □

Wiener obtained the result as part of a general harmonic analysis of non-decaying functions, in which the correlation replaces the divergent transform [673]; Khinchin gave the probabilistic formulation for stationary processes used above [740].

Example 17.60 (Noise spectral densities in SI)**.** For a voltage noise $V(t)$ in V, $R(\tau)$ is in V^2 and, by Equation (17.73), $S(\omega)$ is in $\mathrm{V}^2\,\mathrm{s/rad}$. Laboratory practice quotes instead the *one-sided* density per unit ordinary frequency, $S_V(\nu) = 4\pi S(2\pi\nu)$ in V^2/Hz, so that $\langle V^2\rangle = \int_0^\infty S_V(\nu)\,\mathrm{d}\nu$ with no further factors. The thermal noise of a resistor is white in this measure, with $S_V = 4k_{\mathrm{B}}TR$ — Nyquist's analysis [615], derived from the fluctuation–dissipation theorem in Chapter 124, and quoted here only to fix the units. For $R = 1.0\,\mathrm{k\Omega}$ at $T = 300\,\mathrm{K}$, $S_V = 1.66\times10^{-17}\,\mathrm{V}^2/\mathrm{Hz}$, i.e. an amplitude density $\sqrt{S_V} = 4.1\,\mathrm{nV}$ per root hertz, and in a measurement bandwidth of 100 kHz the root-mean-square noise is $\sqrt{S_V B} = 1.3\,\mu\mathrm{V}$. The whole calculation is Theorem 17.59 plus arithmetic.

One definite integral is worth isolating, because every estimate of the thermal noise floor of a mechanical resonator in this book reduces to it and each would otherwise redo the same contour.

Proposition 17.61 (Mean-square response of a damped resonator)**.** *Let $m > 0$, $b > 0$, $k > 0$ and let*

$$\chi(\omega) = \frac{1}{k - m\omega^2 + \mathrm{i}b\omega} \tag{17.74}$$

be the response of the damped oscillator, with m in kg*, b in* kg/s*, k in* N/m *and χ in* m/N*. Then*

$$\int_{-\infty}^{\infty} |\chi(\omega)|^2\,\mathrm{d}\omega = \frac{\pi}{bk}\,, \qquad \textit{equivalently} \qquad \int_0^\infty |\chi(2\pi\nu)|^2\,\mathrm{d}\nu = \frac{1}{4bk}\,. \tag{17.75}$$

Consequently, by Proposition 17.52 and Theorem 17.59, a resonator driven by a stationary force whose one-sided spectral density S_F in N^2/Hz is constant over the band where χ is appreciable has mean-square displacement $\langle x^2\rangle = S_F/(4bk)$.

Rests on Theorems 8.24 and 17.59 and Proposition 17.52.

Proof. *Derives Proposition 17.61.*

Take first $b^2 \neq 4mk$. For real ω, $|\chi(\omega)|^2 = \chi(\omega)\,\tilde\chi(\omega)$ with $\tilde\chi(\omega) = (k - m\omega^2 - \mathrm{i}b\omega)^{-1}$, and both extend to rational functions of a complex ω decaying like $|\omega|^{-4}$, so the arc at infinity contributes nothing and Theorem 8.24 applies to a contour closed in the upper half-plane. The poles of χ are the roots of $m\omega^2 - \mathrm{i}b\omega - k = 0$,

$$z_\pm = \frac{\mathrm{i}b \pm \Delta}{2m}\,, \qquad \Delta = \sqrt{4mk - b^2}\,, \tag{17.76}$$

and both lie in the upper half-plane: for $4mk > b^2$ each has imaginary part $b/2m > 0$, and for $4mk < b^2$ both are purely imaginary, $\mathrm{i}\left[b \pm \sqrt{b^2 - 4mk}\right]/2m$, with positive imaginary part because $b > \sqrt{b^2 - 4mk}$. The poles of $\tilde\chi$ are $-z_\pm$, in the lower half-plane, so only $z_\pm$ are enclosed. Writing $\chi(\omega) = -\left[m(\omega - z_+)(\omega - z_-)\right]^{-1}$ and using $k - mz_\pm^2 = -\mathrm{i}bz_\pm$, which is the equation the roots satisfy, gives $\tilde\chi(z_\pm) = -(2\mathrm{i}bz_\pm)^{-1}$ and hence, by Proposition 8.23,

$$\operatorname{Res}_{\omega=z_+}\chi\tilde\chi = \frac{1}{2\mathrm{i}bz_+\Delta}\,, \qquad \operatorname{Res}_{\omega=z_-}\chi\tilde\chi = -\frac{1}{2\mathrm{i}bz_-\Delta}\,, \tag{17.77}$$

since $z_+ - z_- = \Delta/m$. Their sum is $(2\mathrm{i}b\Delta)^{-1}(z_- - z_+)/(z_+z_-)$, and the root relations $z_+z_- = -k/m$ and $z_- - z_+ = -\Delta/m$ reduce it to $(2\mathrm{i}bk)^{-1}$. Multiplying by $2\pi\mathrm{i}$ gives the first equality of Equation (17.75); the second follows by substituting $\omega = 2\pi\nu$ and halving, the integrand being even in ω. Both sides of Equation (17.75) are continuous in b at $b^2 = 4mk$, which disposes of the critically damped case. □

Example 17.62 (Noise floor of a torsion balance)**.** A torsion pendulum of stiffness $k = 2.0 \times 10^{-8}\,\mathrm{N\,m/rad}$ and damping $b = 1.0 \times 10^{-11}\,\mathrm{N\,m\,s/rad}$ — the rotational analogues of the constants above, with angle in place of displacement — driven by the thermal torque whose one-sided density is $S_\tau = 4k_{\mathrm{B}}Tb$ at $T = 300\,\mathrm{K}$, has mean-square angle $\langle\theta^2\rangle = S_\tau/(4bk) = k_{\mathrm{B}}T/k$ by Equation (17.75). The damping cancels: the answer is $2.1 \times 10^{-13}\,\mathrm{rad}^2$, an angular fluctuation of 0.46 µrad, and it is equipartition (Chapter 118) recovered from the spectrum. That the cancellation happens is the content of the proposition; that it must happen is why the fluctuation–dissipation relation takes the form it does in Chapter 124.

Theorem 17.63 (Matched filter)**.** *Let the record be $d(t) = s(t) + n(t)$, with s a known signal and n stationary noise of strictly positive power spectral density S. Among all linear filters q, the signal-to-noise ratio*

$$\rho^2 = \frac{\left|\int \overline{\hat{q}(\omega)}\,\hat{s}(\omega)\,\mathrm{d}\omega\right|^2}{\int S(\omega)\,|\hat{q}(\omega)|^2\,\mathrm{d}\omega} \tag{17.78}$$

of the filtered output at the arrival time is maximised by

$$\hat{q}(\omega) = \frac{\hat{s}(\omega)}{S(\omega)}\,, \qquad \textit{giving} \qquad \rho^2_{\max} = \int_{-\infty}^{\infty} \frac{|\hat{s}(\omega)|^2}{S(\omega)}\,\mathrm{d}\omega\,. \tag{17.79}$$

Rests on Definition 17.58.

Proof. *Derives Theorem 17.63.*

Write $\hat{q} = \hat{u}/\sqrt{S}$ and $\hat{\sigma} = \hat{s}/\sqrt{S}$, legitimate since $S > 0$. The numerator of Equation (17.78) is $\left|\int \overline{\hat{u}}\,\hat{\sigma}\,\mathrm{d}\omega\right|^2$ and the denominator is $\int |\hat{u}|^2\,\mathrm{d}\omega$, so $\rho^2 = |\langle\hat{u},\hat{\sigma}\rangle|^2 \,/\, \|\hat{u}\|^2 \le \|\hat{\sigma}\|^2$ by the Cauchy–Schwarz inequality, with equality if and only if $\hat{u}$ is a multiple of $\hat{\sigma}$, i.e. $\hat{q} \propto \hat{s}/S$. Substituting gives $\rho^2_{\max} = \|\hat{\sigma}\|^2$, which is Equation (17.79). □

The optimal filter is therefore the signal itself, weighted inversely by the noise power at each frequency: one trusts the record where the detector is quiet and discounts it where the detector is loud. This is the statistic by which the gravitational-wave strain records of Chapter 47 are searched, and Equation (17.79) is the integral whose value is quoted as the detection significance. The same theorem, read in the frequency domain alone, is why the noise curve of an interferometer — a plot of $\sqrt{S}$ in $1/\mathrm{Hz}^{1/2}$ against ν in Hz — is the complete specification of what the instrument can find.

Remark 17.64 (Spectroscopy by autocorrelation)*.* A two-beam interferometer records, as a function of the path difference x, the intensity $I(x) \propto R_{EE}(x/c)$ of the autocorrelation of the field. By Theorem 17.57 its Fourier transform is the spectrum. A Fourier-transform spectrometer therefore measures no spectrum directly at all: it measures an interferogram and transforms it, which is why its resolution is set by the maximum path difference, $\Delta\nu \approx c/(2x_{\max})$ by Corollary 17.44, and why its signal-to-noise advantage over a scanning instrument is that all frequencies are measured at once. The coherence properties this measures are the subject of Chapter 122.

17.4 The Laplace transform

17.4.1 Definition, convergence and inversion

The Fourier transform requires decay at both ends of the line. Physical initial-value problems supply neither: a system is switched on at $t = 0$ and may grow. The remedy is to keep only $t > 0$ and to insert a convergence factor, which is what Laplace's generating-function transform does [56].

Definition 17.65 (One-sided Laplace transform)**.** For f defined on $[0,\infty)$ and $s \in \mathbb{C}$,

$$F(s) = \mathcal{L}\{f\}(s) = \int_0^\infty f(t)\,\mathrm{e}^{-st}\,\mathrm{d}t\,, \tag{17.80}$$

whenever the improper integral converges. If t is in s then s is in 1/s and F carries the SI unit of f multiplied by s.

Theorem 17.66 (Half-plane of convergence)**.** *If Equation (17.80) converges at s_0, it converges for every s with $\Re s > \Re s_0$, uniformly on every sector $|\arg(s-s_0)| \le \theta_0 < \pi/2$. Hence there is an* abscissa of convergence $\sigma_c \in [-\infty, +\infty]$ *such that the transform exists for $\Re s > \sigma_c$ and fails for $\Re s < \sigma_c$.*

Rests on Definition 17.65 and Equation (7.28).

Proof. *Derives Theorem 17.66.*

Let $g(t) = \int_0^t f(u)\mathrm{e}^{-s_0 u}\,\mathrm{d}u$, which converges to a limit as $t \to \infty$ by hypothesis and is therefore bounded, say $|g| \le M$. Write $z = s - s_0$, with $\Re z > 0$, and integrate by parts (Equation (7.28)), using $g' = f\mathrm{e}^{-s_0 t}$:

$$\int_0^T f(t)\mathrm{e}^{-st}\,\mathrm{d}t = \int_0^T g'(t)\,\mathrm{e}^{-zt}\,\mathrm{d}t = g(T)\,\mathrm{e}^{-zT} + z\int_0^T g(t)\,\mathrm{e}^{-zt}\,\mathrm{d}t\,.$$

The boundary term is bounded by $M\mathrm{e}^{-T\Re z} \to 0$, and the remaining integral converges absolutely as $T \to \infty$ because $\left|g\mathrm{e}^{-zt}\right| \le M\mathrm{e}^{-t\Re z}$. Both estimates depend on z only through $|z|/\Re z \le 1/\cos\theta_0$ and $\Re z$, whence uniform convergence on the sector. The abscissa is the infimum of $\Re s$ over the set of convergence, which the first part shows to be a right half-plane. □

Proposition 17.67 (Holomorphy)**.** *On the half-plane $\Re s > \sigma_a$ of* absolute *convergence, F is holomorphic (Definition 8.5) with*

$$F'(s) = -\int_0^\infty t\,f(t)\,\mathrm{e}^{-st}\,\mathrm{d}t\,, \tag{17.81}$$

and more generally $F^{(n)}(s) = \mathcal{L}\{(-t)^n f\}(s)$.

Rests on Definitions 8.5 and 17.65 and Theorem 7.38.

Proof. *Derives Proposition 17.67.*

Fix s with $\Re s = \sigma > \sigma_a$ and choose $\eta > 0$ with $\sigma - \eta > \sigma_a$. For $|h| < \eta/2$,

$$\frac{F(s+h)-F(s)}{h} + \int_0^\infty t f(t)\mathrm{e}^{-st}\mathrm{d}t = \int_0^\infty f(t)\,\mathrm{e}^{-st}\,\frac{\mathrm{e}^{-ht}-1+ht}{h}\,\mathrm{d}t\,,$$

and the elementary estimate $\left|\mathrm{e}^{-ht}-1+ht\right| \le \tfrac{1}{2}|h|^2\,t^2\mathrm{e}^{|h|t}$, obtained from the Taylor remainder (Theorem 7.38), bounds the integrand by $\tfrac{1}{2}|h|\,t^2\,|f(t)|\,\mathrm{e}^{-(\sigma-\eta/2)t}$. Since $t^2\mathrm{e}^{\eta t/2}$ is dominated by $\mathrm{e}^{\eta t}$ for large t, the bound is integrable and proportional to $|h|$, so the difference quotient converges and Equation (17.81) holds. The higher derivatives follow by induction. □

Proposition 17.68 (The Laplace transform is a Fourier transform)**.** *Let $f_\sigma(t) = f(t)\,\mathrm{e}^{-\sigma t}\,\theta(t)$, the causal signal damped by $\mathrm{e}^{-\sigma t}$. Then for $\sigma > \sigma_a$*

$$F(\sigma + \mathrm{i}\omega) = \sqrt{2\pi}\;\widehat{f_\sigma}(\omega)\,. \tag{17.82}$$

Rests on Definitions 17.29 and 17.65.

Proof. *Derives Proposition 17.68.*

Substitute $s = \sigma + \mathrm{i}\omega$ in Equation (17.80) and read the result as Equation (17.32) applied to f_σ, the step function restricting the range to $t > 0$. □

So the Laplace transform is the Fourier transform of an exponentially damped causal signal, and its values on any vertical line $\Re s = \sigma$ are a Fourier spectrum. The advantage over the Fourier transform is that the damping can be chosen to make the integral converge, and that the resulting function of s is holomorphic, so that its values on one line determine it everywhere in the half-plane by analytic continuation. Inversion follows at once.

Theorem 17.69 (Bromwich inversion integral)**.** *Let $\gamma > \sigma_a$ and suppose $\omega \mapsto F(\gamma + \mathrm{i}\omega)$ is absolutely integrable. Then at every point of continuity of f*

$$f(t) = \frac{1}{2\pi \mathrm{i}} \int_{\gamma - \mathrm{i}\infty}^{\gamma + \mathrm{i}\infty} F(s)\, \mathrm{e}^{st}\, \mathrm{d}s\,, \qquad t > 0\,, \tag{17.83}$$

the integral being taken up the vertical line $\Re s = \gamma$; and the same integral vanishes for $t < 0$.
Rests on Proposition 17.68 and Theorem 17.32.

Proof. *Derives Theorem 17.69.*

By Equation (17.82) the hypothesis says $\widehat{f_\gamma}$ is absolutely integrable, so Theorem 17.32 applies to f_γ:

$$f(t)\, \mathrm{e}^{-\gamma t}\, \theta(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \widehat{f_\gamma}(\omega)\, \mathrm{e}^{\mathrm{i}\omega t}\, \mathrm{d}\omega = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\gamma + \mathrm{i}\omega)\, \mathrm{e}^{\mathrm{i}\omega t}\, \mathrm{d}\omega\,.$$

Multiply by $\mathrm{e}^{\gamma t}$ and substitute $s = \gamma + \mathrm{i}\omega$, so that $\mathrm{d}s = \mathrm{i}\,\mathrm{d}\omega$ and the line is traversed upward:

$$f(t)\, \theta(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\gamma + \mathrm{i}\omega)\, \mathrm{e}^{(\gamma + \mathrm{i}\omega)t}\, \mathrm{d}\omega = \frac{1}{2\pi \mathrm{i}} \int_{\gamma - \mathrm{i}\infty}^{\gamma + \mathrm{i}\infty} F(s)\, \mathrm{e}^{st}\, \mathrm{d}s\,.$$

The factor $\theta(t)$ on the left is the statement that the integral vanishes for $t < 0$. □

The contour of Equation (17.83) is Bromwich's, introduced precisely to justify the operational methods of the next subsection [442]. Evaluating it is a residue computation, and the machinery is that of Section 8.7; the only new ingredient is the estimate that closes the contour.

Lemma 17.70 (Jordan's lemma on the Bromwich contour)**.** *Let C_R be the left-hand semicircle $s = \gamma + R\mathrm{e}^{\mathrm{i}\phi}$, $\phi \in [\pi/2, 3\pi/2]$, and let $M_R = \max_{C_R} |F|$. Then for $t > 0$*

$$\left| \int_{C_R} F(s)\, \mathrm{e}^{st}\, \mathrm{d}s \right| \le \frac{\pi\, \mathrm{e}^{\gamma t}\, M_R}{t}\,, \tag{17.84}$$

so the semicircular contribution vanishes as $R \to \infty$ whenever $M_R \to 0$. For $t < 0$ the same bound holds on the right-hand semicircle.
Rests on Lemma 8.9.

Proof. *Derives Lemma 17.70.*

On C_R, write $\phi = \pi/2 + \psi$ with $\psi \in [0, \pi]$; then $\Re(s - \gamma) = R\cos\phi = -R\sin\psi$ and $|\mathrm{e}^{st}| = \mathrm{e}^{\gamma t}\mathrm{e}^{-Rt\sin\psi}$. The ML estimate (Lemma 8.9) with $|\mathrm{d}s| = R\,\mathrm{d}\psi$ gives

$$\left| \int_{C_R} F\mathrm{e}^{st}\mathrm{d}s \right| \le \mathrm{e}^{\gamma t} M_R\, R \int_0^{\pi} \mathrm{e}^{-Rt\sin\psi}\, \mathrm{d}\psi = 2\,\mathrm{e}^{\gamma t} M_R\, R \int_0^{\pi/2} \mathrm{e}^{-Rt\sin\psi}\, \mathrm{d}\psi\,,$$

and Jordan's inequality $\sin\psi \ge 2\psi/\pi$ on $[0, \pi/2]$ — concavity of the sine there — bounds the last integral by $\int_0^{\pi/2} \mathrm{e}^{-2Rt\psi/\pi}\mathrm{d}\psi \le \pi/(2Rt)$, which is Equation (17.84). □

Corollary 17.71 (Residue evaluation and causality)**.** *Let F be holomorphic except for finitely many poles $s_1, \dots, s_k$, all with $\Re s_j < \gamma$, and let $F(s) \to 0$ uniformly in direction as $|s| \to \infty$. Then*

$$f(t) = \sum_{j=1}^{k} \operatorname{Res}_{s = s_j} \left[F(s)\, \mathrm{e}^{st} \right] \qquad (t > 0)\,, \qquad f(t) = 0 \quad (t < 0)\,. \tag{17.85}$$

Rests on Theorems 8.12, 8.24 and 17.69 and Lemma 17.70.

Proof. *Derives Corollary 17.71.*

For $t > 0$ close the Bromwich line with the left semicircle of Lemma 17.70; the closed contour encircles every pole once counterclockwise, the semicircular contribution vanishes by Equation (17.84), and the residue theorem (Theorem 8.24) evaluates what is left, the $2\pi\mathrm{i}$ cancelling the prefactor of Equation (17.83). For $t < 0$ close to the right instead: the enclosed region contains no singularity, so Cauchy's theorem (Theorem 8.12) gives zero. □

That the same integral gives zero for $t < 0$ is not a technicality: it is causality, built into the transform by the restriction to $t > 0$, and it is the reason the poles of F must lie to the left of the contour.

Example 17.72 (Damped sinusoid)**.** Let $F(s) = \omega_0/\left[(s+\alpha)^2 + \omega_0^2\right]$, with $\alpha, \omega_0 > 0$ in 1/s and rad/s. The poles are simple, at $s_\pm = -\alpha \pm \mathrm{i}\omega_0$, and by Equation (8.16) with denominator derivative $2(s+\alpha)$,

$$\operatorname{Res}_{s=s_+}\left[F\mathrm{e}^{st}\right] = \frac{\omega_0\,\mathrm{e}^{(-\alpha+\mathrm{i}\omega_0)t}}{2\mathrm{i}\omega_0} = \frac{\mathrm{e}^{-\alpha t}\mathrm{e}^{\mathrm{i}\omega_0 t}}{2\mathrm{i}}\,,$$

and the residue at s_- is its complex conjugate with the sign reversed. Adding, $f(t) = \mathrm{e}^{-\alpha t}\sin(\omega_0 t)$ for $t > 0$ — the impulse response of a damped oscillator, recovered from its transform by one contour integral.

Proposition 17.73 (Initial- and final-value theorems)**.** *Let f be continuous on $[0,\infty)$ with f' absolutely integrable. Then*

$$\lim_{s\to\infty} s\,F(s) = f(0^+)\,, \qquad \lim_{s\to 0^+} s\,F(s) = \lim_{t\to\infty} f(t)\,, \tag{17.86}$$

the second whenever the limit on its right exists, the first for s real and increasing without bound.

Rests on Definition 17.65, Equation (7.28), and Theorem 7.43.

Proof. *Derives Proposition 17.73.*

Integrating Equation (17.80) by parts gives $\mathcal{L}\{f'\}(s) = sF(s) - f(0^+)$, so $sF(s) - f(0^+) = \int_0^\infty f'(t)\mathrm{e}^{-st}\mathrm{d}t$. The integrand is dominated by $|f'|$, which is integrable, and tends to 0 pointwise as $s \to \infty$; dominated convergence gives the first limit. As $s \to 0^+$ the same integrand tends pointwise to $f'(t)$ under the same domination, so the integral tends to $\int_0^\infty f' = \lim_{t\to\infty} f(t) - f(0^+)$ by the fundamental theorem of calculus (Theorem 7.43), which rearranges to the second limit. □

17.4.2 Initial-value problems and the operational calculus

Proposition 17.74 (Derivative rule)**.** *If f is n times differentiable with $f^{(n)}$ of exponential order,*

$$\mathcal{L}\left\{f^{(n)}\right\}(s) = s^n F(s) - s^{n-1}f(0) - s^{n-2}f'(0) - \cdots - f^{(n-1)}(0)\,. \tag{17.87}$$

Rests on Definition 17.65 and Equation (7.28).

Proof. *Derives Proposition 17.74.*

For $n = 1$, integrate by parts (Equation (7.28)): $\int_0^\infty f'\mathrm{e}^{-st}\mathrm{d}t = \left[f\mathrm{e}^{-st}\right]_0^\infty + s\int_0^\infty f\mathrm{e}^{-st}\mathrm{d}t = -f(0) + sF(s)$, the boundary term at infinity vanishing for $\Re s$ large. Induction on n, applying the case $n = 1$ to $f^{(n-1)}$, gives Equation (17.87). □

Equation (17.87) is the whole method: it converts a linear ordinary differential equation with constant coefficients into an algebraic equation, *and* it swallows the initial data, which enter as the extra polynomial terms rather than as conditions imposed afterwards. This subsumes the constant-coefficient theory of Section 9.1 and discharges the section reserved for the transform at Section 9.13.

Example 17.75 (The driven damped oscillator, in SI)**.** Consider

$$m\,\frac{\mathrm{d}^2x}{\mathrm{d}t^2}+b\,\frac{\mathrm{d}x}{\mathrm{d}t}+k\,x=f(t)\,,\qquad x(0)=x_0\,,\quad \frac{\mathrm{d}x}{\mathrm{d}t}(0)=v_0\,, \tag{17.88}$$

with m in kg, b in kg/s, k in N/m and f in N. Transforming with Equation (17.87),

$$\left(ms^2+bs+k\right)X(s)=F(s)+m\,(sx_0+v_0)+b\,x_0\,, \tag{17.89}$$

an algebraic equation. Define the *transfer function*

$$G(s)=\frac{1}{ms^2+bs+k}\,, \tag{17.90}$$

in m/N, whose poles are $s_\pm=-\Gamma\pm\mathrm{i}\omega_d$ with $\Gamma=b/(2m)$ and $\omega_d=\sqrt{\omega_0^2-\Gamma^2}$, $\omega_0=\sqrt{k/m}$. By Corollary 17.71 the inverse transform of G is the impulse response $h(t)=\mathrm{e}^{-\Gamma t}\sin(\omega_d t)/(m\omega_d)$, and by the convolution theorem in its Laplace form the forced part of the solution is $x_f=h*f$ — Duhamel's principle, the same statement as the causal Green's function of Section 10.3. For $m=0.50\,\mathrm{kg}$, $k=200\,\mathrm{N/m}$ and $b=2.0\,\mathrm{kg/s}$ one has $\omega_0=20\,\mathrm{rad/s}$, $\Gamma=2.0/\mathrm{s}$, $\omega_d=19.9\,\mathrm{rad/s}$ and a quality factor $Q=m\omega_0/b=5.0$: the free oscillation decays by a factor e in 0.50 s, after about 1.6 cycles.

Corollary 17.76 (Heaviside's expansion theorem)**.** *Let $F=P/Q$ with P,Q polynomials,* $\deg P<\deg Q$*, and Q having only simple zeros s_j. Then*

$$f(t)=\sum_j \frac{P(s_j)}{Q'(s_j)}\,\mathrm{e}^{s_j t}\,,\qquad t>0\,. \tag{17.91}$$

Rests on Corollary 17.71 and Equation (8.16).

Proof. *Derives Corollary 17.76.*

$F(s)\to 0$ as $|s|\to\infty$ because $\deg P<\deg Q$, so Corollary 17.71 applies, and each residue is $P(s_j)\mathrm{e}^{s_j t}/Q'(s_j)$ by Equation (8.16). □

Equation (17.91) is exactly the rule Heaviside used, and taught, without proof: he treated the differentiation operator $p=\mathrm{d}/\mathrm{d}t$ as an algebraic symbol, wrote the solution of $Q(p)x=P(p)w$ as $x=[P(p)/Q(p)]\,w$, expanded the rational function in partial fractions, and interpreted each term by rules justified only by their success [258]. Bromwich's contour integral is what turned the procedure into mathematics [442], and Corollary 17.76 is the translation.

Proposition 17.77 (Poles and stability)**.** *A linear time-invariant system with rational transfer function G proper and with poles s_j has an impulse response that decays to zero for every initial condition if and only if $\Re s_j<0$ for every j; it is bounded but non-decaying if a simple pole sits on the imaginary axis and every other pole is strictly to the left; and it grows without bound otherwise.*

Rests on Corollary 17.71.

Proof. *Derives Proposition 17.77.*

By Corollary 17.71 the impulse response is a finite sum of terms $t^{m_j}\mathrm{e}^{s_j t}$ with m_j below the order of the pole, whose modulus is $t^{m_j}\mathrm{e}^{t\Re s_j}$. Such a term tends to zero iff $\Re s_j<0$; it is bounded and non-decaying iff $\Re s_j=0$ and $m_j=0$; and it diverges otherwise. Distinct exponentials being linearly independent, no cancellation between terms is possible. □

Theorem 17.78 (Causality implies dispersion relations)**.** *Let χ be a causal response function — $\chi(t) = 0$ for $t < 0$ — absolutely integrable, with transform $\hat{\chi}$. Then $\hat{\chi}$ extends to a function holomorphic in the upper half plane $\Im\omega > 0$, and if $\hat{\chi}(\omega) \to 0$ as $|\omega| \to \infty$ there,*

$$\Re\hat{\chi}(\omega) = \frac{1}{\pi}\,\mathrm{PV}\int_{-\infty}^{\infty} \frac{\Im\hat{\chi}(\omega')}{\omega' - \omega}\,\mathrm{d}\omega'\,, \qquad \Im\hat{\chi}(\omega) = -\frac{1}{\pi}\,\mathrm{PV}\int_{-\infty}^{\infty} \frac{\Re\hat{\chi}(\omega')}{\omega' - \omega}\,\mathrm{d}\omega'\,. \tag{17.92}$$

Rests on Definition 17.29, Propositions 17.42 and 17.67, Theorem 8.12, Lemma 8.9, and Equation (8.16).

Derivation. Derives Theorem 17.78.

For $\Im\omega > 0$ the factor $\mathrm{e}^{-\mathrm{i}\omega t}$ decays as $\mathrm{e}^{t\Im\omega}$ on the half-line $t < 0$ — where χ vanishes — and as $\mathrm{e}^{-t\Im\omega}$ for $t > 0$, so $\hat{\chi}(\omega) = \frac{1}{\sqrt{2\pi}}\int_0^\infty \chi(t)\mathrm{e}^{-\mathrm{i}\omega t}\mathrm{d}t$ converges there and, by the argument of Proposition 17.67, is holomorphic. Now integrate $\hat{\chi}(\omega')/(\omega' - \omega)$ for real ω around the closed contour consisting of the real axis indented by a small semicircle of radius η *above* the point $\omega' = \omega$, closed by a large semicircle in the upper half plane. The integrand is holomorphic inside, so Cauchy's theorem (Theorem 8.12) makes the total vanish. The large semicircle contributes nothing by the decay hypothesis and the ML estimate (Lemma 8.9). The small semicircle, traversed clockwise, contributes $-\mathrm{i}\pi\hat{\chi}(\omega)$ — half a residue, by Equation (8.16) and the parametrisation $\omega' = \omega + \eta\mathrm{e}^{\mathrm{i}\phi}$. What remains of the real axis is the principal value. Hence

$$\mathrm{PV}\int_{-\infty}^{\infty} \frac{\hat{\chi}(\omega')}{\omega' - \omega}\,\mathrm{d}\omega' = \mathrm{i}\pi\,\hat{\chi}(\omega)\,,$$

and separating real and imaginary parts gives Equation (17.92). Equivalently, the statement is Equation (17.54) applied to $1/(\omega' - \omega - \mathrm{i}\varepsilon)$. □

Real and imaginary parts of a causal response are thus not independent: knowing how a medium absorbs at all frequencies determines how it refracts at each, and conversely. The physical instances — the Kramers–Kronig relations for the permittivity and the refractive index — belong to Chapter 62; what has been proved here is that they follow from causality and analyticity alone, with no model of the medium.

17.5 Sampling and the discrete transform

17.5.1 The sampling theorem

Every measurement that reaches a computer has been sampled: the continuous output of a detector is read at instants $t_n = n\Delta t$ and everything between is discarded. The question of what is lost has an exact answer.

Definition 17.79 (Band-limited function)**.** f is *band limited* to Ω if it is square integrable and $\hat{f}(\omega) = 0$ for $|\omega| > \Omega$. In terms of ordinary frequency the band is $|\nu| \le \nu_{\max} = \Omega/2\pi$, in Hz.

Rests on Definition 17.29.

Theorem 17.80 (Sampling theorem)**.** *Let f be band limited to Ω and let $\Delta t = \pi/\Omega$. Then f is determined by its samples at the instants $n\Delta t$, and is reconstructed from them exactly by the* cardinal series

$$f(t) = \sum_{n=-\infty}^{\infty} f(n\Delta t)\,\operatorname{sinc}\!\left(\frac{\pi\,(t - n\Delta t)}{\Delta t}\right), \qquad \operatorname{sinc} x = \frac{\sin x}{x}\,. \tag{17.93}$$

Equivalently, in Hz*: a signal containing no frequency above $\nu_{\max}$ is completely determined by samples taken at any rate $\nu_{\mathrm{s}} = 1/\Delta t \ge 2\nu_{\max}$, the* Nyquist rate*.*

Rests on Definitions 17.1 and 17.79 and Theorems 17.32 and 17.34.

Proof. *Derives Theorem 17.80.*

On the interval $[-\Omega,\Omega]$, expand $\hat f$ in a Fourier series of period 2Ω in the variable ω: $\hat f(\omega)=\sum_n \gamma_n \mathrm{e}^{-\mathrm{i}n\pi\omega/\Omega}$ with $\gamma_n=\frac{1}{2\Omega}\int_{-\Omega}^{\Omega}\hat f(\omega)\mathrm{e}^{\mathrm{i}n\pi\omega/\Omega}\mathrm{d}\omega$, the series converging in mean square by Theorem 17.34. Since $\hat f$ vanishes outside the band, the inversion formula Equation (17.43) reads $f(t)=\frac{1}{\sqrt{2\pi}}\int_{-\Omega}^{\Omega}\hat f(\omega)\mathrm{e}^{\mathrm{i}\omega t}\mathrm{d}\omega$; evaluating it at $t=n\pi/\Omega=n\Delta t$ identifies the coefficients,

$$f(n\Delta t)=\frac{2\Omega}{\sqrt{2\pi}}\,\gamma_n\,,\qquad\text{i.e.}\qquad \gamma_n=\frac{\sqrt{2\pi}}{2\Omega}\,f(n\Delta t)\,. \tag{17.94}$$

So the samples *are* the Fourier coefficients of the spectrum, up to a constant, and knowing them is knowing $\hat f$, hence f. To get Equation (17.93) explicitly, substitute the series for $\hat f$ into the inversion integral and exchange sum and integral — legitimate because the series converges in mean square on a set of finite measure, so it converges in mean, and $\mathrm{e}^{\mathrm{i}\omega t}$ is bounded:

$$f(t)=\frac{1}{\sqrt{2\pi}}\sum_n\gamma_n\int_{-\Omega}^{\Omega}\mathrm{e}^{\mathrm{i}\omega(t-n\Delta t)}\mathrm{d}\omega=\frac{1}{\sqrt{2\pi}}\sum_n\gamma_n\,\frac{2\sin\left[\Omega\,(t-n\Delta t)\right]}{t-n\Delta t}\,.$$

Insert Equation (17.94); the constants collapse to $1/\Omega$ and leave

$$\sum_n f(n\,\Delta t)\,\frac{\sin\left[\Omega(t-n\,\Delta t)\right]}{\Omega(t-n\,\Delta t)}\,,$$

which is Equation (17.93) because $\Omega=\pi/\Delta t$. Sampling faster than the Nyquist rate only makes the band a proper subinterval of $[-\Omega,\Omega]$, which changes nothing in the argument. □

Whittaker introduced the cardinal series as the interpolation formula distinguished by containing no frequency above the sampling limit [433]; Nyquist, analysing how many independent symbols a telegraph line of given bandwidth can carry, obtained the rate [614]; and Shannon stated and proved the theorem in the form used ever since, as the bridge between a continuous waveform and a finite list of numbers [947].

Corollary 17.81 (Sampling periodises the spectrum; aliasing)**.** *Let $\omega_{\mathrm{s}}=2\pi/\Delta t$. For f satisfying the decay hypotheses of Theorem 17.47,*

$$\sum_{m=-\infty}^{\infty}\hat f(\omega-m\omega_{\mathrm{s}})=\frac{\Delta t}{\sqrt{2\pi}}\sum_{n=-\infty}^{\infty}f(n\Delta t)\,\mathrm{e}^{-\mathrm{i}n\,\omega\,\Delta t}\,. \tag{17.95}$$

The right-hand side depends on f only through its samples; the left is the spectrum with all its translates by multiples of the sampling frequency superposed. If f is band limited to $\Omega<\omega_{\mathrm{s}}/2$ the translates do not overlap and $\hat f$ is recovered by discarding all but the central copy — which is Theorem 17.80 again. If they overlap, a component at ν is indistinguishable from components at $\nu-m\nu_{\mathrm{s}}$ for every integer m: it is aliased.

Rests on Theorems 17.32 and 17.47 and Definition 17.79.

Proof. *Derives Corollary 17.81.*

The left-hand side is periodic in ω with period ω_{s}, and the periodisation argument of Theorem 17.47 applies verbatim in the frequency variable: its Fourier coefficients are

$$C_n=\frac{1}{\omega_{\mathrm{s}}}\int_{-\infty}^{\infty}\hat f(\omega)\,\mathrm{e}^{-\mathrm{i}n\Delta t\,\omega}\,\mathrm{d}\omega=\frac{\sqrt{2\pi}}{\omega_{\mathrm{s}}}\,f(-n\Delta t)\,,$$

using $2\pi/\omega_{\mathrm{s}}=\Delta t$ and the inversion formula Equation (17.43). Summing the series $\sum_n C_n\mathrm{e}^{\mathrm{i}n\Delta t\,\omega}$ and relabelling $n\mapsto -n$ gives Equation (17.95), since $\sqrt{2\pi}/\omega_{\mathrm{s}}=\Delta t/\sqrt{2\pi}$. □

Example 17.82 (Aliasing in the laboratory)**.** Audio is conventionally sampled at $\nu_{\mathrm{s}} = 44.1\,\mathrm{kHz}$, so the Nyquist frequency is $22.05\,\mathrm{kHz}$. A $25.0\,\mathrm{kHz}$ component that reaches the converter is recorded as $|25.0\,\mathrm{kHz} - 44.1\,\mathrm{kHz}| = 19.1\,\mathrm{kHz}$, squarely inside the audible band and indistinguishable, after sampling, from a real signal there. Nothing downstream can undo this, which is why the analogue low-pass filter that removes such components *before* the converter is part of the apparatus and must be described as such. The gravitational-wave strain channel of Chapter 47 is recorded at $16\,384\,\mathrm{Hz}$, giving a Nyquist frequency of $8192\,\mathrm{Hz}$, comfortably above the few-hundred-hertz band where the signals sit.

Remark 17.83 (What the theorem does not say)*.* Three caveats, each of which has cost somebody a measurement. (i) *No signal of finite duration is band limited.* If $\hat{f}$ vanishes outside $[-\Omega, \Omega]$ then $f(t) = \frac{1}{\sqrt{2\pi}} \int_{-\Omega}^{\Omega} \hat{f}(\omega) \mathrm{e}^{\mathrm{i}\omega t} \mathrm{d}\omega$ converges for complex t and is differentiable there, hence entire; were it to vanish on an interval, all its derivatives would vanish at an interior point, its Taylor series (Theorem 8.20) would vanish identically, and f would be identically zero. Band limitation and finite support are mutually exclusive, so every real record is aliased a little, and the design question is how much. (ii) The reconstruction Equation (17.93) converges slowly: the sinc decays only as $1/t$, so a truncated cardinal series has errors falling as the reciprocal of the number of samples retained. (iii) An error in the sample *times* — jitter — is not an error in the sample values and is not corrected by any amount of averaging; its effect is a phase noise proportional to frequency, which is why timing specifications tighten as the band widens.

17.5.2 The discrete Fourier transform and the FFT

Definition 17.84 (Discrete Fourier transform)**.** For $x = (x_0, \dots, x_{N-1}) \in \mathbb{C}^N$,

$$X_k = \sum_{n=0}^{N-1} x_n \, W_N^{nk}, \qquad W_N = \mathrm{e}^{-2\pi \mathrm{i}/N}, \qquad k = 0, \dots, N-1 . \tag{17.96}$$

Proposition 17.85 (Inversion and Parseval for the DFT)**.** *The roots of unity satisfy*

$$\frac{1}{N} \sum_{n=0}^{N-1} W_N^{n(k-k')} = \delta_{kk'} \qquad \text{for } 0 \le k, k' \le N-1 , \tag{17.97}$$

hence

$$x_n = \frac{1}{N} \sum_{k=0}^{N-1} X_k \, W_N^{-nk}, \qquad \text{and} \qquad \sum_{n=0}^{N-1} |x_n|^2 = \frac{1}{N} \sum_{k=0}^{N-1} |X_k|^2 . \tag{17.98}$$

Rests on Definition 17.84.

Proof. *Derives Proposition 17.85.*

If $k = k'$ every term of Equation (17.97) is 1. If not, $W_N^{k-k'} \neq 1$ and the geometric sum is $\left(1 - W_N^{N(k-k')}\right) / \left(1 - W_N^{k-k'}\right) = 0$, because $W_N^N = 1$. This is Lemma 17.2 for a finite cyclic group in place of the circle. Substituting Equation (17.96) into the right side of Equation (17.98) and using Equation (17.97) returns x_n; the Parseval identity follows by the same computation applied to $\sum_n |x_n|^2 = \sum_n \bar{x}_n x_n$. □

Proposition 17.86 (The DFT is exact for a band-limited periodic signal)**.** *Let f be periodic with period $T_{\mathrm{w}} = N\Delta t$ and have Fourier coefficients c_n vanishing for $|n| \ge N/2$. Then the DFT of the samples $x_n = f(n\Delta t)$ satisfies $X_k = N c_k$ for $0 \le k < N/2$ and $X_{N-k} = N c_{-k}$ for $0 < k \le N/2$. No information is lost and no approximation is made.*

Rests on Definitions 17.1 and 17.84 and Proposition 17.85.

Proof. *Derives Proposition 17.86.*

Insert $f(n\Delta t) = \sum_{|m|<N/2} c_m \mathrm{e}^{2\pi i m n/N}$, which is Equation (17.4) at $t = n\Delta t$ with $\omega_1 \Delta t = 2\pi/N$, into Equation (17.96): $X_k = \sum_m c_m \sum_{n=0}^{N-1} W_N^{n(k-m)} = N c_{k \bmod N}$ by Equation (17.97), the index being read modulo N. Negative m therefore appear at $N - |m|$, which is the stated indexing. □

For a signal that is neither exactly periodic over the record nor exactly band limited — that is, for every real record — the DFT differs from the continuous transform by exactly two effects, both already derived: *aliasing*, Corollary 17.81, from sampling; and *leakage*, from the finite record length, since truncating to N samples multiplies the signal by a rectangular window and hence, by Equation (17.67), convolves the spectrum with the window's transform.

Theorem 17.87 (Cooley–Tukey)**.** *Let $N = 2^q$. Then Equation (17.96) can be evaluated in $\frac{N}{2}\log_2 N$ complex multiplications and $N \log_2 N$ complex additions, rather than the N^2 multiplications of the direct sum.*

Rests on Definition 17.84.

Derivation. *Derives Theorem 17.87.*

Split the sum into even and odd indices, $n = 2r$ and $n = 2r + 1$, and use $W_N^{2rk} = W_{N/2}^{rk}$:

$$X_k = \underbrace{\sum_{r=0}^{N/2-1} x_{2r} W_{N/2}^{rk}}_{E_k} + W_N^k \underbrace{\sum_{r=0}^{N/2-1} x_{2r+1} W_{N/2}^{rk}}_{O_k}, \tag{17.99}$$

so E and O are the discrete transforms of the even- and odd-indexed halves, each of length $N/2$. They are periodic in k with period $N/2$, and $W_N^{k+N/2} = -W_N^k$, so the second half of the output costs nothing new:

$$X_k = E_k + W_N^k O_k\,, \qquad X_{k+N/2} = E_k - W_N^k O_k\,, \qquad 0 \le k < N/2\,. \tag{17.100}$$

Combining the two half-length transforms therefore costs $N/2$ complex multiplications and N additions, whence the recursion $M(N) = 2M(N/2) + N/2$ with $M(1) = 0$. Dividing by N, $M(N)/N = M(N/2)/(N/2) + 1/2$, so $M(N)/N$ increases by $1/2$ at each of the $\log_2 N$ levels of the recursion, giving $M(N) = \frac{N}{2}\log_2 N$; the addition count follows identically. □

Example 17.88 (What the saving is worth)**.** For $N = 2^{20} = 1\,048\,576$ samples — one minute of a channel sampled at 16 384 Hz — the direct sum needs $N^2 \approx 1.1 \times 10^{12}$ complex multiplications and the fast algorithm $\frac{N}{2}\log_2 N \approx 1.05 \times 10^7$, a factor of about 1.0×10^5. This is the difference between an hour of computation and a tenth of a second, and it is why every measured spectrum quoted in this treatise, from the angular power spectrum of Chapter 51 to the strain spectra of Chapter 47, exists.

The algorithm was published by Cooley and Tukey in 1965 [1304] and transformed numerical practice within a few years. It was not new: Gauss had the same doubling recursion in an unpublished note of 1805, written while interpolating the orbit of the asteroid Pallas, and several nineteenth- and twentieth-century authors rediscovered pieces of it — a history reconstructed by Heideman, Johnson and Burrus [1740]. The treatise records the attribution as they establish it: the algorithm is Gauss's, its impact is Cooley and Tukey's.

Example 17.89 (Leakage, windowing and resolution)**.** A record of N samples at spacing Δt spans $T_{\mathrm{w}} = N\Delta t$ and resolves frequencies separated by

$$\Delta\nu = \frac{1}{T_{\mathrm{w}}} = \frac{\nu_{\mathrm{s}}}{N}\,. \tag{17.101}$$

With $N = 2^{16} = 65\,536$ samples at $\nu_s = 16\,384\,\mathrm{Hz}$ the record is 4.0 s long and the resolution 0.25 Hz: no processing of that record can separate two lines closer than that, because Corollary 17.44 forbids it. A sinusoid whose frequency does not fall exactly on a bin is smeared over neighbouring bins by convolution with the transform of the rectangular window, Equation (17.40), whose first side lobe sits at $-13.3\,\mathrm{dB}$ relative to the peak — the value $20\log_{10}|\operatorname{sinc} x|$ at the first stationary point $x \approx 4.4934$ of the sinc, where $\tan x = x$. A weak line 20 dB below a strong neighbour is therefore buried by the neighbour's leakage. Tapering the record with a smooth window suppresses the side lobes at the price of broadening the main lobe: it is Theorem 17.22 again — a non-negative kernel in place of an oscillating one — and the trade between resolution and dynamic range is not avoidable, only chosen.

17.6 Other integral transforms

17.6.1 Hankel and Mellin transforms

The Fourier kernel $\mathrm{e}^{-\mathrm{i}\omega t}$ diagonalises translations of the line. Other symmetries call for other kernels: rotations about an axis call for Bessel functions, and dilations of the half-line call for powers. Both transforms below are, at bottom, the Fourier transform in adapted coordinates, and both are treated systematically by Titchmarsh [802] and Morse and Feshbach [1023].

Proposition 17.90 (Hankel transform as the axially symmetric Fourier transform)**.** *Work in $\mathbb{R}^3$ with cylindrical coordinates (ρ, φ, z), and let $f(\boldsymbol{r}) = g(\rho)\,\mathrm{e}^{\mathrm{i}m\varphi}\mathrm{e}^{\mathrm{i}k_z z}$. Then its three-dimensional Fourier transform is supported on the plane k_z fixed and equals*

$$\mathrm{i}^{-m}\,\mathrm{e}^{\mathrm{i}m\varphi_k}\,(\mathcal{H}_m g)(k_\perp)\,, \qquad (\mathcal{H}_m g)(k_\perp) = \int_0^\infty g(\rho)\,J_m(k_\perp\rho)\,\rho\,\mathrm{d}\rho\,, \tag{17.102}$$

up to the fixed normalisation of the transverse transform, where J_m is the Bessel function of Section 9.8 and $(k_\perp, \varphi_k)$ are polar coordinates in the transverse plane of wavevectors. The transform Equation (17.102) is its own inverse:

$$g(\rho) = \int_0^\infty (\mathcal{H}_m g)(k_\perp)\,J_m(k_\perp\rho)\,k_\perp\,\mathrm{d}k_\perp\,. \tag{17.103}$$

Rests on Definition 17.29 and Proposition 17.41.

Proof. *Derives Proposition 17.90.*

The z dependence separates and produces the constraint on k_z by Equation (17.52). In the transverse plane, write $\boldsymbol{k}_\perp \cdot \boldsymbol{\rho} = k_\perp\rho\cos(\varphi - \varphi_k)$ and do the angular integral with the Bessel integral representation

$$\int_0^{2\pi} \mathrm{e}^{-\mathrm{i}k_\perp\rho\cos\alpha}\,\mathrm{e}^{\mathrm{i}m\alpha}\,\mathrm{d}\alpha = 2\pi\,\mathrm{i}^{-m}\,J_m(k_\perp\rho)\,,$$

which is the generating-function identity of Section 9.8.5 evaluated on the unit circle. What survives is the radial integral Equation (17.102). For the inversion, run the same computation on the two-dimensional inversion integral; the angular factor $\mathrm{e}^{\mathrm{i}m\varphi}$ is reproduced and the radial measure $k_\perp \mathrm{d}k_\perp$ appears, giving Equation (17.103). □

Example 17.91 (Axially symmetric potential problem)**.** Let Φ satisfy Laplace's equation in the half space $z > 0$ of $\mathbb{R}^3$, with axially symmetric boundary data $\Phi(\rho, 0) = \Phi_0(\rho)$ in V and $\Phi \to 0$ as $z \to \infty$. Separating in cylindrical coordinates (Section 10.2) gives solutions $\mathrm{e}^{-kz}J_0(k\rho)$ for each $k > 0$ in 1/m, so

$$\Phi(\rho, z) = \int_0^\infty A(k)\,\mathrm{e}^{-kz}\,J_0(k\rho)\,k\,\mathrm{d}k\,, \qquad A(k) = (\mathcal{H}_0\Phi_0)(k)\,, \tag{17.104}$$

the coefficient being read off by Equation (17.103) at $z = 0$. The Hankel transform does for a cylindrical boundary what the Fourier transform does for a planar one; the diffraction integrals of Chapter 61 for a circular aperture are the same transform with $m = 0$.

The Mellin transform. Where Fourier analysis diagonalises translation, Mellin analysis diagonalises *dilation*. The multiplicative group of positive reals, with its invariant measure $\mathrm{d}x/x$, has characters $x \mapsto x^{-s}$, and the transform against them is the following.

Definition 17.92 (Mellin transform)**.** For f defined on $(0,\infty)$ and $s \in \mathbb{C}$,

$$\tilde f(s) = (\mathcal{M} f)(s) = \int_0^\infty f(x)\, x^{s-1}\, \mathrm{d}x\,, \tag{17.105}$$

whenever the integral converges absolutely. For $s = N+1$ with N a non-negative integer, $\tilde f(N+1) = \int_0^\infty f(x) x^N \mathrm{d}x$ is the N-th *moment* of f; the Mellin transform is thus the analytic continuation of the sequence of moments to complex order.

Theorem 17.93 (Fundamental strip and holomorphy)**.** *Suppose f is continuous on $(0,\infty)$ with*

$$|f(x)| \le C\, x^{-a} \quad (0 < x \le 1)\,, \qquad |f(x)| \le C\, x^{-b} \quad (x \ge 1)\,, \qquad a < b\,. \tag{17.106}$$

Then Equation (17.105) converges absolutely on the open strip $a < \Re s < b$ and defines a holomorphic function there, bounded on every closed substrip. The strip is called fundamental*, and $\tilde f$ determines f on it.*

Rests on Definition 17.92 and Proposition 17.67.

Proof. *Derives Theorem 17.93.*

Split the integral at $x = 1$. With $\sigma = \Re s$, $\int_0^1 |f|\, x^{\sigma-1}\mathrm{d}x \le C \int_0^1 x^{\sigma-a-1}\mathrm{d}x = C/(\sigma - a)$, finite exactly when $\sigma > a$; and $\int_1^\infty |f|\, x^{\sigma-1}\mathrm{d}x \le C \int_1^\infty x^{\sigma-b-1}\mathrm{d}x = C/(b-\sigma)$, finite exactly when $\sigma < b$. Both bounds are uniform on a closed substrip, so the integral converges uniformly there and the argument of Proposition 17.67 — differentiation under the integral sign, the extra factor $\ln x$ being absorbed by shrinking the substrip — gives holomorphy, with $\tilde f'(s) = \int_0^\infty f(x) \ln x\, x^{s-1}\mathrm{d}x$. Uniqueness follows from Theorem 17.94 below. □

Theorem 17.94 (Mellin inversion)**.** *Under the hypotheses of Theorem 17.93, if for some c in the fundamental strip $\omega \mapsto \tilde f(c + \mathrm{i}\omega)$ is absolutely integrable, then at every point of continuity*

$$f(x) = \frac{1}{2\pi \mathrm{i}} \int_{c-\mathrm{i}\infty}^{c+\mathrm{i}\infty} \tilde f(s)\, x^{-s}\, \mathrm{d}s\,, \tag{17.107}$$

the contour being the vertical line $\Re s = c$, traversed upward. The value of the integral is independent of c within the strip.

Rests on Theorems 8.12, 17.32 and 17.93.

Proof. *Derives Theorem 17.94.*

Substitute $x = \mathrm{e}^{-u}$, so $\mathrm{d}x/x = -\mathrm{d}u$ and the half-line $0 < x < \infty$ becomes the whole u line reversed. Writing $\phi(u) = f(\mathrm{e}^{-u})$ and $s = c + \mathrm{i}\omega$,

$$\tilde f(c+\mathrm{i}\omega) = \int_{-\infty}^{\infty} \phi(u)\, \mathrm{e}^{-(c+\mathrm{i}\omega)u}\, \mathrm{d}u = \sqrt{2\pi}\, \widehat{\phi_c}(\omega)\,, \qquad \phi_c(u) = \phi(u)\, \mathrm{e}^{-cu}\,, \tag{17.108}$$

exactly the two-sided analogue of Equation (17.82): the Mellin transform on the line $\Re s = c$ is the Fourier transform of $f(\mathrm{e}^{-u})\mathrm{e}^{-cu}$. The hypothesis makes $\widehat{\phi_c}$ absolutely integrable, so Theorem 17.32 gives

$$\phi(u)\, \mathrm{e}^{-cu} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde f(c+\mathrm{i}\omega)\, \mathrm{e}^{\mathrm{i}\omega u}\, \mathrm{d}\omega\,,$$

and multiplying by e^{cu}, substituting $s = c + \mathrm{i}\omega$ with $\mathrm{d}s = \mathrm{i}\mathrm{d}\omega$ and returning to $x = \mathrm{e}^{-u}$ — so that $\mathrm{e}^{su} = x^{-s}$ — yields Equation (17.107). Independence of c follows from Cauchy's theorem (Theorem 8.12) applied to the rectangle between two admissible lines, the horizontal sides contributing nothing because $\tilde f$ is bounded on the closed substrip and integrable along the verticals. □

Example 17.95 (Two transforms worth knowing)**.** *(i)* For $f(x)=\mathrm{e}^{-x}$ the bounds Equation (17.106) hold with $a=0$ and any b, so the fundamental strip is $\Re s>0$ and, by the definition of the gamma function,

$$\mathcal{M}\left\{\mathrm{e}^{-x}\right\}(s)=\Gamma(s)\,,\qquad \Re s>0\,. \tag{17.109}$$

Its poles at $s=0,-1,-2,\dots$ lie to the left of the strip, with residues $(-1)^n/n!$; by Proposition 17.96 these poles *are* the small-x expansion $\mathrm{e}^{-x}=\sum(-x)^n/n!$. *(ii)* For $f(x)=1/(1+x)$ the strip is $0<\Re s<1$ and $\mathcal{M}f(s)=\pi/\sin(\pi s)$, a function whose poles at every integer encode both the expansion of f in powers of x at the origin and its expansion in powers of $1/x$ at infinity.

Proposition 17.96 (Poles give asymptotics)**.** *Let $\tilde f$ continue meromorphically to $c'<\Re s<b$ with finitely many poles $s_1,\dots,s_k$ there and no pole on $\Re s=c'$, and suppose $\tilde f\to 0$ uniformly as $|\Im s|\to\infty$ in the closed strip. Then, as $x\to 0^+$,*

$$f(x)=\sum_{j=1}^{k}\operatorname{Res}_{s=s_j}\left[\tilde f(s)\,x^{-s}\right]+O\!\left(x^{-c'}\right)\,, \tag{17.110}$$

and a simple pole at s_j with residue r_j contributes $r_jx^{-s_j}$, a double pole a term in $x^{-s_j}\ln x$.
Rests on Theorems 8.24 and 17.94, Lemma 8.9, and Definition 8.22.

Proof. *Derives Proposition 17.96.*

Apply the residue theorem (Theorem 8.24) to the rectangle with vertical sides $\Re s=c$ and $\Re s=c'$ and horizontal sides at $\Im s=\pm T$. Traversed counterclockwise this runs *up* the line $\Re s=c$ and *down* the line $\Re s=c'$, so

$$\frac{1}{2\pi\mathrm{i}}\int_{(c)}-\frac{1}{2\pi\mathrm{i}}\int_{(c')}=\sum_{j}\operatorname{Res}_{s=s_j}\left[\tilde f(s)x^{-s}\right]\,,$$

the horizontal sides vanishing as $T\to\infty$ by the decay hypothesis and the ML estimate (Lemma 8.9). The first term is $f(x)$ by Equation (17.107); the second is bounded by $x^{-c'}\int\left|\tilde f(c'+\mathrm{i}\omega)\right|\mathrm{d}\omega/(2\pi)$, since $|x^{-s}|=x^{-\Re s}$. The residue of a simple pole is $r_jx^{-s_j}$ by Definition 8.22, and of a double pole $\mathrm{d}/\mathrm{d}s$ of $\tilde f_2(s)x^{-s}$, which produces the logarithm. □

This is why the Mellin transform is the natural instrument for asymptotics: the analytic structure of $\tilde f$ to the left of the fundamental strip is, term by term, the expansion of f near the origin, and the structure to the right is the expansion at infinity.

17.6.2 Multiplicative convolution and the moments

The property that makes the Mellin transform indispensable is that it turns a convolution over the multiplicative group into a product — exactly as Theorem 17.53 does for the additive group.

Definition 17.97 (Multiplicative convolution)**.** For f,g on $(0,\infty)$,

$$(f\star g)(x)=\int_0^\infty f(y)\,g\!\left(\frac{x}{y}\right)\frac{\mathrm{d}y}{y}\,. \tag{17.111}$$

The measure $\mathrm{d}y/y$ is the invariant (Haar) measure of the group $((0,\infty),\times)$: it satisfies $\mathrm{d}(\lambda y)/(\lambda y)=\mathrm{d}y/y$ for every $\lambda>0$, which is what makes Equation (17.111) the exact analogue of Equation (17.63).

Theorem 17.98 (Mellin convolution theorem)**.** *If the fundamental strips of $\tilde f$ and $\tilde g$ overlap, then on the common strip*

$$\mathcal{M}\{f\star g\}(s)=\tilde f(s)\,\tilde g(s)\,. \tag{17.112}$$

The transform is commutative and associative, and $(f\star g)\star h$ has transform $\tilde f\tilde g\tilde h$.

Rests on Definitions 17.92 and 17.97.

Proof. *Derives Theorem 17.98.*

Substitute Equation (17.111) into Equation (17.105) and exchange the order of integration, legitimate by Fubini's theorem because on the common strip $\iint |f(y)|\,|g(x/y)|\,x^{\sigma-1}\mathrm{d}x\,\mathrm{d}y/y$ is finite by the same computation performed with absolute values:

$$\mathcal{M}\{f\star g\}(s)=\int_0^\infty \frac{f(y)}{y}\left[\int_0^\infty g\!\left(\frac{x}{y}\right)x^{s-1}\mathrm{d}x\right]\mathrm{d}y\,.$$

In the inner integral put $x=yu$, so $\mathrm{d}x=y\,\mathrm{d}u$ and $x^{s-1}=y^{s-1}u^{s-1}$; the bracket becomes $y^s\int_0^\infty g(u)u^{s-1}\mathrm{d}u=y^s\tilde g(s)$. What remains is $\tilde g(s)\int_0^\infty f(y)y^{s-1}\mathrm{d}y=\tilde f(s)\tilde g(s)$. Commutativity and associativity follow, as for Proposition 17.51, from the substitution $y\mapsto x/y$ and from Equation (17.112) with uniqueness of the transform. □

Corollary 17.99 (Convolution on the unit interval)**.** *Suppose f and g vanish for $x>1$. Then so does $f\star g$, and for $0<x\le 1$*

$$(f\star g)(x)=\int_x^1 f(y)\,g\!\left(\frac{x}{y}\right)\frac{\mathrm{d}y}{y}\,, \tag{17.113}$$

while the Mellin transform reduces to the moment integral

$$\tilde f(N+1)=\int_0^1 f(x)\,x^N\,\mathrm{d}x=:M_N[f]\,. \tag{17.114}$$

Consequently the moments of a multiplicative convolution are the products of the moments:

$$M_N[f\star g]=M_N[f]\;M_N[g]\qquad \text{for every } N\,. \tag{17.115}$$

Rests on Definitions 17.92 and 17.97 and Theorem 17.98.

Proof. *Derives Corollary 17.99.*

In Equation (17.111) the factor $f(y)$ vanishes unless $y\le 1$ and $g(x/y)$ vanishes unless $x/y\le 1$, i.e. $y\ge x$; so the range is $x\le y\le 1$, which is empty for $x>1$ and gives Equation (17.113) otherwise. Equation (17.114) is Definition 17.92 at $s=N+1$ with the support restriction, and Equation (17.115) is Equation (17.112) evaluated at $s=N+1$, the point lying in the common strip whenever the moments converge. □

Equation (17.115) is the statement the rest of this subsection exists for. A convolution over a multiplicative variable — a fraction, a ratio, a scale — is an integral operator whose kernel couples every value of the variable to every other, and it is intractable as it stands. Taking moments replaces it by ordinary multiplication, one independent equation for each N: the moments *diagonalise* the convolution. The consequence for evolution equations is immediate.

Theorem 17.100 (Moments diagonalise a convolution evolution)**.** *Let $f(x,\tau)$ be supported in $0<x\le 1$ and satisfy the integro-differential equation*

$$\frac{\partial f(x,\tau)}{\partial\tau}=(P\star f)(x,\tau)=\int_x^1 P(y)\,f\!\left(\frac{x}{y},\tau\right)\frac{\mathrm{d}y}{y}\,, \tag{17.116}$$

with a fixed kernel P whose moments $\tilde{P}(N+1)$ exist. Then the moments $M_N(\tau) = \int_0^1 f(x,\tau)x^N \mathrm{d}x$ satisfy the decoupled ordinary differential equations

$$\frac{\mathrm{d}M_N(\tau)}{\mathrm{d}\tau} = \tilde{P}(N+1)\, M_N(\tau)\,, \qquad \textit{whence} \qquad M_N(\tau) = M_N(0)\, \mathrm{e}^{\tilde{P}(N+1)\,\tau}\,, \tag{17.117}$$

and $f(x,\tau)$ is recovered from the moments by the inversion contour Equation (17.107), with $M_N = \tilde{f}(N+1)$ continued to complex order.

Rests on Corollary 17.99 and Theorem 17.94.

Proof. *Derives Theorem 17.100.*

Take the N-th moment of Equation (17.116). On the left, differentiation under the integral sign (dominated convergence, the moments being finite on a neighbourhood of τ) gives $\mathrm{d}M_N/\mathrm{d}\tau$. On the right, Equation (17.115) gives $\tilde{P}(N+1)M_N(\tau)$. That is Equation (17.117), a linear first-order equation with constant coefficient, whose solution is the exponential. Recovery of f is Theorem 17.94 applied to the analytic continuation $\tilde{f}(s,\tau) = \tilde{f}(s,0)\mathrm{e}^{\tilde{P}(s)\tau}$, which agrees with M_N at $s = N+1$. □

Corollary 17.101 (Coupled channels)**.** *If $f = (f_1, \dots, f_p)$ is a vector of densities on $(0,1]$ obeying $\partial_\tau f_i = \sum_j P_{ij} \star f_j$ with a fixed matrix of kernels, then the vectors of moments $\boldsymbol{M}_N(\tau)$ obey*

$$\frac{\mathrm{d}\boldsymbol{M}_N}{\mathrm{d}\tau} = \mathbf{A}_N\, \boldsymbol{M}_N\,, \qquad (\mathbf{A}_N)_{ij} = \tilde{P}_{ij}(N+1)\,, \qquad \boldsymbol{M}_N(\tau) = \mathrm{e}^{\mathbf{A}_N \tau}\, \boldsymbol{M}_N(0)\,. \tag{17.118}$$

If $\mathbf{A}_N$ is diagonalisable, with eigenvalues $\lambda_N^{(\alpha)}$ and left *eigenvectors $\boldsymbol{u}_N^{(\alpha)}$ — those satisfying $(\boldsymbol{u}_N^{(\alpha)})^{\mathsf{T}}\mathbf{A}_N = \lambda_N^{(\alpha)}(\boldsymbol{u}_N^{(\alpha)})^{\mathsf{T}}$ — then the scalar combinations $\boldsymbol{u}_N^{(\alpha)} \cdot \boldsymbol{M}_N$, different at each N, evolve as pure exponentials $\mathrm{e}^{\lambda_N^{(\alpha)}\tau}$ and do not mix.*

Rests on Theorem 17.100 and Corollary 17.99.

Proof. *Derives Corollary 17.101.*

Take moments of each component and apply Equation (17.115) to each $P_{ij} \star f_j$; the result is Equation (17.118), a linear system with constant matrix, solved by the matrix exponential. Contracting Equation (17.118) with a left eigenvector gives $\mathrm{d}\left(\boldsymbol{u}_N^{(\alpha)} \cdot \boldsymbol{M}_N\right)/\mathrm{d}\tau = \lambda_N^{(\alpha)}\, \boldsymbol{u}_N^{(\alpha)} \cdot \boldsymbol{M}_N$, which decouples the system. □

Remark 17.102 (Why this is the useful form). Three features of Theorem 17.100 deserve emphasis. First, the diagonalisation is exact, not perturbative: no approximation has been made about the kernel P beyond the existence of its moments. Second, the eigenvalue $\tilde{P}(N+1)$ is a *number* for each N, computed once from the kernel, so an evolution over any interval in τ costs one exponential per moment. Third, and least often stated, reconstructing f from its moments is the ill-conditioned step: the moment problem amplifies small errors in M_N into large errors in f, for the same reason as Remark 17.55, and the stable route is not to invert the moments numerically but to continue $\tilde{f}(s,\tau)$ analytically in s and evaluate the contour integral Equation (17.107) directly. The scale variable τ in Equation (17.116) is dimensionless, being the logarithm of a ratio of two quantities of the same SI dimension; the moments M_N carry whatever dimension $f\,\mathrm{d}x$ carries and N affects none of it.

17.6.3 The Radon transform

The last transform in this chapter integrates a function not against a kernel but over a family of submanifolds, and asks whether the function can be recovered from the integrals. Radon settled the question in 1917 for lines in the plane and planes in space [449], as pure mathematics; the answer became an instrument half a century later.

Definition 17.103 (Radon transform)**.** For f on $\mathbb{R}^3$, integrable and decaying, and for a unit vector $\boldsymbol{n}$ and a real p,

$$(\mathcal{R}f)(\boldsymbol{n},p)=\int_{\mathbb{R}^3} f(\boldsymbol{x})\,\delta(p-\boldsymbol{n}\cdot\boldsymbol{x})\,\mathrm{d}^3x\,, \tag{17.119}$$

the integral of f over the plane $\boldsymbol{n}\cdot\boldsymbol{x}=p$. In a two-dimensional slice $z=\text{const}$ of the same space the identical formula with d^2x gives the integral along the line $\boldsymbol{n}\cdot\boldsymbol{x}=p$, which is what a transmission measurement records: for a beam of initial intensity I_0 and attenuation coefficient $\mu(\boldsymbol{x})$ in $1/\mathrm{m}$, each element of path removes $\mathrm{d}I=-\mu\,I\,\mathrm{d}\ell$, which integrates along the ray to $\ln(I_0/I)=(\mathcal{R}\mu)(\boldsymbol{n},p)$ — the Beer–Lambert law, whose left-hand side is dimensionless.

Theorem 17.104 (Projection-slice theorem)**.** *Let $\hat{f}$ denote the d-dimensional Fourier transform of f and $\mathcal{F}_1$ the one-dimensional transform in the variable p. Then*

$$\mathcal{F}_1\left[(\mathcal{R}f)(\boldsymbol{n},\cdot)\right](\kappa)=(2\pi)^{(d-1)/2}\,\hat{f}(\kappa\boldsymbol{n})\,, \tag{17.120}$$

in the normalisation of Definition 17.29: the one-dimensional transform of one projection is the d-dimensional transform of f restricted to the line through the origin in the direction $\boldsymbol{n}$.
Rests on Definitions 17.29 and 17.103.

Proof. *Derives Theorem 17.104.*
Insert Equation (17.119) and do the p integral first, the delta collapsing it:

$$\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\!\!\int_{\mathbb{R}^d} f(\boldsymbol{x})\,\delta(p-\boldsymbol{n}\cdot\boldsymbol{x})\,\mathrm{e}^{-\mathrm{i}\kappa p}\,\mathrm{d}^dx\,\mathrm{d}p=\frac{1}{\sqrt{2\pi}}\int_{\mathbb{R}^d} f(\boldsymbol{x})\,\mathrm{e}^{-\mathrm{i}\kappa\boldsymbol{n}\cdot\boldsymbol{x}}\,\mathrm{d}^dx\,,$$

which is $\hat{f}(\kappa\boldsymbol{n})$ times $(2\pi)^{d/2}/\sqrt{2\pi}=(2\pi)^{(d-1)/2}$, the d-dimensional transform carrying one factor $(2\pi)^{-1/2}$ per coordinate. □

So the projections do determine f: they fill the transform space along every ray through the origin, hence everywhere. Inversion is the statement of that fact in a form one can compute with.

Theorem 17.105 (Radon inversion in three-dimensional space)**.** *For f smooth and rapidly decreasing on $\mathbb{R}^3$,*

$$f(\boldsymbol{x})=-\frac{1}{8\pi^2}\int_{S^2}\frac{\partial^2}{\partial p^2}\,(\mathcal{R}f)(\boldsymbol{n},p)\Big|_{p=\boldsymbol{n}\cdot\boldsymbol{x}}\,\mathrm{d}\Omega(\boldsymbol{n})\,, \tag{17.121}$$

the integral running over the unit sphere of directions.
Rests on Theorems 17.32 and 17.104.

Derivation. *Derives Theorem 17.105.*
Write the three-dimensional inversion integral in polar coordinates in $\boldsymbol{k}$, using $\boldsymbol{k}=\kappa\boldsymbol{n}$ with $\kappa\in\mathbb{R}$ and $\boldsymbol{n}$ over the whole sphere, which double-counts and so carries a factor $\tfrac12$:

$$f(\boldsymbol{x})=\frac{1}{(2\pi)^3}\int_{\mathbb{R}^3}\left[\int f\,\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{y}}\mathrm{d}^3y\right]\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}\,\mathrm{d}^3k=\frac{1}{2(2\pi)^3}\int_{S^2}\!\!\int_{-\infty}^{\infty}\kappa^2\,g_{\boldsymbol{n}}(\kappa)\,\mathrm{e}^{\mathrm{i}\kappa\boldsymbol{n}\cdot\boldsymbol{x}}\,\mathrm{d}\kappa\,\mathrm{d}\Omega\,,$$

where $g_{\boldsymbol{n}}(\kappa)=\int(\mathcal{R}f)(\boldsymbol{n},p)\mathrm{e}^{-\mathrm{i}\kappa p}\mathrm{d}p$ by Theorem 17.104 in its unnormalised form. Since $\kappa^2\mathrm{e}^{\mathrm{i}\kappa p}=-\partial_p^2\mathrm{e}^{\mathrm{i}\kappa p}$, the inner integral is $-\partial_p^2\left[2\pi\,(\mathcal{R}f)(\boldsymbol{n},p)\right]$ evaluated at $p=\boldsymbol{n}\cdot\boldsymbol{x}$, by one-dimensional Fourier inversion. Collecting the constants, $-2\pi/\left[2(2\pi)^3\right]=-1/(8\pi^2)$, gives Equation (17.121). □

Theorem 17.106 (Filtered back-projection in a plane slice)**.** *In a two-dimensional slice, with* $\boldsymbol{n}(\theta) = (\cos\theta, \sin\theta)$ *and projections* $P_\theta(p) = (\mathcal{R}f)(\boldsymbol{n}(\theta), p)$*,*

$$f(\boldsymbol{x}) = \frac{1}{4\pi^2} \int_0^\pi \int_{-\infty}^{\infty} \left[\int P_\theta(p)\, \mathrm{e}^{-\mathrm{i}\kappa p} \mathrm{d}p \right] |\kappa|\, \mathrm{e}^{\mathrm{i}\kappa \boldsymbol{n}(\theta)\cdot\boldsymbol{x}}\, \mathrm{d}\kappa\, \mathrm{d}\theta\,. \tag{17.122}$$

Reading the formula from the inside out: transform each projection, multiply by the ramp filter $|\kappa|$*, transform back, and smear the result back along the direction it came from (*back-projection*), summing over directions.*

Rests on Theorems 17.32 and 17.104.

Derivation. *Derives Theorem 17.106.*

Repeat the previous computation in two dimensions. The inverse transform in polar coordinates $\boldsymbol{k} = \kappa\boldsymbol{n}(\theta)$ has area element $|\kappa|\,\mathrm{d}\kappa\,\mathrm{d}\theta$ with $\kappa \in \mathbb{R}$ and $\theta \in [0, \pi)$ — the modulus is the Jacobian and the halved angular range compensates the sign of κ — so

$$f(\boldsymbol{x}) = \frac{1}{(2\pi)^2} \int_0^\pi \int_{-\infty}^{\infty} \hat{f}_{\mathrm{u}}\left(\kappa\boldsymbol{n}(\theta)\right) \mathrm{e}^{\mathrm{i}\kappa\boldsymbol{n}\cdot\boldsymbol{x}}\, |\kappa|\, \mathrm{d}\kappa\, \mathrm{d}\theta\,,$$

with $\hat{f}_{\mathrm{u}}$ the unnormalised transform, which Theorem 17.104 identifies with the bracket of Equation (17.122). □

The factor $|\kappa|$ is the whole content of the word "filtered": plain back-projection without it reconstructs f blurred by a $1/r$ kernel, because the polar measure over-weights low frequencies. It is also what makes the reconstruction noise-sensitive, by Remark 17.55: the ramp amplifies exactly the high-frequency components in which detector noise is loudest, so a practical filter is $|\kappa|$ rolled off above a cutoff, and the choice of cutoff is the trade between resolution and noise.

Corollary 17.107 (How many projections)**.** *To reconstruct features of size* d *across an object of diameter* D*, the detector spacing must satisfy* $\Delta p \le d/2$ *by Theorem 17.80 applied to* p*, and the angular spacing must satisfy* $D\,\Delta\theta/2 \le d/2$*, so that adjacent projections do not skip a resolution element at the rim. Hence about* $\pi D/(2d)$ *view angles are needed.*

Rests on Theorem 17.80 and Definition 17.103.

Proof. *Derives Corollary 17.107.*

The first condition is the Nyquist criterion for the variable p, whose band limit is set by the finest structure present. For the second, two projections at angles differing by $\Delta\theta$ differ, at radius $D/2$, by an arc $(D/2)\,\Delta\theta$; requiring that this not exceed the resolution d gives $\Delta\theta \le 2d/D$, and the number of views over the half-turn $[0, \pi)$ is $\pi/\Delta\theta \ge \pi D/(2d)$. □

For an object of diameter $D = 0.30\,\mathrm{m}$ reconstructed to $d = 1.0\,\mathrm{mm}$, Corollary 17.107 asks for about 470 view angles and a detector pitch of $0.5\,\mathrm{mm}$ — numbers of the order that clinical scanners use, arrived at from the sampling theorem alone. Cormack rediscovered the inversion independently, and, unlike Radon, carried it through to reconstruction algorithms and to a laboratory demonstration on a phantom [1250]; computed tomography followed. It remains the most direct vindication in applied mathematics of a transform inversion formula proved for its own sake.

Remark 17.108 (Tomography of a quantum state). The same inversion reconstructs a quantum state from measurements of rotated quadratures. For a single mode with position x in m and momentum p in kg m/s, the Wigner function

$$W(x,p) = \frac{1}{\pi\hbar} \int_{-\infty}^{\infty} \overline{\psi(x+y)}\, \psi(x-y)\, \mathrm{e}^{2\mathrm{i}py/\hbar}\, \mathrm{d}y \tag{17.123}$$

[710] has the property that its integral along any line in the (x,p) plane is the probability density of the corresponding rotated quadrature — that is, the measured quadrature

distributions are precisely the Radon transform of W. Inverting by Equation (17.122) returns W, hence the state. This is how the states prepared in Chapter 122 are characterised, and the $\hbar$ in Equation (17.123) is what makes the phase-space area element dimensionless: $\mathrm{d}x\,\mathrm{d}p/(2\pi\hbar)$ counts states.

Three sections of this chapter have now met the same pattern from three directions. The Fourier transform diagonalises translation, the Mellin transform dilation, the Radon transform the family of hyperplanes; in each case a hard problem — a differential equation, a convolution over a ratio, an inverse problem — becomes multiplication, and the price is an inversion contour and a discipline about what may be assumed of the data. That is the whole method, and the rest of the treatise uses it.

Part III

Classical Mechanics

Chapter 18

Kinematics

Kinematics is the description of motion before any inquiry into its causes: it fixes the arena — space, time, frames of reference — and the quantities — position, velocity, acceleration — with which every later dynamical statement of this treatise is phrased. The chapter closes with the itinerary equation for constant acceleration, the first law of motion in this book to be confronted directly with experiment, in Chapter 20.

18.1 Foundations

18.1.1 Fundamental concepts

Motion

Motion is the subject of this part, and it is worth fixing at the outset what kind of statement a statement about motion is. When a body is said to move, what is asserted is never a property of the body by itself: it is a relation between that body and a second one, chosen — freely, and for convenience alone — to count as fixed. A passenger asleep in an aircraft seat is at rest with respect to the cabin, moving at some $250\,\mathrm{m/s}$ with respect to the ground, and moving at about $3 \times 10^4\,\mathrm{m/s}$ with respect to the Sun; no experiment settles which of the three is the truth, because all three are. The second body, together with the rulers and clocks tied to it, is the *frame of reference* of Definition 18.7, and every kinematic quantity in this chapter carries an unwritten "with respect to K".

Definition 18.1 (Motion and rest)**.** A particle is *in motion* with respect to a given frame of reference when the point of space it occupies is not the same at every instant, and is *at rest* in that frame otherwise. Quantitatively, motion is the statement that the itinerary map Equation (18.1) is not constant.

Rests on Definitions 18.7 and 18.9.

Kinematics answers the question *how* a particle moves and declines the question *why*: it takes the trajectory as given and extracts from it the quantities — velocity, acceleration — in which the dynamics of Chapter 19 is afterwards phrased. The division is not merely pedagogical. A kinematic statement is a statement about a curve, and is settled by measurements of positions and times alone; a dynamical statement asserts in addition what *produces* the curve, and needs a law.

The mathematics that the description requires is already in place and is not rebuilt here. A trajectory is a differentiable curve in $\mathbb{R}^3$ in the sense of Definition 13.8; the instantaneous quantities are its derivatives with respect to the parameter, in the sense of Definition 7.26; and the tangent, principal normal and binormal of Definitions 13.12, 13.14 and 13.15 supply the natural frame in which an acceleration is read, as Section 18.3.4 shows.

Remark 18.2 (What is assumed here, and what is measured). That motion is relational is an assumption of this chapter, not a theorem of it. Newton took the opposite view, holding that there exists an absolute space with respect to which a body is really at rest [14]; Mach objected that no experiment of Newton's own mechanics can identify that space — Postulate 18.16 makes every inertial frame equivalent — and that an unobservable should be struck from the theory [225]. This treatise follows Mach on the evidence, with one qualification the reader should carry forward: *rotation* is not relational in the same way. A rotating frame is detectable from inside it, by the tilt of a plumb line, by the precession of a pendulum [134], or by the surface of water in a spinning bucket, and Phenomenon 29.53 records the measurements. What uniform translation lacks, and rotation possesses, is an acceleration.

Rests on Postulate 18.16 and Phenomenon 29.53.

Space and time

To study nature and the motions that occur in it, we may take the universe and regard it as a three-dimensional Euclidean manifold; that is, we shall consider the universe to be $\mathbb{R}^3$, to which we shall refer simply as *space*.

We may further consider a parameter with respect to which the state of a physical system evolves. We shall refer to this parameter simply as *time*: a real parameter that indicates the state of a system at any instant.

To determine the location of objects of the macrocosm, such as stars and galaxies, and of the microcosm, such as atoms and electrons, we shall employ physical and mathematical resources to be defined in the course of this treatise, always within the context of space and time.

Particle

Definition 18.3 (Particle)**.** A *particle* is a point of space that can be isolated for its study; that is, a particle may be studied in $\mathbb{R}^3$ as if it were alone in the universe.

For example, to study the motion of a ball we may consider that the ball, together with the Earth, is alone in the universe, since the interactions due to a galaxy located millions of light-years away can be entirely negligible.

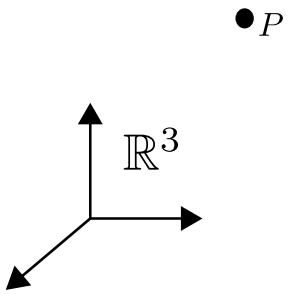

Figure 18.1: A particle: a point of space isolated for its study.

Body

Definition 18.4 (Body)**.** A *body* is a particle with a definite volume in space.

Rests on Definition 18.3.

Remark 18.5. This provisional notion is refined in Chapter 19, where a body is described as a system of many particles occupying a region of space.

Rests on Definition 18.4.

18.1.2 Frames of reference

Free particle

Definition 18.6 (Free particle)**.** A *free particle* is a particle free of any interaction of nature.
Rests on Definition 18.3.

Frame of reference

Definition 18.7 (Frame of reference)**.** A *frame of reference* is the choice of a particle with respect to which the motion of another is observed.
Rests on Definition 18.3.

In order to study distinct frames of reference we shall denote them by K, K', K'', and so on. The choice of a frame of reference allows us to establish the location of the origin of $\mathbb{R}^3$ so as to describe a system mathematically — that is, to introduce distances and angles, which the Euclidean metric permits us to do.

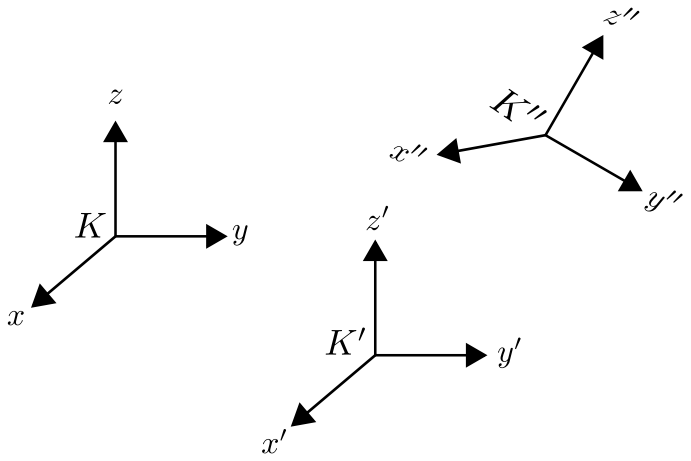

Figure 18.2: A frame of reference: a particle chosen as origin, with respect to which the motion of another particle is observed.

Inertial frame of reference

Definition 18.8 (Inertial frame of reference)**.** An *inertial frame of reference* is a frame of reference located on a free particle.
Rests on Definitions 18.6 and 18.7.

18.1.3 Kinematics of a particle

On the time parameter

We may say that a motion began at the instant t_0 and that, at an arbitrary instant $t \in \mathbb{R}$, the total time of the motion is $\Delta t = t - t_0$.

Just as in space, we may isolate a portion of time in order to study the motion of a particle.

Position

Definition 18.9 (Position)**.** Consider a particle at the point $(x, y, z) \in \mathbb{R}^3$. The *position* of that particle is the vector (as a bilocal object) joining (x, y, z) and the origin, directed towards the particle, which we denote by $\boldsymbol{x}$.
Rests on Definitions 18.3 and 18.7.

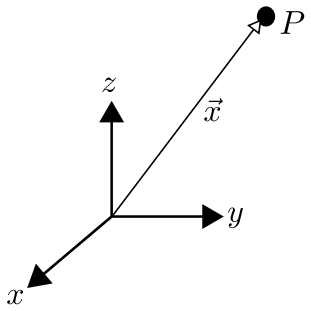

Figure 18.3: The position vector of a particle, joining the origin of the frame of reference to the point occupied by the particle.

We may choose time as a parameter with respect to which the position of a particle varies, that is,

$$\boldsymbol{x} = \boldsymbol{x}(t)\,. \tag{18.1}$$

This equation is called the *itinerary equation* of the particle; it describes a curve in $\mathbb{R}^3$, which we shall call the *trajectory*. In the figure we can see the trajectory of a particle during the time interval $[t_a, t_b]$.

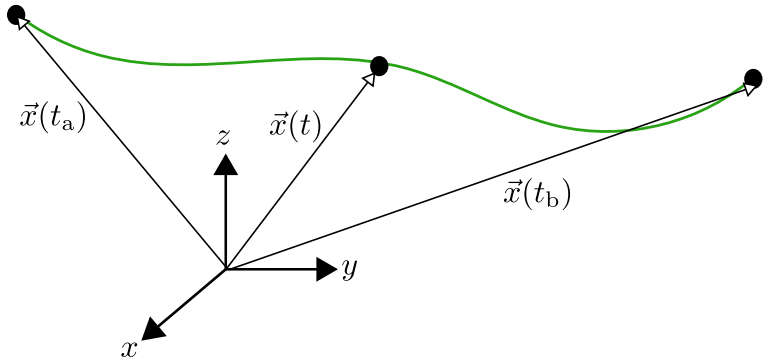

Figure 18.4: The trajectory of a particle: the curve in $\mathbb{R}^3$ described by the itinerary equation $\boldsymbol{x} = \boldsymbol{x}(t)$ over the interval $[t_a, t_b]$.

Velocity

Consider a particle of position $\boldsymbol{x}(t)$ with respect to a given frame of reference. How can we evaluate a change of position between two distinct times t_a and t_b? Define $\Delta\boldsymbol{x} = \boldsymbol{x}(t_b) - \boldsymbol{x}(t_a)$ and $\Delta t = t_b - t_a$. Then the quantity

$$\frac{\Delta\boldsymbol{x}}{\Delta t} = \frac{\boldsymbol{x}(t_b) - \boldsymbol{x}(t_a)}{t_b - t_a} \tag{18.2}$$

is a density, called the *mean velocity*, which indicates how much the position has changed in a given interval of time.

So far we have compared two times. But, given the position of a particle at every time, what quantity can we introduce that indicates the change of position at each instant? To this end, let us recall the definitions of derivative and of vector. When defining a vector on a manifold we concluded that it could not be a bilocal object, and for that purpose we resorted to the definition of the derivative. Something similar happens here: we wish to define a quantity that indicates the change of position at a single point of the time interval — we do not want to compare two points.

We may thus anticipate that the quantity we seek is a vector tangent to a point of the trajectory (conceived as a curve in $\mathbb{R}^3$). The trick that removes the bilocality while retaining

the information corresponding to a single point is to compare two points with the techniques already known, but infinitesimally separated — that is, the derivative.

Definition 18.10 (Velocity)**.** The *velocity* of the particle with respect to the given frame of reference is

$$\boldsymbol{v} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t}\,, \tag{18.3}$$

which is indeed a vector in $\mathbb{R}^3$ tangent to the curve $\boldsymbol{x}$, a known result of the theory of curves (Definition 13.9).

Rests on Definitions 7.26, 13.9 and 18.9.

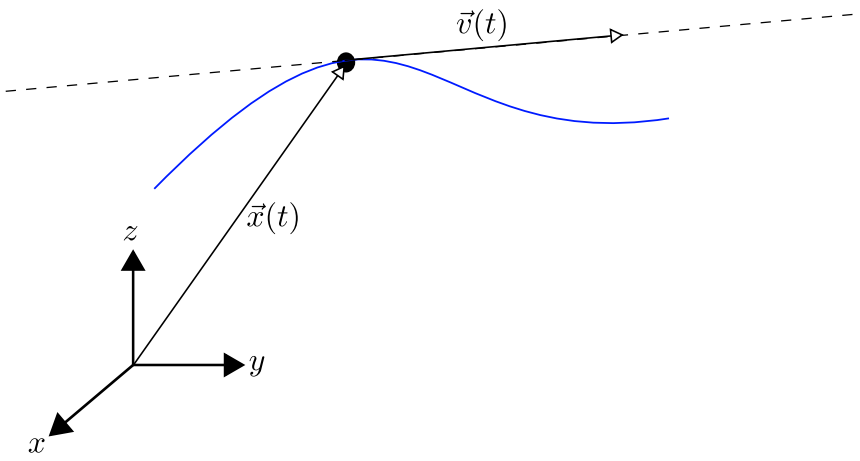

Figure 18.5: The velocity vector: tangent to the trajectory at each of its points.

Acceleration

By the same reasoning as above, we may define a quantity that measures the change of the velocity of a particle in time.

Definition 18.11 (Acceleration)**.** The *acceleration* of the particle with respect to the given frame of reference is

$$\boldsymbol{a} = \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t}\,. \tag{18.4}$$

Rests on Definitions 7.26 and 18.10.

18.1.4 The itinerary equation for constant acceleration

Consider a particle with constant acceleration $\boldsymbol{a}_0$. One has

$$\frac{\mathrm{d}^2\boldsymbol{x}}{\mathrm{d}t^2} = \boldsymbol{a}_0\,, \tag{18.5}$$

which is a differential equation from which the itinerary equation is obtained. Considering the initial conditions

$$\boldsymbol{x}(t_0) = \boldsymbol{x}_0\,, \qquad\qquad \boldsymbol{v}(t_0) = \boldsymbol{v}_0\,,$$

and integrating once, we have

$$\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} = \boldsymbol{v}_0 + \boldsymbol{a}_0(t - t_0)\,,$$

that is, we obtain

$$\boxed{\boldsymbol{v} - \boldsymbol{v}_0 = \boldsymbol{a}_0(t - t_0)}\,. \tag{18.6}$$

Integrating once more, we obtain

$$\boxed{\boldsymbol{x}(t) = \boldsymbol{x}_0 + \boldsymbol{v}_0(t - t_0) + \frac{1}{2}\boldsymbol{a}_0(t - t_0)^2}\,, \tag{18.7}$$

which is known as the *itinerary equation of motion with constant acceleration.*

Phenomenon 18.12 (Uniformly accelerated motion)**.** A body released near the surface of the Earth, with the resistance of the air removed, gains speed in proportion to the elapsed time and falls through a distance proportional to its square; and one and the same constant governs bodies of every mass and composition [4]. The regularity is not a rough one. In a modern ballistic gravimeter the fitted drop reproduces Equation (18.7) at the nanometre level over some 20 cm of fall, and the constant is thereby fixed to about two parts in 10^9 [1906]; the experiment is examined in Chapter 20.

Rests on Equation (18.7) *and Definition 18.11.*

Derivation. *Derives Phenomenon 18.12.*

The kinematical content is the pair of integrations just performed: Equation (18.5) with the stated initial conditions yields Equation (18.6), linear in $t - t_0$, and Equation (18.7), quadratic in it. Nothing else is possible, since prescribing a second derivative fixes a function up to a polynomial of first degree, and the two initial conditions fix that polynomial. What kinematics cannot supply is the observed *universality* of $\boldsymbol{a}_0$: that every body released at the same place receives the same $\boldsymbol{a}_0$ is an experimental input at this stage, and it becomes a statement about mass only in Chapter 19, where the inertial mass of Newton's second law cancels against the gravitational mass in the weight [14]. □

18.2 Galilean relativity

18.2.1 Newton's postulates of absolute space and time

Newton's Scholium to the definitions asserts two absolutes, and this treatise treats them very differently. *Absolute space*, in Newton's words, remains always similar and immovable without relation to anything external, so that a body has a true motion in it as well as the relative motions we measure [14].

Remark 18.13 (Absolute space is stated here, and not adopted). No postulate of absolute space is made in this book. The reason is recorded as Phenomenon 18.17, which is Newton's own fifth corollary: within his mechanics, nothing distinguishes rest in absolute space from uniform motion through it, so the quantity is unmeasurable and the theory is complete without it. What replaces it is Postulate 18.16, which asserts the equivalence of the inertial frames and nothing more. Remark 18.2 states the position and its one qualification — that rotation, unlike uniform translation, *is* locally detectable, which is what makes Newton's bucket a real argument and not a rhetorical one.

Rests on Postulate 18.16 and Phenomenon 18.17.

The postulate on time is a different matter: it is used, constantly and essentially, and it is stated as a postulate of this part.

Postulate 18.14 (Absolute time)**.** Time is an absolute parameter for the whole universe, with respect to any frame of reference.

That is, time elapses equally for every physical system that we can describe in nature [14].

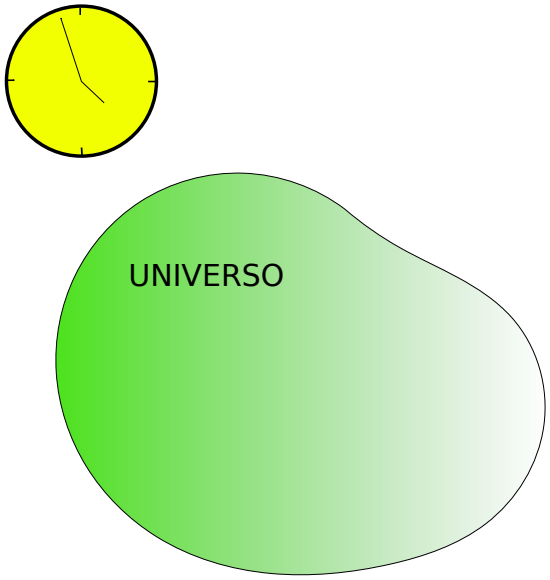

Figure 18.6: Absolute time: a single universal clock, ticking equally for every frame of reference.

Phenomenon 18.15 (A common time, and the speed at which it fails)**.** Clocks of every construction — pendulum, quartz, atomic — that are at rest with respect to one another are observed to keep a common rate, so that a single parameter t serves them all. That, and not more, is the measured content of Postulate 18.14. Clocks in relative motion do *not* keep a common rate: a moving clock runs slow by the factor $\gamma = \left(1 - v^2/c^2\right)^{-1/2}$, as seen in the decay of fast muons [863, 1253], in the transverse Doppler shift of a canal-ray beam [816], and in caesium clocks flown around the world [1476]. Postulate 18.14 is therefore an approximation with a measurable domain of validity, not an identity.

Rests on Postulate 18.14.

Derivation. *Derives Phenomenon 18.15.*

The postulate itself is not derived — it is postulated — but the domain over which it is safe can be quantified. Expanding the factor quoted above for $v \ll c$,

$$\gamma - 1 = \frac{v^2}{2c^2} + O\!\left(\frac{v^4}{c^4}\right), \tag{18.8}$$

so the fractional disagreement between two clocks is second order in their relative speed. At a laboratory speed of 10 m/s it is about 6×10^{-16}; at the 300 m/s of an airliner it is about 5×10^{-13}, which over a two-day circumnavigation accumulates to some tens of nanoseconds — the order of the effect reported in [1476]. The factor γ is derived, rather than quoted, in Chapter 38, and the experiments that exhibit it are collected in Chapter 41. □

18.2.2 Galileo's principle of relativity

We enunciate as a fundamental principle:

Postulate 18.16 (Principle of Galilean relativity)**.** All inertial frames of reference are equivalent.

This is known as *Galileo's principle of relativity*. A consequence is the following: a physical law takes the same form with respect to any inertial frame of reference — or, put differently, the laws of physics do not change according to the observer — a notion known as *Galilean invariance*.

Phenomenon 18.17 (Uniform motion is undetectable from within)**.** No mechanical experiment performed entirely inside a closed cabin discloses whether the cabin is at rest or moving uniformly in a straight line: bodies dropped inside it fall along the same vertical, thrown bodies describe the same arcs, and pendulums keep the same period. Newton records the fact as the fifth corollary to the laws of motion [14]. Whether the same holds of *optical* experiments is a separate question, and an experimental one; the null result of aether-drift interferometry [236] answers it in the affirmative, and it is that extension — not the mechanical statement above — which forces the kinematics of Chapter 38.

Rests on Postulate 18.16 and Definition 18.8.

Derivation. *Derives Phenomenon 18.17.*

Let K' translate with constant velocity $\boldsymbol{V}$ with respect to K, so that the positions the two frames assign to one and the same particle differ by

$$\boldsymbol{x}'(t) = \boldsymbol{x}(t) - \boldsymbol{V}t - \boldsymbol{x}_0 \,. \tag{18.9}$$

Differentiating once gives $\boldsymbol{v}' = \boldsymbol{v} - \boldsymbol{V}$, and differentiating a second time, $\boldsymbol{V}$ being constant,

$$\boldsymbol{a}' = \boldsymbol{a} \,. \tag{18.10}$$

Separations between particles are likewise unchanged, since the terms $\boldsymbol{V}t$ and $\boldsymbol{x}_0$ cancel in a difference $\boldsymbol{x}_1 - \boldsymbol{x}_2$. Every quantity that enters Equation (18.5) — accelerations and relative positions — is therefore identical in the two frames, so an experiment confined to the cabin returns the same numbers whichever frame it is described in. The argument used $\frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} = \boldsymbol{0}$, and it fails at once for a cabin that rotates or accelerates; such motion *is* detectable from inside, as Chapter 29 records. □

18.2.3 Galilean transformations

Postulate 18.16 asserts that all inertial frames are equivalent; it does not say how the coordinates assigned by two of them are related. That relation is fixed by three inputs, each a physical assumption and none of them a mathematical identity: absolute time (Postulate 18.14); the homogeneity of space and of time, that is, that no place and no instant is distinguished; and the isotropy of space, that no direction is distinguished.

Definition 18.18 (Galilean transformation)**.** A *Galilean transformation* is a map of the coordinates $(\boldsymbol{x}, t)$ assigned by an inertial frame K to the coordinates $(\boldsymbol{x}', t')$ assigned by an inertial frame K' of the form

$$\boldsymbol{x}' = R\boldsymbol{x} - \boldsymbol{V}t + \boldsymbol{a} \,, \qquad t' = t + b \,, \tag{18.11}$$

with $R \in \mathrm{SO}(3)$ a rotation, $\boldsymbol{V} \in \mathbb{R}^3$ the velocity of K' with respect to K, $\boldsymbol{a} \in \mathbb{R}^3$ a displacement of the spatial origin and $b \in \mathbb{R}$ a shift of the origin of time. The parameters number $3 + 3 + 3 + 1 = 10$. The pure boost Equation (18.9) is the case $R = \mathbb{1}$, $b = 0$, $\boldsymbol{a} = -\boldsymbol{x}_0$.

Rests on Postulates 18.14 and 18.16 and Definition 18.8.

Remark 18.19 (Why the map is affine, and what is assumed to make it so). The linear-plus-constant form of Equation (18.11) is *assumed* here, not derived, and the assumption should be visible rather than buried. What would derive it is a purely mathematical statement — that a bijection of $\mathbb{R}^3 \times \mathbb{R}$ carrying every uniform rectilinear motion to a uniform rectilinear motion is necessarily affine, the fundamental theorem of affine geometry — and Part II does not at present carry that theorem, so this treatise records the affine form where it is used instead of appealing to a result it has not proved. Physically the assumption is exactly the homogeneity of space and time: were the map not affine, its derivative would differ from

place to place or from instant to instant, which would single out a place or an instant. The same assumption, made in the same place and for the same reason, is what licenses the linear ansatz Equation (38.5) from which the Lorentz transformation is obtained; the two derivations differ in their *second* input, absolute time here and the invariance of c there, and in nothing else.

Rests on Definition 18.18.

Proposition 18.20 (The Galilean group)**.** *The transformations Equation (18.11) form a group of ten parameters under composition, with composition law*

$$(R_2, \boldsymbol{V}_2, \boldsymbol{a}_2, b_2) * (R_1, \boldsymbol{V}_1, \boldsymbol{a}_1, b_1) = (R_2 R_1,\ \boldsymbol{V}_2 + R_2 \boldsymbol{V}_1,\ \boldsymbol{a}_2 + R_2 \boldsymbol{a}_1 - \boldsymbol{V}_2 b_1,\ b_1 + b_2)\ , \tag{18.12}$$

neutral element $(\mathbb{1}, \mathbf{0}, \mathbf{0}, 0)$ *and inverse*

$$(R, \boldsymbol{V}, \boldsymbol{a}, b)^{-1} = \left(R^{-1},\ -R^{-1}\boldsymbol{V},\ -R^{-1}\left(\boldsymbol{a} + \boldsymbol{V} b\right),\ -b\right)\ . \tag{18.13}$$

It is the iterated semidirect product

$$\mathrm{Gal}(3) = \mathbb{R}^4 \rtimes \left(\mathbb{R}^3 \rtimes \mathrm{SO}(3)\right)\ , \tag{18.14}$$

whose normal factor $\mathbb{R}^4$ *consists of the translations of space and time and whose homogeneous factor* $\mathbb{R}^3 \rtimes \mathrm{SO}(3)$ *— boosts and rotations — is isomorphic, as a group, to the Euclidean group* $\mathrm{SE}(3)$ *of Example 4.74.*

Rests on Definitions 4.69 and 18.18 and Example 4.74.

Proof. *Derives Proposition 18.20.*

Apply the transformation labelled 1 and then the one labelled 2. The first gives $\boldsymbol{x}_1 = R_1 \boldsymbol{x} - \boldsymbol{V}_1 t + \boldsymbol{a}_1$ and $t_1 = t + b_1$; substituting these into the second,

$$\begin{aligned} \boldsymbol{x}_2 &= R_2 \boldsymbol{x}_1 - \boldsymbol{V}_2 t_1 + \boldsymbol{a}_2 \\ &= R_2 R_1 \boldsymbol{x} - \left(\boldsymbol{V}_2 + R_2 \boldsymbol{V}_1\right) t + \left(\boldsymbol{a}_2 + R_2 \boldsymbol{a}_1 - \boldsymbol{V}_2 b_1\right)\ , \end{aligned} \tag{18.15}$$

and $t_2 = t + b_1 + b_2$. The result is again of the form Equation (18.11), with $R_2 R_1 \in \mathrm{SO}(3)$ since $\mathrm{SO}(3)$ is a group, and reading off the four slots gives Equation (18.12). Composition of maps is associative, $(\mathbb{1}, \mathbf{0}, \mathbf{0}, 0)$ is plainly neutral, and substituting Equation (18.13) into Equation (18.12) returns the neutral element in each slot, which establishes the group axioms.

For the structure, note first that the translations $T = \{(\mathbb{1}, \mathbf{0}, \boldsymbol{a}, b)\}$ close under Equation (18.12) into $(\boldsymbol{a}_1 + \boldsymbol{a}_2, b_1 + b_2)$, so $T \cong (\mathbb{R}^4, +)$ and is abelian. It is normal: conjugating $(\mathbb{1}, \mathbf{0}, \boldsymbol{a}, b)$ by a general $g = (R, \boldsymbol{V}, \boldsymbol{c}, \beta)$ with Equations (18.12) and (18.13) gives

$$g\,(\mathbb{1}, \mathbf{0}, \boldsymbol{a}, b)\,g^{-1} = (\mathbb{1}, \mathbf{0},\ R\boldsymbol{a} - \boldsymbol{V} b,\ b) \in T\,. \tag{18.16}$$

The complementary subgroup $H = \{(R, \boldsymbol{V}, \mathbf{0}, 0)\}$ closes as $(R_2 R_1, \boldsymbol{V}_2 + R_2 \boldsymbol{V}_1)$, meets T only in the identity, and together with T generates the whole group, since $(R, \boldsymbol{V}, \boldsymbol{a}, b) = (\mathbb{1}, \mathbf{0}, \boldsymbol{a}, b) * (R, \boldsymbol{V}, \mathbf{0}, 0)$. By Theorem 4.72 the group is therefore $T \rtimes H = \mathbb{R}^4 \rtimes H$, which is Equation (18.14) once H is identified. That identification is a comparison of two composition laws: writing the element of H as the pair $(\boldsymbol{V}, R)$, its law reads $(\boldsymbol{V}_2, R_2) * (\boldsymbol{V}_1, R_1) = (\boldsymbol{V}_2 + R_2 \boldsymbol{V}_1, R_2 R_1)$, which is Equation (4.49) verbatim with the boost velocity in the slot the Euclidean translation occupies. Hence $H \cong \mathrm{SE}(3) = \mathbb{R}^3 \rtimes \mathrm{SO}(3)$. □

Proposition 18.21 (Galilean invariants)**.** *Under every transformation Equation (18.11):*

1. *the time interval between two events is unchanged,* $\Delta t' = \Delta t$*;*
2. *simultaneity is absolute, that is,* $\Delta t = 0$ *if and only if* $\Delta t' = 0$*;*

3. the distance between two simultaneous *events is unchanged,* $|\Delta \boldsymbol{x}'| = |\Delta \boldsymbol{x}|$.

Rests on Definition 18.18 and Postulate 18.14.

Proof. *Derives Proposition 18.21.*

For two events labelled A and B, subtract the second equation of Equation (18.11) at A from the same equation at B: the constant b cancels and $\Delta t' = \Delta t$, which is (i), and (ii) is the special case $\Delta t = 0$. Subtracting the first equation likewise gives $\Delta \boldsymbol{x}' = R\,\Delta \boldsymbol{x} - \boldsymbol{V}\Delta t$, so when $\Delta t = 0$ we have $\Delta \boldsymbol{x}' = R\,\Delta \boldsymbol{x}$ and, R being orthogonal, $|R\,\Delta \boldsymbol{x}| = |\Delta \boldsymbol{x}|$, which is (iii). The qualification "simultaneous" in (iii) is not decoration: for $\Delta t \neq 0$ the separation $|\Delta \boldsymbol{x}'|$ depends on $\boldsymbol{V}$, as it must, since the two events then happen at places whose relative position is itself changing. □

Remark 18.22 (Superseded, and in exactly what sense). Equation (18.11) is not the transformation law of nature. The measured law is the Poincaré transformation of Chapter 39, whose homogeneous part is the Lorentz group and under which Proposition 18.21 fails in all three of its parts: time intervals, simultaneity and lengths are all frame dependent. The Galilean group is recovered from the Poincaré group as an Inönü–Wigner contraction in the limit $c \to \infty$ (Example 14.89), which is the precise sense in which the two are related: not as rival descriptions, but as a group and its limit. Since c is finite — $c = 299\,792\,458\,\mathrm{m/s}$ exactly, by the definition of the metre [2333] — the contraction is never exact, and the size of the error is set by v^2/c^2. At the Earth's orbital speed of $2.98 \times 10^4\,\mathrm{m/s}$ that is about 10^{-8}, which is why the whole of Part III may use Equation (18.11) without apology and why the optical experiments of Chapter 37, sensitive at precisely that order, could not.

Rests on Propositions 18.20 and 18.21.

18.2.4 Transformation of velocities and accelerations

Proposition 18.23 (Transformation of velocity and acceleration)**.** *Let K and K' be related by the Galilean transformation Equation (18.11). Then the velocity and the acceleration that the two frames assign to one and the same particle are related by*

$$\boldsymbol{v}' = R\boldsymbol{v} - \boldsymbol{V}\,, \qquad \boldsymbol{a}' = R\boldsymbol{a}\,. \tag{18.17}$$

The acceleration is therefore unaffected by a boost or by a translation of either origin, and is carried by a rotation exactly as a vector is. So too is the relative velocity of two particles, since $\boldsymbol{v}_1' - \boldsymbol{v}_2' = R\,(\boldsymbol{v}_1 - \boldsymbol{v}_2)$ with $\boldsymbol{V}$ cancelling in the difference.

Rests on Definitions 18.10, 18.11 and 18.18.

Proof. *Derives Proposition 18.23.*

By the second equation of Equation (18.11), $\mathrm{d}t'/\mathrm{d}t = 1$, so differentiation with respect to t' and with respect to t are the same operation — this is where Postulate 18.14 enters, and it is the only place it is needed. Differentiating the first equation once, with R, $\boldsymbol{V}$ and $\boldsymbol{a}$ constant,

$$\boldsymbol{v}' = \frac{\mathrm{d}\boldsymbol{x}'}{\mathrm{d}t'} = \frac{\mathrm{d}\boldsymbol{x}'}{\mathrm{d}t} = R\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} - \boldsymbol{V} = R\boldsymbol{v} - \boldsymbol{V}\,,$$

and differentiating a second time removes the constant $\boldsymbol{V}$, leaving $\boldsymbol{a}' = R\boldsymbol{a}$. Both statements are Equation (18.17). The claim about the relative velocity follows by writing Equation (18.17) for each particle and subtracting. □

Corollary 18.24 (Galilean composition of velocities)**.** *If K'' moves with constant velocity $\boldsymbol{V}_2$ with respect to K', and K' with $\boldsymbol{V}_1$ with respect to K, all three sets of axes being parallel, then K'' moves with*

$$\boldsymbol{V} = \boldsymbol{V}_1 + \boldsymbol{V}_2 \tag{18.18}$$

with respect to K: Galilean velocities compose by vector addition, and boosts commute with one another.

Rests on Proposition 18.20.

Proof. *Derives Corollary 18.24.*

Set $R_1 = R_2 = \mathbb{1}$, $\boldsymbol{a}_i = \mathbf{0}$ and $b_i = 0$ in Equation (18.12); the boost slot returns $\boldsymbol{V}_2 + \mathbb{1}\,\boldsymbol{V}_1 = \boldsymbol{V}_1 + \boldsymbol{V}_2$ and every other slot returns its neutral value. The pure boosts are thus a copy of $(\mathbb{R}^3, +)$ inside Gal(3), and addition in $\mathbb{R}^3$ is commutative, so any two boosts commute. □

Remark 18.25 (Where the additivity goes). Two features of Corollary 18.24 fail relativistically, and they fail separately. Additivity is replaced by the composition law Equation (38.29), which returns Equation (18.18) only to leading order and never lets the result exceed c; and commutativity is lost as well, two non-collinear boosts composing to a boost *and* a rotation. Neither failure is visible in the mechanics of this part: the fractional discrepancy in Equation (18.18) is of order $V_1 V_2/c^2$, which for two speeds of 1 km/s is about 10^{-11}.

Rests on Corollary 18.24.

Phenomenon 18.26 (Composition of velocities, and its limit)**.** Two observers in uniform relative motion assign to one and the same body velocities that differ by their relative velocity and by nothing else, and assign to it the *same* acceleration. Everyday mechanics — a ball thrown on a moving ship, a walker on a train — shows no departure from the rule. Light does not obey it. The speed of light in vacuum is found to be the same in frames whose relative velocity is the Earth's orbital velocity of about 29.8 km/s [236], and light in a moving transparent medium is carried along by only a fraction of the medium's speed, not by all of it [133].

Rests on Proposition 18.23 and Corollary 18.24.

Derivation. *Derives Phenomenon 18.26.*

The first claim is Proposition 18.23 with $R = \mathbb{1}$: differentiating Equation (18.9) once and twice gives

$$\boldsymbol{v}' = \boldsymbol{v} - \boldsymbol{V}\,, \qquad \boldsymbol{a}' = \boldsymbol{a}\,, \tag{18.19}$$

the second of which is the invariance of the acceleration already recorded as Equation (18.10).

The second claim is not derived here; it is measured, and the two measurements cited are worth separating. Fizeau sent the two arms of an interferometer through water flowing in opposite directions and found the light dragged not by the full speed u of the water, as Equation (18.19) requires, but by a fraction of it close to Fresnel's $1 - 1/n^2$, which for water at $n = 1.33$ is 0.43 [133]. Michelson and Morley looked for the motion of the Earth through the supposed medium and found no shift at all where Equation (18.19) predicted one of order $v/c \approx 10^{-4}$ in the arrival times [236]. Against those two results, the departure of the exact law of Chapter 38 from Equation (18.19) can be stated once and for all: it is of relative order vV/c^2, which for two speeds of 1 km/s is about 10^{-11} and for light, $v = c$, is of order unity. The failure is thus invisible throughout the mechanics of this part and total in optics; the historical situation this created is the subject of Chapter 37. □

18.3 Circular motion

Circular motion is the simplest motion that is not uniform, and it is the one the rest of mechanics leans on most: a planet held in orbit, a pendulum bob on its arc, an electron in a magnetic field and a point of a spinning body all move, instantaneously, on circles. Everything in this section is kinematics and nothing in it is dynamics — what is computed is the acceleration a circular path *requires*, never the agent that supplies it.

18.3.1 The angular description

Definition 18.27 (Angular position, velocity and acceleration)**.** Let a particle move on a circle of fixed radius r centred on the origin, in the plane $z = 0$, and let $\theta(t)$ be the angle its position makes with a fixed axis of that plane, measured in radians. The *angular velocity* and *angular acceleration* are

$$\omega = \frac{\mathrm{d}\theta}{\mathrm{d}t}\,, \qquad \alpha = \frac{\mathrm{d}\omega}{\mathrm{d}t} = \frac{\mathrm{d}^2\theta}{\mathrm{d}t^2}\,, \tag{18.20}$$

of SI units rad/s and rad/s^2. The arc travelled is $s = r\theta$ and the speed is

$$v = \left|\frac{\mathrm{d}s}{\mathrm{d}t}\right| = r\,|\omega|\ . \tag{18.21}$$

Rests on Definitions 18.9 to 18.11.

Remark 18.28 (The radian carries no dimension). The radian is the coherent SI unit of plane angle and is equal to the number one, being the ratio of two lengths [2333]. It is written in Equation (18.20) because it identifies what is being counted, not because it contributes a dimension: ωr comes out in m/s and $\omega^2 r$ in m/s^2 with no conversion factor. This is also why Equation (18.21) fails if θ is measured in any other angular unit.

Rests on Definition 18.27.

When the motion is periodic it is convenient to name its *period* T, the time of one complete revolution, and its *frequency* $f = 1/T$ in Hz. For constant ω these are

$$T = \frac{2\pi}{|\omega|}\,, \qquad f = \frac{1}{T} = \frac{|\omega|}{2\pi}\,. \tag{18.22}$$

Definition 18.29 (Angular velocity vector)**.** Let $\hat{\boldsymbol{n}}$ be the unit normal to the plane of the motion, oriented by the right-hand rule about the sense of increasing θ. The *angular velocity vector* is $\boldsymbol{\omega} = \omega\,\hat{\boldsymbol{n}}$, and it reproduces the velocity as

$$\boldsymbol{v} = \boldsymbol{\omega} \times \boldsymbol{x}\,. \tag{18.23}$$

Rests on Definitions 18.10 and 18.27.

Remark 18.30 (The angular velocity is an element of $\mathfrak{so}(3)$). Writing Equation (18.23) in components with the basis Equation (14.32) of $\mathfrak{so}(3)$,

$$(\boldsymbol{\omega} \times \boldsymbol{x})_i = \epsilon_{ijk}\omega_j x_k = \omega_k\,(L_k)_{ij}\,x_j\,, \tag{18.24}$$

so the cross product with $\boldsymbol{\omega}$ *is* the antisymmetric matrix $\omega_k L_k$ acting on $\boldsymbol{x}$. The angular velocity is thus not a vector by nature but an element of the Lie algebra of the rotation group, which the three-dimensionality of space allows us to label by three numbers; the finite rotation it generates is $\exp(t\,\omega_k L_k)$, evaluated in closed form by Proposition 14.30. Nothing in this chapter depends on the distinction, but Section 29.1.1 does, and so does every statement about how $\boldsymbol{\omega}$ behaves under a reflection.

Rests on Definition 18.29 and Proposition 14.27.

18.3.2 Uniform circular motion

Phenomenon 18.31 (Uniform circular motion is accelerated motion)**.** A body carried at constant speed v around a circle of radius r is not in uniform motion. It has to be held to the circle by something — a string, a rail, a gravitational attraction — and what is required of that agent is an acceleration of constant magnitude v^2/r directed at every instant towards the centre. Withdraw the agent and the body departs along the tangent, as a stone

released from a sling. The rule v^2/r is Huygens', stated among the theorems on centrifugal force appended to the *Horologium Oscillatorium* [11]; the observation is Newton's point of departure for orbital motion [14].

Rests on Definitions 18.11 and 18.27.

Derivation. *Derives Phenomenon 18.31.*

Take the circle in the plane $z = 0$, with the angular speed $\omega = v/r$ constant, so that the itinerary equation Equation (18.1) reads

$$\boldsymbol{x}(t) = r\,(\cos\omega t,\ \sin\omega t,\ 0)\ . \tag{18.25}$$

Differentiating once, by Equation (18.3),

$$\boldsymbol{v}(t) = r\omega\,(-\sin\omega t,\ \cos\omega t,\ 0)\ ,$$

whose magnitude is the constant $r\omega = v$ and whose scalar product with $\boldsymbol{x}$ vanishes — the velocity is tangent to the circle, as it must be. Differentiating again, by Equation (18.4),

$$\boldsymbol{a}(t) = -r\omega^2\,(\cos\omega t,\ \sin\omega t,\ 0) = -\omega^2\boldsymbol{x}(t)\,, \tag{18.26}$$

so the acceleration points from the body straight at the centre and has the constant magnitude

$$|\boldsymbol{a}| = \omega^2 r = \frac{v^2}{r}\,. \tag{18.27}$$

The result is purely kinematical: it says what acceleration a circular path at constant speed *requires*, and says nothing whatever about what supplies it. Supplying it is the business of Chapter 19, and identifying the supplier for the planets is the business of Chapter 27. □

Two features of Equation (18.26) deserve to be named, because both are constantly misread. First, a motion at constant *speed* is nevertheless an accelerated motion, since it is the velocity *vector* that Definition 18.11 differentiates and that vector is turning. Second, the acceleration Equation (18.26) is directed towards the centre, and there is no outward acceleration anywhere in the calculation: the "centrifugal" term of everyday speech is an artefact of describing the motion in a frame rotating with the body, which is not inertial, and it is derived — with its sign and its companion Coriolis term — in Section 29.5.1.

18.3.3 Non-uniform circular motion

Proposition 18.32 (Tangential and centripetal components)**.** *Let a particle move on the circle of radius r in the plane $z = 0$ with an arbitrary angle $\theta(t)$ of class C^2, and write $\hat{\boldsymbol{r}} = (\cos\theta, \sin\theta, 0)$ and $\hat{\boldsymbol{t}} = (-\sin\theta, \cos\theta, 0)$ for the outward radial and the tangential unit vectors. Then*

$$\boldsymbol{v} = r\omega\,\hat{\boldsymbol{t}}\,, \qquad \boldsymbol{a} = r\alpha\,\hat{\boldsymbol{t}} - r\omega^2\,\hat{\boldsymbol{r}}\,, \tag{18.28}$$

with ω and α as in Equation (18.20). The tangential component $r\alpha = \mathrm{d}v/\mathrm{d}t$ changes the speed; the radial component $-r\omega^2\hat{\boldsymbol{r}}$, of magnitude v^2/r, changes only the direction.

Rests on Definition 18.27 and Phenomenon 18.31.

Proof. *Derives Proposition 18.32.*

The itinerary equation is $\boldsymbol{x}(t) = r\hat{\boldsymbol{r}}(\theta(t))$. Since $\mathrm{d}\hat{\boldsymbol{r}}/\mathrm{d}\theta = \hat{\boldsymbol{t}}$ and $\mathrm{d}\hat{\boldsymbol{t}}/\mathrm{d}\theta = -\hat{\boldsymbol{r}}$, the chain rule (Proposition 7.31) gives $\mathrm{d}\hat{\boldsymbol{r}}/\mathrm{d}t = \omega\hat{\boldsymbol{t}}$ and $\mathrm{d}\hat{\boldsymbol{t}}/\mathrm{d}t = -\omega\hat{\boldsymbol{r}}$. Hence $\boldsymbol{v} = r\omega\hat{\boldsymbol{t}}$, and differentiating once more,

$$\boldsymbol{a} = \frac{\mathrm{d}}{\mathrm{d}t}\left(r\omega\hat{\boldsymbol{t}}\right) = r\alpha\,\hat{\boldsymbol{t}} + r\omega\frac{\mathrm{d}\hat{\boldsymbol{t}}}{\mathrm{d}t} = r\alpha\,\hat{\boldsymbol{t}} - r\omega^2\,\hat{\boldsymbol{r}}\,,$$

which is Equation (18.28). Setting $\alpha = 0$ recovers Equation (18.26), and $|\boldsymbol{a}| = \sqrt{r^2\alpha^2 + r^2\omega^4}$ reduces to Equation (18.27) in that case. □

18.3.4 The intrinsic decomposition of the acceleration

The split of Equation (18.28) into a part along the motion and a part across it is not special to a circle. It holds for every trajectory, with the radius of the circle replaced by the radius of curvature of the curve at the point in question, and it is the reason the curve theory of Section 13.3.1 was set up.

Proposition 18.33 (Intrinsic decomposition of the acceleration)**.** *Let $\boldsymbol{x}(t)$ be a trajectory of class C^2 whose speed $v = |\mathrm{d}\boldsymbol{x}/\mathrm{d}t|$ is nowhere zero, let s be its arc length Equation (13.35), and let $\hat{T}$, $\hat{N}$, $\hat{B}$ be the Frenet frame of Definitions 13.12, 13.14 and 13.15, with curvature $\kappa > 0$. Then*

$$\boldsymbol{v} = v\,\hat{T} \tag{18.29}$$

and

$$\boldsymbol{a} = \frac{\mathrm{d}v}{\mathrm{d}t}\,\hat{T} + \kappa v^2\,\hat{N} = \frac{\mathrm{d}v}{\mathrm{d}t}\,\hat{T} + \frac{v^2}{\rho}\,\hat{N}\,, \tag{18.30}$$

where $\rho = 1/\kappa$ is the radius of curvature. In particular $\boldsymbol{a}\cdot\hat{B} = 0$: the acceleration always lies in the osculating plane, its component across the motion is directed towards the centre of curvature, and it never has a component out of that plane.

Rests on Definitions 13.12, 13.14 and 18.11.

Proof. *Derives Proposition 18.33.*

By Equation (13.36) the arc length satisfies $\mathrm{d}s/\mathrm{d}t = v$, and by Equation (13.38) the unit tangent is $\hat{T} = \mathrm{d}\boldsymbol{x}/\mathrm{d}s$. The chain rule (Proposition 7.31) therefore gives Equation (18.29),

$$\boldsymbol{v} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}\frac{\mathrm{d}s}{\mathrm{d}t} = v\,\hat{T}\,.$$

Differentiating that product and using the chain rule once more on $\hat{T}$,

$$\boldsymbol{a} = \frac{\mathrm{d}}{\mathrm{d}t}\left(v\hat{T}\right) = \frac{\mathrm{d}v}{\mathrm{d}t}\,\hat{T} + v\,\frac{\mathrm{d}\hat{T}}{\mathrm{d}s}\frac{\mathrm{d}s}{\mathrm{d}t} = \frac{\mathrm{d}v}{\mathrm{d}t}\,\hat{T} + v^2\,\frac{\mathrm{d}\hat{T}}{\mathrm{d}s}\,, \tag{18.31}$$

From Equations (13.36) and (13.38) (differentiating $\boldsymbol{v} = v\hat{T}$ and converting $\mathrm{d}\hat{T}/\mathrm{d}t$ to $\mathrm{d}\hat{T}/\mathrm{d}s$ with $\mathrm{d}s/\mathrm{d}t = v$).

and the first Frenet equation Equation (13.43), $\mathrm{d}\hat{T}/\mathrm{d}s = \kappa\hat{N}$, turns Equation (18.31) into Equation (18.30). The last claim follows because $\hat{T}, \hat{N}, \hat{B}$ are orthonormal by Definition 13.15, so the expansion Equation (18.30) has no $\hat{B}$ component to begin with. □

Remark 18.34 (The two ways an acceleration can be zero)*.* Equation (18.30) makes the classification immediate. The tangential term vanishes when the speed is constant, and the normal term vanishes when the curvature is zero, that is when the path is straight; only when both vanish is the motion unaccelerated, which is uniform motion in a straight line. Uniform circular motion is the second case made non-trivial: $\mathrm{d}v/\mathrm{d}t = 0$ and $\kappa = 1/r$ constant, so Equation (18.30) returns $|\boldsymbol{a}| = v^2/r$, which is Equation (18.27) again, now derived without ever choosing coordinates. Where $\kappa = 0$ the principal normal Equation (13.42) is undefined and the statement degenerates to $\boldsymbol{a} = (\mathrm{d}v/\mathrm{d}t)\,\hat{T}$, which is correct as it stands.

Rests on Proposition 18.33.

18.3.5 Magnitudes

Centripetal accelerations in nature and in the laboratory span some ten orders of magnitude, and it is worth having a few of them in mind.

The first row is not a curiosity: it is measured, and measured easily. A body at rest on the equator is in circular motion, so the free-fall acceleration read by a gravimeter there is smaller than the gravitational attraction by the $3.39 \times 10^{-2}\,\mathrm{m/s^2}$ of Table 18.1 — against an

Table 18.1: Centripetal accelerations $\omega^2 r$ for four circular motions, computed from Equation (18.27). The Earth's spin rate is the sidereal one and r its equatorial radius; the orbital row uses the mean Sun–Earth distance; the car travels at 28 m/s on a curve of 300 m radius; the rotor is a laboratory ultracentrifuge of 5 cm radius. For comparison, the conventional standard acceleration of free fall is $g_0 = 9.806\,65\,\mathrm{m/s^2}$ exactly [2333].

motion	r	ω	$\omega^2 r$
Earth, spin at the equator	$6.378 \times 10^{6}\,\mathrm{m}$	$7.292 \times 10^{-5}\,\mathrm{rad/s}$	$3.39 \times 10^{-2}\,\mathrm{m/s^2}$
Earth, orbit about the Sun	$1.496 \times 10^{11}\,\mathrm{m}$	$1.991 \times 10^{-7}\,\mathrm{rad/s}$	$5.93 \times 10^{-3}\,\mathrm{m/s^2}$
Car on a highway curve	$3.0 \times 10^{2}\,\mathrm{m}$	$9.3 \times 10^{-2}\,\mathrm{rad/s}$	$2.6\,\mathrm{m/s^2}$
Ultracentrifuge rotor	$5.0 \times 10^{-2}\,\mathrm{m}$	$1.05 \times 10^{4}\,\mathrm{rad/s}$	$5.5 \times 10^{6}\,\mathrm{m/s^2}$

instrumental accuracy of about $2 \times 10^{-8}\,\mathrm{m/s^2}$ [1906], which resolves the effect a million times over. The observed equator-to-pole difference is larger still, $5.2 \times 10^{-2}\,\mathrm{m/s^2}$, the remainder coming from the equatorial bulge that the same rotation produces; Phenomenon 29.55 treats both together, and Equation (29.68) is its quantitative form.

The itinerary equation for constant acceleration, Equation (18.7), is the first quantitative law of this treatise, and it is not left as a formal statement: in Chapter 20 it is confronted with experiment — from Galileo's inclined planes to the modern ballistic gravimeters — with every assumption behind it declared and tested.

Chapter 19

Newtonian Dynamics

When we seek what is most fundamental — an idea that governs the whole of mechanics — we meet the concept of force, as the motive of the motion of a particle. In this respect, the laws formulated by Isaac Newton are essential [14]. Even so, as we shall see, there exist further formulations, resting on other axioms, from which Newton's laws can be derived (Chapters 21 and 22).

A particle can translate; and if it has a volume — that is, if it is a body — it can also rotate. We shall introduce the axioms and definitions that allow us to understand the mechanics of a particle and of a body.

19.1 Inertia and mass

Inertia

Consider a particle. On what does its kinematics depend when nature interacts with it? We may suppose a property of the particle that plays a role in the motive of its motion, simply by virtue of its being in nature. We postulate:

Postulate 19.1 (Inertia)**.** If a particle moves in uniform rectilinear motion with respect to some inertial frame of reference, it will continue to do so unless it interacts with nature.

Rests on Definitions 18.3 and 18.8.

This is a property possessed by every particle, known as *inertia*.

Interaction

Definition 19.2 (Interaction)**.** An *interaction* is the motive by which a particle changes its position $\boldsymbol{x}(t) = \mathbf{0}\ \forall t$ to another position $\boldsymbol{x}'$.

Rests on Definition 18.3 and Postulate 19.1.

Mass

One particle can have more inertia than another.

Definition 19.3 (Mass)**.** The *mass* is the scalar quantity that quantifies inertia, in the following sense: the mass of a particle is proportional to how much it costs nature to move it.

Rests on Postulate 19.1 and Definition 18.3.

Remark 19.4. The Fundamentos formulary accordingly sharpens the notion of a particle introduced in Definition 18.3: a particle is a point of space to which a mass m is assigned.

19.2 Newton's laws and the Newtonian formulation: translation

19.2.1 Linear momentum and Newton's first law

Consider the following fact of nature. When a very heavy truck moves at great speed, we feel that it carries great power, implacable in any collision (let us not forget that if the truck moves at great speed it is because our frame of reference is outside the truck; if we were inside it and did not notice what lies outside, for us it would be at rest). Now, if we have a light piece of wood that moves very slowly, we feel that it carries less power than the truck.

On the other hand, we may consider the crossed case. What would happen if the truck moved very slowly while the piece of wood travelled at extravagant speeds close to the speed of light? Clearly we must introduce a quantity that manifests the power of which we speak — one that unifies the mass and the velocity associated with a given motion.

Definition 19.5 (Linear momentum)**.** The *linear momentum* of a particle of mass m moving with velocity $\boldsymbol{v}$ with respect to some frame of reference is

$$\boxed{\boldsymbol{p} = m\boldsymbol{v}}\,. \tag{19.1}$$

Rests on Definitions 18.10 and 19.3.

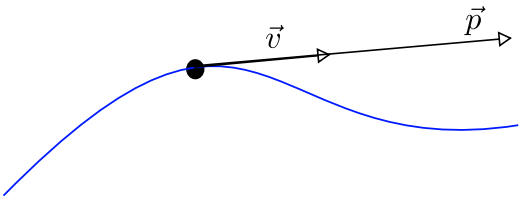

Figure 19.1: Linear momentum: the quantity unifying the mass of a particle with the velocity of its motion.

We enunciate as a fundamental principle:

Postulate 19.6 (Newton's first law)**.** The linear momentum of a free particle is constant, with respect to any inertial frame of reference.

Rests on Definitions 18.8 and 19.5.

Phenomenon 19.7 (Persistence of uniform motion)**.** A body on which nothing acts keeps its velocity: neither its speed nor its direction changes, and no agent whatever is needed to maintain the motion. The fact is never directly visible on Earth, where friction and air resistance are never absent; it is exposed by removing them by degrees — a ball on a horizontal plane runs the farther the smoother the plane, which is Galileo's argument [4] — and it is seen outright in a coasting spacecraft. The contrary Aristotelian expectation, that motion requires a mover and ceases with it, is the oldest falsified theory in mechanics.

Rests on Postulate 19.6 and Equation (19.1)*.*

Derivation. Derives Phenomenon 19.7.

By Postulate 19.6 the linear momentum of a free particle is constant. If in addition the mass of the particle is constant, then from Equation (19.1)

$$\boldsymbol{v} = \frac{\boldsymbol{p}}{m}$$

is constant as well, so the velocity keeps both magnitude and direction, and the trajectory is a straight line traversed uniformly. The observation therefore tests two things at once,

and separating them matters: the constancy of $\boldsymbol{p}$, which is the postulate, and the constancy of m, which fails for a rocket and for a body accumulating or shedding matter. It is only with both that Equation (19.3) collapses to Equation (19.4) and the familiar statement follows. □

19.2.2 Force and Newton's second law

Until now we have used the concept of an interaction of nature with particles. But what, at bottom, is an interaction? We must quantify this concept in order to introduce fundamental equations that govern the entire dynamics of a system. An interaction certainly perturbs the inertia of a particle, and so we introduce as a fundamental postulate:

Postulate 19.8 (Newton's second law)**.** The sum of all the interactions upon a particle is the measure of how much its linear momentum fails to be conserved.

Rests on Definition 19.5 and Postulate 19.6.

We shall call the total *force* upon a particle the sum of all the interactions upon it, and we shall denote it by $\boldsymbol{F}$. Newton's second law is then mathematically expressed by

$$\boxed{\boldsymbol{F} = \frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t}}\,. \tag{19.2}$$

Newton's second law is fundamental because it provides the equations of motion. That is, given the sum of the forces acting upon a particle, we can compute its trajectory. Moreover, we can finally conclude the following: a particle will continue its rectilinear motion unless a nonvanishing total force acts upon it — this with respect to an inertial frame of reference. The figure illustrates a particle that moves along a straight line and deviates from its trajectory.

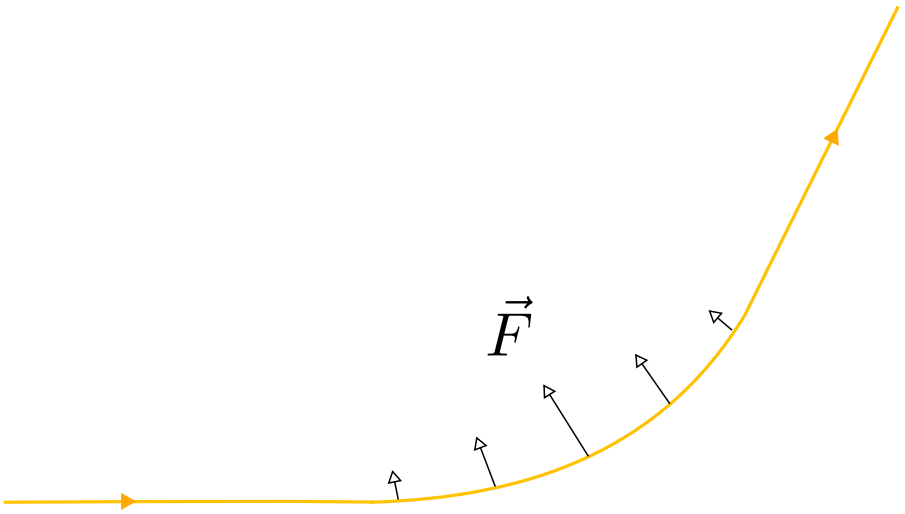

Figure 19.2: A particle moving in a straight line is deflected from its trajectory by a nonvanishing total force.

From Equation (19.1) we see that

$$\boxed{\boldsymbol{F} = \frac{\mathrm{d}m}{\mathrm{d}t}\boldsymbol{v} + m\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t}}\,. \tag{19.3}$$

If the mass of the particle is constant, then from Equation (19.3) we see that

$$\boxed{\boldsymbol{F} = m\boldsymbol{a}}\,. \tag{19.4}$$

Remark 19.9. The Fundamentos formulary states the second law in the summary form: the change with respect to time of the linear momentum of a particle is proportional to its mass and to its acceleration, $\boldsymbol{F} = \frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t} = m\boldsymbol{a}$.

Phenomenon 19.10 (Force, mass and acceleration)**.** For a body of fixed mass the acceleration produced is proportional to the applied force and parallel to it; for a fixed applied force it is inversely proportional to the mass. The classical demonstration is Atwood's machine, in which two masses $m_1 > m_2$ hang from the ends of a cord over a light pulley and the pair is observed to move with a uniform acceleration smaller than that of free fall, in the ratio $(m_1 - m_2)/(m_1 + m_2)$. Bringing the two masses close in value makes the acceleration as small as the timing apparatus requires without changing its constancy — the same dilution trick as Galileo's inclined plane [4], and the arrangement by which the second law was first checked quantitatively in the laboratory [14].

Rests on Equation (19.4) *and Postulate 19.8.*

Derivation. *Derives Phenomenon 19.10.*

Idealize the cord as inextensible and massless and the pulley as light and frictionless, so that the tension T is the same throughout and the two masses have accelerations of equal magnitude a and opposite sense. Applying Equation (19.4) to each mass along the vertical, with the descending mass taken positive,

$$m_1 a = m_1 g - T\,, \qquad m_2 a = T - m_2 g\,.$$

Adding the two eliminates the unknown tension, which is the point of the arrangement, and gives

$$a = \frac{m_1 - m_2}{m_1 + m_2}\, g\,, \qquad T = \frac{2 m_1 m_2}{m_1 + m_2}\, g\,. \tag{19.5}$$

The acceleration is constant, so the descent obeys the itinerary equation for constant acceleration of Chapter 18 and can be timed over a measured distance. Two limits check the result: for $m_2 = 0$ it returns $a = g$, free fall; and for $m_1 = m_2$ it returns $a = 0$, equilibrium. What the experiment establishes is that a single number m suffices — the same m that measures the weight mg also measures the resistance to acceleration in Equation (19.4) — which is the assumption whose exactness is tested in Chapter 42. □

Covariance

A law of motion earns the name only if it says the same thing in every inertial frame; were it otherwise, Postulate 18.16 would fail, and an experiment performed inside a closed cabin could disclose the cabin's velocity. That Equation (19.4) passes this test is the content of the present heading. It is worth doing carefully, because the demonstration constrains the admissible *forces* a good deal more than it constrains the equation.

The transformation itself belongs to kinematics and is stated there: Definition 18.18 defines the Galilean transformation

$$\boldsymbol{x}' = R\boldsymbol{x} - \boldsymbol{V}t + \boldsymbol{a}\,, \qquad t' = t + b\,,$$

with $R \in \mathrm{SO}(3)$, $\boldsymbol{V}$ a relative velocity in m/s, $\boldsymbol{a}$ a displacement in m and b a time offset in s, and Proposition 18.20 proves that the ten of them close into the Galilei group with the composition law Equation (18.12). Both are used below without being restated.

Remark 19.11 (Mass is a Galilean scalar). The mass of a particle is the same number in every inertial frame, $m' = m$: mass is a scalar by Definition 19.3, and nothing in Definition 18.18 acts on it. This is an assumption about what mass *is*, not a theorem, and it is exactly the assumption relativity abandons — see Chapter 40, where the inertia of a body depends on its speed.

Rests on Definitions 18.18 and 19.3.

Theorem 19.12 (Galilean covariance of the second law)**.** *Let the mass of a particle be constant and let the total force upon it transform as* $\boldsymbol{F}' = R\boldsymbol{F}$ *under Equation* (18.11)*. Then Equation* (19.4) *holds in* K *if and only if* $\boldsymbol{F}' = m\boldsymbol{a}'$ *holds in* K'*.*
Rests on Definition 18.18, Equation (19.4)*, and Postulate 18.14.*

Proof. *Derives Theorem 19.12.*

By Postulate 18.14 the two frames measure the same time increments, $\mathrm{d}t' = \mathrm{d}t$, so differentiating with respect to t' is differentiating with respect to t. Differentiating the second of Equation (18.11) once, R, $\boldsymbol{V}$ and $\boldsymbol{b}$ being constant,

$$\boldsymbol{v}' = R\boldsymbol{v} - \boldsymbol{V}\,, \tag{19.6}$$

and a second time,

$$\boldsymbol{a}' = R\boldsymbol{a}\,. \tag{19.7}$$

Multiplying Equation (19.7) by the constant mass and subtracting the assumed transformation of the force,

$$\boldsymbol{F}' - m\boldsymbol{a}' = R\,(\boldsymbol{F} - m\boldsymbol{a})\,,$$

and R is invertible, so the left-hand side vanishes exactly when the right-hand side does. □

The hypothesis on the force is not a formality, and it is the half of the statement the source note omits: Equation (19.4) is covariant *provided* the force is the kind of object that transforms as a vector and does not depend on the absolute position, the absolute time or the absolute velocity of the particle. That is a genuine restriction on the interactions nature is allowed to have, and it is satisfied by the ones it does have.

Proposition 19.13 (Which forces are admissible)**.** *Let the force on particle* s *of a system be a sum of pair terms*

$$\boldsymbol{F}_s = \sum_{r \neq s} \boldsymbol{f}\,(\boldsymbol{x}_s - \boldsymbol{x}_r,\, \boldsymbol{v}_s - \boldsymbol{v}_r)\,, \tag{19.8}$$

with $\boldsymbol{f}$ *equivariant under rotations,* $\boldsymbol{f}\,(R\boldsymbol{u}, R\boldsymbol{w}) = R\,\boldsymbol{f}\,(\boldsymbol{u}, \boldsymbol{w})$ *for every* $R \in \mathrm{SO}(3)$*. Then* $\boldsymbol{F}'_s = R\boldsymbol{F}_s$*, so Theorem 19.12 applies to every particle of the system.*
Rests on Definition 18.18 and Theorem 19.12.

Proof. *Derives Proposition 19.13.*

The displacement $\boldsymbol{b}$ and the term $\boldsymbol{V}t$ cancel in a difference of positions, and $\boldsymbol{V}$ cancels in a difference of velocities: by Equations (18.11) and (19.6),

$$\boldsymbol{x}'_s - \boldsymbol{x}'_r = R\,(\boldsymbol{x}_s - \boldsymbol{x}_r)\,, \qquad \boldsymbol{v}'_s - \boldsymbol{v}'_r = R\,(\boldsymbol{v}_s - \boldsymbol{v}_r)\,.$$

Equivariance then returns each pair term as R times its unprimed value, and the finite sum Equation (19.8) with it. □

Corollary 19.14 (Central pair forces are admissible)**.** *A pair force of the form* $\boldsymbol{f}\,(\boldsymbol{u}) = f(|\boldsymbol{u}|)\,\boldsymbol{u}/|\boldsymbol{u}|$ *satisfies the hypothesis of Proposition 19.13, a rotation preserving both* $|\boldsymbol{u}|$ *and the direction of* $\boldsymbol{u}$ *relative to itself. Newtonian gravitation and the Coulomb force are of this kind, and so is a Hooke spring joining two particles; the central case is developed in Chapter 27.*
Rests on Proposition 19.13.

Remark 19.15 (Covariance is not invariance)*.* What the two frames share is the *form* of the law, not the values of the quantities in it. Under a pure boost the momentum of Equation (19.1) changes by $-m\boldsymbol{V}$ and the kinetic energy of Equation (19.18) becomes

$$T' = T - m\,\boldsymbol{v}\cdot\boldsymbol{V} + \tfrac{1}{2}mV^2\,, \tag{19.9}$$

neither of which is unchanged. What is boost-invariant is the acceleration Equation (19.7), together with the separations between particles and their relative velocities — exactly the quantities Equation (19.8) is built from. The distinction returns in Section 19.5.5: a quantity can be conserved in every inertial frame without taking the same value in any two of them.

Remark 19.16 (Variable mass breaks the covariance of the momentum form). Theorem 19.12 was stated for constant mass, and the restriction cannot be lifted. Allowing m to depend on time and transforming under a pure boost,

$$\frac{\mathrm{d}\boldsymbol{p}'}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\left[m\left(\boldsymbol{v}-\boldsymbol{V}\right)\right] = \frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t} - \frac{\mathrm{d}m}{\mathrm{d}t}\,\boldsymbol{V}\,, \tag{19.10}$$

so the two frames disagree by $-\dot{m}\,\boldsymbol{V}$. No transformation law for the force can absorb that term, because it depends on the arbitrary boost velocity $\boldsymbol{V}$ and not on anything physical. Equation (19.2) is therefore Galilean covariant only for a system whose mass is constant. A rocket is not a counterexample but a lesson in bookkeeping: the closed system is the rocket *together with* the exhaust it has already ejected, its total mass is constant, and Equation (19.2) applies to that. The same caveat was recorded in the derivation of Phenomenon 19.7.

Remark 19.17 (Absolute time is doing the work). The proof of Theorem 19.12 leaned on Postulate 18.14 at the very first step: only because t' and t differ by a constant does the second derivative in K' agree with the second derivative in K. If instead the time of K' is allowed to depend on position — as the Lorentz transformations of Chapter 38 require it to — then Equation (19.7) is false, and no redefinition of the force restores Equation (19.4). The mechanics built on that other group is Chapter 40, and the disagreement between the two is of relative order v^2/c^2, which Equation (18.8) bounds.

The observational counterpart of Theorem 19.12 is Phenomenon 18.17: mechanical experiments in a closed cabin do not disclose its uniform velocity. Nothing in the theorem is tested by that observation alone, however, since the covariance was built into the postulates; what is tested is the conjunction of Postulate 18.14 with the assumption that the real forces are of the admissible form Equation (19.8).

19.3 Newton's laws and the Newtonian formulation: rotation

19.3.1 Angular momentum

Let us note the following fact of nature. When we try to push a door, we can clearly observe that it costs much less to push it from a point far from the hinge (for example, the handle) than from a point closer to it. What is happening? We are applying the same force, yet we do not achieve the same motion. In other words, to succeed in opening the door we must apply more or less force depending on where we do it.

This suggests the following. To study the motion of a body we must introduce an analogue of the translational Newton laws, but with a quantity that carries information about the location at which there is a surge of momentum — that is, a quantity that is a function of the position and the momentum of a particle.

Thus we define:

Definition 19.18 (Angular momentum)**.** The *angular momentum* of a particle of position $\boldsymbol{x}$ and momentum $\boldsymbol{p}$ is

$$\boldsymbol{L} = \boldsymbol{x} \times \boldsymbol{p}\,, \tag{19.11}$$

with units of $\mathrm{kg\,m^2/s}$.

Rests on Definitions 18.3 and 19.5.

The principle the source manuscript was reaching for at this point is the rotational counterpart of Postulate 19.6.

Postulate 19.19 (Newton's first law, rotational case)**.** The angular momentum of a free particle, taken about any point at rest in an inertial frame, is constant.

Rests on Definition 19.18 and Postulate 19.6.

Proposition 19.20 (For one particle the rotational first law is not independent)**.** *Postulate 19.19 follows from Postulate 19.6 and Definition 19.18; it is therefore a theorem for a single particle, and only becomes an independent statement for a system of interacting particles (Section 19.5.4).*

Rests on Postulate 19.6 and Definition 19.18.

Proof. *Derives Proposition 19.20.*

Let $\boldsymbol{x}$ be measured from the fixed point. Differentiating Equation (19.11) and using the product rule for the cross product,

$$\frac{\mathrm{d}\boldsymbol{L}}{\mathrm{d}t} = \boldsymbol{v} \times \boldsymbol{p} + \boldsymbol{x} \times \frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t}\,.$$

The first term vanishes because $\boldsymbol{p} = m\boldsymbol{v}$ is parallel to $\boldsymbol{v}$ by Equation (19.1), and the second vanishes because $\boldsymbol{p}$ is constant for a free particle by Postulate 19.6. Hence $\boldsymbol{L}$ is constant. The argument uses only that the point about which $\boldsymbol{L}$ is taken does not move; about a point in arbitrary motion the statement is false, since then $\mathrm{d}\boldsymbol{x}/\mathrm{d}t$ is no longer $\boldsymbol{v}$. □

For a system the situation is different and the postulate does real work: the internal forces of a system need not cancel in the torque sum merely because they cancel in the force sum, and what is required of them is stated as Postulate 19.61 below.

Phenomenon 19.21 (Equal areas in equal times)**.** A body moving under a force always directed towards one fixed centre sweeps out equal areas about that centre in equal times: it moves quickest where it is nearest and slowest where it is farthest, in exact compensation. This is Kepler's second law, proved from the laws of motion as the first proposition of the *Principia* [14], and it holds for every central force whatever, not only for the inverse square. The Earth's orbit is eccentric enough for the effect to be conspicuous: Newcomb's reduction of the inner-planet observations gives its eccentricity as $e = 0.01675$ at the epoch 1900.0, slowly decreasing [267]. With a semi-major axis of one astronomical unit, $a = 1.495\,978\,707 \times 10^{11}\,\mathrm{m}$ by definition [2333], the perihelion and aphelion distances differ by $2ae \approx 5.0 \times 10^{9}\,\mathrm{m}$, and the Earth runs correspondingly faster in January than in July.

Rests on Postulate 19.19.

Derivation. *Derives Phenomenon 19.21.*

Let the force be central about the origin, $\boldsymbol{F} = F(\boldsymbol{x})\,\boldsymbol{x}/\,|\boldsymbol{x}|$. Then $\boldsymbol{x} \times \boldsymbol{F} = \boldsymbol{0}$, so by Equations (19.14) and (19.15) the angular momentum about that centre is constant. The area swept by the radius vector in a time $\mathrm{d}t$ is that of the triangle spanned by $\boldsymbol{x}$ and $\mathrm{d}\boldsymbol{x}$,

$$\frac{\mathrm{d}A}{\mathrm{d}t} = \frac{1}{2}\,|\boldsymbol{x} \times \boldsymbol{v}| = \frac{|\boldsymbol{L}|}{2m}\,, \tag{19.12}$$

of SI unit m^2/s, which is constant with $|\boldsymbol{L}|$. Since $\boldsymbol{L}$ is moreover fixed in direction, the motion stays in the plane through the centre perpendicular to it. At the two apses the velocity is perpendicular to the radius, so $|\boldsymbol{L}| = mrv$ there and the speeds are in the inverse ratio of the distances,

$$\frac{v_{\mathrm{peri}}}{v_{\mathrm{apo}}} = \frac{r_{\mathrm{apo}}}{r_{\mathrm{peri}}} = \frac{1+e}{1-e}\,, \tag{19.13}$$

which for the eccentricity quoted above is 1.03407. That figure is a prediction computed from e, not a second measurement: the independent test of the areal law, and of the

inverse-square force behind the Earth's particular value of e, belongs to Chapter 27. The derivation assumed only that the force points along $\boldsymbol{x}$; it says nothing at all about how the force depends on distance, which is why the areal law survived every revision of the force law between Kepler and Newton. □

19.3.2 Torque

Analogously to Newton's second law in the translational case, we introduce as a fundamental postulate:

Postulate 19.22 (Newton's second law, rotational case)**.** The sum of all the interactions upon a body at a given point is the measure of how much its angular momentum fails to be conserved.

Rests on Definition 19.18 and Postulate 19.8.

We shall call the total *torque*, or *moment of force*, upon a body the sum of all the forces applied at a given point, and we shall denote it by $\boldsymbol{\tau}$. Newton's second law in the rotational case is then expressed as

$$\boxed{\boldsymbol{\tau} = \frac{\mathrm{d}\boldsymbol{L}}{\mathrm{d}t}}\,, \tag{19.14}$$

with units of $\mathrm{N\,m} = \mathrm{kg\,m^2/s^2}$, dimensionally those of an energy.

Substituting the definition of angular momentum into Equation (19.14), we have

$$\begin{aligned}\boldsymbol{\tau} &= \frac{\mathrm{d}}{\mathrm{d}t}\left(\boldsymbol{x}\times\boldsymbol{p}\right)\\ &= \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t}\times\boldsymbol{p} + \boldsymbol{x}\times\frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t}\\ &= \boldsymbol{v}\times\boldsymbol{p} + \boldsymbol{x}\times\boldsymbol{F}\,,\end{aligned}$$

where the last step uses Equation (19.2); and since the velocity of a particle is always parallel to its linear momentum, we find the relation

$$\boxed{\boldsymbol{\tau} = \boldsymbol{x}\times\boldsymbol{F}}\,. \tag{19.15}$$

This is a very important relation, for it yields the following conclusion: the torque is a quantity that manifests the total force applied at the place where the particle is. We can use this equation to describe the motion of a body when we apply a force at a specific point of it, as in the example of the door: it costs us more or less to move it depending on where we apply the force.

Phenomenon 19.23 (The lever arm)**.** The same force applied to a door opens it easily at the handle and scarcely at all near the hinge, and a rigid bar pivoted at a point balances two weights when, and only when, the products of weight and distance from the pivot agree on the two sides — Archimedes' law of the lever, the oldest quantitative law in mechanics and the principle of every balance, crowbar and wheelbarrow. What governs rotation is therefore not the force alone but the force together with its point of application, and specifically the product of the force with the perpendicular distance from the axis to its line of action: a force directed straight at the axis has no such distance and never turns anything, which is why pulling a door towards its hinge is futile [14].

Rests on Equations (19.14) and (19.15).

Derivation. *Derives Phenomenon 19.23.*

Equation (19.15) gives $\boldsymbol{\tau} = \boldsymbol{x}\times\boldsymbol{F}$. Let $\boldsymbol{x}$ be the position of the point of application relative to the axis and θ the angle between $\boldsymbol{x}$ and $\boldsymbol{F}$. The magnitude of the torque is then

$$|\boldsymbol{\tau}| = |\boldsymbol{x}|\;|\boldsymbol{F}|\sin\theta = d\;|\boldsymbol{F}|\;, \qquad d := |\boldsymbol{x}|\sin\theta\,, \tag{19.16}$$

where d is the perpendicular distance from the axis to the line of action — the lever arm. It grows in proportion to the distance at which the force is applied, which is the door; and it vanishes when $\boldsymbol{F}$ is parallel or antiparallel to $\boldsymbol{x}$, so that $\sin\theta = 0$, which is the futile pull towards the hinge. For the balanced bar, the angular momentum about the pivot does not change, so by Equation (19.14) the torques must cancel; with the two weights applied on opposite sides and perpendicular to the bar this reads $d_1 F_1 = d_2 F_2$, the law of the lever. Note that the derivation used Equation (19.15), which was itself obtained by discarding $\boldsymbol{v} \times \boldsymbol{p}$; that term vanishes identically, so nothing was approximated. □

Covariance

Theorem 19.12 settled the translational law. The rotational law raises a question the translational one does not, because $\boldsymbol{L}$ and $\boldsymbol{\tau}$ are both defined relative to a chosen point, and a change of frame moves that point.

Remark 19.24 (A transformation law owed by the tensor chapter). The argument below uses the fact that the cross product of two vectors transforms under an orthogonal change of Cartesian axes a_{ij} as

$$(\boldsymbol{u} \times \boldsymbol{w})'_i = (\det a)\, a_{ij}\, (\boldsymbol{u} \times \boldsymbol{w})_j \,, \tag{19.17}$$

that is, as a vector for a rotation and with an extra sign for a reflection — the reason $\boldsymbol{L}$ and $\boldsymbol{\tau}$ are called *axial*, or pseudo-, vectors. Chapter 13 defines the cross product in the index form $(\boldsymbol{u} \times \boldsymbol{w})_i = \varepsilon_{ijk} u_j w_k$ of Equation (13.225) and names it a pseudo-vector, but does not state Equation (19.17); the statement belongs there rather than here. It follows in one line from the Leibniz expansion Equation (5.19) of a determinant, which gives $\varepsilon_{lmn} \det a = \varepsilon_{ijk} a_{il} a_{jm} a_{kn}$, combined with the transformation rule Equation (13.21) for Cartesian tensors. For $R \in \mathrm{SO}(3)$, where $\det R = +1$, Equation (19.17) reads $(R\boldsymbol{u}) \times (R\boldsymbol{w}) = R\,(\boldsymbol{u} \times \boldsymbol{w})$, and that is the form used below.

Theorem 19.25 (Galilean covariance of the rotational second law)**.** *Let a particle of constant mass be subject to a force transforming as $\boldsymbol{F}' = R\boldsymbol{F}$ under Equation (18.11), and let $\boldsymbol{L}'$ and $\boldsymbol{\tau}'$ be formed from the primed position and momentum, that is, about the origin of K'. Then Equation (19.14) holds in K if and only if $\boldsymbol{\tau}' = \mathrm{d}\boldsymbol{L}'/\mathrm{d}t'$ holds in K', even though neither $\boldsymbol{L}$ nor $\boldsymbol{\tau}$ is invariant.*

Rests on Equation (19.14), Definition 18.18, and Theorem 19.12.

Proof. *Derives Theorem 19.25.*

Write $\boldsymbol{c}(t) = \boldsymbol{V}t + \boldsymbol{b}$ for the displacement of the origin of K', so that Equations (18.11) and (19.6) read $\boldsymbol{x}' = R\boldsymbol{x} - \boldsymbol{c}$ and $\boldsymbol{v}' = R\boldsymbol{v} - \boldsymbol{V}$ with $\mathrm{d}\boldsymbol{c}/\mathrm{d}t = \boldsymbol{V}$. Then

$$\begin{aligned} \boldsymbol{\tau}' &= \boldsymbol{x}' \times \boldsymbol{F}' \\ &= (R\boldsymbol{x} - \boldsymbol{c}) \times R\boldsymbol{F} \\ &= R\boldsymbol{\tau} - \boldsymbol{c} \times R\boldsymbol{F} \qquad \text{by Remark 19.24}\,, \end{aligned}$$

using Equation (19.15) in the last line. For the angular momentum, $\boldsymbol{p}' = m\boldsymbol{v}'$ by Equation (19.1) and Definition 18.18, so

$$\begin{aligned} \boldsymbol{L}' &= (R\boldsymbol{x} - \boldsymbol{c}) \times m\,(R\boldsymbol{v} - \boldsymbol{V}) \\ &= R\boldsymbol{L} - m\,(R\boldsymbol{x}) \times \boldsymbol{V} - m\,\boldsymbol{c} \times R\boldsymbol{v} + m\,\boldsymbol{c} \times \boldsymbol{V}\,. \end{aligned}$$

Differentiating with respect to t, which by Postulate 18.14 is the same as differentiating with respect to t', and using $\mathrm{d}\boldsymbol{c}/\mathrm{d}t = \boldsymbol{V}$ together with $\boldsymbol{V} \times \boldsymbol{V} = \boldsymbol{0}$,

$$\begin{aligned} \frac{\mathrm{d}\boldsymbol{L}'}{\mathrm{d}t} &= R\boldsymbol{\tau} - m\,(R\boldsymbol{v}) \times \boldsymbol{V} - m\,\boldsymbol{V} \times R\boldsymbol{v} - m\,\boldsymbol{c} \times R\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} \\ &= R\boldsymbol{\tau} - \boldsymbol{c} \times R\boldsymbol{F}\,, \end{aligned}$$

because the two middle terms are equal and opposite by the antisymmetry of the cross product, and $m\,\mathrm{d}\boldsymbol{v}/\mathrm{d}t = \boldsymbol{F}$ by Equation (19.4). The two computations agree, so $\mathrm{d}\boldsymbol{L}'/\mathrm{d}t' = \boldsymbol{\tau}'$; and running the argument with R^{-1}, $-R^{-1}\boldsymbol{V}$ and $-R^{-1}\boldsymbol{b}$ gives the converse. □

Remark 19.26 (The extra terms are not an embarrassment). The displayed expression for $\boldsymbol{L}'$ shows that angular momentum is frame-dependent in a way linear momentum is not: it depends on where the origin is put, on how fast that origin moves, and — through the term $m\,\boldsymbol{c}\times R\boldsymbol{v}$ — on the time. A body at rest at $\boldsymbol{x} = \boldsymbol{0}$ has $\boldsymbol{L} = \boldsymbol{0}$ in K and a nonzero, time-varying $\boldsymbol{L}'$ in any frame whose origin is elsewhere and moving. What survives the change of frame is the *balance* Equation (19.14) between the two sides, which is all a law of motion is ever asked to do.

Remark 19.27 (Parity). The proof of Theorem 19.25 was written for $R \in \mathrm{SO}(3)$, but it does not need $\det R = +1$. For a reflection, Equation (19.17) carries an extra minus sign, so the same two computations return $\boldsymbol{\tau}' = -R\boldsymbol{\tau} - \boldsymbol{c}\times R\boldsymbol{F}$ and $\mathrm{d}\boldsymbol{L}'/\mathrm{d}t = -R\boldsymbol{\tau} - \boldsymbol{c}\times R\boldsymbol{F}$: the sign appears on both sides and cancels between them, and the law is form-invariant under the full orthogonal group $\mathrm{O}(3)$. Newtonian mechanics is therefore exactly parity-symmetric, and the mirror image of a mechanical process is again a mechanical process. That this is a property of mechanics rather than of nature was established only in 1957, when the beta decay of oriented cobalt-60 nuclei was found to distinguish left from right [1133]; the experiment is reported in Chapter 110.

Remark 19.28 (How well is the invariance of space tested?). Theorems 19.12 and 19.25 assert that no experiment can detect the orientation, position, epoch or uniform velocity of a laboratory. Each of the ten parameters of Equation (18.11) therefore carries an experimental bound, and the bounds are severe: the compilation of limits on violations of rotation and boost invariance [2176] collects them across atomic, nuclear and particle physics. They are quoted there for the Lorentz group rather than the Galilei group, which is the correct modern setting; the Galilean statements of this chapter inherit whatever bound applies at speeds where Equation (18.8) is negligible.

19.4 Energy

19.4.1 Kinetic energy

Definition 19.29 (Kinetic energy)**.** The *kinetic energy* of a particle moving with velocity $\boldsymbol{v}$ with respect to a frame of reference K is

$$T = \frac{1}{2}mv^2\,, \tag{19.18}$$

with units of J.

Rests on Definitions 18.10 and 19.3.

19.4.2 Potential energy and conservative forces

Definition 19.30 (Conservative force and potential energy)**.** Consider a force $\boldsymbol{F}_V$ upon a particle. This force is *conservative* if and only if there exists a real function V, which we shall call the *potential energy*, such that

$$\boldsymbol{F}_V = -\boldsymbol{\nabla}V\,. \tag{19.19}$$

Rests on Postulate 19.8 and Equation (19.2).

Let us see that if $\boldsymbol{F}$ is conservative one has

$$\boldsymbol{\nabla}\times\boldsymbol{F} = -\boldsymbol{\nabla}\times\boldsymbol{\nabla}V\,,$$

and therefore

$$\boldsymbol{\nabla} \times \boldsymbol{F} = \boldsymbol{0}\,. \tag{19.20}$$

We may consider that a free particle is subject to a constant potential energy V_0, since the force $\boldsymbol{F}_V$ upon it would still be zero.

On occasion, instead of saying that a particle is subject to a conservative force $\boldsymbol{F}_V$, one says that it is subject to a *potential* V.

19.4.3 Energy

Definition 19.31 (Energy)**.** Consider a particle subject to a potential V. The total *energy* of the particle is

$$E = T + V\,. \tag{19.21}$$

Rests on Definitions 19.29 and 19.30.

19.4.4 The law of conservation of energy

The source manuscript reserves this heading with the instruction to demonstrate that $\mathrm{d}E/\mathrm{d}t = 0$ for every inertial frame. Carried out, the instruction turns out to be right for a closed system and wrong for a single particle in an externally imposed field, and the difference is worth stating precisely.

Theorem 19.32 (Conservation of energy)**.** *Let the total force upon a particle derive from a potential V that carries no explicit dependence on time. Then the energy $E = T + V$ satisfies*

$$\frac{\mathrm{d}E}{\mathrm{d}t} = 0 \tag{19.22}$$

with respect to the inertial frame in which V is time-independent, but not in general with respect to any other. If instead the system is a closed one of N particles of constant masses, whose internal forces derive from a potential U depending only on the mutual distances $|\boldsymbol{x}_s - \boldsymbol{x}_r|$, then Equation (19.22) holds for $E = \sum_s \frac{1}{2} m_s |\boldsymbol{v}_s|^2 + U$ with respect to every *inertial frame.*

Rests on Definition 19.31 and Equations (19.4) and (19.19).

Proof. *Derives Theorem 19.32.*

One particle, one frame. Differentiating Equation (19.18) along the motion and using Equation (19.4), $\mathrm{d}T/\mathrm{d}t = \boldsymbol{F} \cdot \boldsymbol{v}$; and since V carries no explicit time dependence, the chain rule gives $\mathrm{d}V/\mathrm{d}t = \boldsymbol{\nabla} V \cdot \boldsymbol{v} = -\boldsymbol{F} \cdot \boldsymbol{v}$ by Equation (19.19). The two cancel, which is Equation (19.22).

One particle, another frame. Boost to a frame K' moving with constant velocity $\boldsymbol{V}$, so that $\boldsymbol{x} = \boldsymbol{x}' + \boldsymbol{V}t$ and $\boldsymbol{v}' = \boldsymbol{v} - \boldsymbol{V}$ by Equation (19.6). The potential seen there is $V(\boldsymbol{x}' + \boldsymbol{V}t)$, which *does* depend explicitly on the time, and

$$\frac{\mathrm{d}E'}{\mathrm{d}t} = m\,\boldsymbol{v}' \cdot \frac{\mathrm{d}\boldsymbol{v}'}{\mathrm{d}t} + \boldsymbol{\nabla} V \cdot (\boldsymbol{v}' + \boldsymbol{V}) = \boldsymbol{F} \cdot \boldsymbol{v}' - \boldsymbol{F} \cdot (\boldsymbol{v}' + \boldsymbol{V}) = -\boldsymbol{F} \cdot \boldsymbol{V}\,, \tag{19.23}$$

which vanishes only when the force is perpendicular to the boost. The reading is physical rather than paradoxical: in K' the agent maintaining the external field is itself in motion, and it does work at the rate $-\boldsymbol{F} \cdot \boldsymbol{V}$. An external static potential is always an idealization of a second body held fixed, and holding it fixed is what the second frame sees being paid for.

The closed system. Here there is no external agent. Under the general transformation Equation (18.11) the mutual distances are unchanged, since $\boldsymbol{x}'_s - \boldsymbol{x}'_r = R(\boldsymbol{x}_s - \boldsymbol{x}_r)$ and R preserves lengths, so $U' = U$. The kinetic energy transforms by Equation (19.6) as

$$T' = \sum_s \frac{1}{2} m_s |R\boldsymbol{v}_s - \boldsymbol{V}|^2 = T - \boldsymbol{V} \cdot R\boldsymbol{P} + \frac{1}{2} M V^2\,, \tag{19.24}$$

with $\boldsymbol{P} = \sum_s \boldsymbol{p}_s$ the total momentum and M the total mass Equation (19.32). Hence $E' = E - \boldsymbol{V} \cdot R\boldsymbol{P} + \frac{1}{2}MV^2$. Each of the three terms on the right is constant in time — E by the first part of this proof applied to the system, $\boldsymbol{P}$ by Theorem 19.67, and M and $\boldsymbol{V}$ by hypothesis — so E' is constant too. Note what this does *not* say: $E' \neq E$, and the two frames disagree about how much energy the system has. They agree only that the number does not change. □

Phenomenon 19.33 (Mechanical energy is conserved)**.** A pendulum bob released from rest at a given height rises on the far side to that same height, and continues to do so when a nail placed beneath the point of suspension catches the cord in mid-swing and forces the bob onto a shorter arc of a different radius: what the descent confers is fixed by the vertical drop alone and not by the path taken. Galileo reports the interrupted-pendulum experiment for exactly this purpose [4]. The same law governs a ball rolling in a bowl, a mass bouncing on a spring, and a projectile exchanging height for speed; and it fails visibly, as a decaying amplitude, precisely when friction is present — that is, precisely when the total force does not derive from a potential.

Rests on Theorem 19.32 and Equation (19.19)*.*

Derivation. Derives Phenomenon 19.33.

Let the total force on a particle of constant mass derive from a potential that does not depend explicitly on time, $\boldsymbol{F} = -\boldsymbol{\nabla} V$ as in Equation (19.19). Differentiating the kinetic energy Equation (19.18) along the motion and using Equation (19.4),

$$\frac{\mathrm{d}T}{\mathrm{d}t} = m\,\boldsymbol{v} \cdot \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = \boldsymbol{F} \cdot \boldsymbol{v}\,,$$

while the potential energy evaluated along the same motion changes, by the chain rule, at the rate

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \boldsymbol{\nabla} V \cdot \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} = -\boldsymbol{F} \cdot \boldsymbol{v}\,.$$

Adding the two, the energy Equation (19.21) obeys $\frac{\mathrm{d}E}{\mathrm{d}t} = 0$, which is Equation (19.22). For the pendulum, $V = mgh$ and $T = \frac{1}{2}mv^2$, so a bob released from rest at height h_0 carries $E = mgh_0$ throughout and can be momentarily at rest only where $h = h_0$ — whatever the shape of the arc it has travelled, which is the interrupted-pendulum observation. Two limitations are worth recording. The frame-dependence is real and is settled in Theorem 19.32: for the bob taken alone, in a frame moving horizontally, the energy is *not* constant by Equation (19.23), and constancy is recovered only when the Earth is included and the system is closed. And the argument fails as soon as V depends explicitly on time or the force has a non-conservative part, which is why Equation (19.20) is the criterion to test before invoking the result — the decaying amplitude of a real pendulum is that criterion failing. □

19.4.5 Work

Definition 19.34 (Work)**.** The *work* performed by a particle along a curve C, whose trajectory is due to a total force $\boldsymbol{F}$, is

$$W = \int_C \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x}\,, \tag{19.25}$$

with units of J.

Rests on Postulate 19.8 and Definition 18.3.

Let us see that if $\boldsymbol{F}$ is conservative and C is a closed curve, one has

$$\begin{aligned} W &= \oint_C \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} \\ &= -\oint_C \boldsymbol{\nabla} V \cdot \mathrm{d}\boldsymbol{x} && \text{by Equation (19.19)} \\ &= -\int_S \boldsymbol{\nabla} \times \boldsymbol{\nabla} V \cdot \mathrm{d}\boldsymbol{s} \\ &= 0\,. \end{aligned}$$

Therefore, the work performed by a particle under a conservative total force along a closed curve is null.

The differential of work performed by a particle in a displacement $\mathrm{d}\boldsymbol{x}$, due to a force $\boldsymbol{F}$, is given by

$$\mathrm{d}W = \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x}\,.$$

Now, if the total force upon the particle comes from a potential V, one has

$$\begin{aligned} \mathrm{d}W &= \boldsymbol{F}_V \cdot \mathrm{d}\boldsymbol{x} \\ &= -\boldsymbol{\nabla} V \cdot \mathrm{d}\boldsymbol{x} \\ &= -\frac{\partial V}{\partial x^i}\,\mathrm{d}x^i \\ &= -\mathrm{d}V\,, \end{aligned}$$

and, integrating, we see that

$$\Delta W = -\Delta V\,. \tag{19.26}$$

Power

Definition 19.35 (Power)**.** The *power* is the rate at which work is performed,

$$P = \frac{\mathrm{d}W}{\mathrm{d}t}\,, \tag{19.27}$$

with units of $\mathrm{W} = \mathrm{J/s}$.

Rests on Definition 19.34.

Work for the magnitude of a torque

The formulary asserts, without derivation, that the differential of work associated with the magnitude of a torque τ through an angle ϕ is

$$\mathrm{d}W = \tau\,\mathrm{d}\phi\,. \tag{19.28}$$

The relation is true under a hypothesis the formulary leaves unsaid, and stating it is the whole of the derivation.

Proposition 19.36 (Work of a torque)**.** *Let a body turn by an infinitesimal rotation $\mathrm{d}\boldsymbol{\phi} = \hat{\boldsymbol{n}}\,\mathrm{d}\phi$ about an axis $\hat{\boldsymbol{n}}$ through the origin, and let a force $\boldsymbol{F}$ be applied at the point $\boldsymbol{x}$. Then the work done is*

$$\mathrm{d}W = \boldsymbol{\tau} \cdot \mathrm{d}\boldsymbol{\phi} = (\hat{\boldsymbol{n}} \cdot \boldsymbol{\tau})\,\mathrm{d}\phi\,, \tag{19.29}$$

in J*, with $\boldsymbol{\tau}$ the torque Equation (19.15) about the origin. The scalar form Equation (19.28) is the special case in which the torque is parallel to the axis of rotation.*

Rests on Definition 19.34 and Equation (19.15).

Proof. *Derives Proposition 19.36.*

Under a rotation by $\mathrm{d}\boldsymbol{\phi}$ about an axis through the origin the point of application moves by $\mathrm{d}\boldsymbol{x} = \mathrm{d}\boldsymbol{\phi} \times \boldsymbol{x}$. This is the generator of $\mathfrak{so}(3)$ acting on a vector: with the basis Equation (14.32) of Proposition 14.27, whose entries are $(L_k)_{ij} = -\epsilon_{kij}$, one has $\left(\mathrm{d}\phi^k L_k \boldsymbol{x}\right)_i = \epsilon_{ikj}\mathrm{d}\phi^k x_j = (\mathrm{d}\boldsymbol{\phi} \times \boldsymbol{x})_i$. Then, by Definition 19.34,

$$\begin{aligned} \mathrm{d}W &= \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} \\ &= \boldsymbol{F} \cdot (\mathrm{d}\boldsymbol{\phi} \times \boldsymbol{x}) \\ &= \mathrm{d}\boldsymbol{\phi} \cdot (\boldsymbol{x} \times \boldsymbol{F}) \\ &= \boldsymbol{\tau} \cdot \mathrm{d}\boldsymbol{\phi}\,, \end{aligned}$$

the third line by the cyclic invariance of the scalar triple product, which in the index notation Equation (13.225) is the cyclic symmetry of ε_{ijk}, and the fourth by Equation (19.15). Writing $\mathrm{d}\boldsymbol{\phi} = \hat{\boldsymbol{n}}\,\mathrm{d}\phi$ gives Equation (19.29). The component of $\boldsymbol{\tau}$ perpendicular to $\hat{\boldsymbol{n}}$ does no work: it is taken up by whatever constrains the axis, which is why a door hinge does not absorb energy while the door swings. Consequently Equation (19.28) as the formulary states it holds when, and only when, $\boldsymbol{\tau}$ is parallel to $\hat{\boldsymbol{n}}$ — the case of a body free to turn about a single fixed axis with the force applied in the plane perpendicular to it. □

Corollary 19.37 (Rotational power)**.** *Dividing Equation (19.29) by* $\mathrm{d}t$ *and using Equation (19.27),*

$$P = \boldsymbol{\tau} \cdot \boldsymbol{\omega}\,, \tag{19.30}$$

with $\boldsymbol{\omega} = \mathrm{d}\boldsymbol{\phi}/\mathrm{d}t$ *the angular velocity in* rad/s *and* P *in* W*. This is the relation by which the shaft power of an engine is computed from a dynamometer reading of the torque and a tachometer reading of the rotation rate.*

Rests on Proposition 19.36 and Equation (19.27).

19.4.6 The work–energy theorem

Theorem 19.38 (Work–energy theorem)**.** *The work performed by a particle equals the variation of its kinetic energy,*

$$\boxed{W = \Delta T}\,. \tag{19.31}$$

Rests on Definitions 19.29 and 19.34 and Equation (19.4).

Derivation. *Derives Theorem 19.38.*

Consider a particle under a total force $\boldsymbol{F}$ that performs a work W. From the definition

of work and Equation (19.4),

$$\begin{aligned} W &= \int_C \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} \\ &= m \int_{t_a}^{t_b} \left(\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} \cdot \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} \right) \mathrm{d}t \\ &= m \int_{t_a}^{t_b} \left(\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} \cdot \boldsymbol{v} \right) \mathrm{d}t \\ &= \frac{1}{2} m \int_{t_a}^{t_b} \frac{\mathrm{d}(\boldsymbol{v} \cdot \boldsymbol{v})}{\mathrm{d}t} \, \mathrm{d}t \\ &= \frac{1}{2} m \int_{t_a}^{t_b} \mathrm{d} \left| \boldsymbol{v} \right|^2 \\ &= \frac{1}{2} m \left(\left| \boldsymbol{v}(t_b) \right|^2 - \left| \boldsymbol{v}(t_a) \right|^2 \right) . \end{aligned}$$

Therefore, from Equation (19.18), $W = \Delta T$. □

This result is known as the *work–energy theorem*, or the theorem of the *vires vivae* (living forces).

19.5 Systems of particles

In the preceding sections we introduced all the fundamental principles that govern the dynamics of a particle and of a body. We began with particles because Newton's laws take their simplest form there. We did not do the same with bodies of definite volume, since in essence it is not necessary: to speak of particles is not more general, but it is more canonical.

We shall now introduce the concepts, and extend the definitions in the appropriate manner, for systems of many particles and bodies.

19.5.1 Inertia and mass of a system

Body as a system of particles

Definition 19.39 (Body)**.** A *body* is a set of N particles occupying a region V of space. This region of space is called the *volume* of the body.

Rests on Definitions 18.4 and 19.3.

Total mass of the system

Consider a closed system of N particles of masses m_s, with $s = 1, \ldots, N$.

Definition 19.40 (Total mass)**.** The total mass of the system is simply the sum of all the masses,

$$M = \sum_{s}^{N} m_s \, . \tag{19.32}$$

Rests on Definitions 19.3 and 19.39.

Because we have considered the system to be closed, M is constant.

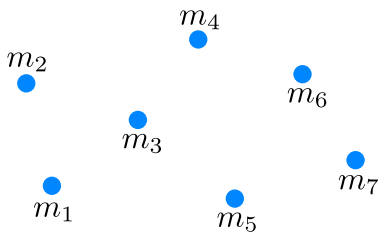

Figure 19.3: A closed system of N particles: the total mass is the sum of the individual masses.

Moment of inertia of the system

Definition 19.3 makes the mass the measure of how much a particle resists being translated. A body resists being *turned* as well, and by an amount that depends on how its mass is distributed about the axis of the turn: this is the everyday fact that a long pole is harder to spin about its middle than a compact one of the same weight.

Definition 19.41 (Moment of inertia about an axis)**.** Let a system of N particles of masses m_s have positions $\boldsymbol{x}_s$ measured from a point O, and let $\hat{\boldsymbol{n}}$ be a unit vector through O. The *moment of inertia* of the system about the axis $(O, \hat{\boldsymbol{n}})$ is

$$I = \sum_{s}^{N} m_s d_s^2 \,, \qquad d_s = |\hat{\boldsymbol{n}} \times \boldsymbol{x}_s| \,, \tag{19.33}$$

with d_s the perpendicular distance from the particle to the axis, of SI unit $\mathrm{kg\,m^2}$. For a body of mass density ρ the sum is replaced by $I = \int_V \rho\, d^2 \,\mathrm{d}V$.

Rests on Definitions 19.3 and 19.39.

The dependence on the axis is quadratic and can be separated out.

Definition 19.42 (Inertia tensor)**.** The *inertia tensor* of the system about the point O is the array

$$I_{ij} = \sum_{s}^{N} m_s \left(|\boldsymbol{x}_s|^2 \, \delta_{ij} - x_{s,i}\, x_{s,j} \right) \,, \tag{19.34}$$

of SI unit $\mathrm{kg\,m^2}$.

Rests on Definitions 13.5 and 19.41.

Proposition 19.43 (The moment of inertia is a quadratic form in the axis)**.** *For every unit vector $\hat{\boldsymbol{n}}$,*

$$I = \hat{n}_i \, I_{ij} \, \hat{n}_j \,, \tag{19.35}$$

and I_{ij} is symmetric, is a Cartesian tensor of rank two in the sense of Definition 13.5, and is positive semidefinite, vanishing on $\hat{\boldsymbol{n}}$ only when every particle of the system lies on the axis.

Rests on Definitions 13.5 and 19.42.

Proof. *Derives Proposition 19.43.*

Since $\hat{\boldsymbol{n}}$ is a unit vector, $d_s^2 = |\hat{\boldsymbol{n}} \times \boldsymbol{x}_s|^2 = |\boldsymbol{x}_s|^2 - (\hat{\boldsymbol{n}} \cdot \boldsymbol{x}_s)^2$, which is Pythagoras' theorem applied to the decomposition of $\boldsymbol{x}_s$ into its components along and across the axis. Substituting into Equation (19.33) and writing $|\boldsymbol{x}_s|^2 = \hat{n}_i \delta_{ij} \hat{n}_j \, |\boldsymbol{x}_s|^2$ and $(\hat{\boldsymbol{n}} \cdot \boldsymbol{x}_s)^2 = \hat{n}_i x_{s,i} x_{s,j} \hat{n}_j$ gives Equation (19.35) with I_{ij} as in Equation (19.34). Symmetry is manifest. Each summand of Equation (19.34) is built from δ_{ij}, which is invariant, and from the outer product $x_{s,i} x_{s,j}$ of a vector with itself, which obeys Equation (13.22) because each factor obeys the vector rule; the finite sum of tensors is a tensor, so I_{ij} satisfies Definition 13.5. Finally Equation (19.33) exhibits I as a sum of terms $m_s d_s^2 \geq 0$, so $I \geq 0$, with equality precisely when every $d_s = 0$. □

Theorem 19.44 (Parallel axes; Steiner)**.** *Let I_{CM} be the moment of inertia of the system about an axis of direction $\hat{\boldsymbol{n}}$ through its centre of mass (Definition 19.47, below), and let I be the moment of inertia about the parallel axis of the same direction through a point at perpendicular distance D from it. Then*

$$\boxed{I = I_{CM} + MD^2}, \tag{19.36}$$

with M the total mass Equation (19.32).

Rests on Definition 19.41 and Equations (19.32) and (19.38).

Proof. *Derives Theorem 19.44.*

Take the origin at the centre of mass and let the second axis pass through the point $\boldsymbol{D}$, chosen perpendicular to $\hat{\boldsymbol{n}}$ without loss of generality, so that $|\boldsymbol{D}| = D$. Write $\boldsymbol{x}_s^{\perp}$ for the component of $\boldsymbol{x}_s$ perpendicular to $\hat{\boldsymbol{n}}$, so that $d_s = \left|\boldsymbol{x}_s^{\perp}\right|$ for the first axis and $\left|\boldsymbol{x}_s^{\perp} - \boldsymbol{D}\right|$ for the second. Then

$$\begin{aligned} I &= \sum_s^N m_s \left|\boldsymbol{x}_s^{\perp} - \boldsymbol{D}\right|^2 \\ &= \sum_s^N m_s \left|\boldsymbol{x}_s^{\perp}\right|^2 - 2\boldsymbol{D}\cdot\sum_s^N m_s \boldsymbol{x}_s^{\perp} + D^2 \sum_s^N m_s \\ &= I_{\mathrm{CM}} + MD^2 \,, \end{aligned}$$

because the middle sum is M times the perpendicular component of the position of the centre of mass Equation (19.38), which vanishes when the origin is the centre of mass itself. The theorem therefore singles the centre of mass out: among all parallel axes of a given direction, the one through the centre of mass has the smallest moment of inertia, and Equation (19.36) says by how much any other exceeds it. □

Example 19.45 (The uniform solid sphere)**.** For a homogeneous sphere of mass M and radius R the symmetry forces $I_{ij} = I\delta_{ij}$, so every axis through the centre gives the same moment of inertia and it may be extracted from the trace of Equation (19.34), which is $I_{ii} = 2\int_V \rho\,|\boldsymbol{x}|^2\,\mathrm{d}V = 3I$. With $\rho = 3M/\left(4\pi R^3\right)$ constant,

$$\int_V \rho\,|\boldsymbol{x}|^2\,\mathrm{d}V = \rho\int_0^R r^2\,4\pi r^2\,\mathrm{d}r = \frac{4\pi\rho R^5}{5} = \frac{3}{5}MR^2\,,$$

whence

$$I = \frac{2}{5}MR^2\,. \tag{19.37}$$

A measured moment of inertia smaller than $\frac{2}{5}MR^2$ is therefore direct evidence that a body's mass is concentrated towards its centre, which is how the internal structure of a planet is read off its precession.

Rests on Definition 19.42 and Equation (19.33).

Remark 19.46 (Principal axes, and what is owed for them). Because I_{ij} is real and symmetric, there is an orthonormal basis of $\mathbb{R}^3$ in which it is diagonal, $I_{ij} = \mathrm{diag}\,(I_1, I_2, I_3)$ with $I_k \geq 0$; the basis directions are the *principal axes* and the I_k the *principal moments*. Theorem 5.75 proves the spectral theorem for a self-adjoint operator on a complex inner-product space, which gives the reality of the I_k at once; the statement actually used here is its real form, that a real symmetric matrix is diagonalized by a *real orthogonal* change of basis, and Part II does not state it separately. It is a standard corollary — the eigenvalues being real, the eigenvectors may be taken real — but it is mathematics and belongs in Chapter 5, not here. Everything that follows from the principal axes, from Euler's equations to the free precession of a symmetric top, is the subject of Chapter 29 [32, 99].

Kinematics of the centre of mass

Consider the preceding system, in which the positions of the particles are $\boldsymbol{x}_s$. How can we assign to the system a quantity that allows us to treat it as a single particle? We can define a point of space that takes an average of the positions, according to the amount of mass assigned to each particle.

Definition 19.47 (Position of the centre of mass)**.** The *position of the centre of mass* of a system of particles is

$$\boldsymbol{x}_{\mathrm{CM}} = \frac{\sum_s^N m_s \boldsymbol{x}_s}{M} \,. \tag{19.38}$$

Rests on Definitions 19.39 and 19.40.

The centre of mass may itself be regarded as a point of space to which the mass M is assigned. By definition, the *velocity of the centre of mass*, with respect to a frame of reference in which its position is $\boldsymbol{x}_{\mathrm{CM}}$, is given by

$$\boldsymbol{v}_{\mathrm{CM}} = \frac{\mathrm{d}\boldsymbol{x}_{\mathrm{CM}}}{\mathrm{d}t} \,, \tag{19.39}$$

and, in the same fashion, the *acceleration of the centre of mass* is given by

$$\boldsymbol{a}_{\mathrm{CM}} = \frac{\mathrm{d}\boldsymbol{v}_{\mathrm{CM}}}{\mathrm{d}t} \,. \tag{19.40}$$

19.5.2 Internal dynamics of the system

Newton's third law

Let us note the following fact of nature. When we push a wall with a given force, directed towards it, it is as if the wall pushed us back with the same force, but in the opposite direction.

Considering again the aforementioned system of particles: what about the interaction among them? Well, since the particles can interact, one of them feels a total force due to the others, and it exerts a force upon the others. What is the relation between these forces? To give an answer, let us take two particles of the system, which we shall call particle 1 and particle 2.

We shall denote by $\boldsymbol{F}_{12}$ the force felt by particle 1 due to particle 2, and by $\boldsymbol{F}_{21}$ the force felt by particle 2 due to particle 1.

On the basis of the philosophical conclusions about *action and reaction*, we may intuit that the magnitudes of these forces must be equal; but we must in addition specify an orientation for these vectors. In any case, owing to the interaction between these two particles they approach or recede from each other; and we may also intuit that this trajectory of approach or recession is in principle a straight line, so that these forces would be parallel.

We then enunciate as a fundamental principle:

Postulate 19.48 (Newton's third law)**.** The force that one particle exerts upon another is equal to the force that the latter exerts upon the former, but with opposite sign,

$$\boldsymbol{F}_{12} = -\boldsymbol{F}_{21} \,. \tag{19.41}$$

Rests on Postulate 19.8 and Definition 19.2.

This is known by the name of *Newton's third law*, or the *principle of action and reaction.*

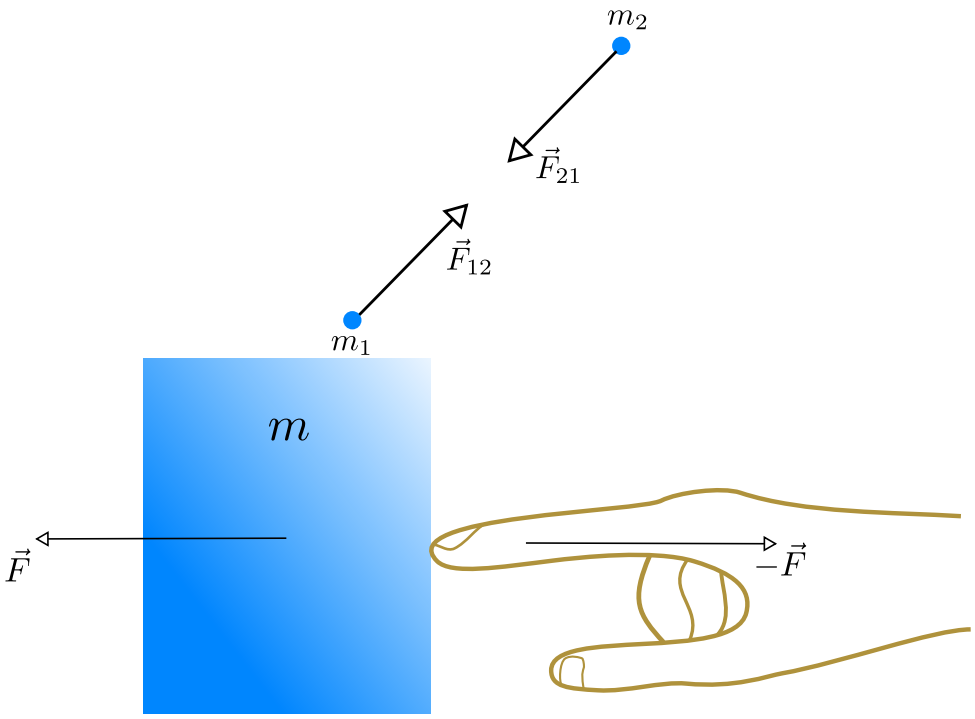

Figure 19.4: Action and reaction: the force one particle exerts upon another is equal and opposite to the force it receives from it.

Net internal force

There are two types of forces to which our system of particles is subject: the internal ones, $\boldsymbol{F}_{\text{INT}}$, which are the interactions among the particles; and the external ones, $\boldsymbol{F}_{\text{EXT}}$, which are those alien to the system — they affect it as a whole, not each particle separately. An example of this can be a gas of molecules inside a balloon: the particles interact with one another repulsively, forming the gas, while an external force could be the action of gravity upon the balloon. We shall assume:

Postulate 19.49 (Net internal force)**.** The internal interactions of the system do not contribute to its motion as a whole,

$$\boldsymbol{F}_{\text{INT}} = \boldsymbol{0}\,, \tag{19.42}$$

Rests on Postulate 19.48.

since for the most part they cancel by Newton's third law. In our example applied to nature, this amounts to the following: the molecular interactions are of no great importance for the motion of the balloon as such.

Phenomenon 19.50 (Recoil and the conservation of momentum)**.** When two bodies interact and nothing external acts on the pair, the vector sum of their linear momenta is the same after the interaction as before. A gun recoils as the shot leaves it; a swimmer moves forward by driving water backward; a rocket accelerates in vacuum with nothing to push against. In a collision on an air track the sum $m_1\boldsymbol{v}_1 + m_2\boldsymbol{v}_2$ is found unchanged whether the bodies rebound or stick together, and whether or not the kinetic energy is conserved — which it usually is not. Newton records the result as the third corollary to the laws of motion [14].

Rests on Postulate 19.48 and Equation (19.2)*.*

Derivation. *Derives Phenomenon 19.50.*

Take two particles subject only to their mutual interaction. Applying Equation (19.2) to each,

$$\frac{\mathrm{d}\boldsymbol{p}_1}{\mathrm{d}t} = \boldsymbol{F}_{12}\,, \qquad \frac{\mathrm{d}\boldsymbol{p}_2}{\mathrm{d}t} = \boldsymbol{F}_{21}\,,$$

and adding the two, Newton's third law Equation (19.41) makes the right-hand side vanish identically:

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\boldsymbol{p}_1 + \boldsymbol{p}_2\right) = \boldsymbol{F}_{12} + \boldsymbol{F}_{21} = \boldsymbol{0}\,. \tag{19.43}$$

The total momentum is therefore constant throughout the interaction, however violent and however brief, and — this is the strength of the result — no property of the interaction law enters, so the same conclusion covers collisions whose forces are entirely unknown. For N particles the internal contributions cancel in the same way, pair by pair, which is the content of Postulate 19.49. Energy is not similarly protected: Equation (19.43) holds for an inelastic collision, in which kinetic energy is demonstrably lost to heat and deformation. □

19.5.3 Translational Newton laws for systems of particles

Linear momentum of the centre of mass

Consider a (closed) system of particles, in which the s-th particle has position $\boldsymbol{x}_s$ and linear momentum $\boldsymbol{p}_s$.

Definition 19.51 (Linear momentum of the centre of mass)**.** The *linear momentum of the centre of mass* is

$$\boldsymbol{p}_{\mathrm{CM}} = M\boldsymbol{v}_{\mathrm{CM}}\,. \tag{19.44}$$

Rests on Definitions 19.5 and 19.47.

Completeness

Let us compute:

$$\begin{aligned}
\boldsymbol{v}_{\mathrm{CM}} &= \frac{\mathrm{d}\boldsymbol{x}_{\mathrm{CM}}}{\mathrm{d}t} \\
&= \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\sum_s^N m_s\boldsymbol{x}_s}{M}\right) && \text{by Equation (19.38)} \\
&= \frac{1}{M}\sum_s^N \frac{\mathrm{d}}{\mathrm{d}t}(m_s\boldsymbol{x}_s) \\
&= \frac{1}{M}\sum_s^N \left(\frac{\mathrm{d}m_s}{\mathrm{d}t}\boldsymbol{x}_s + m_s\frac{\mathrm{d}\boldsymbol{x}_s}{\mathrm{d}t}\right)\,,
\end{aligned}$$

so that, by Equation (19.44),

$$\begin{aligned}
\boldsymbol{p}_{\mathrm{CM}} &= \sum_s^N \frac{\mathrm{d}m_s}{\mathrm{d}t}\boldsymbol{x}_s + \sum_s^N m_s\frac{\mathrm{d}\boldsymbol{x}_s}{\mathrm{d}t} \\
&= \sum_s^N \frac{\mathrm{d}m_s}{\mathrm{d}t}\boldsymbol{x}_s + \sum_s^N \boldsymbol{p}_s\,.
\end{aligned}$$

Restricting to the case in which the mass of each particle is constant, we obtain the following *completeness of the total linear momentum* of the system:

$$\boldsymbol{p}_{\mathrm{CM}} = \sum_{s=1}^N \boldsymbol{p}_s\,, \tag{19.45}$$

that is, the sum of the linear momenta of all the particles of the system is equal to the linear momentum of the centre of mass.

Translational Newton's second law for the centre of mass

Let us consider the centre of mass as a particle. Denote the total force upon our system of particles by $\boldsymbol{F}$. Recalling the discussion of the net internal force, one has

$$\boldsymbol{F} = \boldsymbol{F}_{\text{EXT}} + \boldsymbol{F}_{\text{INT}}\,,$$

and, as we have assumed, $\boldsymbol{F}_{\text{INT}} = \boldsymbol{0}$. Thus, applying Newton's second law to our centre of mass, we arrive at the expression

$$\begin{aligned}\boldsymbol{F}_{\text{EXT}} &= \frac{\mathrm{d}\boldsymbol{p}_{\text{CM}}}{\mathrm{d}t} \\ &= \frac{\mathrm{d}}{\mathrm{d}t}(M\boldsymbol{v}_{\text{CM}}) \qquad\qquad \text{by Equation (19.44)}\,,\end{aligned}$$

and, since M is constant, one has

$$\boxed{\boldsymbol{F}_{\text{EXT}} = M\boldsymbol{a}_{\text{CM}}}\,. \tag{19.46}$$

The source flags at this point, without carrying it out, the demonstration that the interaction of the centre of mass with the remaining particles cancels, so that Newton's second law may legitimately be applied to it. That demonstration is the following, and its by-product is that Postulate 19.49 need not have been postulated at all.

Theorem 19.52 (The centre of mass moves as a particle)**.** *Let a closed system of N particles of constant masses have internal forces obeying Equation (19.41). Then the net internal force vanishes,*

$$\boldsymbol{F}_{INT} = \sum_{s}^{N}\sum_{r\neq s}\boldsymbol{F}_{sr} = \boldsymbol{0}\,, \tag{19.47}$$

and consequently Equation (19.46) holds: the centre of mass accelerates as a single particle of mass M acted on by the total external force alone.

Rests on Postulate 19.48 and Equations (19.44) and (19.45).

Proof. *Derives Theorem 19.52.*

Group the double sum in Equation (19.47) into unordered pairs. The pair $\{s, r\}$ contributes $\boldsymbol{F}_{sr} + \boldsymbol{F}_{rs}$, which is $\boldsymbol{0}$ by Equation (19.41); every pair occurs exactly once, so the whole sum vanishes. Now differentiate the completeness relation Equation (19.45) and apply Equation (19.2) to each particle:

$$\begin{aligned}\frac{\mathrm{d}\boldsymbol{p}_{\text{CM}}}{\mathrm{d}t} &= \sum_{s}^{N}\frac{\mathrm{d}\boldsymbol{p}_s}{\mathrm{d}t} \\ &= \sum_{s}^{N}\boldsymbol{F}_s \\ &= \boldsymbol{F}_{\text{EXT}} + \boldsymbol{F}_{\text{INT}} = \boldsymbol{F}_{\text{EXT}}\,,\end{aligned}$$

and since M is constant, $\mathrm{d}\boldsymbol{p}_{\text{CM}}/\mathrm{d}t = M\boldsymbol{a}_{\text{CM}}$ by Equations (19.40) and (19.44), which is Equation (19.46). □

Remark 19.53 (A postulate that was a theorem). Equation (19.47) is exactly the statement Postulate 19.49 assumes, so that assumption may be discharged: for a system whose particles interact in pairs obeying the third law, the vanishing of the net internal force is a consequence, not an independent principle. The hedge in the discussion following Postulate 19.49 — "for the most part they cancel" — is therefore too weak, and can be strengthened to an exact cancellation. What it does require is that the forces be *pair* forces: a genuine three-body interaction, one not expressible as a sum over pairs, is not covered by Equation (19.41) and would have to be examined on its own. No such force is known among the fundamental interactions.

Phenomenon 19.54 (The centre of mass ignores internal forces)**.** A body that flies apart in mid-air does not thereby alter the path of its centre of mass: the fragments of a bursting firework, and the two halves of a rod that breaks in flight, continue to straddle the same smooth arc their common centre was already describing, and the arc shows no kink at the instant of the burst. A wrench tossed spinning across a room follows, in its centre of mass, exactly the path of a wrench that does not spin, however complicated the tumbling superposed on it. The observation is what licenses the everyday practice of treating an extended body as a point.

Rests on Equation (19.46) *and Postulate 19.49.*

Derivation. *Derives Phenomenon 19.54.*

By Equation (19.46) the acceleration of the centre of mass answers to $\boldsymbol{F}_{\mathrm{EXT}}$ alone; the internal forces have already dropped out through Postulate 19.49, cancelling pair by pair by Equation (19.41). An explosion, a rotation, or any other rearrangement of the parts is internal by definition, so it alters neither $\boldsymbol{F}_{\mathrm{EXT}}$ nor the total mass M, and therefore leaves $\boldsymbol{a}_{\mathrm{CM}}$ untouched at the instant it occurs and afterwards. With the external force of a body near the ground, $\boldsymbol{F}_{\mathrm{EXT}} = M\boldsymbol{g}$, one has $\boldsymbol{a}_{\mathrm{CM}} = \boldsymbol{g}$ constant, so the centre of mass describes the parabola of Chapter 20 whatever the fragments do individually. Two caveats belong with the result: the cancellation of the internal forces requires the third law in the form Equation (19.41), and M must be constant, which excludes bodies that expel matter altogether rather than merely redistributing it. □

19.5.4 Rotational Newton laws for systems of particles

Angular momentum of the centre of mass

Definition 19.55 (Angular momentum of the centre of mass)**.** The *angular momentum of the centre of mass* is

$$\boldsymbol{L}_{\mathrm{CM}} = \boldsymbol{x}_{\mathrm{CM}} \times \boldsymbol{p}_{\mathrm{CM}} \,. \tag{19.48}$$

Rests on Definitions 19.18 and 19.51.

Completeness

The translational case gave the clean identity Equation (19.45): the momentum of the centre of mass is the sum of the momenta of the particles, with nothing left over. The rotational case does not, and the difference is the single most consequential fact about the mechanics of extended bodies.

Notation 19.56 (Positions and velocities relative to the centre of mass)*.* Throughout this subsection, a primed symbol denotes a quantity referred to the centre of mass:

$$\boldsymbol{x}_s = \boldsymbol{x}_{\mathrm{CM}} + \boldsymbol{x}'_s \,, \qquad \boldsymbol{v}_s = \boldsymbol{v}_{\mathrm{CM}} + \boldsymbol{v}'_s \,, \qquad \boldsymbol{p}'_s = m_s \boldsymbol{v}'_s \,. \tag{19.49}$$

The primes here have nothing to do with the change of inertial frame of Equation (18.11); the centre of mass need not move uniformly.

Lemma 19.57 (The centre of mass is the origin of its own frame)**.** *With the masses constant,*

$$\sum_{s}^{N} m_s \boldsymbol{x}'_s = \boldsymbol{0} \,, \qquad \sum_{s}^{N} \boldsymbol{p}'_s = \boldsymbol{0} \,. \tag{19.50}$$

Rests on Equations (19.38) *and* (19.49)*.*

Proof. *Derives Lemma 19.57.*

By Equations (19.38) and (19.49),

$$\sum_s^N m_s \boldsymbol{x}'_s = \sum_s^N m_s \boldsymbol{x}_s - \left(\sum_s^N m_s\right) \boldsymbol{x}_{\mathrm{CM}} = M\boldsymbol{x}_{\mathrm{CM}} - M\boldsymbol{x}_{\mathrm{CM}} = \boldsymbol{0}\,,$$

using Equation (19.32). Differentiating with respect to time, the masses being constant, gives the second identity. □

Theorem 19.58 (Decomposition of the angular momentum)**.** *The total angular momentum of the system about a fixed origin is*

$$\boxed{\sum_s^N \boldsymbol{x}_s \times \boldsymbol{p}_s = \boldsymbol{L}_{CM} + \boldsymbol{S}}\,, \qquad \boldsymbol{S} := \sum_s^N \boldsymbol{x}'_s \times \boldsymbol{p}'_s\,, \tag{19.51}$$

with $\boldsymbol{L}_{CM}$ the angular momentum Equation (19.48) of the centre of mass and $\boldsymbol{S}$ the internal, *or* spin, *angular momentum, both of SI unit* $\mathrm{kg\,m^2/s}$.

Rests on Definition 19.55, Lemma 19.57, and Equation (19.44).

Proof. *Derives Theorem 19.58.*

Substituting Equation (19.49) into the sum and expanding the four cross products,

$$\begin{aligned}\sum_s^N \boldsymbol{x}_s \times \boldsymbol{p}_s = \boldsymbol{x}_{\mathrm{CM}} \times \left(\sum_s^N m_s\right) \boldsymbol{v}_{\mathrm{CM}} + \boldsymbol{x}_{\mathrm{CM}} \times \sum_s^N \boldsymbol{p}'_s \\ + \left(\sum_s^N m_s \boldsymbol{x}'_s\right) \times \boldsymbol{v}_{\mathrm{CM}} + \sum_s^N \boldsymbol{x}'_s \times \boldsymbol{p}'_s\,.\end{aligned}$$

The two middle sums vanish by Equation (19.50), and the first term is $\boldsymbol{x}_{\mathrm{CM}} \times M\boldsymbol{v}_{\mathrm{CM}} = \boldsymbol{x}_{\mathrm{CM}} \times \boldsymbol{p}_{\mathrm{CM}} = \boldsymbol{L}_{\mathrm{CM}}$ by Equations (19.44) and (19.48). □

Corollary 19.59 (Decomposition of the kinetic energy)**.** *With the same notation,*

$$T = \frac{1}{2} M \left|\boldsymbol{v}_{CM}\right|^2 + \sum_s^N \frac{1}{2} m_s \left|\boldsymbol{v}'_s\right|^2\,. \tag{19.52}$$

Rests on Lemma 19.57 and Equation (19.18).

Proof. *Derives Corollary 19.59.*

Expanding $|\boldsymbol{v}_{\mathrm{CM}} + \boldsymbol{v}'_s|^2$ in $T = \sum_s \frac{1}{2} m_s |\boldsymbol{v}_s|^2$ gives three groups of terms; the cross term is $\boldsymbol{v}_{\mathrm{CM}} \cdot \sum_s \boldsymbol{p}'_s$, which vanishes by Equation (19.50). □

Remark 19.60 (Why there is no rotational completeness). Equation (19.51) is not the analogue of Equation (19.45): the angular momentum of the centre of mass is *not* the total angular momentum, and the defect $\boldsymbol{S}$ does not vanish for any system that is turning. A flywheel spinning in place has $\boldsymbol{L}_{\mathrm{CM}} = \boldsymbol{0}$ and $\boldsymbol{S} \neq \boldsymbol{0}$; the Earth in its orbit carries both, and they are independent — the one associated with the year, the other with the day. The reason the linear case is simpler is that translation has no internal counterpart: there is no way to redistribute the parts of a system so as to give it internal momentum, because Equation (19.50) forbids it, while $\boldsymbol{x}'_s \times \boldsymbol{p}'_s$ can perfectly well sum to something nonzero. The two pieces obey separate equations of motion, which is the subject of the next heading, and it is that separation which lets an extended body be treated as a point for its translation while keeping a full rotational dynamics of its own (Chapter 29).

Rotational Newton's second law for the centre of mass

For the translational law it sufficed that the internal forces cancel in pairs, which is Postulate 19.49. For the rotational law that is not enough: two equal and opposite forces applied at different points cancel as forces but form a couple, and a couple turns things. What is needed in addition is that the pair force act along the line joining the two particles.

Postulate 19.61 (Newton's third law, strong form)**.** The force between two particles is directed along the line joining them,

$$\boldsymbol{F}_{12} \parallel (\boldsymbol{x}_1 - \boldsymbol{x}_2) \ , \tag{19.53}$$

in addition to satisfying Equation (19.41).

Rests on Postulate 19.48 and Corollary 19.14.

Theorem 19.62 (Rotational second law for a system)**.** *Let the internal forces of a system satisfy Postulate 19.61 and let the masses be constant. Then, about any point at rest in an inertial frame,*

$$\boxed{\frac{\mathrm{d}}{\mathrm{d}t}\sum_{s}^{N} \boldsymbol{x}_s \times \boldsymbol{p}_s = \boldsymbol{\tau}_{EXT}}, \qquad \boldsymbol{\tau}_{EXT} := \sum_{s}^{N} \boldsymbol{x}_s \times \boldsymbol{F}_s^{EXT}, \tag{19.54}$$

where $\boldsymbol{F}_s^{EXT}$ is the external force on the s-th particle. Only the external torques appear.

Rests on Postulate 19.61 and Equations (19.2) and (19.14).

Proof. *Derives Theorem 19.62.*

Split the force on particle s into external and internal parts, $\boldsymbol{F}_s = \boldsymbol{F}_s^{\mathrm{EXT}} + \sum_{r\neq s} \boldsymbol{F}_{sr}$, and differentiate the sum, the term $\boldsymbol{v}_s \times \boldsymbol{p}_s$ vanishing for each s as in Proposition 19.20:

$$\frac{\mathrm{d}}{\mathrm{d}t}\sum_{s}^{N} \boldsymbol{x}_s \times \boldsymbol{p}_s = \sum_{s}^{N} \boldsymbol{x}_s \times \boldsymbol{F}_s^{\mathrm{EXT}} + \sum_{s}^{N}\sum_{r\neq s} \boldsymbol{x}_s \times \boldsymbol{F}_{sr} \ .$$

In the double sum group the terms in pairs. Using Equation (19.41) in the form $\boldsymbol{F}_{rs} = -\boldsymbol{F}_{sr}$, the pair (s, r) contributes

$$\boldsymbol{x}_s \times \boldsymbol{F}_{sr} + \boldsymbol{x}_r \times \boldsymbol{F}_{rs} = (\boldsymbol{x}_s - \boldsymbol{x}_r) \times \boldsymbol{F}_{sr} \ ,$$

which vanishes precisely because Equation (19.53) makes the two factors parallel. Every pair vanishes, so the double sum does, leaving Equation (19.54). □

Theorem 19.63 (The spin obeys the same law about the centre of mass)**.** *Under the same hypotheses, and with $\boldsymbol{S}$ the internal angular momentum of Equation (19.51),*

$$\boxed{\frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}t} = \boldsymbol{\tau}'_{EXT}}, \qquad \boldsymbol{\tau}'_{EXT} := \sum_{s}^{N} \boldsymbol{x}'_s \times \boldsymbol{F}_s^{EXT}, \tag{19.55}$$

and this holds even when the centre of mass is accelerating, *so that its rest frame is not inertial.*

Rests on Theorem 19.58, Lemma 19.57, and Postulate 19.61.

Proof. *Derives Theorem 19.63.*

Differentiating $\boldsymbol{S}$ as defined in Equation (19.51), the term $\boldsymbol{v}'_s \times m_s \boldsymbol{v}'_s$ vanishes for each s, and by Equations (19.40) and (19.49)

$$m_s \frac{\mathrm{d}\boldsymbol{v}'_s}{\mathrm{d}t} = m_s \left(\boldsymbol{a}_s - \boldsymbol{a}_{\mathrm{CM}}\right) = \boldsymbol{F}_s - m_s \boldsymbol{a}_{\mathrm{CM}} \ ,$$

using Equation (19.4) for the s-th particle. Hence

$$\frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}t} = \sum_{s}^{N} \boldsymbol{x}'_s \times \boldsymbol{F}_s - \left(\sum_{s}^{N} m_s \boldsymbol{x}'_s \right) \times \boldsymbol{a}_{\mathrm{CM}} \,,$$

and the second term vanishes by Equation (19.50) — which is exactly why the accelerating centre of mass costs nothing here, and why no other point of the body enjoys the same privilege. The internal contributions to the first term cancel pair by pair as in Theorem 19.62, since $\boldsymbol{x}'_s - \boldsymbol{x}'_r = \boldsymbol{x}_s - \boldsymbol{x}_r$ by Equation (19.49), leaving Equation (19.55). □

Corollary 19.64 (The orbital part obeys the point-particle law)**.** *Differentiating Equation* (19.48) *and using Equation* (19.46)*,*

$$\frac{\mathrm{d}\boldsymbol{L}_{CM}}{\mathrm{d}t} = \boldsymbol{x}_{CM} \times \boldsymbol{F}_{EXT} \,, \tag{19.56}$$

so the centre of mass turns about a fixed origin exactly as a single particle of mass M at $\boldsymbol{x}_{CM}$ would. Together with Equation (19.55) *this splits the rotational dynamics of any system into an orbital equation and a spin equation that can be solved separately.*

Rests on Equations (19.46) *and* (19.48)*.*

Phenomenon 19.65 (Spin is conserved when no external torque acts)**.** A skater turning on the spot spins faster the closer the arms are drawn to the axis, and slower as they are extended again, without any push from outside; a diver in the air completes a somersault by tucking; a falling cat that begins with no rotation at all can turn itself over and land on its feet, ending as it began with zero total internal angular momentum. In each case the body changes its own shape, hence its moment of inertia Equation (19.33), while nothing external exerts a torque about the centre of mass.

Rests on Theorem 19.63.

Derivation. *Derives Phenomenon 19.65.*

Gravity acting on a body near the ground contributes $\sum_s \boldsymbol{x}'_s \times m_s \boldsymbol{g} = (\sum_s m_s \boldsymbol{x}'_s) \times \boldsymbol{g} = \boldsymbol{0}$ by Equation (19.50), so a uniform gravitational field exerts no torque about the centre of mass. With the skate pivot and the air resistance also contributing nothing appreciable, $\boldsymbol{\tau}'_{\mathrm{EXT}} = \boldsymbol{0}$ and Equation (19.55) gives $\boldsymbol{S}$ constant. For a body turning about a fixed principal axis (Remark 19.46) the component of $\boldsymbol{S}$ along the axis is $I\omega$ with I the moment of inertia Equation (19.33) about it, so

$$I_1 \omega_1 = I_2 \omega_2 \,, \tag{19.57}$$

and drawing the arms in, which lowers I, raises ω in the same proportion. Note what *is* not conserved: by Equation (19.52) the rotational kinetic energy is $\frac{1}{2} I \omega^2 = \frac{1}{2} S^2 / I$, which *rises* as I falls — the skater's muscles do the work, and the energy budget is what distinguishes this from a free body. The cat is subtler, since its axis is not fixed and I_{ij} changes shape as well as scale; $\boldsymbol{S} = \boldsymbol{0}$ throughout, and the reorientation is possible because the body is not rigid. Both cases are treated properly in Chapter 29 [32]. □

Remark 19.66 (The strong form is a real assumption, and it fails)*.* Postulate 19.61 holds for gravitation, for the Coulomb force and for elastic contact — for every force of the central kind of Corollary 19.14 — and for those Equation (19.54) is exact. It fails for the magnetic force between two moving charges, which is not directed along the line joining them and for which even the weak form Equation (19.41) can fail instantaneously. The angular momentum of the two charges alone is then not conserved; what is conserved is the total including the angular momentum stored in the electromagnetic field, as Chapter 60 shows. This is the characteristic pattern of every later repair to the Newtonian scheme: the conservation law is not abandoned but enlarged, by finding the carrier of what appeared to have been lost.

19.5.5 Conservation laws

Everything a closed system does leaves certain numbers unchanged. There are two ways to see which numbers those are, and this book uses both because they have different reach.

The first is direct: apply the laws already postulated and see what their time derivative turns out to be. This route asks nothing of the forces beyond Equation (19.41), so it survives friction, plastic deformation and every other dissipative process, and it is what justifies the everyday use of momentum conservation in collision problems where the interaction is entirely unknown.

The second is by symmetry. Each of the ten parameters of the Galilei group Equation (18.11) that leaves a system's description unchanged yields one conserved quantity, by Noether's first theorem Theorem 16.84 [456]. That route explains *why* these particular quantities and no others, but it requires the dynamics to come from an action, which excludes the dissipative cases the first route covers.

The three laws, directly

Theorem 19.67 (Conservation of linear momentum)**.** *For a closed system of constant masses subject to no external force, the total momentum*

$$\boldsymbol{P} = \sum_{s}^{N} \boldsymbol{p}_s = M \boldsymbol{v}_{CM}\,, \tag{19.58}$$

of SI unit kg m/s*, is constant in time.*

Rests on Theorem 19.52 and Equation (19.45)*.*

Proof. *Derives Theorem 19.67.*

By Equation (19.45) the sum is $\boldsymbol{p}_{\mathrm{CM}}$, and by Theorem 19.52 $\mathrm{d}\boldsymbol{P}/\mathrm{d}t = \boldsymbol{F}_{\mathrm{EXT}}$, which vanishes by hypothesis. Nothing was assumed about the internal forces except that they obey Equation (19.41); in particular they may be dissipative, which is why the total momentum is conserved in a perfectly inelastic collision, as recorded in Phenomenon 19.50, while the kinetic energy is not. □

Theorem 19.68 (Conservation of angular momentum)**.** *For a closed system of constant masses whose internal forces satisfy Postulate 19.61, and on which the external torque about a fixed point of an inertial frame vanishes, the total angular momentum about that point is constant. If the external torque about the centre of mass vanishes, the spin $\boldsymbol{S}$ is constant separately.*

Rests on Theorems 19.62 and 19.63.

Proof. *Derives Theorem 19.68.*

Immediate from Equation (19.54) and Equation (19.55) with the respective right-hand sides set to zero. The two statements are independent, because Equation (19.51) splits the total into two pieces obeying separate equations: a body may conserve its spin while its orbital angular momentum changes, which is the case of a spinning projectile in flight. □

Theorem 19.69 (Uniform motion of the centre of mass)**.** *For a closed system of constant masses subject to no external force, the quantity*

$$\boldsymbol{G} = \boldsymbol{P}t - M\boldsymbol{x}_{CM}\,, \tag{19.59}$$

of SI unit kg m*, is constant in time. Equivalently, the centre of mass moves in a straight line with constant velocity.*

Rests on Theorem 19.67 and Equation (19.44)*.*

Proof. *Derives Theorem 19.69.*
Differentiating Equation (19.59),

$$\frac{\mathrm{d}\boldsymbol{G}}{\mathrm{d}t} = \boldsymbol{P} + t\,\frac{\mathrm{d}\boldsymbol{P}}{\mathrm{d}t} - M\boldsymbol{v}_{\mathrm{CM}} = \boldsymbol{P} - \boldsymbol{P} = \boldsymbol{0}\,,$$

using $\mathrm{d}\boldsymbol{P}/\mathrm{d}t = \boldsymbol{0}$ from Theorem 19.67 and $\boldsymbol{P} = M\boldsymbol{v}_{\mathrm{CM}}$ from Equation (19.44). Solving Equation (19.59) for $\boldsymbol{x}_{\mathrm{CM}}$ gives $\boldsymbol{x}_{\mathrm{CM}}(t) = \boldsymbol{x}_{\mathrm{CM}}(0) + \boldsymbol{v}_{\mathrm{CM}}t$, the second form of the statement. □

Remark 19.70 (The boost law is usually left unnamed). Theorem 19.69 looks like a restatement of Theorem 19.67 and is often passed over as one, but it is a separate conserved quantity: $\boldsymbol{G}$ depends explicitly on the time, and knowing $\boldsymbol{P}$ does not fix the constant $\boldsymbol{x}_{\mathrm{CM}}(0)$ that $\boldsymbol{G}$ encodes. The three components of $\boldsymbol{G}$ are what the three boost parameters of Equation (18.11) contribute, and without them the count in Table 19.1 would come to seven rather than ten. It is also the one of the four whose Noether derivation is not routine, for the reason given in Remark 19.72.

Energy is the remaining kind, and it was settled in Theorem 19.32: for a closed system whose internal forces derive from a potential in the mutual distances, E is constant with respect to every inertial frame, though it takes different values in different ones by Equation (19.24). Unlike the three above, it requires the internal forces to be conservative — exactly the condition Equation (19.20) tests.

Table 19.1: The ten conserved quantities of a closed Newtonian system, one for each parameter of the Galilei group Equation (18.11). The count is the dimension of the group, and it is no coincidence: each entry is the Noether charge Equation (16.76) of the corresponding one-parameter subgroup.

Symmetry	Parameters	Conserved quantity	SI unit
Time translation	1	Energy E	J
Space translation	3	Momentum $\boldsymbol{P}$	kg m/s
Rotation	3	Angular momentum $\boldsymbol{L}$	kg m^2/s
Boost	3	$\boldsymbol{G} = \boldsymbol{P}t - M\boldsymbol{x}_{\mathrm{CM}}$	kg m

The same laws from symmetry

Chapter 16 proves both of Noether's theorems, and the first of them (Theorem 16.84) is stated exactly in the form needed here: one independent variable, several dependent ones. Its two standard corollaries are already the first two entries of Table 19.1 — Corollary 16.87 for energy from invariance under time translation, and Corollary 16.88 for momentum and angular momentum from invariance under space translation and rotation. Nothing of that needs repeating; what belongs here is the identification of the mechanical system to which it applies, and the one case the corollaries do not cover.

Proposition 19.71 (The Newtonian closed system is a Lagrangian system)**.** *Let a closed system of N particles of constant masses have internal forces derived from a potential U depending only on the mutual distances. Then the equations of motion Equation (19.4) for all N particles are the Euler–Lagrange equations of the action Equation (16.86) built from*

$$\mathcal{L} = \sum_{s}^{N} \frac{1}{2} m_s \left|\dot{\boldsymbol{x}}_s\right|^2 - U\left(\{|\boldsymbol{x}_s - \boldsymbol{x}_r|\}_{s<r}\right)\,, \tag{19.60}$$

in J*, and* $\mathcal{L}$ *is invariant under all ten transformations Equation* (18.11) *up to a total time derivative.*

Rests on Theorem 16.97, Equation (19.4)*, and Definition 19.30.*

Proof. *Derives Proposition 19.71.*

Theorem 16.97 establishes the equivalence for one particle in a potential; the N-particle statement is the same computation carried out for each of the $3N$ coordinates in turn, the Euler–Lagrange system Equation (16.30) being one equation per dependent variable. For the invariance: the kinetic term is a sum of squared speeds, unchanged by a rotation and by a time or space translation, and U depends only on the distances $|\boldsymbol{x}_s - \boldsymbol{x}_r|$, which Proposition 19.13 showed to be invariant under the whole group. The one transformation that does not leave $\mathcal{L}$ strictly unchanged is the boost, and it changes it by a total derivative, as Remark 19.72 computes. □

Remark 19.72 (The boost charge needs the divergence term)*.* Under the one-parameter family of boosts $\boldsymbol{x}_s \longmapsto \boldsymbol{x}_s + \varepsilon \boldsymbol{u}\, t$, with $\boldsymbol{u}$ a fixed velocity, the Lagrangian Equation (19.60) is not invariant: to first order in ε it acquires

$$\mathcal{L} \longmapsto \mathcal{L} + \varepsilon \sum_{s}^{N} m_s \dot{\boldsymbol{x}}_s \cdot \boldsymbol{u} = \mathcal{L} + \varepsilon \frac{\mathrm{d}}{\mathrm{d}t} \left(M \boldsymbol{x}_{\mathrm{CM}} \cdot \boldsymbol{u} \right) , \tag{19.61}$$

by Equation (19.38). This is precisely the case Theorem 16.84 admits with a nonzero divergence term Λ, and taking $\xi = 0$, $\phi_s = \boldsymbol{u}t$ and $\Lambda = M\boldsymbol{x}_{\mathrm{CM}} \cdot \boldsymbol{u}$ in the Noether charge Equation (16.76) gives

$$I = \sum_{s}^{N} \boldsymbol{p}_s \cdot \boldsymbol{u}\, t - M\boldsymbol{x}_{\mathrm{CM}} \cdot \boldsymbol{u} = \boldsymbol{u} \cdot \boldsymbol{G} ,$$

with $\boldsymbol{G}$ the quantity Equation (19.59) of Theorem 19.69, and $\boldsymbol{u}$ arbitrary. Had Λ been dropped, the charge would have come out as $\boldsymbol{P} \cdot \boldsymbol{u}\, t$, which is not conserved. The term that cannot be dropped is the same object that appears in Chapter 14 as the central charge of the Galilei algebra — the mass, in Example 14.80 — and in Chapter 25 as the constant defect in the Poisson brackets of a free particle (Proposition 25.14). Three descriptions of one fact: the free particle realizes not the Galilei algebra but its central extension by the mass.

Remark 19.73 (Which route is stronger, and where)*.* The two derivations are not redundant, and neither contains the other.

- The direct route is stronger in *scope*. It needs only Equation (19.41) and yields Theorem 19.67 for internal forces of any kind, dissipative ones included. A perfectly inelastic collision has no Lagrangian description of the colliding bodies alone, yet conserves momentum exactly.

- The symmetry route is stronger in *explanation*. It says why there are ten conserved quantities and not eleven, ties each to a geometrical property of space and time, and generalizes: replacing the Galilei group by the Poincaré group repeats the argument unchanged and delivers the relativistic conservation laws of Chapter 40, while the field-theoretic form Theorem 16.90 delivers those of Chapter 64.

Both are used in what follows. The systematic development of the symmetry route for mechanical systems, with generalized coordinates and constraints, is Chapter 21; the conserved quantities reappear there as first integrals and cyclic coordinates (Proposition 16.28), and again in Chapter 22 as generators of the very transformations they are conserved under.

The Newtonian formulation presented in this chapter provides the equations of motion whenever all the forces are known explicitly. When the motion is restricted by constraints, however, the constraint forces are not known in advance, and the formulation must be recast in terms of generalized coordinates; this is the subject of Chapter 21. The special cases of equilibrium and of central forces — the latter the gateway to celestial mechanics — are developed in Chapter 27.

Chapter 20

Experiment: Free Fall and Projectile Motion

Every experimental chapter of this treatise follows the same arc: a phenomenon is stated as it is observed, the observation is confronted with a derivation from explicitly declared assumptions, and the residual disagreement — there is always one — marks the domain of validity of those assumptions. This chapter is the exemplar. Its subject, the free fall of heavy bodies and the flight of projectiles, is the oldest quantitative experiment in physics, and it remains one of the most precise: the same law of fall that Galileo extracted from a bronze ball and a water clock is today verified, in ballistic gravimeters, to nine significant figures. The derivation given in Section 20.2 is deliberately complete — every assumption numbered, every integration displayed — because it is the pattern to which all later derivations in this book, whether inline, in Appendix A, or pending, are referred.

20.1 Historical context: the Aristotelian expectation and its collapse

For nearly two thousand years the educated expectation about falling bodies was Aristotle's: that a body falls with a speed proportional to its weight and inversely proportional to the resistance of the medium, so that a stone of ten pounds should reach the ground ten times faster than a stone of one pound. That doctrine, together with the companion difficulty of explaining why a projectile keeps moving after it leaves the hand, is rehearsed at length — and demolished — in the book that founded modern mechanics, Galileo's *Discorsi e dimostrazioni matematiche intorno a due nuove scienze*, composed under house arrest at Arcetri and printed by the Elzevirs at Leiden in 1638 [4]. There the Aristotelian position is put in the mouth of Simplicio, and Salviati answers it first with an argument requiring no apparatus at all: if a heavy body fell faster than a light one, then tying the two together should produce a compound body that falls both faster (being heavier than either) and slower (the light body retarding the heavy one) — a contradiction, from which Galileo concludes that all bodies must fall alike once the disturbance of the medium is removed [4].

The argument disposes of the Aristotelian *ratio*, but it does not by itself yield the law of fall. That required measurement, and here lies the historical significance of the experiments described in Section 20.3: free fall was the first phenomenon in history to be captured by a mathematical law that was extracted from, and tested against, quantitative data with an explicit appeal to reproducibility. The Third Day of the *Discorsi* defines uniformly accelerated motion, proves as a theorem that the distances traversed from rest are as the squares of the elapsed times, and derives as a corollary the *odd-number rule* — that the spaces covered in equal successive intervals of time stand in the ratios $1 : 3 : 5 : 7 : \dots$ — before

reporting the inclined-plane measurements that confirm it; the Fourth Day then compounds uniform horizontal motion with naturally accelerated vertical motion and demonstrates that the resulting trajectory is a semi-parabola [4]. The conceptual order — definition, theorem, experiment — is precisely the one this treatise adopts.

What Galileo established kinematically, Newton grounded dynamically. In the *Principia* of 1687 the parabolic trajectory appears no longer as a brute geometrical fact but as the immediate consequence of the second law of motion applied to a uniform downward force, and Newton, in the scholium to the laws, credits Galileo with exactly this pair of discoveries: the squared-time law of descent and the parabola of projectiles [14]. The present chapter retraces that inference in modern notation, and then holds it against four centuries of data.

20.2 The observed phenomenon and its derivation

Phenomenon 20.1. Near the surface of the Earth, and wherever the resistance of the air may be neglected, projectiles follow arcs that are parabolic: the height depends quadratically on the horizontal distance, the axis of the arc is vertical, and the arc opens downward. Moreover a body released from rest falls through distances that grow as the square of the elapsed time, so that the spaces traversed in equal successive intervals stand in the ratios $1 : 3 : 5 : 7 : \dots$ (Galileo's odd-number rule). Both regularities are independent of the weight and composition of the body [4].

Rests on Equation (18.7) *and Phenomenon 18.12.*

This phenomenon admits a short, complete derivation from Newtonian dynamics, which we now give in full; it is the model derivation of the treatise.

Theorem 20.2 (Parabolic trajectory)**.** *Consider a point projectile launched from the origin with speed $v_0 > 0$ at an angle $\theta \in (0, 90^\circ)$ above the horizontal, in a uniform gravitational field and in the absence of air resistance, the ground being treated as flat and non-rotating. Then the motion remains in the vertical plane containing the initial velocity, and the trajectory is the arc of a parabola with vertical axis, opening downward,*

$$z = x \tan\theta - \frac{g\,x^2}{2v_0^2 \cos^2\theta}\,. \tag{20.1}$$

Rests on Postulate 19.8, Equation (18.7)*, and Phenomenon 20.1.*

Derivation. *Derives Theorem 20.2.*

We first state the assumptions explicitly.

1. *Point mass.* The projectile is treated as a point particle of mass m; its extension, internal structure and rotation are ignored.

2. *Uniform field.* The gravitational field is $\boldsymbol{g} = -g\,\hat{\boldsymbol{z}}$, constant in magnitude and direction over the region of flight; numerically g is close to the conventional standard value $g_0 = 9.806\,65\,\mathrm{m/s^2}$ [2333].

3. *No air resistance.* The only force acting during flight is gravity.

4. *Flat, non-rotating Earth.* The laboratory frame is treated as inertial: the curvature of the Earth and the centrifugal and Coriolis accelerations of its rotation are neglected.

Under assumptions 1–4, Newton's second law [14, 2027] reads

$$m\,\ddot{\boldsymbol{r}} = -mg\,\hat{\boldsymbol{z}}\,. \tag{20.2}$$

The mass cancels — an innocuous-looking step whose depth is the subject of Section 20.6 — leaving the kinematic statement $\ddot{\boldsymbol{r}} = -g\,\hat{\boldsymbol{z}}$. Since the right-hand side is constant, two elementary integrations suffice. Integrating once from the initial condition $\dot{\boldsymbol{r}}(0) = \boldsymbol{v}_0$,

$$\dot{\boldsymbol{r}}(t) = \boldsymbol{v}_0 - g t\,\hat{\boldsymbol{z}}\,, \tag{20.3}$$

and integrating again from $\boldsymbol{r}(0) = \boldsymbol{0}$,

$$\boldsymbol{r}(t) = \boldsymbol{v}_0\, t - \tfrac{1}{2} g t^2\,\hat{\boldsymbol{z}}\,. \tag{20.4}$$

Choose the x-axis along the horizontal component of $\boldsymbol{v}_0$, so that $\boldsymbol{v}_0 = (v_0\cos\theta,\, 0,\, v_0\sin\theta)$. The y component of Equation (20.4) vanishes identically: the motion is confined to the vertical plane $y = 0$, as claimed. In that plane the parametric solution is

$$x(t) = v_0\cos\theta\; t\,, \qquad z(t) = v_0\sin\theta\; t - \tfrac{1}{2} g t^2\,. \tag{20.5}$$

Because $\theta \neq 90^\circ$ we have $\cos\theta \neq 0$, and the first equation can be solved for the time, $t = x/(v_0\cos\theta)$. Substituting into the second eliminates t and yields Equation (20.1):

$$z = x\tan\theta - \frac{g\,x^2}{2v_0^2\cos^2\theta}\,.$$

This is a polynomial of degree exactly two in x with constant coefficients; its leading coefficient $-g/(2v_0^2\cos^2\theta)$ is strictly negative. A quadratic graph $z = ax^2 + bx$ with $a < 0$ is a parabola whose axis is parallel to the z-axis and which opens downward — completing the square,

$$z - z_{\mathrm{apex}} = -\frac{g}{2v_0^2\cos^2\theta}\,\bigl(x - x_{\mathrm{apex}}\bigr)^2\,, \tag{20.6}$$

with the apex coordinates given in the corollary below. This proves the first claim of Phenomenon 20.1.

For the second claim, set $\theta = 90^\circ$ and reverse the sign convention so that $s(t)$ denotes the distance fallen from rest; then Equation (20.5) with $v_0 = 0$ gives

$$s(t) = \tfrac{1}{2} g t^2\,. \tag{20.7}$$

Partition time into equal intervals of length τ. The distance covered during the n-th interval is

$$\Delta_n = s(n\tau) - s\bigl((n-1)\tau\bigr) = \tfrac{1}{2} g\tau^2\bigl(n^2 - (n-1)^2\bigr) = \tfrac{1}{2} g\tau^2\,(2n-1)\,, \tag{20.8}$$

so that $\Delta_1 : \Delta_2 : \Delta_3 : \cdots = 1 : 3 : 5 : \ldots$ — Galileo's odd-number rule [4]. Finally, nothing in the derivation refers to m after the cancellation in Equation (20.2), which reproduces the observed independence of the motion from the weight and composition of the body. □

Corollary 20.3 (Range, apex, time of flight)**.** *With launch and landing at the same height, the time of flight, the horizontal range and the apex height are*

$$T = \frac{2v_0\sin\theta}{g}\,, \qquad R = \frac{v_0^2\sin 2\theta}{g}\,, \qquad H = \frac{v_0^2\sin^2\theta}{2g}\,, \tag{20.9}$$

and for fixed v_0 the range is greatest at $\theta = 45^\circ$, where $R_{\max} = v_0^2/g$.

Rests on Theorem 20.2 and Equation (20.5).

Proof. *Derives Corollary 20.3.*

From Equation (20.5), $z(t) = t\,(v_0\sin\theta - \tfrac{1}{2} g t)$ vanishes at $t = 0$ and at $t = T = 2v_0\sin\theta/g$. The range is $R = x(T) = v_0\cos\theta\cdot T = 2v_0^2\sin\theta\cos\theta/g = v_0^2\sin 2\theta/g$, using the double-angle identity. Since $\sin 2\theta \le 1$ with equality precisely when $2\theta = 90^\circ$, the range is maximal at $\theta = 45^\circ$. The apex occurs where $\dot z = v_0\sin\theta - g t = 0$, i.e. at $t = T/2$, by which symmetry of the parabola is recovered; substitution gives $H = v_0^2\sin^2\theta/(2g)$. □

Example 20.4. A ball thrown at $v_0 = 10\,\mathrm{m/s}$ and $\theta = 45^\circ$ has, by Equation (20.9) with $g = g_0$, a time of flight $T \approx 1.44\,\mathrm{s}$, a range $R = v_0^2/g_0 \approx 10.2\,\mathrm{m}$ and an apex height $H \approx 2.55\,\mathrm{m}$. These are the magnitudes of everyday experience, and the fact that everyday experience does *not* flagrantly contradict them is already a statement about air drag: for dense projectiles at such speeds the neglect of resistance in assumption 3 is a percent-level idealisation (Section 20.5).

Rests on Corollary 20.3.

Remark 20.5. The derivation used nothing but the second law and two integrations, yet its logical anatomy repays attention. Each of the four assumptions is independently falsifiable, and each *does* fail at some level of precision: assumption 1 for spinning or extended bodies, assumption 2 over heights where the field gradient matters (Section 20.4), assumption 3 for fast or light projectiles, and assumption 4 for long-range or long-duration motion (Section 20.5). The parabola of Equation (20.1) is therefore not "the" trajectory of a real projectile but the zeroth term of a systematic approximation — which is exactly what an idealised law of nature is.

Rests on Theorem 20.2 and Equation (20.1).

Two experiments anchor the phenomenon, separated by almost four centuries and by eight orders of magnitude in timing precision: Galileo's inclined planes, which established the form of the law, and modern ballistic gravimetry, which turns the law around and uses free fall as a measuring instrument.

20.3 Galileo's Inclined Planes (1604–1638)

Tests Phenomenon 20.1 and Equation (20.8).

Assuming Equation (18.7).

20.3.1 Apparatus

A hard, smooth, very round ball of bronze, and a straight wooden beam or moulding some twelve *braccia* long (roughly 7 m), half a braccio wide and three finger-breadths thick, along whose upper face a channel a little more than one finger in breadth was cut, planed straight, and lined with polished parchment to make it as smooth as possible. One end of the beam could be raised one or two braccia above the horizontal, tilting the groove into an inclined plane of small, adjustable slope. Time was measured with a water clock: a large elevated vessel discharged through a thin pipe into a beaker during the motion, and the collected water was weighed after each run on a sensitive balance, the mass of the effluent serving as the measure of the elapsed time [4].

20.3.2 Procedure

The ball was released from rest at the top of the groove and timed over the full length of the channel; then over one quarter of the length, one half, two thirds, and other fractions; the tilt of the plane was varied; and, in Galileo's own report, each configuration was repeated "a full hundred times" to establish the reproducibility of the timings [4].

20.3.3 Observations and data

The distances traversed from rest were found proportional to the squares of the measured times, at every inclination of the plane: the full length was covered in exactly twice the time of the first quarter, and the spaces covered in equal successive time intervals followed the odd-number progression,

interval n	space in interval	cumulative space
1	1	1
2	3	4
3	5	9
4	7	16

(in units of the distance covered in the first interval), in agreement with Equation (20.8). Galileo states that repeated timings of the same descent never differed by more than one tenth of a pulse beat — of order 0.1 s on a total descent time of several seconds — and that the result did not depend on the weight of the ball [4].

20.3.4 Interpretation

The measurements identify the motion as uniformly accelerated: equal increments of speed in equal times, the definition adopted in the Third Day of the *Discorsi* [4]. The inclined plane is itself the decisive methodological invention: rolling down a slope of inclination α dilutes the effective acceleration by the factor $\sin\alpha$, slowing the motion until a water clock of 0.1 s resolution can resolve it, while leaving the *form* of the law — distance proportional to time squared — untouched. Extrapolating the diluted experiments to vertical inclination, Galileo obtained the law of free fall, Equation (20.7), without ever timing a free vertical drop. The observed independence from the ball's weight is the seed of the universality discussed in Section 20.6. (A modern reader will note what the water clock could not resolve: rolling, as opposed to sliding, reduces the acceleration by a further constant factor — 5/7 for a homogeneous sphere — which drops out of all of Galileo's *ratios* of distances and times, and so left his conclusions intact.)

20.3.5 Primary references

[4]; Newton's dynamical reading of these results is in the scholium to the laws of motion [14].

20.4 Absolute Ballistic Gravimetry (1995–present)

Tests Equations (18.7) *and* (20.7).
Assuming Phenomenon 20.1.

20.4.1 Apparatus

The FG5 class of absolute gravimeters realises Galileo's experiment with interferometric metrology [1906]. The falling body is a corner-cube retroreflector enclosed in a co-falling "drag-free" carriage inside an evacuated drop chamber, the carriage tracking the cube so as to shield it from residual gas drag and to carry the electrostatic environment with it. The falling cube forms one arm of a Michelson-type interferometer; the reference cube is suspended from an actively servo-controlled long-period isolation stage (a "superspring") to decouple it from ground vibration. The length standard is an iodine-stabilised helium–neon laser at 633 nm; the time standard is a rubidium atomic clock [1906].

20.4.2 Procedure

The carriage releases the cube, which falls freely through about 20 cm in about 0.2 s. Interference fringes — one per 316.5 nm of fall, half the laser wavelength — are counted and time-stamped against the atomic clock, and the fringe record is scaled to roughly 200 position–time pairs per drop. Each drop is fitted by least squares to the free-fall trajectory

of Equation (20.5) augmented by the vertical field gradient, and standard corrections are applied for solid-Earth tides, ocean loading, polar motion and local barometric pressure. A measurement campaign comprises hundreds of drops per hour, combined over one or more days; the statistical treatment of the drop-to-drop scatter follows the standard error analysis of repeated measurements [1906, 1945].

20.4.3 Observations and data

quantity	value
conventional standard g_0, exact [2333]	$9.806\,65\,\mathrm{m/s^2}$
FG5 instrumental accuracy [1906]	$\approx 2\times10^{-8}\,\mathrm{m/s^2}$ ($2\,\mu$Gal)
drop-to-drop scatter [1906]	$\approx 5\times10^{-8}\,\mathrm{m/s^2}$
geographic variation of g (equator–pole, altitude)	$\approx \pm 0.03\,\mathrm{m/s^2}$
free-air height gradient [1906]	$\approx -3.1\times10^{-6}\,\mathrm{m/s^2}$ per metre

Here $1\,\mathrm{Gal} = 1\times10^{-2}\,\mathrm{m/s^2}$ is the conventional unit of the gravimetric literature; the mean of a measurement set converges on the drop-to-drop scatter as $1/\sqrt{N}$ in the number of drops [1945]. The fitted trajectories reproduce $s(t) = s_0 + v_0 t + \tfrac{1}{2}gt^2$ at the nanometre level over the whole drop, and the instrument accuracy of $2\times10^{-8}\,\mathrm{m/s^2}$ against $g \approx 9.8\,\mathrm{m/s^2}$ means that the local acceleration of free fall is determined to about two parts in 10^9 — nine significant figures [1906].

20.4.4 Interpretation

Three centuries of refinement have inverted the logic of the experiment. Galileo needed the inclined plane to make the law of fall measurable; the FG5 assumes the law — Newtonian free fall in a locally uniform field with a known gradient — and measures its single parameter g so precisely that the instrument serves geodesy and metrology: monitoring ground-water and magma movements, realising the unit of force, and calibrating the watt-balance experiments that underpin the 2019 redefinition of the SI [2333, 2392]. Equally important is what the fits do *not* show: dropped test bodies of different construction yield the same g within the stated uncertainty, in line with the far sharper torsion-balance (Eötvös-type) tests of the universality of free fall discussed in Chapter 42. The residual systematic budget — laser stability, clock calibration, vertical alignment, residual drag — is itself a textbook exercise in the error analysis of Chapter 2 [1945].

20.4.5 Primary references

[1906, 2392]; conventions for g_0 in [2333].

20.5 Deviations and the domain of validity

The parabola of Equation (20.1) is exact only within assumptions 1–4 of the derivation. Each assumption fails observably, and the pattern of failure is itself lawful. We record here the two deviations that dominate at laboratory and ballistic scales, air resistance and the Earth's rotation, stating in each case what is observed; the corresponding derivations are pending and will follow the standards set by the exemplar above.

Phenomenon 20.6 (Air drag)**.** Real trajectories in air fall short of Equation (20.9) and are asymmetric: the descending branch is steeper than the ascending one, and the range at fixed muzzle speed is maximised at launch angles *below* 45°. A body falling for long enough ceases to accelerate altogether and reaches a constant terminal speed — raindrops arrive at

metres per second, not at the hundreds of metres per second that Equation (20.7) would assign to their fall height [14, 384].

Rests on Theorem 20.2 and Corollary 20.3.

The observed deviations follow from adding to Equation (20.2) a resistive force directed against the velocity,

$$m\ddot{\boldsymbol{r}} = -mg\,\hat{\boldsymbol{z}} - f(|\boldsymbol{v}|)\,\boldsymbol{v}\,, \qquad f > 0\,, \tag{20.10}$$

in which f carries the SI unit kg/s. Two regimes cover the practical cases [1585]. At low Reynolds number the resistance is linear in the velocity, $f = b$ constant; at the Reynolds numbers of a macroscopic projectile in air it is quadratic, $f = c\,|\boldsymbol{v}|$ with $c = \tfrac{1}{2}\rho\,C_{\mathrm{D}}A$ in kg/m, built from the density ρ of the fluid, the frontal area A and a dimensionless drag coefficient C_{D} which is itself a function of the Reynolds number and which drops abruptly at the drag crisis of a sphere [384].

Proposition 20.7 (Terminal speed and the approach to it)**.** *Let a body fall from rest along the vertical under Equation* (20.10)*, and let $v > 0$ be its downward speed. Then v increases monotonically towards the* terminal speed v_{t} *fixed by $f(v_{\mathrm{t}})\,v_{\mathrm{t}} = mg$,*

$$v_{\mathrm{t}} = \frac{mg}{b} \quad \textit{(linear)}\,, \qquad v_{\mathrm{t}} = \sqrt{\frac{mg}{c}} \quad \textit{(quadratic)}\,, \tag{20.11}$$

and the approach to it is

$$v(t) = v_{\mathrm{t}}\left(1 - \mathrm{e}^{-gt/v_{\mathrm{t}}}\right), \qquad v(t) = v_{\mathrm{t}}\tanh\!\left(\frac{gt}{v_{\mathrm{t}}}\right), \tag{20.12}$$

in the linear and quadratic cases respectively. In both the characteristic time is v_{t}/g.

Rests on Equation (20.10) *and Theorem 9.8.*

Proof. *Derives Proposition 20.7.*

Along the vertical, Equation (20.10) reads $m\,\mathrm{d}v/\mathrm{d}t = mg - f(v)\,v$. Dividing by m and using $f(v_{\mathrm{t}})v_{\mathrm{t}} = mg$ to eliminate the constants,

$$\frac{\mathrm{d}v}{\mathrm{d}t} = g\left(1 - \frac{v}{v_{\mathrm{t}}}\right), \qquad \frac{\mathrm{d}v}{\mathrm{d}t} = g\left(1 - \frac{v^2}{v_{\mathrm{t}}^2}\right), \tag{20.13}$$

for $f = b$ and for $f = c\,|v|$ respectively, with Equation (20.11) for v_{t} in each case. Each right-hand side is of class C^1 in v and hence Lipschitz on any bounded interval, so by Theorem 9.8 the initial-value problem with $v(0) = 0$ has exactly one solution; it is therefore enough to check that Equation (20.12) solves it. In the linear case $\mathrm{d}v/\mathrm{d}t = g\,\mathrm{e}^{-gt/v_{\mathrm{t}}} = g\,(1 - v/v_{\mathrm{t}})$; in the quadratic case the identity $\tanh' = 1 - \tanh^2$ gives $\mathrm{d}v/\mathrm{d}t = g\left(1 - \tanh^2(gt/v_{\mathrm{t}})\right) = g\,(1 - v^2/v_{\mathrm{t}}^2)$; and both vanish at $t = 0$. Monotonicity and the limit follow from Equation (20.13), whose right-hand side is strictly positive for $0 \le v < v_{\mathrm{t}}$ and vanishes only at $v = v_{\mathrm{t}}$, which is therefore approached but never attained in finite time. □

Example 20.8 (A raindrop)**.** For a spherical water drop of radius 1.0 mm — mass $m = \tfrac{4}{3}\pi r^3\rho_{\mathrm{w}} = 4.19 \times 10^{-6}$ kg, frontal area $A = \pi r^2 = 3.14 \times 10^{-6}\,\mathrm{m}^2$ — falling in air of density $\rho = 1.2\,\mathrm{kg/m}^3$ with $C_{\mathrm{D}} = 0.5$, Equation (20.11) gives

$$v_{\mathrm{t}} = \sqrt{\frac{2mg}{\rho\,C_{\mathrm{D}}A}} \approx 6.6\,\mathrm{m/s}\,, \tag{20.14}$$

reached to within one per cent after about 1.8 s of fall. Without resistance, Equation (20.7) would give a drop falling from 1 km an arrival speed of $\sqrt{2gh} \approx 140\,\mathrm{m/s}$ — a factor of twenty in speed and some four hundred in kinetic energy, which is the difference between rain and gunfire.

Rests on Proposition 20.7.

Proposition 20.9 (Linear resistance: exact motion, and the lost range)**.** *Let $f = b$ be constant and write $\tau = m/b = v_{\mathrm{t}}/g$. The solution of Equation (20.10) with $\boldsymbol{r}(0) = \mathbf{0}$ and $\dot{\boldsymbol{r}}(0) = \boldsymbol{v}_0$ is*

$$\dot{\boldsymbol{r}}(t) = (\boldsymbol{v}_0 + v_{\mathrm{t}}\hat{\boldsymbol{z}})\,\mathrm{e}^{-t/\tau} - v_{\mathrm{t}}\hat{\boldsymbol{z}}\,, \tag{20.15}$$

$$\boldsymbol{r}(t) = \tau\,(\boldsymbol{v}_0 + v_{\mathrm{t}}\hat{\boldsymbol{z}})\left(1 - \mathrm{e}^{-t/\tau}\right) - v_{\mathrm{t}}\,t\,\hat{\boldsymbol{z}}\,. \tag{20.16}$$

For launch and landing at the same height, and to first order in the small parameter v_0/v_{t}, the range is

$$R = R_0\left(1 - \frac{4}{3}\,\frac{v_0 \sin\theta}{v_{\mathrm{t}}}\right) + O\!\left(\frac{v_0^2}{v_{\mathrm{t}}^2}\right), \qquad R_0 = \frac{v_0^2 \sin 2\theta}{g}\,, \tag{20.17}$$

and $\mathrm{d}R/\mathrm{d}\theta < 0$ at $\theta = 45^\circ$, so that at fixed v_0 the range is greatest at a launch angle strictly below 45°.

Rests on Equation (20.10) and Corollaries 9.9 and 20.3.

Proof. *Derives Proposition 20.9.*

The solution. Differentiating Equation (20.16) returns Equation (20.15), and differentiating once more,

$$\ddot{\boldsymbol{r}} = -\frac{1}{\tau}\,(\boldsymbol{v}_0 + v_{\mathrm{t}}\hat{\boldsymbol{z}})\,\mathrm{e}^{-t/\tau} = -\frac{1}{\tau}\,(\dot{\boldsymbol{r}} + v_{\mathrm{t}}\hat{\boldsymbol{z}}) = -\frac{b}{m}\dot{\boldsymbol{r}} - g\hat{\boldsymbol{z}}\,,$$

since $v_{\mathrm{t}}/\tau = g$; the initial conditions are met by inspection. The system is linear with constant coefficients, so by Corollary 9.9 this is the only solution.

The range. Choose the x-axis along the horizontal component of $\boldsymbol{v}_0$ and write $v_{0x} = v_0\cos\theta$, $v_{0z} = v_0\sin\theta$. Expanding $1 - \mathrm{e}^{-u} = u - u^2/2 + u^3/6 + \dots$ in Equation (20.16) and keeping terms through first order in $1/\tau$, with $v_{\mathrm{t}}/\tau = g$,

$$x(t) = v_{0x}\left(t - \frac{t^2}{2\tau}\right), \qquad z(t) = v_{0z}t - \frac{1}{2}gt^2 - \frac{v_{0z}t^2}{2\tau} + \frac{gt^3}{6\tau}\,. \tag{20.18}$$

The time of flight solves $z(T) = 0$; dividing by T and writing $T = T_0 + T_1$ about the drag-free value $T_0 = 2v_{0z}/g$ of Equation (20.9), the residual at T_0 is

$$-\frac{v_{0z}T_0}{2\tau} + \frac{gT_0^2}{6\tau} = -\frac{v_{0z}^2}{g\tau} + \frac{2v_{0z}^2}{3g\tau} = -\frac{v_{0z}^2}{3g\tau}\,,$$

which against the slope $-g/2$ gives $T_1 = -2v_{0z}^2/\left(3g^2\tau\right)$, that is $T = T_0\,(1 - v_{0z}/3v_{\mathrm{t}})$. Substituting into the first of Equation (20.18),

$$R = v_{0x}T - \frac{v_{0x}T^2}{2\tau} = R_0\left(1 - \frac{v_{0z}}{3v_{\mathrm{t}}}\right) - R_0\frac{v_{0z}}{v_{\mathrm{t}}} = R_0\left(1 - \frac{4}{3}\frac{v_{0z}}{v_{\mathrm{t}}}\right),$$

using $R_0 = v_{0x}T_0 = 2v_{0x}v_{0z}/g$ in both terms, which is Equation (20.17).

The optimal angle. Write $R(\theta) = (v_0^2/g)\sin 2\theta\,(1 - \varepsilon\sin\theta)$ with $\varepsilon = 4v_0/3v_{\mathrm{t}}$. Then

$$\frac{\mathrm{d}R}{\mathrm{d}\theta} = \frac{v_0^2}{g}\left[2\cos 2\theta\,(1 - \varepsilon\sin\theta) - \varepsilon\sin 2\theta\cos\theta\right],$$

and at $\theta = 45^\circ$ the first bracket vanishes with $\cos 2\theta$, leaving $\mathrm{d}R/\mathrm{d}\theta = -\varepsilon v_0^2/\left(g\sqrt{2}\right) < 0$. The stationary point has therefore moved below 45°. □

Proposition 20.10 (The descending branch is the steeper, whatever the resistive law)**.** *Let the motion obey Equation* (20.10) *with any continuous $f > 0$, launched from the origin with $v_{0x} > 0$ and $v_{0z} > 0$ and followed until it returns to $z = 0$. Then v_x is positive and strictly decreasing throughout the flight, and the slope of the trajectory at landing exceeds the launch slope in magnitude,*

$$\left| \left. \frac{\mathrm{d}z}{\mathrm{d}x} \right|_{landing} \right| > \tan\theta\,. \tag{20.19}$$

With $f \equiv 0$ the two are equal, which is the symmetry of the parabola Equation (20.6).
Rests on Equations (20.6) *and* (20.10).

Proof. *Derives Proposition 20.10.*

In components, Equation (20.10) reads $m\dot{v}_x = -f v_x$ and $m\dot{v}_z = -mg - f v_z$. The first is linear and homogeneous in v_x with continuous coefficient, so $v_x(t) = v_{0x} \exp\left(-\int_0^t f/m\,\mathrm{d}t'\right) > 0$, and $\dot{v}_x = -(f/m)\,v_x < 0$: horizontal speed is positive and strictly decreasing. Hence x is strictly increasing and may be used as a parameter along the trajectory. For the slope $p = \mathrm{d}z/\mathrm{d}x = v_z/v_x$,

$$\frac{\mathrm{d}p}{\mathrm{d}t} = \frac{\dot{v}_z v_x - v_z \dot{v}_x}{v_x^2} = \frac{\left(-g - \frac{f}{m} v_z\right) v_x + \frac{f}{m} v_z v_x}{v_x^2} = -\frac{g}{v_x}\,, \qquad \frac{\mathrm{d}p}{\mathrm{d}x} = -\frac{g}{v_x^2}\,, \tag{20.20}$$

the resistance cancelling identically. So p decreases strictly and monotonically from $p = \tan\theta$ at launch, through $p = 0$ at the apex x_a, to $p = -q_\mathrm{f} < 0$ at landing; each value of the slope is attained exactly once, and p may itself be used as parameter, with $\mathrm{d}x = -(v_x^2/g)\,\mathrm{d}p$.

Let $v_\uparrow(u)$ and $v_\downarrow(u)$ denote the horizontal speed at the instants where the slope is $+u$ on the way up and $-u$ on the way down. The apex height is reached and then lost, so the two integrals

$$H = \int_0^{x_\mathrm{a}} p\,\mathrm{d}x = \frac{1}{g}\int_0^{\tan\theta} u\,v_\uparrow(u)^2\mathrm{d}u\,, \qquad H = \int_{x_\mathrm{a}}^{x_\mathrm{f}} (-p)\,\mathrm{d}x = \frac{1}{g}\int_0^{q_\mathrm{f}} u\,v_\downarrow(u)^2\mathrm{d}u \tag{20.21}$$

are equal. Every instant of the descent is later than every instant of the ascent and v_x is strictly decreasing, so $v_\downarrow(u) < v_\uparrow(u)$ wherever both are defined. Were $q_\mathrm{f} \le \tan\theta$, the second integral would be strictly smaller than the first, contradicting their equality; hence $q_\mathrm{f} > \tan\theta$, which is Equation (20.19). With $f \equiv 0$, v_x is constant, both integrands are $u\,v_{0x}^2$, and the two limits coincide. □

Derivation. *Derives Phenomenon 20.6.*

Each clause of Phenomenon 20.6 is now accounted for. The shortfall against Equation (20.9) is Equation (20.17), first order in v_0/v_t and negative. The asymmetry of the two branches is Proposition 20.10, which needs no assumption about the resistive law beyond its sign, and which is why the effect is seen for bodies of every kind. The optimum below 45° is the last claim of Proposition 20.9. The terminal speed is Proposition 20.7, and the numbers for a raindrop are Example 20.8: 6.6 m/s, not the 140 m/s that Equation (20.7) would assign to a fall of 1 km. □

Remark 20.11 (What has no closed form, and what to do about it). Proposition 20.9 is exact only for the linear law. The two-dimensional quadratic problem — Equation (20.10) with $f = c\,|\boldsymbol{v}|$ — couples the two components through $|\boldsymbol{v}| = \sqrt{v_x^2 + v_z^2}$ and has no solution in closed form; the vertical motion of Proposition 20.7 is integrable only because there the motion is one-dimensional and $|\boldsymbol{v}| = v$. What survives without integration is exactly what the three propositions above deliver, and the rest is obtained numerically. Whether a given experiment may ignore resistance is then an error-budget question, settled by comparing the estimated correction with the measurement uncertainty [1945]: Galileo's dense bronze

ball, at speeds of a few m/s on a plane whose water clock resolved 0.1 s, could; a musket ball could not.

Rests on Propositions 20.9 and 20.10.

Phenomenon 20.12 (Coriolis deflection)**.** A body dropped from rest in a tall shaft does not land at the plumb point below its release: it lands displaced towards the *east*, in either hemisphere, by an amount that grows with the fall height — about 1.5 cm for a 100 m drop at latitude 45° [92]. Long-range projectiles are likewise deflected sideways relative to the parabolic plane of Equation (20.1).

Rests on Equation (20.1) and Phenomenon 29.53.

Assumption 4 is the one at fault, and the argument that replaces it can be made without ever leaving an inertial frame — which is worth doing once, because the fictitious-force bookkeeping of Section 29.5 is easy to perform and easy to mistrust.

Proposition 20.13 (Eastward deflection of a body dropped from rest)**.** *Let a body be released from rest with respect to the ground, at a height $h \ll R$ above the surface of the Earth at geographic latitude λ, with R the Earth's radius and $\omega = 7.292 \times 10^{-5}\,\mathrm{rad/s}$ its sidereal rotation rate. To leading order in ω and in h/R it strikes the ground east of the point vertically below its release by*

$$d = \frac{1}{3}\,\omega g\, t_{\mathrm{f}}^{3} \cos\lambda = \frac{\omega \cos\lambda}{3}\sqrt{\frac{8h^{3}}{g}}\,, \qquad t_{\mathrm{f}} = \sqrt{\frac{2h}{g}}\,, \tag{20.22}$$

in either hemisphere, since $\cos\lambda > 0$ at every latitude but the poles, where the deflection vanishes.

Rests on Equations (19.14) and (20.7) and Postulate 19.19.

Proof. *Derives Proposition 20.13.*

Work in a frame that does not rotate with the Earth, with its origin at the Earth's centre, and take cylindrical coordinates $(\varrho, \varphi, \zeta)$ about the polar axis with φ increasing eastward. Treat the Earth's attraction as central, $\boldsymbol{F} = -F(r)\hat{\boldsymbol{r}}$. Then the torque about the centre vanishes identically, $\boldsymbol{x} \times \boldsymbol{F} = \boldsymbol{0}$, so by Equation (19.14) the angular momentum is conserved; in particular its polar component

$$L_{\zeta} = m\varrho^{2}\dot{\varphi} = \text{constant} \tag{20.23}$$

is constant throughout the fall.

At release the body shares the motion of the ground, so $\dot{\varphi}(0) = \omega$, and it stands at radius $r_0 = R + h$, that is at $\varrho_0 = r_0 \cos\lambda$ from the axis. To leading order in ω the fall is radial and obeys Equation (20.7), so $r(t) = r_0 - \tfrac{1}{2}gt^{2}$ at unchanged latitude and $\varrho(t) = r(t)\cos\lambda$. Then Equation (20.23) gives

$$\dot{\varphi}(t) = \omega\left(\frac{r_0}{r(t)}\right)^{2}, \qquad \text{so} \qquad \dot{\varphi} - \omega \simeq \omega\,\frac{2\,(r_0 - r)}{R} = \frac{\omega g t^{2}}{R}\,, \tag{20.24}$$

the body running ahead of the rotation because, as it approaches the axis, conservation of L_{ζ} speeds its azimuthal rate up.

The ground point that lay directly below at release keeps the azimuthal rate ω exactly. The body's lead in azimuth after the flight time t_{f} of Equation (20.7) is therefore

$$\Delta\varphi = \int_{0}^{t_{\mathrm{f}}} (\dot{\varphi} - \omega)\,\mathrm{d}t = \frac{\omega g\, t_{\mathrm{f}}^{3}}{3R}\,, \tag{20.25}$$

and the arc this subtends at the ground, at distance $R\cos\lambda$ from the axis, is $d = R\cos\lambda\,\Delta\varphi$, which is Equation (20.22). Substituting $t_{\mathrm{f}} = \sqrt{2h/g}$ gives the second form.

Three things were dropped and each is small, the numbers being quoted for a hundred-metre drop. Terms of relative order $\omega t_\mathrm{f} \approx 3 \times 10^{-4}$ come from the departure of the fall from radial; terms of relative order $h/R \approx 2 \times 10^{-5}$ come from replacing r_0 by R; and the plumb vertical is tilted from the radial direction by the centrifugal term of Equation (29.68), by about 2×10^{-3} radians, but that tilt lies in the meridian plane and so displaces the plumb point north or south, not east. □

Remark 20.14 (Why the elementary argument gives three halves of this). The argument that suggests itself first — at release the body's eastward speed exceeds the ground's by $\omega h \cos\lambda$, so in a time t_f it should gain $\omega h \cos\lambda\, t_\mathrm{f} = \frac{1}{2}\omega g t_\mathrm{f}^3 \cos\lambda$ — returns three halves of Equation (20.22). It fails on two counts, which is why the discrepancy is not obviously either way: the excess is not held constant, since Equation (20.24) has the azimuthal rate rising during the fall; and what must be compared with the ground is the *angle* swept, not a linear speed measured at a different distance from the axis. The rotating-frame route reaches Equation (20.22) in fewer lines, through the Coriolis acceleration $-2\boldsymbol{\omega} \times \boldsymbol{v}$ of Section 29.5, whose leading contribution $-2\boldsymbol{\omega} \times (-gt\hat{\boldsymbol{z}})$ has magnitude $2\omega g t \cos\lambda$ and points due east, and integrates twice from rest to the same $\frac{1}{3}\omega g t^3 \cos\lambda$ [100, 1585]. The two routes agree, as they must.

Rests on Proposition 20.13.

Derivation. *Derives Phenomenon 20.12.*

Proposition 20.13 is the statement, and the numbers follow from it. For a drop of $h = 100\,\mathrm{m}$ at $\lambda = 45°$, Equation (20.22) gives $t_\mathrm{f} = 4.52\,\mathrm{s}$ and $d = 1.55\,\mathrm{cm}$, which is the figure quoted in Phenomenon 20.12. Reich's measurement is the test: dropping balls down a mine shaft at Freiberg, at latitude about 50.9° and through some 158 m, he reported a mean eastward deviation of about 28 mm [92], against the 27.5 mm that Equation (20.22) gives for those parameters. The lateral deflection of a long-range projectile has the same origin, the Coriolis term acting on a horizontal velocity instead of a vertical one, and the whole effect is the free-fall counterpart of the Foucault pendulum [134] — a direct mechanical signature of assumption 4 failing, that is, of the laboratory frame not being inertial. □

Beyond these two, the remaining assumptions set their own limits. The uniform-field assumption 2 fails at the level of the free-air gradient measured in Section 20.4 — already relevant inside a 20 cm gravimeter drop at nine significant figures — and fails qualitatively for ranges comparable with the Earth's radius, where the trajectory closes into an ellipse about the Earth's centre: Newton's celebrated diagram of a cannonball fired from a mountaintop makes the parabola visibly a local approximation to an orbit [14]. Assumption 1 excludes the spin of real projectiles, whose coupling to the air (the Magnus effect) bends every driven golf ball and curled football; these lie beyond the scope of this chapter.

20.6 From Galileo's ratios to the equivalence principle

One step of the derivation above deserves to be read twice. In Equation (20.2) the mass m multiplies both sides — once as the *inertial* mass, the coefficient of resistance to acceleration in Newton's second law, and once as the *gravitational* mass, the coupling of the body to the field. Their cancellation is what made the trajectory independent of the body, and that independence is not a theorem but an experimental fact: Galileo's inclined planes could not distinguish the bronze ball from a heavier one [4], Newton checked the equality with pendulums of many materials [14], and its modern descendants — Eötvös-type torsion balances and satellite tests reviewed in Chapter 42 — constrain any composition-dependence of free fall at the level of parts in 10^{13} and beyond.

Einstein's insight of 1907, developed into the general theory of relativity [436], was to take this oldest of experimental facts as a founding principle: if all bodies fall alike, then

free fall is not a forced motion at all but the natural, unforced state, and gravitation is a property of spacetime geometry rather than of the falling body. The uniform field $\boldsymbol{g}$ of assumption 2 becomes, in that reading, the first-order description of a curved spacetime in a small laboratory. The bronze ball on the parchment-lined groove thus stands at the head of a straight line of inference that runs through this treatise to Part V; the reader will meet Phenomenon 20.1 again there, restated as the geodesic motion of a test body.

Chapter 21

Lagrangian Mechanics

The Newtonian formulation of Chapter 19 describes a system of particles through the forces acting on each of them, referred to the Cartesian coordinates of an inertial frame. When the motion is restricted by constraints this description carries two burdens: the constraint forces are not known in advance, and the Cartesian coordinates are no longer independent. The present chapter removes both. Constraints and generalized coordinates eliminate the redundant variables; the principle of virtual work and d'Alembert's principle eliminate the constraint forces; and the resulting Euler–Lagrange equations recast the dynamics in terms of a single scalar function of the generalized coordinates, the Lagrangian. The chapter closes with Hamilton's principle, which condenses the equations of motion into the stationarity of one functional, the action [1585, 2027].

Notation 21.1. Throughout this chapter and Chapter 22, the particles of an N-particle system are labelled $s = 1, \dots, N$, carried as a superscript; $i, j = 1, 2, 3$ label Cartesian components; $k = 1, \dots, n$ labels holonomic constraints; and $a, b = 1, \dots, f$ label generalized coordinates. Repeated Cartesian and generalized-coordinate indices are summed over; sums over particles and over constraints are written explicitly, except where the suppression of the particle label is expressly noted. The symbol ∇^s denotes the gradient with respect to the coordinates $\boldsymbol{x}^s$ of the s-th particle. Active forces are denoted $\boldsymbol{F}$, constraint forces $\boldsymbol{\Phi}$, and the total external force on a particle is their sum.

21.1 Generalized coordinates

21.1.1 Constraints

A *constraint* is a condition that relates the coordinates of a particle. Constraints encode, at the level of the description, everything that the environment forbids the system from doing: a bead cannot leave its wire, a ball cannot penetrate the floor. We classify them as follows.

Definition 21.2 (Holonomic constraint)**.** A *holonomic constraint* is a condition imposed on the coordinates of a reference frame, with respect to which the motion of a particle is described, expressible in the form

$$\phi(x^i, t) = C\,, \tag{21.1}$$

where ϕ is the function that describes the constraint and C is a constant.

Example 21.3 (Planar motion)**.** A particle whose motion with respect to some reference frame is two-dimensional is subject to the constraint $z = 0$. In this case $\phi(x^i, t) = z$ and $C = 0$.

Example 21.4 (Circular motion)**.** A particle describing a circular path of radius R is subject to the constraints given by the equations

$$z = 0\,, \qquad x^2 + y^2 = R^2\,. \tag{21.2}$$

Definition 21.5 (Non-holonomic constraint)**.** A *non-holonomic constraint* is a condition imposed on the coordinates of a reference frame, with respect to which the motion of a particle is described, that can be written as

$$\phi(x^i, t) \geq C\,. \tag{21.3}$$

Example 21.6 (Ball on a court)**.** A ball on a tennis court is confined to move only in the region

$$z \geq 0 \tag{21.4}$$

with respect to the ground.

Remark 21.7. More generally, a constraint is called *anholonomic* whenever it cannot be written in the form Equation (21.1); the inequality constraints of Definition 21.5 are one instance.

Remark 21.8 (Scleronomous and rheonomous constraints)*.* A constraint that does not depend explicitly on time is called *scleronomous*; one that does depend explicitly on time is called *rheonomous* [2027].

21.1.2 Degrees of freedom

Definition 21.9 (Degrees of freedom)**.** The number of *degrees of freedom* of a system of particles is the minimum number of independent, time-dependent variables required to describe the state of the system completely.

If we have N particles, $3N$ variables describe the system (three coordinates for each particle, since the motion takes place in $\mathbb{R}^3$). If the system is subject to n holonomic constraints, each removes one variable, and the number of degrees of freedom is

$$f = 3N - n\,. \tag{21.5}$$

Example 21.10. A particle describing circular motion is subject to the two constraints of Equation (21.2); the number of degrees of freedom of the system is therefore $f = 3 - 2 = 1$.

If instead we have a system of N bodies, these can also rotate. Three variables are needed to describe the rotation of each body and three for its translation, so that the total number of degrees of freedom is

$$f = 6N - n\,. \tag{21.6}$$

Example 21.11. A pair of scissors has seven degrees of freedom: three of translation, three of rotation, and one variable describing its opening.

21.1.3 Generalized coordinates

Definition 21.12 (Generalized coordinates)**.** Consider a system of N particles with f degrees of freedom. The f independent, time-dependent variables q^a, $a = 1, \ldots, f$, sufficient to describe the motion of the N particles, are called *generalized coordinates* of the system. There exists, accordingly, a general coordinate transformation of the form

$$\boldsymbol{x}^s = \boldsymbol{x}^s(q^a, t)\,, \qquad s = 1, \ldots, N\,. \tag{21.7}$$

Example 21.13. For circular motion there is a single degree of freedom, to which one may assign as generalized coordinate the angle formed by the line joining the particle to the centre with respect to a fixed line. Alternatively, one may assign as generalized coordinate the arc length traversed by the particle with respect to some fixed point. The choice of generalized coordinates is not unique.

21.1.4 Constraint forces and active forces

Definition 21.14 (Constraint force)**.** Consider a system of N particles with f degrees of freedom. A force acting on the s-th particle is called a *constraint force* if it is due to the action of a constraint; equivalently, it is the force $\boldsymbol{\Phi}$ that replaces the action of a constraint while producing the same effect. We denote by $\boldsymbol{\Phi}_k^s$ the constraint force on the s-th particle due to the k-th constraint.

Definition 21.15 (Active force)**.** A force is called *active* if it is not a constraint force; the active forces are the external forces on a particle, the constraint forces excepted. Denoting the individual active forces on the s-th particle by $\boldsymbol{F}_r^s$, $r = 1, \dots, R$, the total force on that particle is

$$\boldsymbol{F}'^s = \sum_{r=1}^{R} \boldsymbol{F}_r^s + \sum_{k=1}^{n} \boldsymbol{\Phi}_k^s \,. \tag{21.8}$$

By Newton's second law (Chapter 19), for a system of N particles subject to n holonomic constraints and to R active forces,

$$\sum_{r=1}^{R} \boldsymbol{F}_r^s + \sum_{k=1}^{n} \boldsymbol{\Phi}_k^s = m^s \ddot{\boldsymbol{x}}^s \,, \qquad s = 1, \dots, N \,. \tag{21.9}$$

We shall write $\boldsymbol{F}^s = \sum_r \boldsymbol{F}_r^s$ for the total active force and $\boldsymbol{\Phi}^s = \sum_k \boldsymbol{\Phi}_k^s$ for the total constraint force on the s-th particle.

21.2 Virtual work

21.2.1 Virtual displacements

Consider a system of N particles, the position of the s-th particle being $\boldsymbol{x}^s(t)$. The *physical displacement* performed by this particle when the system evolves during a time $\mathrm{d}t$ is the variation $\mathrm{d}\boldsymbol{x}^s$ of the position,

$$\boldsymbol{x}^s(t + \mathrm{d}t) = \boldsymbol{x}^s(t) + \mathrm{d}\boldsymbol{x}^s(t) \,. \tag{21.10}$$

That the system is evolving implies, however, that the constraints may be changing in time. We can construct the idea of another kind of displacement, one performed at fixed time, so that the constraints do not change. As stated this is impossible, since the system does not evolve at a fixed time; nevertheless, in order to adopt principles that are independent of time, we define the *virtual displacement* performed by the s-th particle as a displacement at fixed time, required at least to be compatible with the constraints (which, time being fixed, are not evolving). We denote the virtual displacement by $\delta\boldsymbol{x}^s$.

Definition 21.16 (Compatible and invertible virtual displacements)**.** A virtual displacement is *compatible with the constraints* if it respects them; if it fails to respect some constraint it is called *incompatible*. A compatible virtual displacement is *invertible* if the reversed displacement is also compatible with the constraints; there may exist compatible virtual displacements that are *not invertible*.

21.2.2 The constraint-force hypothesis

We state as a principle that

> *the constraint force on a particle is always perpendicular to the surface of the constraint.*

Thus the constraint force on the s-th particle due to the k-th holonomic constraint, with constraint function $\phi^k(x^i, t)$, is proportional to $\nabla^s \phi^k$; that is,

$$\boldsymbol{\Phi}^s_k = \lambda^k \nabla^s \phi^k \qquad \text{(no sum over } k\text{)}\,. \tag{21.11}$$

Summing all the constraint forces acting on each particle,

$$\boldsymbol{\Phi}^s = \sum_{k=1}^{n} \lambda^k \nabla^s \phi^k\,. \tag{21.12}$$

The quantities λ^k are properties of each surface (that is, of the k-th constraint) and may depend on the coordinates and on time,

$$\lambda^k = \lambda^k(\boldsymbol{x}^s, t)\,. \tag{21.13}$$

Virtual displacements compatible with the constraints

By the constraint-force hypothesis, for virtual displacements compatible with the holonomic constraints—displacements in which the particle moves on the surface of the constraint—the virtual displacement is tangent to that surface, and hence perpendicular to each constraint force. Thus

$$\boldsymbol{\Phi}^s_k \cdot \delta\boldsymbol{x}^s = \lambda^k \nabla^s \phi^k \cdot \delta\boldsymbol{x}^s = 0 \qquad \text{(no sum over } k\text{)}\,, \tag{21.14}$$

and, summing over the constraints,

$$\boldsymbol{\Phi}^s \cdot \delta\boldsymbol{x}^s = 0\,. \tag{21.15}$$

21.2.3 Virtual work and its principle

Definition 21.17 (Virtual work)**.** The *virtual work* performed on the s-th particle by a force $\boldsymbol{F}$ under the virtual displacement $\delta\boldsymbol{x}^s$ is

$$\delta W^s = \boldsymbol{F} \cdot \delta\boldsymbol{x}^s\,. \tag{21.16}$$

Theorem 21.18 (Principle of virtual work)**.** *Consider a system of N particles, subject on each particle to the total active force $\boldsymbol{F}^s$ and the total constraint force $\boldsymbol{\Phi}^s$, and suppose the particles are in equilibrium with respect to an inertial frame, so that the total force on each of them vanishes. Then, for virtual displacements compatible with the constraints, the virtual work of the active forces vanishes:*

$$\sum_{s=1}^{N} \boldsymbol{F}^s \cdot \delta\boldsymbol{x}^s = 0\,. \tag{21.17}$$

Derivation. Equilibrium means $\boldsymbol{F}^s + \boldsymbol{\Phi}^s = \boldsymbol{0}$ for each s. Taking the scalar product with $\delta\boldsymbol{x}^s$ and summing over the particles,

$$\sum_{s=1}^{N} \boldsymbol{F}^s \cdot \delta\boldsymbol{x}^s + \sum_{s=1}^{N} \boldsymbol{\Phi}^s \cdot \delta\boldsymbol{x}^s = 0\,.$$

The second term is the sum of the virtual works performed on the particles by the constraint forces. In general this constraint-force virtual work is different from zero; but if we consider only virtual displacements compatible with the constraints, it vanishes by Equation (21.15), and Equation (21.17) follows. □

21.3 d'Alembert's principle

The principle of virtual work is a statement about statics. d'Alembert's device extends it to dynamics: the accelerations are absorbed into fictitious forces, so that every problem of motion becomes a problem of equilibrium.

Definition 21.19 (Inertial force)**.** The *inertial force* on the s-th particle is defined as

$$\boldsymbol{\varphi}^s = -\dot{\boldsymbol{p}}^s = -m^s \ddot{\boldsymbol{x}}^s \,, \tag{21.18}$$

the force introduced to counteract the fictitious effects that appear when the motion is observed from a non-inertial reference frame.

Theorem 21.20 (d'Alembert's principle)**.** *For a system of N particles, each subject to the total active force $\boldsymbol{F}^s$ and the total constraint force $\boldsymbol{\Phi}^s$, and for virtual displacements compatible with the constraints,*

$$\sum_{s=1}^{N} (\boldsymbol{F}^s - \dot{\boldsymbol{p}}^s) \cdot \delta \boldsymbol{x}^s = 0 \,. \tag{21.19}$$

Derivation. By Newton's second law,

$$\boldsymbol{F}^s + \boldsymbol{\Phi}^s = \dot{\boldsymbol{p}}^s \,.$$

We may pass to a frame in which each particle is in equilibrium by treating the inertial force $\boldsymbol{\varphi}^s = -\dot{\boldsymbol{p}}^s$ as an active force:

$$\boldsymbol{F}^s + \boldsymbol{\Phi}^s + \boldsymbol{\varphi}^s = \boldsymbol{0} \,.$$

Proceeding as in the principle of virtual work, we take the scalar product with $\delta \boldsymbol{x}^s$ and sum over the particles:

$$\sum_{s=1}^{N} \boldsymbol{F}^s \cdot \delta \boldsymbol{x}^s + \sum_{s=1}^{N} \boldsymbol{\Phi}^s \cdot \delta \boldsymbol{x}^s + \sum_{s=1}^{N} \boldsymbol{\varphi}^s \cdot \delta \boldsymbol{x}^s = 0 \,.$$

Again, for virtual displacements compatible with the constraints the second sum vanishes by Equation (21.15), leaving

$$\sum_{s=1}^{N} \boldsymbol{F}^s \cdot \delta \boldsymbol{x}^s + \sum_{s=1}^{N} \boldsymbol{\varphi}^s \cdot \delta \boldsymbol{x}^s = 0 \,,$$

which, on substituting Equation (21.18), is Equation (21.19). □

d'Alembert's principle states that the virtual works performed by the impressed forces and by the inertial forces form a system in equilibrium. Denoting the total virtual work performed by the active forces and by the inertial forces as δW^A and δW^N respectively, it reads

$$\delta W^A + \delta W^N = 0 \,. \tag{21.20}$$

21.4 The Euler–Lagrange equations

21.4.1 Lagrange equations of the first kind

Theorem 21.21 (Lagrange equations of the first kind)**.** *Consider a system of N particles, subject on each particle to the total active force $\boldsymbol{F}^s$ and to the action of n holonomic constraints*

$$\phi^k(x^i, t) = C^k \,, \qquad k = 1, \dots, n \,. \tag{21.21}$$

Then the motion satisfies

$$\boldsymbol{F}^s + \sum_{k=1}^{n} \lambda^k \nabla^s \phi^k = \dot{\boldsymbol{p}}^s \,, \qquad s = 1, \dots, N \,, \tag{21.22}$$

which, together with the conditions Equation (21.21)*, are known as the* Lagrange equations of the first kind.

Derivation. The total virtual work δW^V performed by the constraint forces is, by the constraint-force hypothesis Equation (21.12),

$$\delta W^V = \sum_{s=1}^{N} \boldsymbol{\Phi}^s \cdot \delta \boldsymbol{x}^s = \sum_{s=1}^{N} \sum_{k=1}^{n} \lambda^k \nabla^s \phi^k \cdot \delta \boldsymbol{x}^s \,,$$

and for virtual displacements compatible with the constraints,

$$\sum_{s=1}^{N} \sum_{k=1}^{n} \lambda^k \nabla^s \phi^k \cdot \delta \boldsymbol{x}^s = 0 \,. \tag{21.23}$$

In this case d'Alembert's principle takes the form

$$\delta W^A + \delta W^N + \delta W^V = 0 \,,$$

so that, combining Equation (21.19) and Equation (21.23),

$$\sum_{s=1}^{N} \left(\boldsymbol{F}^s - \dot{\boldsymbol{p}}^s + \sum_{k=1}^{n} \lambda^k \nabla^s \phi^k \right) \cdot \delta \boldsymbol{x}^s = 0 \,.$$

Since the coordinates are linearly independent, the coefficient of each displacement must vanish, which yields Equation (21.22). □

21.4.2 Lagrange multipliers as constraint forces

The multipliers λ^k were introduced by the constraint-force hypothesis Equation (21.12) without being assumed known, and Equation (21.22) does not determine the motion until they are found. That they exist, and that a constrained stationarity problem is equivalent to an unconstrained one for the augmented integrand $\mathcal{L} + \sum_k \lambda^k \phi^k$ whenever the constraint gradients have full rank, is the multiplier rule of Theorem 16.41, proved in Section 16.3.1 and not reproved here [40]. What belongs to mechanics, and is the subject of this subsection, is what the multipliers physically *are*: each one is a constraint force, in newtons, and it is usually the number the experiment measures.

The multipliers are determined by the motion

Proposition 21.22 (Determinacy of the first-kind system)**.** *Let the n constraint functions ϕ^k of Equation* (21.21) *be of class C^2 and let the n vectors of $\mathbb{R}^{3N}$ with components $(m^s)^{-1/2} \nabla^s \phi^k$, $s = 1, \dots, N$, be linearly independent at each point of the motion. Then the multipliers are fixed algebraically by the instantaneous state $(\boldsymbol{x}^s, \dot{\boldsymbol{x}}^s, t)$: the Gram matrix*

$$M^{kl} = \sum_{s=1}^{N} \frac{1}{m^s} \nabla^s \phi^k \cdot \nabla^s \phi^l \tag{21.24}$$

is symmetric positive definite, and

$$\sum_{l=1}^{n} M^{kl} \lambda^l = -\,\Xi^k - \sum_{s=1}^{N} \frac{1}{m^s} \nabla^s \phi^k \cdot \boldsymbol{F}^s \,, \tag{21.25}$$

where Ξ^k collects the terms of $\mathrm{d}^2\phi^k/\mathrm{d}t^2$ that do not contain the accelerations. The first-kind system Equation (21.22)–Equation (21.21) is therefore determinate: $3N+n$ equations for the $3N$ coordinates and the n multipliers.

Rests on Equations (21.12), (21.21) and (21.22).

Derivation. *Derives Proposition 21.22.*

Differentiating $\phi^k(\boldsymbol{x}^s, t) = C^k$ twice along the motion and separating the acceleration terms,

$$\frac{\mathrm{d}^2\phi^k}{\mathrm{d}t^2} = \sum_{s=1}^{N} \nabla^s\phi^k \cdot \ddot{\boldsymbol{x}}^s + \Xi^k = 0\,, \tag{21.26}$$

with

$$\Xi^k = \sum_{s,s'} \dot{\boldsymbol{x}}^s \cdot \left(\nabla^s\nabla^{s'}\phi^k\right)\dot{\boldsymbol{x}}^{s'} + 2\sum_{s} \frac{\partial}{\partial t}\left(\nabla^s\phi^k\right)\cdot\dot{\boldsymbol{x}}^s + \frac{\partial^2\phi^k}{\partial t^2}\,,$$

a function of the state alone (the mixed second derivatives are symmetric by Proposition 7.73). Substituting the accelerations from Equation (21.22),

$$\ddot{\boldsymbol{x}}^s = \frac{1}{m^s}\left(\boldsymbol{F}^s + \sum_{l=1}^{n}\lambda^l\nabla^s\phi^l\right)\,,$$

into Equation (21.26) gives Equation (21.25) with M^{kl} as in Equation (21.24). That matrix is symmetric by inspection, and for any $u \in \mathbb{R}^n$

$$\sum_{k,l=1}^{n} u_k M^{kl} u_l = \sum_{s=1}^{N}\frac{1}{m^s}\left|\sum_{k=1}^{n} u_k\nabla^s\phi^k\right|^2 \geq 0\,,$$

with equality only if $\sum_k u_k\,(m^s)^{-1/2}\,\nabla^s\phi^k = \mathbf{0}$ for every s, that is only if $u = 0$ under the independence hypothesis. So M is invertible and Equation (21.25) has a unique solution λ^l. The count of equations and unknowns follows. □

Remark 21.23 (Failure of the rank condition is physical). The hypothesis is not a technicality. Two constraint surfaces whose gradients become parallel at a point are, at that point, *statically indeterminate*: the same total constraint force can be apportioned between them in infinitely many ways, and no equation of motion can decide the split. The elementary instance is a table with four legs on a rigid floor, where the four normal forces are not determined by rigid-body mechanics and the real answer comes from the elasticity of Chapter 30. Positive definiteness of Equation (21.24) is exactly the statement that this has not happened.

Remark 21.24 (SI dimensions of a multiplier). Since $\boldsymbol{\Phi}^s_k = \lambda^k\nabla^s\phi^k$ is a force, the multiplier carries whatever unit makes the product a newton: $[\lambda^k] = \mathrm{N\,m}/[\phi^k]$, equivalently $[\lambda^k\phi^k] = \mathrm{J}$, which is the mechanical face of the statement in Remark 16.42 that the augmented integrand must remain an energy. For the commonest case, a constraint written as a length — a rod of fixed length, a bead on a wire, a body resting on a surface — ϕ^k is in metres and λ^k is a force in newtons outright. Writing the same constraint as $\phi = r^2 = R^2$ instead of $\phi = r = R$ rescales the multiplier to N/m and halves it; the constraint force $\lambda\nabla\phi$ is of course unchanged. The multiplier is not an invariant of the constraint, only of the constraint *as written*.

A worked case: when does a body leave the surface?

The reason to keep the multipliers rather than eliminate the constraint is that the eliminated description cannot answer questions about the constraint force — and one such question is when the constraint stops acting at all.

Proposition 21.25 (Departure from a smooth sphere)**.** *A point mass m slides without friction on the outside of a fixed sphere of radius R in a uniform gravitational field of magnitude g, starting from rest at polar angle θ_0 measured from the upward vertical. While it remains in contact, the outward normal force is*

$$\lambda(\theta) = mg\,(3\cos\theta - 2\cos\theta_0)\ , \tag{21.27}$$

and the body leaves the surface at the angle θ_* given by

$$\cos\theta_* = \tfrac{2}{3}\cos\theta_0 \qquad \xrightarrow[\theta_0\to 0]{} \qquad \cos\theta_* = \tfrac{2}{3}\,, \quad \theta_* = 48.19^\circ\,, \tag{21.28}$$

independently of m, of R and of g.

Rests on Equations (21.12) and (21.22) and Proposition 21.22.

Derivation. Derives Proposition 21.25.

Take plane polar coordinates (r,θ) in the vertical plane of the motion, θ measured from the upward vertical, and impose the single constraint $\phi = r = R$, so that $\nabla\phi = \hat{\boldsymbol{r}}$ is the outward radial unit vector and λ is the outward normal force in newtons (Remark 21.24). The active force is $\boldsymbol{F} = -mg\hat{\boldsymbol{z}}$, whose radial and tangential components are $-mg\cos\theta$ and $+mg\sin\theta$. With the acceleration in polar coordinates, Equation (21.22) reads

$$m\left(\ddot r - r\dot\theta^2\right) = -mg\cos\theta + \lambda\,, \tag{21.29}$$

$$m\left(r\ddot\theta + 2\dot r\dot\theta\right) = mg\sin\theta\,. \tag{21.30}$$

On the constraint $r = R$, $\dot r = \ddot r = 0$, so Equation (21.29) gives $\lambda = m\left(g\cos\theta - R\dot\theta^2\right)$, which is Equation (21.25) in this one-constraint case. The constraint force is radial and the velocity tangential, so the constraint does no work and the energy of Equation (21.44) is conserved; measuring heights from the centre,

$$\tfrac{1}{2}mR^2\dot\theta^2 = mgR\,(\cos\theta_0 - \cos\theta) \qquad\Longrightarrow\qquad R\dot\theta^2 = 2g\,(\cos\theta_0 - \cos\theta)\ .$$

Substituting gives Equation (21.27). The sphere can push but not pull, so the description holds only while $\lambda \geq 0$; the first angle at which Equation (21.27) vanishes is Equation (21.28), and beyond it the body is a projectile with the free trajectory of Chapter 20. Everything cancels except the ratio $\frac{2}{3}$, so the prediction is a pure number. □

Example 21.26 (The same statement in SI)**.** Take the stipulated values $m = 0.100\,\mathrm{kg}$ and $R = 0.500\,\mathrm{m}$, with the standard gravitational acceleration $g_0 = 9.806\,65\,\mathrm{m/s^2}$ (Appendix B; a local g differs from g_0 by a few parts in 10^3, and since it enters Equation (21.27) linearly it shifts the force by that much and the angle not at all). Release from $\theta_0 \to 0$ then gives a normal force $\lambda(0) = mg_0 = 0.981\,\mathrm{N}$ at the top, departure at $\theta_* = 48.19^\circ$ after a fall of $R/3 = 0.167\,\mathrm{m}$, and a departure speed $v_* = \sqrt{2g_0R/3} = 1.81\,\mathrm{m/s}$, each quoted to the three significant figures of the inputs. Only the angle is falsifiable without reference to those inputs: it depends on nothing that was put in.

Rests on Equation (21.28).

Remark 21.27 (The constraint was an inequality all along). Proposition 21.25 is the promised instance of the distinctions drawn in Definition 21.5 and Definition 21.16. Resting on a surface is the inequality constraint $r \geq R$, not the equality $r = R$; the equality is merely the part of it that is active. At a point of the boundary $r = R$ an outward virtual displacement is *compatible* with $r \geq R$ while the inward one is not, so the compatible displacements there are not invertible, and the argument of Equation (21.14) — which required a displacement tangent to the surface — covers only the tangential ones. What survives is the inequality $\boldsymbol{\Phi}^s \cdot \delta\boldsymbol{x}^s \geq 0$: a one-sided constraint can do no negative virtual work. Its mechanical content

is the sign condition $\lambda \geq 0$, and Equation (21.28) is the instant at which that condition ceases to hold. A model that keeps the equality past θ_* predicts a surface that pulls the body back, which is not a small error but the wrong phenomenon.

Remark 21.28 (Two routes, two purposes). The alternative treatment eliminates the constraint at the outset, taking θ as the single generalized coordinate; the second-kind equations of Section 21.4.3 then reduce to Equation (21.30) with $r = R$, namely $R\ddot{\theta} = g\sin\theta$, and the normal force never appears. That is the right route when only the trajectory is wanted, and the wrong one whenever the quantity of interest is carried by the constraint: the tension in a suspension wire, the load on a bearing, the normal force that decides whether a rolling body slips, the reaction that a structure must be built to withstand. Those are the multipliers themselves, and the price of eliminating them is that they cannot be recovered afterwards from the reduced description.

21.4.3 Lagrange equations of the second kind

The Lagrange equations of the first kind are a manifestation of Newton's second law in the presence of n holonomic constraints, written in Cartesian coordinates. As we saw, each holonomic constraint on a system of N particles removes one degree of freedom, so that fewer variables are needed to describe the system. What we must now do is find a set of f equations that describe the system without reference to the constraints, that is, in terms of the generalized coordinates.

Definition 21.29 (Generalized force)**.** In analogy with the definition of virtual work, we define

$$Q_a = \sum_{s=1}^{N} \boldsymbol{F}^s \cdot \frac{\partial \boldsymbol{x}^s}{\partial q^a} \tag{21.31}$$

as the *total generalized force corresponding to the generalized coordinate* q^a.

Theorem 21.30 (Lagrange equations of the second kind)**.** *For a system of N particles with f degrees of freedom, subject to holonomic constraints and to active forces of total generalized force Q_a, the kinetic energy T satisfies*

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial T}{\partial \dot{q}^a}\right) - \frac{\partial T}{\partial q^a} = Q_a\,, \qquad a = 1, \dots, f\,, \tag{21.32}$$

which are known as the Lagrange equations of the second kind*.*

Derivation. We start from d'Alembert's principle,

$$\sum_{s=1}^{N} (\boldsymbol{F}^s - \dot{\boldsymbol{p}}^s) \cdot \delta \boldsymbol{x}^s = 0\,.$$

Suppressing the particle label (all expressions below carry an implicit sum over the suppressed index s, the mass accompanying its particle), this reads

$$\left(F^i - \dot{p}^i\right) \delta x^i = 0 \qquad \Longleftrightarrow \qquad F^i\, \delta x^i = m\ddot{x}^i\, \delta x^i\,.$$

Since the virtual displacement is performed at fixed time, the variation of Equation (21.7) contains no time term,

$$\delta x^i = \frac{\partial x^i}{\partial q^a}\, \delta q^a\,,$$

and therefore

$$F^i\, \frac{\partial x^i}{\partial q^a}\, \delta q^a = m\ddot{x}^i\, \frac{\partial x^i}{\partial q^a}\, \delta q^a\,. \tag{21.33}$$

We must analyse each side of Equation (21.33) separately.

The left-hand side is, restoring the particle sum, $Q_a\,\delta q^a$ by Equation (21.31).

For the right-hand side we compute, using the product rule,

$$\begin{aligned}
m\ddot{x}^i\,\frac{\partial x^i}{\partial q^a}\,\delta q^a &= m\frac{\mathrm{d}\dot{x}^i}{\mathrm{d}t}\,\frac{\partial x^i}{\partial q^a}\,\delta q^a \\
&= m\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\dot{x}^i\,\frac{\partial x^i}{\partial q^a}\right) - \dot{x}^i\,\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial x^i}{\partial q^a}\right)\right]\delta q^a \\
&= m\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\dot{x}^i\,\frac{\partial x^i}{\partial q^a}\right) - \dot{x}^i\left(\frac{\partial}{\partial q^b}\left(\frac{\partial x^i}{\partial q^a}\right)\frac{\mathrm{d}q^b}{\mathrm{d}t} + \frac{\partial}{\partial t}\left(\frac{\partial x^i}{\partial q^a}\right)\right)\right]\delta q^a \\
&= m\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\dot{x}^i\,\frac{\partial x^i}{\partial q^a}\right) - \dot{x}^i\left(\frac{\partial^2 x^i}{\partial q^b\partial q^a}\dot{q}^b + \frac{\partial^2 x^i}{\partial t\,\partial q^a}\right)\right]\delta q^a \\
&= m\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\dot{x}^i\,\frac{\partial x^i}{\partial q^a}\right) - \dot{x}^i\left(\frac{\partial^2 x^i}{\partial q^a\partial q^b}\dot{q}^b + \frac{\partial^2 x^i}{\partial q^a\partial t}\right)\right]\delta q^a \\
&= m\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\dot{x}^i\,\frac{\partial x^i}{\partial q^a}\right) - \dot{x}^i\,\frac{\partial}{\partial q^a}\left(\frac{\partial x^i}{\partial q^b}\dot{q}^b + \frac{\partial x^i}{\partial t}\right)\right]\delta q^a \\
&= m\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\dot{x}^i\,\frac{\partial x^i}{\partial q^a}\right) - \dot{x}^i\,\frac{\partial \dot{x}^i}{\partial q^a}\right]\delta q^a \\
&= m\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\dot{x}^i\,\frac{\partial x^i}{\partial q^a}\right) - \frac{\partial}{\partial q^a}\left(\frac{1}{2}\dot{x}^i\dot{x}^i\right)\right]\delta q^a\,,
\end{aligned}$$

where the third line applies the chain rule to $\frac{\partial x^i}{\partial q^a}\left(q^b,t\right)$, the fifth uses the symmetry of mixed partial derivatives, and the sixth and seventh recognize the total time derivative of x^i,

$$\dot{x}^i = \frac{\partial x^i}{\partial q^b}\dot{q}^b + \frac{\partial x^i}{\partial t}\,. \tag{21.34}$$

Differentiating Equation (21.34) with respect to $\dot{q}^a$ gives the "cancellation of the dots",

$$\frac{\partial \dot{x}^i}{\partial \dot{q}^a} = \frac{\partial x^i}{\partial q^a}\,, \tag{21.35}$$

so that

$$\begin{aligned}
m\ddot{x}^i\,\frac{\partial x^i}{\partial q^a}\,\delta q^a &= m\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\dot{x}^i\,\frac{\partial \dot{x}^i}{\partial \dot{q}^a}\right) - \frac{\partial}{\partial q^a}\left(\frac{1}{2}\dot{x}^i\dot{x}^i\right)\right]\delta q^a \\
&= \left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial}{\partial \dot{q}^a}\left(\frac{1}{2}m\dot{x}^i\dot{x}^i\right)\right) - \frac{\partial}{\partial q^a}\left(\frac{1}{2}m\dot{x}^i\dot{x}^i\right)\right]\delta q^a\,.
\end{aligned}$$

Since the kinetic energy of the N particles is

$$T = \frac{1}{2}\sum_{s=1}^{N} m^s\,\dot{\boldsymbol{x}}^s\cdot\dot{\boldsymbol{x}}^s$$

(the sum over the suppressed index s being understood throughout), we obtain

$$m\ddot{x}^i\,\frac{\partial x^i}{\partial q^a}\,\delta q^a = \left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial T}{\partial \dot{q}^a}\right) - \frac{\partial T}{\partial q^a}\right]\delta q^a\,. \tag{21.36}$$

Substituting Equation (21.31) and Equation (21.36) into Equation (21.33),

$$Q_a\,\delta q^a = \left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial T}{\partial \dot{q}^a}\right) - \frac{\partial T}{\partial q^a}\right]\delta q^a\,,$$

and since the δq^a are arbitrary, Equation (21.32) follows. □

21.4.4 The Lagrangian

The total generalized force Q_a may arise from conservative active forces and also from non-conservative ones; in the most general case the potential of the conservative forces may depend on the velocities.

Definition 21.31 (Lagrangian)**.** The *Lagrangian* of a system with kinetic energy T and potential energy V is

$$\mathcal{L} = T - V\,. \tag{21.37}$$

Theorem 21.32 (Lagrange equations)**.** *For a system that feels R active forces, of which D are conservative and derive from the potential V, the equations of motion take the form*

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) - \frac{\partial \mathcal{L}}{\partial q^a} = \sum_{r=1}^{R-D} Q_a^{(r)}\,, \tag{21.38}$$

where the right-hand side sums the generalized forces of the $R-D$ non-conservative active forces. In particular, when all the active forces are conservative,

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) - \frac{\partial \mathcal{L}}{\partial q^a} = 0\,. \tag{21.39}$$

Rests on Equations (21.31)*,* (21.32) *and* (21.37)*.*

Derivation. *Derives Theorem 21.32.*

Split the active force on each particle into the resultant $\boldsymbol{F}_{\mathrm{c}}^s$ of the D conservative forces and the remainder $\boldsymbol{F}_{\mathrm{nc}}^s$. By Definition 7.103 the former derives from a potential $V\left(\boldsymbol{x}^1, \ldots, \boldsymbol{x}^N, t\right)$ in joules,

$$\boldsymbol{F}_{\mathrm{c}}^s = -\nabla^s V\,,$$

so that the corresponding part of the generalized force Equation (21.31) is, by the chain rule in several variables (Proposition 7.72) applied to $V\left(\boldsymbol{x}^s(q,t), t\right)$,

$$\sum_{s=1}^{N} \boldsymbol{F}_{\mathrm{c}}^s \cdot \frac{\partial \boldsymbol{x}^s}{\partial q^a} = -\sum_{s=1}^{N} \nabla^s V \cdot \frac{\partial \boldsymbol{x}^s}{\partial q^a} = -\frac{\partial V}{\partial q^a}\,. \tag{21.40}$$

Hence $Q_a = -\partial V/\partial q^a + \sum_{r=1}^{R-D} Q_a^{(r)}$, where the sum runs over the non-conservative forces, and Equation (21.32) becomes

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial T}{\partial \dot{q}^a}\right) - \frac{\partial T}{\partial q^a} + \frac{\partial V}{\partial q^a} = \sum_{r=1}^{R-D} Q_a^{(r)}\,. \tag{21.41}$$

Because V is a function of the coordinates and time only, it contributes nothing to the velocity derivative, $\partial V/\partial \dot{q}^a = 0$, so with $\mathcal{L} = T - V$ of Equation (21.37)

$$\frac{\partial \mathcal{L}}{\partial \dot{q}^a} = \frac{\partial T}{\partial \dot{q}^a}\,, \qquad \frac{\partial \mathcal{L}}{\partial q^a} = \frac{\partial T}{\partial q^a} - \frac{\partial V}{\partial q^a}\,,$$

and Equation (21.41) is exactly Equation (21.38). When every active force is conservative the right-hand side is empty and Equation (21.39) follows. □

Remark 21.33 (Velocity-dependent potentials). The hypothesis $\partial V/\partial \dot{q}^a = 0$ can be weakened, and must be, because the Lorentz force on a charge is velocity-dependent and yet has a Lagrangian. Suppose the generalized force derives from a *generalized potential* $U\left(q, \dot{q}, t\right)$ in joules in the sense

$$Q_a = -\frac{\partial U}{\partial q^a} + \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial U}{\partial \dot{q}^a}\right)\,. \tag{21.42}$$

Substituting Equation (21.42) into Equation (21.32) and collecting terms gives Equation (21.39) with $\mathcal{L} = T - U$, by the same two lines as above; the extra total time derivative in Equation (21.42) is precisely what is needed to cancel the $\partial U/\partial \dot{q}^a$ that now survives in $\partial \mathcal{L}/\partial \dot{q}^a$. The electromagnetic case $U = q_{\mathrm{e}}\,(\Phi - \dot{\boldsymbol{x}} \cdot \boldsymbol{A})$, with q_{e} the charge in coulombs, Φ in volts and $\boldsymbol{A}$ in T m, belongs to Chapter 64; it is also the reason Theorem 21.46 below is stated for a potential $V\,(q, \dot{q}, t)$. Velocity-dependent forces that are *not* of the form Equation (21.42) — sliding friction is the standard example — have no Lagrangian and must be carried on the right-hand side of Equation (21.38) as they stand.

Definition 21.34 (Generalized momentum)**.** The *generalized momentum* corresponding to the generalized coordinate q^a is

$$p_a = \frac{\partial \mathcal{L}}{\partial \dot{q}^a}\,. \tag{21.43}$$

21.4.5 Cyclic coordinates

Definition 21.35 (Cyclic coordinate)**.** A generalized coordinate q^a is said to be *cyclic* if the Lagrangian does not depend on it.

Theorem 21.36 (Conservation of the conjugate momentum)**.** *If q^a is cyclic and every active force is conservative, then the generalized momentum p_a is a constant of the motion.*
Rests on Definition 21.35 and Equations (21.39) *and* (21.43)*.*

Derivation. *Derives Theorem 21.36.*
By Definition 21.35 the index a is one for which $\partial \mathcal{L}/\partial q^a = 0$, so the Lagrange equation Equation (21.39) for that index reduces to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) = \frac{\mathrm{d}p_a}{\mathrm{d}t} = 0 \qquad (\text{no sum over } a)\,,$$

and a C^1 function whose derivative vanishes on an interval is constant there (Corollary 7.36). The same statement in the general variational setting is Proposition 16.28. □

Remark 21.37 (A cyclic coordinate is a symmetry)*.* The name is opaque and the content is not. That $\mathcal{L}$ does not depend on q^a says that the translation $q^a \mapsto q^a + \varepsilon$, with the other coordinates held fixed, leaves the Lagrangian — and therefore the action — invariant. Theorem 21.36 is thus the simplest instance of Noether's first theorem (Theorem 16.84), and the conserved quantity it produces is the Noether charge of that one-parameter group. Two cases carry names: invariance under a rigid translation of the whole system conserves the total linear momentum, and invariance under a rigid rotation conserves the total angular momentum (Corollary 16.88). The reading in terms of symmetry is the one that survives into field theory and quantum mechanics, where no coordinate is "absent" in any literal sense.

21.4.6 The energy of a Lagrangian system

The total energy of a system with kinetic energy T and potential energy V is

$$E = T + V\,. \tag{21.44}$$

The function that will turn out to represent it in the Lagrangian formalism is the *Jacobi integral*,

$$h\,(q, \dot{q}, t) := \dot{q}^a \frac{\partial \mathcal{L}}{\partial \dot{q}^a} - \mathcal{L} = \dot{q}^a p_a - \mathcal{L}\,, \tag{21.45}$$

also in joules — the Legendre transform of $\mathcal{L}$ with respect to the velocities, which is what will become the Hamiltonian in Chapter 22, and the mechanical instance of the Beltrami constant of Remark 16.30. That h equals E is a proposition with hypotheses, not a definition.

Proposition 21.38 (Energy in generalized coordinates)**.** *Suppose the coordinate transformation Equation* (21.7) *is scleronomous,* $\partial \boldsymbol{x}^s/\partial t = \mathbf{0}$ *(Remark 21.8), and the potential is velocity-independent,* $V = V(q,t)$*. Then*

$$E = \dot{q}^a \frac{\partial \mathcal{L}}{\partial \dot{q}^a} - \mathcal{L} = \dot{q}^a p_a - \mathcal{L} = h\,. \tag{21.46}$$

Rests on Equations (21.7)*,* (21.44) *and* (21.45)*.*

Derivation. Derives Proposition 21.38.

With $\partial \boldsymbol{x}^s/\partial t = \mathbf{0}$ the velocity relation Equation (21.34) loses its inhomogeneous term, $\dot{\boldsymbol{x}}^s = (\partial \boldsymbol{x}^s/\partial q^a)\,\dot{q}^a$, so the kinetic energy is the quadratic form

$$T = \tfrac{1}{2}\sum_{s=1}^{N} m^s\, \dot{\boldsymbol{x}}^s \cdot \dot{\boldsymbol{x}}^s = \tfrac{1}{2}\, g_{ab}(q)\, \dot{q}^a \dot{q}^b\,, \tag{21.47}$$

with g_{ab} the kinetic metric Equation (21.74), a function of the coordinates alone. Differentiating Equation (21.47) and using $g_{ab} = g_{ba}$,

$$\dot{q}^a \frac{\partial T}{\partial \dot{q}^a} = \dot{q}^a g_{ab} \dot{q}^b = 2T\,, \tag{21.48}$$

which is Euler's relation for a function homogeneous of degree two, obtained here by direct differentiation of the explicit form rather than from a general theorem (Remark 21.40). Since V carries no velocity, $\partial \mathcal{L}/\partial \dot{q}^a = \partial T/\partial \dot{q}^a$, and therefore

$$h = \dot{q}^a \frac{\partial T}{\partial \dot{q}^a} - (T - V) = 2T - T + V = T + V = E\,,$$

which is Equation (21.46). □

Remark 21.39 (The hypothesis actually needed). It is not enough that T carry no explicit t. A single particle in one dimension described from a frame translating at constant speed v, $x = q + vt$, has $T = \tfrac{1}{2}m\,(\dot{q} + v)^2$ — no explicit time dependence whatever — and yet $\dot{q}\,\partial T/\partial \dot{q} - T = \tfrac{1}{2}m\,(\dot{q}^2 - v^2) \neq T$. What fails is homogeneity, not time-independence, and it is the transformation Equation (21.7) rather than T that must be free of t. In the general rheonomous case Equation (21.34) gives $T = T_2 + T_1 + T_0$, homogeneous of degrees two, one and zero in the $\dot{q}^a$, and the same computation yields

$$h = T_2 - T_0 + V\,, \tag{21.49}$$

which is a perfectly good constant of the motion when $\partial \mathcal{L}/\partial t = 0$ but is *not* the energy $T + V$. The rotating frame of Chapter 29 is the case that matters in practice: there h is the Jacobi constant of the restricted three-body problem, T_0 is the centrifugal term, and confusing it with the energy is a standard way to get a wrong answer.

Remark 21.40 (A result Part II does not carry). The general statement behind Equation (21.48) is Euler's theorem on homogeneous functions: if f is differentiable and $f(\mu u) = \mu^k f(u)$ for all $\mu > 0$, then $u^i\, \partial f/\partial u^i = k f(u)$. It is a result of multivariable calculus and belongs in Chapter 7, which does not at present state it. Nothing above rests on it: the kinetic energy is an explicit quadratic form, so Equation (21.48) is one line of differentiation, and Equation (21.49) is obtained the same way term by term. The general theorem is nevertheless wanted elsewhere in this treatise — the virial theorem of Chapter 27 and the thermodynamic Euler relation of Part VI both use it in degrees other than two — and is recorded here as owed.

Proposition 21.41 (Time derivative of the Jacobi integral)**.** *Along any motion obeying Equation* (21.38)*,*

$$\dot{h} = \dot{q}^a Q_a - \frac{\partial \mathcal{L}}{\partial t}\,, \tag{21.50}$$

where $Q_a = \sum_r Q_a^{(r)}$ is the generalized force of the non-conservative active forces, as in Equation (21.38)*. Under the hypotheses of Proposition 21.38, $h = E$ and Equation* (21.50) *is the power balance for the total energy; if in addition the active forces are all conservative,*

$$\dot{E} = -\frac{\partial \mathcal{L}}{\partial t}\,. \tag{21.51}$$

Rests on Equations (21.38)*,* (21.45) *and* (21.46)*.*

Derivation. *Derives Proposition 21.41.*

Differentiate Equation (21.45) along the motion. The total time derivative of $\mathcal{L}(q, \dot{q}, t)$ is, by the chain rule (Proposition 7.72),

$$\frac{\mathrm{d}\mathcal{L}}{\mathrm{d}t} = \frac{\partial \mathcal{L}}{\partial q^a}\dot{q}^a + \frac{\partial \mathcal{L}}{\partial \dot{q}^a}\ddot{q}^a + \frac{\partial \mathcal{L}}{\partial t} = \frac{\partial \mathcal{L}}{\partial q^a}\dot{q}^a + p_a \ddot{q}^a + \frac{\partial \mathcal{L}}{\partial t}\,,$$

while $\mathrm{d}\left(\dot{q}^a p_a\right)/\mathrm{d}t = \ddot{q}^a p_a + \dot{q}^a \dot{p}_a$. The terms in $\ddot{q}^a$ cancel between the two, leaving

$$\dot{h} = \dot{q}^a \left(\dot{p}_a - \frac{\partial \mathcal{L}}{\partial q^a}\right) - \frac{\partial \mathcal{L}}{\partial t}\,,$$

and the bracket is the left-hand side of Equation (21.38), hence equal to Q_a. This is Equation (21.50). If every active force is conservative then $Q_a = 0$, and if the hypotheses of Proposition 21.38 hold as well then $h = E$, giving Equation (21.51). □

Remark 21.42 (Reading the two terms). Equation (21.50) is a power balance in watts, and its two terms are physically distinct. The first, $\dot{q}^a Q_a$, is the rate at which the non-conservative active forces do work on the system — the friction that drains a pendulum, the drive that sustains it. The second, $-\partial\mathcal{L}/\partial t$, is the rate at which work is done *by whatever imposes the explicit time dependence*: the hand that shortens the string of a pendulum, the motor that spins a constraint. Neither is a failure of energy conservation; both record energy crossing the boundary of the system as it was drawn. Note also that the constraint forces appear in neither term, which is the whole economy of the Lagrangian method — they were eliminated at Equation (21.15) precisely because they do no virtual work.

Theorem 21.43 (Conservation of energy)**.** *If the coordinate transformation Equation* (21.7) *is scleronomous, the potential is velocity-independent, every active force is conservative, and the Lagrangian carries no explicit time dependence, $\partial\mathcal{L}/\partial t = 0$, then the total energy $E = T + V$ is a constant of the motion. This is not the Newtonian statement Theorem 19.32 repeated in new notation. That one assumes a potential and reads the constancy of $T + V$ off $\boldsymbol{F} = m\boldsymbol{a}$ directly; this one holds in the presence of constraints, where T is a quadratic form in the generalized velocities with coordinate-dependent coefficients and the conserved quantity is identified from $\partial\mathcal{L}/\partial t$ rather than from a force balance. The logical route is not independent of Newton — the Lagrange equations themselves come from $\boldsymbol{F} = m\boldsymbol{a}$ by d'Alembert's principle, at Equation* (21.36) *— but the hypotheses and the argument are different ones, and the two statements agree, as they must, for an unconstrained particle in a time-independent potential.*

Rests on Equations (21.46) *and* (21.51) *and Theorem 19.32.*

Derivation. *Derives Theorem 21.43.*

The first three hypotheses put Proposition 21.41 in the form Equation (21.51), $\dot{E} = -\partial\mathcal{L}/\partial t$; the fourth makes the right-hand side vanish, and a C^1 function with vanishing derivative is constant (Corollary 7.36). □

Remark 21.44 (Which symmetry this is). $\partial\mathcal{L}/\partial t = 0$ says that the action is invariant under a shift of the origin of time, so Theorem 21.43 is Noether's theorem for time translation (Corollary 16.87), exactly as Theorem 21.36 is Noether's theorem for a translation in a coordinate. The two extra hypotheses — scleronomous constraints and a velocity-independent potential — are not needed for a conserved *quantity*; they are needed only for that quantity to be the energy, per Remark 21.39. It is worth being explicit about what is and is not assumed: nothing here derives conservation of energy from a deeper principle, since time-translation invariance is itself an empirical property of the interactions, tested wherever energy accounting is tested. What the theorem supplies is the exact link between the two.

21.5 Hamilton's principle

The differential principles of this chapter—virtual work and d'Alembert—characterize the motion instant by instant. Hamilton's principle characterizes it globally: among all conceivable histories of the system between two fixed instants, the physical one is singled out by a variational property of a single integral.

21.5.1 The action

Definition 21.45 (Action)**.** The *action* of a system with Lagrangian $\mathcal{L}$ along a history $q^a(t)$ between the instants t_a and t_b is the functional

$$S[q] = \int_{t_a}^{t_b} \mathcal{L}(q, \dot{q}, t)\, \mathrm{d}t\,. \tag{21.52}$$

Since $\mathcal{L}$ is an energy in joules and the integration is over a time, the action carries the SI dimension J s, the dimension of angular momentum and of the Planck constant — a coincidence that stops being one in Chapter 106. The functional is the mechanical instance of Definition 16.96.

Rests on Equation (21.37) *and Definition 16.96.*

21.5.2 Hamilton's principle

Theorem 21.46 (Hamilton's principle)**.** *For a physical system in which the active forces derive from a potential $V = V(q, \dot{q}, t)$ and the constraint forces are produced by holonomic constraints, the line integral*

$$S[q] = \int_{t_a}^{t_b} \mathcal{L}(q, \dot{q}, t)\, \mathrm{d}t$$

has a stationary value on the trajectory of motion of the physical system; that is,

$$\delta S = \delta \int_{t_a}^{t_b} \mathcal{L}(q, \dot{q}, t)\, \mathrm{d}t = 0\,. \tag{21.53}$$

This principle is a necessary and sufficient condition for the Lagrange equations with active forces derived from $V(q, \dot{q}, t)$,

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) - \frac{\partial \mathcal{L}}{\partial q^a} = 0\,. \tag{21.54}$$

Rests on Equations (21.38) *and* (21.52) *and Definition 21.12.*

Derivation. *Derives Theorem 21.46.*

The mathematics is Theorem 16.35, the Euler–Lagrange system for a functional of several dependent variables, read with the independent variable x taken to be the time t and the dependent variables y^i taken to be the f generalized coordinates q^a; the first variation is computed in Proposition 16.17, the integration by parts and the passage from $\int E_a \eta^a \mathrm{d}t = 0$

to $E_a = 0$ in Theorem 16.22 and Lemma 16.18. Applied to Equation (21.52) that theorem states exactly that S is stationary among C^1 histories with $q^a(t_a)$ and $q^a(t_b)$ prescribed if and only if Equation (21.54) holds, which is the assertion.

What is physics, and is the reason the hypotheses are stated as they are, is that the theorem may be applied at all. It requires the variations δq^a to be *independent* and otherwise arbitrary, and that is precisely what the two hypotheses secure. Because the constraints are holonomic, Equation (21.5) leaves f independent generalized coordinates and every nearby history obeying the constraints is reached by an unrestricted variation of them — so the comparison class is a full neighbourhood in the q^a, with no condition surviving from the constraints. Because the active forces derive from V, the whole content of the dynamics is inside $\mathcal{L} = T - V$, with no leftover generalized force on the right-hand side of Equation (21.38) to be accounted for. Drop either hypothesis and the equivalence fails: a non-conservative force leaves $\sum_r Q_a^{(r)} \neq 0$, which is not the Euler–Lagrange equation of any functional, and a non-integrable constraint restricts the admissible variations in a way that the unconstrained theorem does not model — the subject of Section 21.6. □

Remark 21.47 (Stationary, not least). The traditional name "principle of least action" overstates the result, and Equation (21.53) says only what is true: the first variation vanishes. For a mechanical Lagrangian the action is indeed a minimum over sufficiently short intervals, but past the first conjugate point — the kinetic focus — it is a saddle, never a maximum; for a harmonic oscillator of angular frequency ω that happens after a time π/ω, half a period. The second-variation machinery that decides this is Section 16.4, and the statement for mechanics specifically is Remark 16.98. The physical reason the *stationary* path is the one that matters is not classical at all: in the path-integral formulation of Chapter 106 every history contributes a phase $\exp(\mathrm{i}S/\hbar)$, and neighbouring histories interfere destructively except where S is stationary.

Remark 21.48. If the potential depends on the coordinates alone, $V = V(q)$, the system is conservative: the hypotheses of Proposition 21.38 and, given scleronomous constraints, of Theorem 21.43 are met, so $h = E$ and E is constant.

Remark 21.49 (Two principles, one content). It is worth recording what has and has not been shown. d'Alembert's principle Equation (21.19) and Hamilton's principle Equation (21.53) both yield Equation (21.54) for a holonomically constrained system with forces derived from a potential, so on that class they are equivalent and the choice between them is one of convenience. They are not equivalent in general. d'Alembert's principle is the more robust of the two: it survives non-conservative forces, which merely appear as Q_a on the right-hand side, and it survives non-integrable constraints, which restrict δq^a without restricting the histories. Hamilton's principle needs a Lagrangian to exist, and needs the admissible histories to form a neighbourhood. The historical order is the reverse of the logical one: Hamilton's essays [96] came ninety years after d'Alembert and half a century after [40], and the variational principle is the later and narrower statement, not the foundation from which the rest descends [1585, 2027].

21.6 Nonholonomic constraints

Every result so far has assumed holonomic constraints. A rolling wheel does not satisfy one. The constraint that a wheel does not slip is a condition on velocities that cannot be integrated to a condition on configurations, and the whole chain of the chapter — eliminate the constraints, count the degrees of freedom, vary freely — breaks at the first link. This section states what survives, and settles a question that is often presented as a matter of taste and is not: given a non-integrable constraint, two inequivalent sets of equations can be written down, and only one of them describes a rolling body.

21.6.1 Pfaffian constraints

Definition 21.50 (Pfaffian constraint)**.** A *Pfaffian* (or *linear kinematic*) constraint on a system with generalized coordinates q^a is a condition of the form

$$A^{\alpha}{}_{a}(q,t)\,\dot{q}^a + A^{\alpha}{}_{0}(q,t) = 0\,, \qquad \alpha = 1,\dots,m\,, \tag{21.55}$$

with the $m \times f$ matrix $A^{\alpha}{}_{a}$ of rank m; throughout this section m counts the Pfaffian constraints and never denotes a mass, the masses appearing only inside the kinetic metric Equation (21.74). It is *integrable*, and the system is then holonomic after all, if the one-forms $A^{\alpha}{}_{a}\mathrm{d}q^a + A^{\alpha}{}_{0}\mathrm{d}t$ admit an invertible matrix of integrating factors turning them into exact differentials $\mathrm{d}g^{\alpha}$; the criterion is the Frobenius condition recorded in Definition 16.47. A non-integrable Equation (21.55) is called *nonholonomic*.

Rests on Definitions 16.47 and 21.2.

Remark 21.51 (What a nonholonomic constraint does and does not remove)*.* A holonomic constraint removes one configuration variable and, with it, one velocity: the counting Equation (21.5) is exact and the system genuinely lives on a lower-dimensional space. A nonholonomic constraint removes a velocity and no configuration at all. The vertical rolling disc of Example 16.48 has four configuration variables and two constraints Equation (16.44), leaving two velocity degrees of freedom — and yet every one of the four configurations is reachable, by rolling the disc round a suitable closed loop. There is therefore no reduced coordinate set to pass to, and Definition 21.9 must be read with care: the number of independent velocities and the dimension of the accessible set are different numbers, which for holonomic systems coincide. This is the mechanical content of non-integrability, and it is why the parking of a car is possible at all.

21.6.2 The d'Alembert–Chetaev prescription

The principle of virtual work is stated for virtual displacements *compatible with the constraints*, and for a Pfaffian constraint that phrase must be given a meaning, since Equation (21.55) constrains velocities and δq^a is taken at fixed time. The answer that mechanics uses is the natural one: a virtual displacement is admissible when it lies in the annihilator of the constraint forms.

Definition 21.52 (Chetaev condition)**.** A virtual displacement is *compatible* with the Pfaffian constraints Equation (21.55) if

$$A^{\alpha}{}_{a}(q,t)\,\delta q^a = 0\,, \qquad \alpha = 1,\dots,m\,. \tag{21.56}$$

The term $A^{\alpha}{}_{0}$ is absent because the displacement is taken at fixed time, exactly as in Equation (21.14).

Rests on Equation (21.55) and Definition 21.16.

Theorem 21.53 (Equations of motion of a nonholonomic system)**.** *Let $q^1,\dots,q^f$ be coordinates on the configuration space that remains after any holonomic constraints have been eliminated, so that they are unrestricted as* configurations*. For a system with Lagrangian $\mathcal{L}$ in those coordinates, subject to the Pfaffian constraints Equation (21.55) whose constraint forces do no virtual work on displacements obeying Equation (21.56), and to non-conservative generalized forces Q_a, the motion satisfies*

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) - \frac{\partial \mathcal{L}}{\partial q^a} = Q_a + \sum_{\alpha=1}^{m} \mu_{\alpha} A^{\alpha}{}_{a}\,, \qquad a = 1,\dots,f\,, \tag{21.57}$$

together with the m constraints Equation (21.55). The $f+m$ equations determine the f coordinates and the m multipliers μ_{α}, and $\sum_{\alpha}\mu_{\alpha}A^{\alpha}{}_{a}$ is the generalized constraint force.

Rests on Equations (21.19), (21.38) and (21.56).

Derivation. *Derives Theorem 21.53.*

d'Alembert's principle Equation (21.19), rewritten in generalized coordinates by the computation of Theorem 21.30 and then split as in Theorem 21.32, states that

$$\left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) - \frac{\partial \mathcal{L}}{\partial q^a} - Q_a\right] \delta q^a = 0 \tag{21.58}$$

for every δq^a obeying Equation (21.56). Unlike the holonomic case, the δq^a are now *not* arbitrary, so the bracket need not vanish; what Equation (21.58) says is that the covector in brackets annihilates the subspace $\{\delta q \mid A^\alpha{}_a \delta q^a = 0\}$ of $\mathbb{R}^f$ — the kernel of the linear map A, of dimension $f - m$ by Theorem 5.38 and the rank hypothesis. The covectors annihilating that kernel form a subspace of the dual (Definition 5.56) of dimension m, and it contains the m independent rows $A^\alpha{}_a$, so it is exactly their span. Hence there are numbers $\mu_\alpha(t)$ with

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) - \frac{\partial \mathcal{L}}{\partial q^a} - Q_a = \sum_{\alpha=1}^{m} \mu_\alpha A^\alpha{}_a \,,$$

which is Equation (21.57). They are determined algebraically: differentiating Equation (21.55) once in time gives m linear relations among the $\ddot{q}^a$, and substituting the accelerations from Equation (21.57) yields an $m \times m$ linear system for the μ_α. For a Lagrangian of the mechanical type $\mathcal{L} = T - V$ with $T = \frac{1}{2} g_{ab} \dot{q}^a \dot{q}^b$, that system has matrix $A^\alpha{}_a g^{ab} A^\beta{}_b$, with g^{ab} inverse to the kinetic metric Equation (21.74) and hence positive definite; the same one-line argument as in Proposition 21.22 makes the matrix positive definite under the rank hypothesis, so the μ_α are unique. □

Remark 21.54 (The initial-value problem). The last step is the one to hold on to. Given a configuration q^a and a velocity $\dot{q}^a$ that satisfies Equation (21.55), the multipliers μ_α follow at once, and Equation (21.57) then fixes the accelerations. The motion of a nonholonomic system is therefore determined by its mechanical state alone, exactly as a Newtonian system is. This is not a formality; it is what the next subsection turns on.

21.6.3 Why the vakonomic prescription is not the observed one

There is a second, formally impeccable way to write equations for a constrained system, and for a nonholonomic constraint it gives different answers.

Definition 21.55 (Vakonomic prescription)**.** The *vakonomic* equations of a system with Lagrangian $\mathcal{L}$ and constraints Equation (21.55) are the Euler–Lagrange equations obtained by making $S[q]$ stationary within the class of histories that *satisfy* Equation (21.55), that is by applying the multiplier rule to the augmented integrand $\mathcal{L} + \sum_\alpha \lambda_\alpha \left(A^\alpha{}_a \dot{q}^a + A^\alpha{}_0\right)$ and varying q^a and λ_α freely.

Rests on Equations (21.53) and (21.55).

Proposition 21.56 (The two prescriptions and their difference)**.** *The vakonomic equations of Definition 21.55 read*

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) - \frac{\partial \mathcal{L}}{\partial q^a} = -\sum_{\alpha=1}^{m} \dot{\lambda}_\alpha A^\alpha{}_a + \sum_{\alpha=1}^{m} \lambda_\alpha \left(C^\alpha{}_{ab}\, \dot{q}^b + c^\alpha{}_a\right) , \tag{21.59}$$

with the obstruction coefficients

$$C^\alpha{}_{ab} = \frac{\partial A^\alpha{}_b}{\partial q^a} - \frac{\partial A^\alpha{}_a}{\partial q^b} \,, \qquad c^\alpha{}_a = \frac{\partial A^\alpha{}_0}{\partial q^a} - \frac{\partial A^\alpha{}_a}{\partial t} \,. \tag{21.60}$$

If the constraint one-forms are exact, $A^\alpha{}_a = \partial g^\alpha / \partial q^a$ and $A^\alpha{}_0 = \partial g^\alpha / \partial t$, then $C^\alpha{}_{ab} = c^\alpha{}_a = 0$ identically and Equation (21.59) coincides with the d'Alembert–Chetaev equations

Equation (21.57) *with* $Q_a = 0$*, under the identification* $\mu_\alpha = -\dot\lambda_\alpha$*. Otherwise the two differ by the obstruction terms, which are exactly the components of the exterior derivative of the constraint forms — the quantity whose vanishing is the Frobenius integrability condition of Definition 21.50.*

Rests on Definition 21.55, Equation (21.57)*, and Theorem 16.41.*

Derivation. Derives Proposition 21.56.

Write $F = \mathcal{L} + \sum_\alpha \lambda_\alpha G^\alpha$ with $G^\alpha = A^\alpha{}_a \dot q^a + A^\alpha{}_0$. Varying λ_α returns Equation (21.55). For the q^a,

$$\frac{\partial F}{\partial \dot q^a} = \frac{\partial \mathcal{L}}{\partial \dot q^a} + \sum_\alpha \lambda_\alpha A^\alpha{}_a\,, \qquad \frac{\partial F}{\partial q^a} = \frac{\partial \mathcal{L}}{\partial q^a} + \sum_\alpha \lambda_\alpha \left(\frac{\partial A^\alpha{}_b}{\partial q^a}\dot q^b + \frac{\partial A^\alpha{}_0}{\partial q^a} \right),$$

and

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial F}{\partial \dot q^a}\right) = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot q^a}\right) + \sum_\alpha \dot\lambda_\alpha A^\alpha{}_a + \sum_\alpha \lambda_\alpha \left(\frac{\partial A^\alpha{}_a}{\partial q^b}\dot q^b + \frac{\partial A^\alpha{}_a}{\partial t} \right).$$

Subtracting and rearranging gives Equation (21.59) with Equation (21.60). If $A^\alpha{}_a = \partial_a g^\alpha$ and $A^\alpha{}_0 = \partial_t g^\alpha$ then every entry of Equation (21.60) is a difference of mixed second derivatives of g^α and vanishes by Proposition 7.73, leaving only the $\dot\lambda_\alpha$ term, which is Equation (21.57) with $\mu_\alpha = -\dot\lambda_\alpha$ and $Q_a = 0$. □

Example 21.57 (The difference is not small for a rolling disc)**.** For the vertical rolling disc of Example 16.48, with coordinates $(x, y, \varphi, \vartheta)$ and the constraints Equation (16.44) written as Equation (21.55),

$$A^1{}_x = 1\,, \quad A^1{}_\vartheta = -R\cos\varphi\,, \qquad A^2{}_y = 1\,, \quad A^2{}_\vartheta = -R\sin\varphi\,, \tag{21.61}$$

all other components and all $A^\alpha{}_0$ being zero. The only nonvanishing obstruction coefficients Equation (21.60) are

$$C^1{}_{\varphi\vartheta} = -C^1{}_{\vartheta\varphi} = R\sin\varphi\,, \qquad C^2{}_{\varphi\vartheta} = -C^2{}_{\vartheta\varphi} = -R\cos\varphi\,, \tag{21.62}$$

which cannot all vanish, since $\sin\varphi$ and $\cos\varphi$ have no common zero. The discrepancy between Equation (21.59) and Equation (21.57) in the φ equation is therefore $R\dot\vartheta\,(\lambda_1\sin\varphi - \lambda_2\cos\varphi)$, a term of the same order as the ones beside it whenever the disc is actually rolling ($\dot\vartheta \neq 0$) and the constraint is actually doing something ($\lambda \neq 0$). The two prescriptions are not two approximations to one answer; they are two different answers.

Rests on Equations (16.44) *and* (21.60)*.*

Remark 21.58 (Which one is observed, and how one can tell)*.* The equations of a rolling body are the d'Alembert–Chetaev ones Equation (21.57). Three things settle it, in increasing order of force.

The physical realization of the constraint. Rolling without slipping is enforced by static friction at the contact point: a real force, exerted instant by instant, whose magnitude adjusts to whatever the state requires. It does no work, because the material point of the body at the contact is instantaneously at rest, which is precisely the Chetaev condition Equation (21.56). Nothing in the physical situation restricts which histories the body is permitted to consider, which is what Definition 21.55 assumes.

Determinism. By Remark 21.54 the d'Alembert–Chetaev system fixes the motion from $(q, \dot q)$ alone. The vakonomic system does not: in Equation (21.59) the multipliers obey their own differential equations, so their initial values $\lambda_\alpha(t_0)$ are extra data, and one mechanical initial state gives rise to an m-parameter family of vakonomic motions. A disc released twice from the same place with the same velocity does the same thing twice; that observation alone excludes the vakonomic equations as a description of it, and it can be made in a lecture room.

The two answer different questions. The vakonomic equations are not wrong — they are the correct equations of the optimal-control problem in which the constraint is imposed on the admissible curves by decree and one asks which admissible curve extremizes the action. That is a real and useful problem, and the extra initial data $\lambda_\alpha(t_0)$ are what select a particular optimal trajectory in it. It is simply not the problem a rolling disc solves. The mathematical statement of the dichotomy, and the reason Theorem 16.41 does not cover the nonholonomic case, is Remark 16.49.

Two honest caveats. First, the standard mechanics texts [1585, 2027] present Equation (21.57) as the equations of a nonholonomic system, and the derivation above is theirs in substance; but this treatise's bibliography holds no reference reporting a controlled *experiment* that discriminates the two prescriptions on a rolling body, and the claim of observational adequacy above therefore rests on the accumulated agreement of nonholonomic rigid-body dynamics with measurement — the rolling and spinning experiments of Chapter 29 — rather than on a single cited test. Second, systems whose constraints are not imposed from outside but follow from a degenerate Lagrangian are a third case entirely, governed by the Dirac–Bergmann algorithm of Chapter 26, and nothing here applies to them.

21.7 General coordinate transformations

Generalized coordinates were introduced in Section 21.1.3 as *any* independent set of labels sufficient to locate the system in its configuration space: lengths, angles, or arbitrary mixtures of them, chosen for convenience and carrying no privileged status. That freedom has a consequence which is easy to state and hard to overstate: the equations of motion must not care which labels were chosen. This section proves that they do not, identifies the geometric objects that appear when one changes labels, and—in Section 21.8—shows that the same structure recurs verbatim in special and general relativity. The machinery is the differential geometry of Chapter 13, instantiated here on configuration space.

Remark 21.59 (Indices in this section). The conventions of Notation 21.1 continue to apply: $a, b, \dots$ label the f generalized coordinates. They are *not* the frame indices of Section 13.1, which label directions in spacetime; where spacetime enters, in Section 21.8.1, it carries $\mu, \nu, \dots$ as usual.

21.7.1 Point transformations

Definition 21.60 (Point transformation)**.** A *point transformation* is a change of generalized coordinates

$$Q^a = Q^a\big(q^1, \dots, q^f, t\big) \,, \qquad a = 1, \dots, f \,, \tag{21.63}$$

that is smooth and invertible, i.e. whose Jacobian $J^a{}_b = \frac{\partial Q^a}{\partial q^b}$ is everywhere nonsingular, $\det J \neq 0$. When Equation (21.63) carries an explicit t the transformation is *time-dependent*; a rotating or accelerating frame is of this kind.

Differentiating Equation (21.63) along a trajectory gives the induced transformation of the generalized velocities,

$$\dot{Q}^a = \frac{\partial Q^a}{\partial q^b}\,\dot{q}^b + \frac{\partial Q^a}{\partial t} \,, \tag{21.64}$$

which is affine—not linear—in the velocities whenever the transformation depends on time. Two identities follow from Equation (21.64) and are used repeatedly; the first is the "cancellation of the dots" already met at Equation (21.35), in the special case $q \to x$.

Lemma 21.61 (Cancellation of the dots; commutation of the derivatives)**.** *For any point transformation,*

$$\frac{\partial \dot{Q}^a}{\partial \dot{q}^b} = \frac{\partial Q^a}{\partial q^b}\,, \tag{21.65}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial Q^a}{\partial q^b}\right) = \frac{\partial \dot{Q}^a}{\partial q^b}\,. \tag{21.66}$$

Derivation. The right-hand side of Equation (21.64) contains $\dot{q}^b$ only in the first term, and there linearly with coefficient $\frac{\partial Q^a}{\partial q^b}$, which is a function of q and t alone; differentiating with respect to $\dot{q}^b$ therefore gives Equation (21.65). For Equation (21.66), expand the total time derivative of $\frac{\partial Q^a}{\partial q^b}(q,t)$ by the chain rule and compare with the q^b-derivative of Equation (21.64):

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial Q^a}{\partial q^b} = \frac{\partial^2 Q^a}{\partial q^c \partial q^b}\dot{q}^c + \frac{\partial^2 Q^a}{\partial t\,\partial q^b} = \frac{\partial}{\partial q^b}\left(\frac{\partial Q^a}{\partial q^c}\dot{q}^c + \frac{\partial Q^a}{\partial t}\right) = \frac{\partial \dot{Q}^a}{\partial q^b}\,,$$

the middle step using the symmetry of mixed partial derivatives (Proposition 7.73) and the independence of q^c and $\dot{q}^c$ as coordinates on velocity phase space, so that $\dot{q}^c$ is held fixed by $\partial/\partial q^b$. □

21.7.2 Covariance of the Euler–Lagrange equations

Definition 21.62 (Euler–Lagrange operator)**.** For a Lagrangian $\mathcal{L}$ the *Euler–Lagrange operator* is

$$\mathcal{E}_a[\mathcal{L}] \equiv \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^a}\right) - \frac{\partial \mathcal{L}}{\partial q^a}\,, \tag{21.67}$$

so that the equations of motion Equation (21.39) read $\mathcal{E}_a[\mathcal{L}] = 0$. When a second chart Q^a is in play, $\widetilde{\mathcal{E}}_a[\widetilde{\mathcal{L}}]$ denotes the same operator formed with $Q^a, \dot{Q}^a$ in place of $q^a, \dot{q}^a$.

Theorem 21.63 (Covariance of the Euler–Lagrange equations)**.** *Let $\mathcal{L}$ be a Lagrangian and let $\widetilde{\mathcal{L}}(Q,\dot{Q},t) = \mathcal{L}\Big(q(Q,t), \dot{q}(Q,\dot{Q},t), t\Big)$ be its expression in new coordinates related to the old by a point transformation Equation (21.63). Then the Euler–Lagrange operator transforms as a covector,*

$$\mathcal{E}_b[\mathcal{L}] = \frac{\partial Q^a}{\partial q^b}\,\widetilde{\mathcal{E}}_a[\widetilde{\mathcal{L}}]\,. \tag{21.68}$$

Consequently $\mathcal{E}_b[\mathcal{L}] = 0$ if and only if $\widetilde{\mathcal{E}}_a[\widetilde{\mathcal{L}}] = 0$: the Euler–Lagrange equations hold in one system of generalized coordinates precisely when they hold in every other.

Derivation. Since the transformation is invertible, the defining relation may be read as $\mathcal{L}(q,\dot{q},t) = \widetilde{\mathcal{L}}\Big(Q(q,t), \dot{Q}(q,\dot{q},t), t\Big)$, and it is this composition that is differentiated below. As $\mathcal{L}$ and $\widetilde{\mathcal{L}}$ are the same function of the physical state in different labels, the chain rule gives

$$\frac{\partial \mathcal{L}}{\partial \dot{q}^b} = \frac{\partial \widetilde{\mathcal{L}}}{\partial \dot{Q}^a}\frac{\partial \dot{Q}^a}{\partial \dot{q}^b} = \frac{\partial \widetilde{\mathcal{L}}}{\partial \dot{Q}^a}\frac{\partial Q^a}{\partial q^b}\,, \tag{21.69}$$

using Equation (21.65); note that $\frac{\partial Q^a}{\partial \dot{q}^b} = 0$, because Q depends on q and t only. Differentiating Equation (21.69) totally in time,

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}^b}\right) = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \widetilde{\mathcal{L}}}{\partial \dot{Q}^a}\right)\frac{\partial Q^a}{\partial q^b} + \frac{\partial \widetilde{\mathcal{L}}}{\partial \dot{Q}^a}\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial Q^a}{\partial q^b}\right)\,. \tag{21.70}$$

The other term of the operator, again by the chain rule, is

$$\frac{\partial \mathcal{L}}{\partial q^b} = \frac{\partial \widetilde{\mathcal{L}}}{\partial Q^a}\frac{\partial Q^a}{\partial q^b} + \frac{\partial \widetilde{\mathcal{L}}}{\partial \dot{Q}^a}\frac{\partial \dot{Q}^a}{\partial q^b}\,. \tag{21.71}$$

Subtracting Equation (21.71) from Equation (21.70), the two terms carrying $\frac{\partial \widetilde{\mathcal{L}}}{\partial \dot{Q}^a}$ cancel by Equation (21.66), and what remains is

$$\mathcal{E}_b[\mathcal{L}] = \left[\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial \widetilde{\mathcal{L}}}{\partial \dot{Q}^a}\right) - \frac{\partial \widetilde{\mathcal{L}}}{\partial Q^a}\right]\frac{\partial Q^a}{\partial q^b} = \widetilde{\mathcal{E}}_a[\widetilde{\mathcal{L}}]\,\frac{\partial Q^a}{\partial q^b}\,,$$

which is Equation (21.68). The final claim follows because the Jacobian is invertible (Definition 21.60): a covector vanishes in one basis exactly when it vanishes in all. □

Remark 21.64 (Why this is automatic). There is a one-line reason behind the computation. The action Equation (21.52) is a *number* attached to a path—a scalar, independent of how the path is labelled—and Hamilton's principle (Theorem 21.46) characterizes the motion as a stationary point of that number. Stationarity is a property of the functional, not of the chart used to write it, so the resulting equations cannot depend on the chart either. Theorem 21.63 is that observation made explicit, and Equation (21.68) records the precise sense in which it holds: not that the components $\mathcal{E}_a$ are unchanged, but that they transform as the components of a covector, which is what makes the statement $\mathcal{E}_a = 0$ coordinate-independent.

Remark 21.65 (Gauge freedom of the Lagrangian). A second, distinct freedom leaves the equations of motion untouched: adding to $\mathcal{L}$ the total time derivative of any function $F(q,t)$,

$$\mathcal{L}' = \mathcal{L} + \frac{\mathrm{d}F(q,t)}{\mathrm{d}t}\,, \tag{21.72}$$

changes the action only by the boundary term $F(q_b,t_b) - F(q_a,t_a)$, which is fixed once the endpoints are fixed and therefore does not affect the variation. The Lagrangian of a system is thus not unique; only its equivalence class modulo point transformations and total derivatives is physical.

That the equations are untouched can also be seen without mentioning the boundary at all, and this is the sharper statement: the Euler–Lagrange operator annihilates a total time derivative *identically*, on every curve, extremal or not. Writing $G = \mathrm{d}F(q,t)/\mathrm{d}t = \left(\partial F/\partial q^b\right)\dot{q}^b + \partial F/\partial t$ for F of class C^2, the velocity derivative of G is $\partial G/\partial \dot{q}^a = \partial F/\partial q^a$, so

$$\mathcal{E}_a[G] = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial F}{\partial q^a}\right) - \frac{\partial G}{\partial q^a} = \left(\frac{\partial^2 F}{\partial q^b \partial q^a}\dot{q}^b + \frac{\partial^2 F}{\partial t\,\partial q^a}\right) - \left(\frac{\partial^2 F}{\partial q^a \partial q^b}\dot{q}^b + \frac{\partial^2 F}{\partial q^a \partial t}\right) = 0 \tag{21.73}$$

by the symmetry of mixed partial derivatives (Proposition 7.73). Since $\mathcal{E}_a$ is linear in its argument, $\mathcal{E}_a[\mathcal{L}'] = \mathcal{E}_a[\mathcal{L}]$, which is the claim. A function with $\mathcal{E}_a \equiv 0$ is called a *null Lagrangian*; in one independent variable Equation (21.73) has a converse, every null Lagrangian being a total derivative, and it is the freedom Equation (21.72) that reappears as the gauge freedom of the electromagnetic potentials and as the boundary terms that must be added to the Einstein–Hilbert action.

21.7.3 The kinetic metric and the geodesic form

Covariance says the equations keep their *form*. The next question is what objects appear in that form, and the answer is the metric and connection of Chapter 13.

For a system of particles with $T = \frac{1}{2}\sum_i m_i\,\dot{\boldsymbol{x}}_i \cdot \dot{\boldsymbol{x}}_i$ and time-independent constraints, substituting $\dot{\boldsymbol{x}}_i = \frac{\partial \boldsymbol{x}_i}{\partial q^a}\dot{q}^a$ (Equation (21.34) with $\frac{\partial \boldsymbol{x}}{\partial t} = 0$) gives a quadratic form in the generalized velocities.

Definition 21.66 (Kinetic metric)**.** The *kinetic metric* of such a system is the symmetric, positive-definite $(0,2)$ tensor field on configuration space

$$g_{ab}(q) = \sum_i m_i \frac{\partial \boldsymbol{x}_i}{\partial q^a} \cdot \frac{\partial \boldsymbol{x}_i}{\partial q^b}\,, \qquad \text{so that} \qquad T = \tfrac{1}{2}\, g_{ab}(q)\, \dot q^a \dot q^b\,. \tag{21.74}$$

It is a metric in the sense of Definition 13.117, of signature $(f,0)$: configuration space is a Riemannian manifold, and $2T\,\mathrm{d}t^2$ is its line element.

Theorem 21.67 (Free motion is geodesic motion)**.** *For $\mathcal{L} = T = \frac{1}{2} g_{ab}(q)\dot q^a \dot q^b$ with no potential, the Euler–Lagrange equations are the autoparallel equation of the Levi-Civita connection of g_{ab},*

$$\ddot q^c + \mathring{\Gamma}^c{}_{ab}\, \dot q^a \dot q^b = 0\,, \qquad \mathring{\Gamma}^c{}_{ab} = \tfrac{1}{2} g^{cd}\left(\partial_a g_{db} + \partial_b g_{ad} - \partial_d g_{ab}\right)\,, \tag{21.75}$$

with $\mathring{\Gamma}$ exactly the Christoffel symbols of Theorem 13.150.

Derivation. From Equation (21.74), $\frac{\partial \mathcal{L}}{\partial \dot q^c} = g_{cb}\dot q^b$ (using $g_{ab} = g_{ba}$) and $\frac{\partial \mathcal{L}}{\partial q^c} = \frac{1}{2}\,\partial_c g_{ab}\,\dot q^a \dot q^b$. Hence

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(g_{cb}\dot q^b\right) - \tfrac{1}{2}\,\partial_c g_{ab}\,\dot q^a \dot q^b = g_{cb}\ddot q^b + \partial_a g_{cb}\,\dot q^a \dot q^b - \tfrac{1}{2}\,\partial_c g_{ab}\,\dot q^a \dot q^b = 0\,.$$

The middle term is contracted with the symmetric $\dot q^a \dot q^b$, so only its symmetric part in ab contributes; replacing it by $\frac{1}{2}\left(\partial_a g_{cb} + \partial_b g_{ca}\right)$ and multiplying through by g^{dc},

$$\ddot q^d + \tfrac{1}{2} g^{dc}\left(\partial_a g_{cb} + \partial_b g_{ca} - \partial_c g_{ab}\right)\dot q^a \dot q^b = 0\,,$$

which is Equation (21.75). □

Remark 21.68 (Reading the result). A free system does not travel in straight lines through configuration space; it travels along the *straightest available* lines, the autoparallels of the metric its own kinetic energy defines. With a potential the right-hand side acquires $-g^{cd}\partial_d V$, so V acts as a force pushing the motion off the geodesics. Every statement here is the general apparatus of Section 13.10 specialized to a Riemannian configuration space.

21.7.4 Inertial forces are connection coefficients

The Christoffel symbols in Equation (21.75) are built from derivatives of g_{ab}, and g_{ab} depends on the coordinates chosen. They therefore do not vanish merely because the physics is simple—as the flattest possible example shows.

Example 21.69 (A free particle in plane polar coordinates)**.** For one particle of mass m in a plane, Cartesian coordinates give $T = \frac{m}{2}\left(\dot x^2 + \dot y^2\right)$, so $g_{ab} = m\,\delta_{ab}$, all $\partial_c g_{ab} = 0$, all $\mathring{\Gamma} = 0$, and Equation (21.75) reads $\ddot x = \ddot y = 0$. Passing to polar coordinates $x = r\cos\varphi$, $y = r\sin\varphi$—a point transformation Equation (21.63)—the same kinetic energy becomes

$$T = \frac{m}{2}\left(\dot r^2 + r^2\dot\varphi^2\right)\,, \qquad g_{ab} = m\begin{pmatrix} 1 & 0 \\ 0 & r^2 \end{pmatrix}\,, \tag{21.76}$$

on the chart $r > 0$, where the polar labelling is nondegenerate (at $r = 0$ the metric Equation (21.76) degenerates and g^{ab} fails to exist — a defect of the labels, not of the plane). Its only nonvanishing Christoffel symbols are

$$\mathring{\Gamma}^r{}_{\varphi\varphi} = -r\,, \qquad \mathring{\Gamma}^\varphi{}_{r\varphi} = \mathring{\Gamma}^\varphi{}_{\varphi r} = \frac{1}{r}\,. \tag{21.77}$$

The overall factor m has cancelled, as it must: $\mathring{\Gamma}$ is invariant under a constant rescaling $g \to \lambda g$, the λ from differentiating the metric cancelling the λ^{-1} from its inverse. Mass sets

the scale of the metric but not of the connection. The geodesic equation Equation (21.75) then gives

$$\ddot{r} - r\dot{\varphi}^2 = 0\,, \qquad \ddot{\varphi} + \frac{2}{r}\dot{r}\dot{\varphi} = 0\,, \tag{21.78}$$

in which one recognizes the centripetal term $-r\dot{\varphi}^2$ and the Coriolis-like term $2\dot{r}\dot{\varphi}/r$. These are the same straight lines as before, described in different labels.

Remark 21.70 (The lesson: connection $\neq$ curvature). Example 21.69 is worth pausing on, because it isolates a distinction that the rest of this treatise depends upon. The Christoffel symbols Equation (21.77) are not zero, yet the plane is flat: inserting the symbols Equation (21.77) into the Riemann tensor Equation (13.306) gives $R^a{}_{bcd} = 0$ identically, as it must, since curvature is a tensor (Theorem 13.152) and vanishes in the Cartesian chart.

So *in a flat space* a nonvanishing connection means only one of two things, which are worth separating. Curvilinear coordinates in an inertial frame — Example 21.69 — produce $\mathring{\Gamma}$ terms that are pure bookkeeping: no observer feels anything, and an accelerometer carried along reads zero. A non-inertial frame, obtained by a *time-dependent* point transformation, produces $\mathring{\Gamma}$ terms that an accelerometer does register; these are the *inertial* (fictitious) forces of Definition 21.19 proper — centrifugal, Coriolis and their relatives. What the two cases share is that both are removable everywhere at once, by returning to inertial Cartesian coordinates, and they are removable precisely because $R^a{}_{bcd} = 0$. Curvature is what cannot be removed. Keeping these apart is what makes the equivalence principle a sharp statement rather than a slogan (Chapter 42).

21.8 The universality of general covariance

Nothing in Section 21.7.2 used the number of particles, the signature of the metric, or the presence of gravity. The construction is generic, and it is worth stating plainly how far it reaches, because the same formalism is often presented as though it were the private property of general relativity.

21.8.1 Flat spacetime in arbitrary coordinates

Special relativity is usually written in inertial Cartesian coordinates, in which the metric takes the constant form $\eta_{\mu\nu}$ of Equation (13.1). Nothing compels that choice. Minkowski space is a manifold (Chapter 13), its coordinates are labels, and a general coordinate transformation $x^\mu \to x'^\mu(x)$ is as legitimate there as a point transformation is in mechanics.

Definition 21.71 (Relativistic free particle)**.** Let the worldline be timelike and future-directed, parametrized monotonically by any λ, so that $g_{\mu\nu}\dot{x}^\mu\dot{x}^\nu < 0$ in the signature $(-,+,+,+)$ used throughout (Appendix E). Proper time is then defined by $c^2\mathrm{d}\tau^2 = -g_{\mu\nu}\,\mathrm{d}x^\mu\mathrm{d}x^\nu$, and the action of a free massive particle is proportional to the proper time elapsed along the worldline,

$$S = -mc^2\int \mathrm{d}\tau = -mc\int \sqrt{-g_{\mu\nu}(x)\,\frac{\mathrm{d}x^\mu}{\mathrm{d}\lambda}\frac{\mathrm{d}x^\nu}{\mathrm{d}\lambda}}\;\mathrm{d}\lambda\,. \tag{21.79}$$

Two independent invariances hold, for two different reasons. The integrand is a *scalar*, which makes S independent of the coordinates x^μ; and it is *homogeneous of degree one* in $\mathrm{d}x^\mu/\mathrm{d}\lambda$, which makes S independent of the parametrization. The timelike hypothesis is what keeps the square root real.

Remark 21.72 (Sign conventions). With the mostly-plus signature this treatise uses, the interval itself is $\mathrm{d}s^2 = g_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu$, *negative* on a timelike worldline, so $\mathrm{d}s$ is not the proper

distance travelled by a massive particle and $c^2 \mathrm{d}\tau^2 = -\mathrm{d}s^2$. Writing the action in terms of $\mathrm{d}\tau$ rather than $\mathrm{d}s$, as in Equation (21.79), keeps this consistent with the interval classification of Chapter 38 and with Example 21.74 below. A timelike geodesic *maximizes* proper time, so the leading minus sign is what makes S stationary at a minimum.

Proposition 21.73 (Free motion in flat spacetime, any coordinates)**.** *Extremizing Equation* (21.79) *with $g_{\mu\nu}$ the flat metric written in arbitrary coordinates, and choosing $\lambda = \tau$ the proper time, gives*

$$\frac{\mathrm{d}^2 x^\mu}{\mathrm{d}\tau^2} + \mathring{\Gamma}^\mu{}_{\nu\rho} \frac{\mathrm{d}x^\nu}{\mathrm{d}\tau} \frac{\mathrm{d}x^\rho}{\mathrm{d}\tau} = 0\,, \tag{21.80}$$

the same geodesic equation as Equation (21.75)*, now on spacetime. In inertial Cartesian coordinates $\mathring{\Gamma} = 0$ and it reduces to $\mathrm{d}^2 x^\mu / \mathrm{d}\tau^2 = 0$, uniform motion.*

Rests on Equations (21.75) *and* (21.79) *and Theorem 13.150.*

Derivation. *Derives Proposition 21.73.*

Write $\dot{x}^\mu = \mathrm{d}x^\mu/\mathrm{d}\lambda$ and

$$\mathcal{L}_1 = -mc\,u\,, \qquad u := \sqrt{-g_{\mu\nu}\dot{x}^\mu \dot{x}^\nu} > 0\,, \tag{21.81}$$

so that $S = \int \mathcal{L}_1 \mathrm{d}\lambda$ is Equation (21.79); u carries m/s if λ is a time, and $\mathcal{L}_1 \mathrm{d}\lambda$ is an action in J s whatever λ is, since $u\,\mathrm{d}\lambda = c\,\mathrm{d}\tau$. Differentiating Equation (21.81),

$$\frac{\partial \mathcal{L}_1}{\partial \dot{x}^\mu} = \frac{mc}{u} g_{\mu\nu}\dot{x}^\nu\,, \qquad \frac{\partial \mathcal{L}_1}{\partial x^\mu} = \frac{mc}{2u} \partial_\mu g_{\nu\rho}\, \dot{x}^\nu \dot{x}^\rho\,, \tag{21.82}$$

and the Euler–Lagrange equation $\mathcal{E}_\mu[\mathcal{L}_1] = 0$ of Equation (21.67) reads

$$\frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{mc}{u} g_{\mu\nu}\dot{x}^\nu\right) - \frac{mc}{2u}\partial_\mu g_{\nu\rho}\dot{x}^\nu \dot{x}^\rho = 0\,. \tag{21.83}$$

Nothing has been assumed about λ so far, and nothing could be: $\mathcal{L}_1$ is homogeneous of degree one in the $\dot{x}^\mu$, so S is unchanged by any monotone reparametrization, and the four equations Equation (21.83) are not independent — contracting them with $\dot{x}^\mu$ gives $0 = 0$ identically. That is the degeneracy of Corollary 16.94, and it is what leaves one function's worth of freedom to be fixed by a gauge choice, exactly as the arclength gauge is imposed *after* the differentiation in Lemma 16.100.

Fix it by $\lambda = \tau$, legitimate because the worldline is timelike and future-directed, so τ is a strictly increasing function of any admissible λ and $u = c$ identically along the curve. With u constant, Equation (21.83) may be divided by $mc/u = m$:

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\left(g_{\mu\nu}\frac{\mathrm{d}x^\nu}{\mathrm{d}\tau}\right) - \tfrac{1}{2}\,\partial_\mu g_{\nu\rho}\frac{\mathrm{d}x^\nu}{\mathrm{d}\tau}\frac{\mathrm{d}x^\rho}{\mathrm{d}\tau} = 0\,.$$

Expanding the derivative, replacing $\partial_\nu g_{\mu\rho}$ by its part symmetric in $\nu\rho$ (the only part that survives contraction with $\mathrm{d}x^\nu/\mathrm{d}\tau\,\mathrm{d}x^\rho/\mathrm{d}\tau$) and multiplying by $g^{\sigma\mu}$ gives Equation (21.80), with $\mathring{\Gamma}$ the Christoffel symbols of Theorem 13.150 — the identical algebra as in the proof of Theorem 21.67, with g_{ab} replaced by $g_{\mu\nu}$.

Finally, the equivalence with the quadratic Lagrangian $\mathcal{L}_2 = \frac{1}{2} m\, g_{\mu\nu}\dot{x}^\mu \dot{x}^\nu$ used in Theorem 21.67. $\mathcal{L}_2$ has no explicit λ, so Theorem 16.29 makes $\dot{x}^\mu \partial \mathcal{L}_2/\partial \dot{x}^\mu - \mathcal{L}_2 = \mathcal{L}_2$ constant along its extremals; hence u is automatically constant for $\mathcal{L}_2$, and normalizing that constant to $u = c$ selects proper time. Under that normalization the two Lagrangians have the same extremals: $\mathcal{E}_\mu[\mathcal{L}_2] = 0$ is the display above multiplied by m. The square-root form is the one with a geometric meaning (Equation (21.79)); the quadratic form is the one that is easier to vary, and $\mathcal{L}_2$ is what will be used whenever a computation is wanted. Note that $\mathcal{L}_2$ is *not* reparametrization invariant — it fixes λ to be affine — which is exactly the trade being made. □

Example 21.74 (Rindler coordinates)**.** The coordinates natural to a uniformly accelerated observer in flat spacetime are

$$ct = X\sinh\!\left(\frac{aT}{c}\right), \qquad x = X\cosh\!\left(\frac{aT}{c}\right), \qquad X > 0\,, \tag{21.84}$$

covering the wedge $x > |ct|$. Differentiating and substituting into $\mathrm{d}s^2 = -c^2\mathrm{d}t^2 + \mathrm{d}x^2$, the cross terms cancel and the hyperbolic identity $\cosh^2 - \sinh^2 = 1$ leaves

$$\mathrm{d}s^2 = -\frac{a^2X^2}{c^2}\,\mathrm{d}T^2 + \mathrm{d}X^2\,, \tag{21.85}$$

a metric with nonconstant components and hence nonvanishing Christoffel symbols. Both statements can be checked in a few lines, and it is worth doing so, because the example carries the whole distinction of Remark 21.70.

The transverse directions y, z are untouched by Equation (21.84) and contribute $\mathrm{d}y^2+\mathrm{d}z^2$ with constant components, so only the (T, X) block of Equation (21.85) can produce anything. There $g_{TT} = -a^2X^2/c^2$ and $g_{XX} = 1$ are diagonal and depend on X alone, so Equation (21.75) gives, for the only two nonvanishing symbols,

$$\mathring{\Gamma}^X{}_{TT} = -\tfrac{1}{2}g^{XX}\partial_X g_{TT} = \frac{a^2X}{c^2}\,, \qquad \mathring{\Gamma}^T{}_{TX} = \mathring{\Gamma}^T{}_{XT} = \tfrac{1}{2}g^{TT}\partial_X g_{TT} = \frac{1}{X}\,, \tag{21.86}$$

carrying $\mathrm{m/s^2}$ and $1/\mathrm{m}$ respectively, which is what makes every term of Equation (21.80) dimensionally uniform. An observer at fixed X has $\mathrm{d}X/\mathrm{d}\tau = 0$ and, from Equation (21.85), $\mathrm{d}T/\mathrm{d}\tau = c^2/(aX)$; the only nonvanishing component of the four-acceleration $A^\mu = \mathrm{d}^2x^\mu/\mathrm{d}\tau^2 + \mathring{\Gamma}^\mu{}_{\nu\rho}\,(\mathrm{d}x^\nu/\mathrm{d}\tau)\,(\mathrm{d}x^\rho/\mathrm{d}\tau)$ is therefore

$$A^X = \mathring{\Gamma}^X{}_{TT}\left(\frac{\mathrm{d}T}{\mathrm{d}\tau}\right)^2 = \frac{a^2X}{c^2}\cdot\frac{c^4}{a^2X^2} = \frac{c^2}{X}\,, \tag{21.87}$$

whose magnitude, g_{XX} being unity, is c^2/X: the observer must accelerate to stay put, and feels a weight, exactly as the connection terms of Equation (21.80) predict. It equals a only on the worldline $X = c^2/a$, which is also the only one on which Equation (21.85) makes T the proper time.

And yet the curvature vanishes. With only the two symbols Equation (21.86), and both independent of T, the (T, X) block has a single independent curvature component (Proposition 13.154), and Equation (13.306) gives

$$R^T{}_{XTX} = \partial_T\mathring{\Gamma}^T{}_{XX} - \partial_X\mathring{\Gamma}^T{}_{TX} + \mathring{\Gamma}^T{}_{T\lambda}\mathring{\Gamma}^\lambda{}_{XX} - \mathring{\Gamma}^T{}_{X\lambda}\mathring{\Gamma}^\lambda{}_{TX} = 0 + \frac{1}{X^2} + 0 - \frac{1}{X^2} = 0\,, \tag{21.88}$$

the two surviving terms being $-\partial_X(1/X)$ and $-\mathring{\Gamma}^T{}_{XT}\mathring{\Gamma}^T{}_{TX}$. So $R^\mu{}_{\nu\rho\sigma} = 0$ identically, as it must, curvature being a tensor (Theorem 13.152) that vanishes in the inertial Cartesian chart. This is flat spacetime in curvilinear clothing, and $X = 0$ is a horizon where the chart degenerates, not a place where anything happens to the spacetime.

Rests on Equations (21.75) *and* (21.85) *and Theorem 13.152.*

21.8.2 What general relativity adds

The three settings just surveyed share their entire formal apparatus: a manifold of states, a metric, its Levi-Civita connection, geodesics as free motion, and equations of motion that hold in any coordinates whatever. Table 21.1 sets them side by side.

Example 21.75 (Configuration space can itself be curved)**.** It would be tidy, but false, to say that curvature is what separates mechanics from gravitation. A particle constrained

Table 21.1: One formalism, three instantiations. General covariance — the freedom to relabel — is present in all three and therefore distinguishes none of them. Nor does curvature as such (Example 21.75): what distinguishes general relativity is that the curved manifold is spacetime itself, and that its geometry is dynamical rather than fixed in advance.

	Classical mechanics	Special relativity	General relativity
Manifold	configuration space, f degrees of freedom	Minkowski spacetime, $3+1$	spacetime, $3+1$
Metric	kinetic metric $g_{ab}(q)$, signature $(f,0)$ (time-independent constraints)	$\eta_{\mu\nu}$ in any coordinates, $(3,1)$	$g_{\mu\nu}(x)$, $(3,1)$
Relabelling	point transformations $Q(q,t)$; the geometric rows assume $Q(q)$	general coordinate transformations	general coordinate transformations
Free motion	geodesics of g_{ab}, for $V=0$	geodesics of η	geodesics of $g_{\mu\nu}$
Connection	may be nonzero (curvilinear coordinates)	may be nonzero (accelerated frames)	generally nonzero
Curvature	$R^{a}{}_{bcd}$ may be nonzero: constrained systems have genuinely curved configuration spaces	$R^{\mu}{}_{\nu\rho\sigma}=0$ always: spacetime is flat	$R^{\mu}{}_{\nu\rho\sigma}$ generically nonzero and *dynamical*: the field equations fix its Ricci part from $T_{\mu\nu}$, while the Weyl part propagates

to a sphere of radius ρ has $T = \frac{m\rho^2}{2}\left(\dot\theta^2 + \sin^2\theta\,\dot\varphi^2\right)$, so its kinetic metric Equation (21.74) is $m\rho^2$ times the round metric on the unit sphere. Its Gaussian curvature is therefore $K = 1/(m\rho^2)$ — carrying units $1/(\mathrm{kg\,m^2})$, as the SI axiom demands of the curvature of a metric whose components are masses times areas, and *not* the $1/\rho^2$ of the geometric sphere in Example 13.33, which is a different metric. The distinction is one of scale only: the $(1,3)$ tensor $R^a{}_{bcd}$ is invariant under the constant rescaling $g \to \lambda g$, so it is the same as the geometric sphere's and is nonzero either way. Free trajectories are the great circles, geodesics of a genuinely curved space. The same holds for the double pendulum and for rigid-body rotation.

What distinguishes general relativity is therefore not curvature as such, but *which* manifold is curved and what determines it: in mechanics the curvature belongs to an abstract space of configurations and is fixed once the constraints are imposed by hand, whereas in general relativity it belongs to spacetime itself and is dynamical — its Ricci part fixed algebraically by the local energy–momentum, its Weyl part propagating as a field in its own right (Chapter 44).

Three conclusions follow, and they are the point of this section.

1. **General covariance by itself carries little physical content.** The freedom to use arbitrary coordinates is available in Newtonian mechanics (Theorem 21.63) and in flat spacetime (Proposition 21.73) just as much as in curved spacetime, so a theory written covariantly is not thereby a theory of gravity. This is Kretschmann's objection to Einstein, raised in 1917 [454]: essentially any theory can be put in generally covariant form. The price, usually left unsaid, is that covariantizing a theory with fixed background structure requires promoting that structure to explicit fields — Newtonian gravity becomes Newton–Cartan theory — so what does real work is not general covariance but *background independence*, the absence of non-dynamical absolute objects. Whether, and in what form, general covariance retains physical content has been disputed for a century and is not settled here [1869]; the position this treatise takes is the majority one just stated.

2. **The value of the connection at a point carries no invariant information; curvature does.** $\mathring{\Gamma}$ is not a tensor (Equation (13.296)), and for a torsion-free connection its components can always be made to vanish *at any chosen point* — indeed along an entire geodesic, which is what an extended freely falling observer enjoys. What cannot be done, once the space is curved, is to make them vanish throughout a neighbourhood, however small. The Riemann tensor is a tensor (Theorem 13.152): nonzero in one chart, nonzero in all, and no relabelling removes it. Inertial forces belong to the first category and tidal forces to the second, which is why the observable *local* content of gravity is tidal (Section 43.2). "Local" is not idle: a flat connection can still carry global physical content through its holonomy, as the conical geometry around a cosmic string shows, so vanishing curvature guarantees removability only region by region.

3. **The equivalence principle is what licenses describing gravity by a connection at all.** Its empirical core is the universality of free fall: all test bodies fall identically, whatever their mass or composition — the content of the Eötvös-type experiments of Chapter 42. That universality is what makes a gravitational field describable as a property of spacetime rather than as a force with body-dependent couplings, and it is not a theorem but a measured fact. (The stronger forms add local Lorentz invariance and local position invariance, and extend the claim to self-gravitating bodies.)

   Once gravity is represented by a metric connection, the vanishing of $\mathring{\Gamma}$ in a freely falling frame follows as *geometry*, not as further physics: Riemann normal coordinates

make $\mathring{\Gamma}$ vanish at any chosen point, and Fermi normal coordinates make it vanish along an entire freely falling worldline, for any metric whatever. What no choice of chart can do is make $\mathring{\Gamma}$ vanish on an open neighbourhood, because the second derivatives of the metric there carry the curvature, which is a tensor: tidal deviation between neighbouring free-fall trajectories enters at second order in the separation and is chart-independent. That is the precise sense in which the equivalence principle is *local*, and the failure is not merely "global". Gravity is thus the one "inertial force" that relabelling removes along a worldline but never on a neighbourhood of it, and that irremovability *is* spacetime curvature. This is the bridge from the present chapter to Part V.

Remark 21.76 (Where the mathematics lives). Every geometric object used above — manifold, chart, metric, connection, geodesic, curvature — is defined once and in full generality, for dimension $D = p + q$ and signature (p, q), in Chapter 13. This chapter has developed no new mathematics; it has pointed out that the mathematics classical mechanics has used since Lagrange is the mathematics general relativity uses, and that what separates the theories is not the language but the physics it is asked to describe: in mechanics the geometry is a bookkeeping device for constraints imposed by hand, while in general relativity the geometry of spacetime is itself the dynamical variable, determined by its own field equations.

With the Lagrangian formulation complete, the natural next step is to trade the generalized velocities for the generalized momenta Equation (21.43) as independent variables. That exchange—the Legendre transformation of the Lagrangian—produces the Hamiltonian formulation of mechanics, developed in Chapter 22.

Chapter 22

Hamiltonian Mechanics

The Lagrangian formulation of Chapter 21 describes a system with f degrees of freedom by the generalized coordinates q^a and their velocities $\dot{q}^a$. The Hamiltonian formulation trades the velocities for the generalized momenta $p_a = \partial\mathcal{L}/\partial\dot{q}^a$, and in doing so moves the dynamics onto *phase space*, the $2f$-dimensional space of the pairs (q^a, p_a). The reward for the exchange is structural: the equations of motion become a symmetric first-order system, the transformations that preserve their form—the canonical transformations—constitute a far larger class than the point transformations of Lagrangian mechanics, and the whole dynamics is expressed through a single algebraic operation, the Poisson bracket [1585, 2027].

Notation 22.1. The index conventions of Notation 21.1 remain in force; additionally $c, d, e = 1, \dots, 2f$ label phase-space components. Poisson brackets are written with braces, $\{u, v\}$, and Lagrange brackets with square brackets, $[u, v]$, a subscript indicating the coordinate pair in which they are computed.

22.1 From the Lagrangian to the Hamiltonian

22.1.1 The Legendre transformation of the Lagrangian

The generalized momentum conjugate to the coordinate q^a was defined in Definition 21.34 as $p_a = \partial\mathcal{L}/\partial\dot{q}^a$. It is the variable that replaces the generalized velocity in the description that follows.

Definition 22.2 (Hamiltonian)**.** The *Hamiltonian* of a system is the Legendre transformation, in the generalized velocities $\dot{q}^a$, of the Lagrangian of the system:

$$\mathcal{H}(q, p, t) = \dot{q}^a p_a - \mathcal{L}(q, \dot{q}, t)\,, \tag{22.1}$$

the generalized velocities being expressed in terms of (q, p, t) through the inversion of Equation (21.43).

Rests on Definitions 21.31 and 21.34.

The definition presupposes that the inversion can be carried out, and that is a genuine hypothesis rather than a formality: it is the exact point at which the two formulations can fail to be equivalent.

Proposition 22.3 (Invertibility of the Legendre map)**.** *Let $\mathcal{L}$ be of class C^2 and let the* velocity Hessian

$$W_{ab}(q, \dot{q}, t) = \frac{\partial^2 \mathcal{L}}{\partial\dot{q}^a \partial\dot{q}^b} \tag{22.2}$$

be non-singular at a point of the tangent bundle. Then Equation (21.43) can be solved near that point for the velocities, $\dot{q}^a = \dot{q}^a(q, p, t)$, by a C^1 function, and Equation (22.1) defines $\mathcal{H}$ there.

Rests on Equation (21.43) and Corollary A.292.

Proof. *Derives Proposition 22.3.*

At fixed (q,t) the map $\dot q \longmapsto p$ of Equation (21.43) is C^1, and its Jacobian matrix is

$$\frac{\partial p_a}{\partial \dot q^b} = \frac{\partial^2 \mathcal{L}}{\partial \dot q^b \partial \dot q^a} = W_{ab}\,,$$

symmetric by Proposition 7.73. Where $\det W \neq 0$ the inverse function theorem Corollary A.292 supplies a C^1 local inverse, and the dependence on the parameters (q,t) is inherited from that of $\mathcal{L}$. □

Remark 22.4 (When the Legendre map is singular). For the Lagrangians of Section 21.7.3, $\mathcal{L} = \frac{1}{2} g_{ab}(q)\dot q^a \dot q^b - V(q)$, the Hessian is the kinetic metric itself, $W_{ab} = g_{ab}$, which is positive definite, so the inversion is global in the velocities and gives $\dot q^a = g^{ab} p_b$. The condition $\det W \neq 0$ is also the strict form of Legendre's necessary condition Theorem 16.51 for the variational problem the Lagrangian poses, which is why the same convexity governs minimality and the passage to the Hamiltonian. When it fails — as it does for every gauge theory, where the Lagrangian does not depend on some of the velocities at all — the momenta are not independent functions of the velocities, the relations among them are constraints, and the formalism of this chapter must be rebuilt: that is the subject of Chapter 26.

Rests on Proposition 22.3 and Definition 21.66.

Remark 22.5 (Units). $\mathcal{H}$ carries the unit of energy, J, whatever the units of the individual q^a. Each product $\dot q^a p_a$ in Equation (22.1) is an energy, and necessarily so: by Equation (21.43) the unit of p_a is that of $\mathcal{L}$ divided by that of $\dot q^a$, so the two units cancel term by term. For a Cartesian coordinate p_a is a linear momentum, kg m/s; for an angle it is an angular momentum, J s. The one combination whose unit never depends on the choice of coordinates is $p_a\,\mathrm{d}q^a$, which is an action, J s — the unit of $\hbar$, and the reason the symplectic structure built from it in Chapter 24 is measured in the same units as the quantum of action (Remark 5.116).

Rests on Equations (21.43) and (22.1).

22.1.2 Hamilton's equations

The equations that follow are Hamilton's, from the general method in dynamics of [96]; he obtained them as the characteristic-function formulation whose partial differential equation is the subject of Chapter 23, and the canonical pair is what remains when that function is not solved for.

Theorem 22.6 (Hamilton's equations)**.** *The equations of motion of a system with Hamiltonian $\mathcal{H}(q,p,t)$ are*

$$\dot q^a = \frac{\partial \mathcal{H}}{\partial p_a}\,, \tag{22.3}$$

$$\dot p_a = -\frac{\partial \mathcal{H}}{\partial q^a}\,, \tag{22.4}$$

together with the relation

$$\frac{\partial \mathcal{H}}{\partial t} = -\frac{\partial \mathcal{L}}{\partial t}\,. \tag{22.5}$$

Here the active forces are taken to be conservative, so that the Lagrangian obeys Equation (21.39).

Rests on Definition 22.2 and Equations (21.39) and (21.43).

Proof. *Derives Theorem 22.6.*

Differentiate the Lagrangian as a function of its own arguments $(q,\dot q,t)$:

$$\mathrm{d}\mathcal{L} = \frac{\partial \mathcal{L}}{\partial q^a}\,\mathrm{d}q^a + \frac{\partial \mathcal{L}}{\partial \dot q^a}\,\mathrm{d}\dot q^a + \frac{\partial \mathcal{L}}{\partial t}\,\mathrm{d}t = \frac{\partial \mathcal{L}}{\partial q^a}\,\mathrm{d}q^a + p_a\,\mathrm{d}\dot q^a + \frac{\partial \mathcal{L}}{\partial t}\,\mathrm{d}t\,, \tag{22.6}$$

the last step by the definition Equation (21.43) of the momentum. Differentiating Equation (22.1) instead, and subtracting,

$$\mathrm{d}\mathcal{H} = \dot{q}^a\,\mathrm{d}p_a + p_a\,\mathrm{d}\dot{q}^a - \mathrm{d}\mathcal{L} = \dot{q}^a\,\mathrm{d}p_a - \frac{\partial\mathcal{L}}{\partial q^a}\,\mathrm{d}q^a - \frac{\partial\mathcal{L}}{\partial t}\,\mathrm{d}t\,. \tag{22.7}$$

From Equations (22.1) and (22.6) (the two terms in $\mathrm{d}\dot{q}^a$ cancel).

The cancellation of $p_a\,\mathrm{d}\dot{q}^a$ is the whole content of the Legendre transformation: no differential of a velocity survives in Equation (22.7), so $\mathcal{H}$ is genuinely a function of (q, p, t) and of nothing else — which is what Proposition 22.3 licenses us to assume.

Comparing Equation (22.7) with the differential of $\mathcal{H}$ read off its own arguments,

$$\mathrm{d}\mathcal{H} = \frac{\partial\mathcal{H}}{\partial q^a}\,\mathrm{d}q^a + \frac{\partial\mathcal{H}}{\partial p_a}\,\mathrm{d}p_a + \frac{\partial\mathcal{H}}{\partial t}\,\mathrm{d}t\,,$$

and using that $\mathrm{d}q^a$, $\mathrm{d}p_a$ and $\mathrm{d}t$ are independent, gives three identities:

$$\frac{\partial\mathcal{H}}{\partial p_a} = \dot{q}^a\,, \qquad \frac{\partial\mathcal{H}}{\partial q^a} = -\frac{\partial\mathcal{L}}{\partial q^a}\,, \qquad \frac{\partial\mathcal{H}}{\partial t} = -\frac{\partial\mathcal{L}}{\partial t}\,. \tag{22.8}$$

The first is Equation (22.3) and the third is Equation (22.5). Neither uses the equations of motion: both are properties of the transformation alone.

The dynamics enters only now. By the Euler–Lagrange equations Equation (21.39) and Equation (21.43),

$$\dot{p}_a = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial\mathcal{L}}{\partial\dot{q}^a}\right) = \frac{\partial\mathcal{L}}{\partial q^a} = -\frac{\partial\mathcal{H}}{\partial q^a}\,,$$

the last step by the second identity of Equation (22.8). This is Equation (22.4). □

Remark 22.7 (Which half is kinematics and which is dynamics). The asymmetry exposed by the proof is worth keeping in view. Equation (22.3) holds for *any* $\mathcal{H}$ obtained by the Legendre transformation, whether or not the motion satisfies the equations of motion; it merely says that the transformation is invertible and inverts the way a Legendre transformation does. Equation (22.4) is Newton's second law in disguise. The elegance of the pair is therefore partly notational — but only partly, since it is exactly this symmetry of appearance that makes the canonical transformations of Section 22.2 available, and those have no Lagrangian counterpart.

Rests on Theorem 22.6.

Remark 22.8 (Non-conservative forces). If some active forces are not derivable from a potential, the Euler–Lagrange equations carry the generalized force Q_a of Equation (21.38) on their right-hand side, and the last line of the proof gives instead

$$\dot{p}_a = -\frac{\partial\mathcal{H}}{\partial q^a} + Q_a\,, \tag{22.9}$$

Equation (22.3) being untouched, since it does not use the equations of motion. Everything in this chapter that rests on the pair Equations (22.3) and (22.4) — conservation of $\mathcal{H}$, the Poisson bracket form of the evolution, Liouville's theorem — fails in exactly the way Equation (22.9) predicts when $Q_a \neq 0$.

Rests on Theorem 22.6 and Equation (21.38).

Where the Lagrange equations are f second-order equations for the $q^a(t)$, Hamilton's equations are $2f$ first-order equations for the phase-space trajectory $(q^a(t), p_a(t))$.

22.1.3 The Hamiltonian and the energy

Proposition 22.9 (Time derivative of the Hamiltonian)**.** *Along the motion,*

$$\frac{\mathrm{d}\mathcal{H}}{\mathrm{d}t} = \frac{\partial \mathcal{H}}{\partial t}\,. \tag{22.10}$$

Rests on Equations (22.3) and (22.4).

Proof. *Derives Proposition 22.9.*

$\mathcal{H}$ depends on time both through the trajectory and explicitly, so by the chain rule Proposition 7.72,

$$\frac{\mathrm{d}\mathcal{H}}{\mathrm{d}t} = \frac{\partial \mathcal{H}}{\partial q^a}\dot{q}^a + \frac{\partial \mathcal{H}}{\partial p_a}\dot{p}_a + \frac{\partial \mathcal{H}}{\partial t} = \frac{\partial \mathcal{H}}{\partial q^a}\frac{\partial \mathcal{H}}{\partial p_a} - \frac{\partial \mathcal{H}}{\partial p_a}\frac{\partial \mathcal{H}}{\partial q^a} + \frac{\partial \mathcal{H}}{\partial t}\,,$$

substituting Equations (22.3) and (22.4). The first two terms are the same sum with opposite signs and cancel. □

Theorem 22.10 (Conservation of the Hamiltonian)**.** *If the active forces of a system are conservative and the Hamiltonian of the system does not depend explicitly on time, then the Hamiltonian is constant.*

Rests on Proposition 22.9.

Proof. *Derives Theorem 22.10.*

The hypothesis on the forces is what puts Equation (22.4) in force and hence Equation (22.10); the hypothesis $\partial\mathcal{H}/\partial t = 0$ then makes its right-hand side vanish, so $\mathrm{d}\mathcal{H}/\mathrm{d}t = 0$ along every motion and $\mathcal{H}$ is constant on each trajectory (Corollary 7.36). By Equation (22.5) the condition $\partial\mathcal{H}/\partial t = 0$ is the same as $\partial\mathcal{L}/\partial t = 0$, so the hypothesis may be tested on whichever of the two functions is in hand. □

Proposition 22.11 (Hamiltonian and total energy)**.** *If the kinetic energy T does not depend explicitly on time, then the Hamiltonian is the total energy of the system,*

$$\mathcal{H} = E\,. \tag{22.11}$$

Rests on Equation (22.1) and Proposition 21.38.

Proof. *Derives Proposition 22.11.*

Under the stated hypothesis Proposition 21.38 gives $E = \dot{q}^a p_a - \mathcal{L}$, and the right-hand side is Equation (22.1) verbatim. The two quantities are therefore the same function, expressed once in the velocities and once in the momenta. □

Remark 22.12 (The hypothesis, stated sharply). "T does not depend explicitly on time" is the wording of Proposition 21.38 and is a shorthand. What the identification $\mathcal{H} = T + V$ actually needs is that T be a homogeneous quadratic form in the generalized velocities and V be independent of them — which follows from Equation (21.74) when the constraints are scleronomous (Remark 21.8), and fails when they are not. The step is Euler's theorem on homogeneous functions: if T is homogeneous of degree k in the $\dot{q}^a$, then $\dot{q}^a\,\partial T/\partial\dot{q}^a = kT$, so for $k = 2$,

$$\dot{q}^a p_a = \dot{q}^a \frac{\partial T}{\partial \dot{q}^a} = 2T\,, \qquad \mathcal{H} = 2T - (T - V) = T + V = E\,. \tag{22.12}$$

A rheonomous constraint makes T the sum of terms of degrees 2, 1 and 0 in the velocities, the theorem then gives $\dot{q}^a p_a = 2T_2 + T_1$, and $\mathcal{H} = T_2 - T_0 + V$ is a conserved quantity that is *not* the energy — the rotating-frame case of Chapter 29, where the difference is the centrifugal term. Conservation of $\mathcal{H}$ and conservation of E are thus two different statements that coincide only under the hypothesis above.

Rests on Proposition 22.11 and Equation (21.74).

Remark 22.13 (Euler's theorem on homogeneous functions is owed). Euler's theorem on homogeneous functions, used in Equation (22.12), is a statement of several-variable differential calculus and belongs in Chapter 7 beside the chain rule Proposition 7.72, which is all its one-line proof requires. It is not stated there, and it is quoted here rather than proved, so that the gap is visible rather than papered over. Nothing else in this chapter depends on it: Proposition 22.11 itself rests only on Proposition 21.38, and Theorem 22.10 does not use it at all.

Rests on Propositions 7.72 and 22.11.

22.2 Canonical transformations

22.2.1 Definition and transformation conditions

Definition 22.14 (Phase-space coordinate transformation)**.** A *transformation of coordinates* of phase space is a transformation of the form

$$Q^a = Q^a(q, p, t)\,, \tag{22.13}$$

$$P_a = P_a(q, p, t)\,. \tag{22.14}$$

It is assumed invertible and twice continuously differentiable, so that (q, p) may equally be regarded as functions of (Q, P, t).

Rests on Definition 22.2.

Definition 22.15 (Canonical transformation)**.** A *canonical transformation* is a transformation of phase-space coordinates that leaves Hamilton's equations invariant in form; that is, one for which

$$\delta S[q, p] = \delta S[Q, P]\,. \tag{22.15}$$

Here $S[q,p] = \int_{t_a}^{t_b} (p_a \dot{q}^a - \mathcal{H})\,\mathrm{d}t$ is the action of Definition 21.45 written in phase-space variables, and $S[Q,P] = \int_{t_a}^{t_b} \left(P_a \dot{Q}^a - K\right)\mathrm{d}t$ is the same functional built from the new variables and from a new Hamiltonian K.

Rests on Definitions 21.45 and 22.14 and Theorem 22.6.

Remark 22.16 (Why the class is larger than the point transformations). Equation (22.13) lets Q^a depend on the momenta, which a point transformation Equation (21.63) of Lagrangian mechanics cannot. The gain is not cosmetic: a canonical transformation may exchange coordinates and momenta outright — $Q = p$, $P = -q$ satisfies every condition below — so the distinction between a "position" and a "momentum" has no invariant meaning in phase space. That is what makes it possible to look for a transformation in which *every* new coordinate is cyclic, which is the programme of Chapter 23.

Rests on Definitions 21.60 and 22.15.

Proposition 22.17 (Transformation conditions)**.** *A transformation Equations (22.13) and (22.14) is canonical if and only if*

$$\frac{\partial Q^a}{\partial q^b} = \frac{\partial p_b}{\partial P_a}\,, \qquad \frac{\partial Q^a}{\partial p_b} = -\frac{\partial q^b}{\partial P_a}\,, \tag{22.16}$$

$$\frac{\partial P_a}{\partial q^b} = -\frac{\partial p_b}{\partial Q^a}\,, \qquad \frac{\partial P_a}{\partial p_b} = \frac{\partial q^b}{\partial Q^a}\,, \tag{22.17}$$

where the derivatives on the left-hand sides are taken in the old variables and those on the right-hand sides in the new. That is: on the left, the variables held fixed are the remaining (q, p); on the right, the remaining (Q, P).

Rests on Definition 22.15 and Equations (22.13) and (22.14).

The conditions are $4f^2$ scalar equations relating derivatives taken in two different sets of variables, and the shortest route to them runs through the generating function of Section 22.2.2. The derivation is therefore deferred to Section 22.2.3, once that function is available.

22.2.2 Generating functions

Postulating a canonical transformation leaves an arbitrary function F at our disposal: since the variational statements Equation (22.15) agree, the two actions may differ by the integral of a total time derivative,

$$S[q,p] = S[Q,P] + \int_{t_a}^{t_b} \frac{\mathrm{d}F}{\mathrm{d}t}\,\mathrm{d}t\,. \tag{22.18}$$

The function F is called the *generating function* of the transformation. Once it is known, the transformation from (q,p) to (Q,P) is determined uniquely. To obtain the transformation one must take

$$F = F(q,p,Q,P)\,, \tag{22.19}$$

which involves the $4f$ phase-space variables, of which only $2f$ are independent, the transformation itself relating the two sets; the dependent variables are eliminated by passing to one of the following mixed forms. In each case K denotes the Hamiltonian that governs the transformed variables (Q,P).

Proposition 22.18 (The mixed generating functions)**.** *Let a canonical transformation admit a generating function depending on one old and one new variable of each conjugate pair, the two being independent. Then the transformation and the new Hamiltonian are given by the following relations.*

Transformation $(q,Q)\to(p,P)$**.**

$$F_1 = F_1(q,Q,t)\,,\qquad p_a = \frac{\partial F_1}{\partial q^a}\,,\qquad P_a = -\frac{\partial F_1}{\partial Q^a}\,,\qquad K = \mathcal{H} + \frac{\partial F_1}{\partial t}\,. \tag{22.20}$$

Transformation $(q,P)\to(p,Q)$**.**

$$F_2 = F_2(q,P,t)\,,\qquad p_a = \frac{\partial F_2}{\partial q^a}\,,\qquad Q^a = \frac{\partial F_2}{\partial P_a}\,,\qquad K = \mathcal{H} + \frac{\partial F_2}{\partial t}\,. \tag{22.21}$$

Transformation $(p,Q)\to(q,P)$**.**

$$F_3 = F_3(p,Q,t)\,,\qquad q^a = -\frac{\partial F_3}{\partial p_a}\,,\qquad P_a = -\frac{\partial F_3}{\partial Q^a}\,,\qquad K = \mathcal{H} + \frac{\partial F_3}{\partial t}\,. \tag{22.22}$$

Rests on Equation (22.18) *and Definition 22.15.*

Proof. *Derives Proposition 22.18.*

Write out Equation (22.18) with the two actions of Definition 22.15. Since the equality of the two variational problems must hold for every comparison path between the same endpoints, and not merely for solutions, the integrands agree identically on phase space:

$$p_a\dot q^a - \mathcal{H} = P_a\dot Q^a - K + \frac{\mathrm{d}F}{\mathrm{d}t}\,. \tag{22.23}$$

Take first $F = F_1(q,Q,t)$, which is legitimate when (q,Q) are $2f$ independent variables. Then

$$\frac{\mathrm{d}F_1}{\mathrm{d}t} = \frac{\partial F_1}{\partial q^a}\dot q^a + \frac{\partial F_1}{\partial Q^a}\dot Q^a + \frac{\partial F_1}{\partial t}\,,$$

and substituting into Equation (22.23) and collecting terms,

$$\left(p_a - \frac{\partial F_1}{\partial q^a}\right)\dot{q}^a - \left(P_a + \frac{\partial F_1}{\partial Q^a}\right)\dot{Q}^a - \mathcal{H} + K - \frac{\partial F_1}{\partial t} = 0\,.$$

At a given instant the $2f$ quantities $\dot{q}^a$ and $\dot{Q}^a$ may be prescribed arbitrarily and independently, because (q, Q) are independent coordinates and the relation holds along every path. An affine expression that vanishes for all values of its variables has vanishing coefficients, which gives the three relations of Equation (22.20).

The remaining forms follow by Legendre transformation in one pair of variables, exactly as $\mathcal{H}$ followed from $\mathcal{L}$. Put $F_2 = F_1 + P_a Q^a$; then

$$\mathrm{d}F_2 = \mathrm{d}F_1 + P_a\,\mathrm{d}Q^a + Q^a\,\mathrm{d}P_a = p_a\,\mathrm{d}q^a + Q^a\,\mathrm{d}P_a + \frac{\partial F_1}{\partial t}\,\mathrm{d}t\,,$$

using $\mathrm{d}F_1 = p_a \mathrm{d}q^a - P_a \mathrm{d}Q^a + (\partial F_1/\partial t)\mathrm{d}t$ from Equation (22.20). No $\mathrm{d}Q^a$ survives, so F_2 is a function of (q, P, t), and reading off its partial derivatives gives Equation (22.21) — the last of them because $\partial F_2/\partial t = \partial F_1/\partial t$. Put instead $F_3 = F_1 - p_a q^a$; the same computation gives $\mathrm{d}F_3 = -q^a \mathrm{d}p_a - P_a \mathrm{d}Q^a + (\partial F_1/\partial t)\mathrm{d}t$, which is Equation (22.22). The fourth member of the family, $F_4 = F_1 + P_a Q^a - p_a q^a$, is obtained by performing both Legendre transformations and satisfies $q^a = -\partial F_4/\partial p_a$, $Q^a = \partial F_4/\partial P_a$, $K = \mathcal{H} + \partial F_4/\partial t$. □

Remark 22.19 (Which form exists). Not every canonical transformation admits every mixed form, and some admit none of the four. The identity transformation $Q^a = q^a$, $P_a = p_a$ is generated by $F_2 = q^a P_a$ but has no F_1 at all, since q and Q are not then independent; the exchange $Q^a = p_a$, $P_a = -q^a$ has $F_1 = q^a Q^a$ but no F_2. The requirement in each case is the independence assumed in Proposition 22.18, which by Corollary A.292 is the non-vanishing of the corresponding Jacobian — $\det\left(\partial^2 F_1/\partial q^a \partial Q^b\right) \neq 0$ for the first form, and correspondingly for the others. Nothing in the results of this chapter depends on a generating function existing in a particular form: Lemma 22.20 below is proved from Equation (22.18) itself, which asks only that *some* F exist.

Rests on Proposition 22.18 and Corollary A.292.

22.2.3 Derivation of the transformation conditions

Assembling the $2f$ new coordinates into a single column, as Equation (22.55) does for the old ones, the transformation Equations (22.13) and (22.14) has at each instant the Jacobian matrix

$$M = \frac{\partial\,(Q, P)}{\partial\,(q, p)} = \begin{pmatrix} A & B \\ C & D \end{pmatrix}, \qquad \begin{aligned} A_{ab} &= \frac{\partial Q^a}{\partial q^b}\,, & B_{ab} &= \frac{\partial Q^a}{\partial p_b}\,, \\ C_{ab} &= \frac{\partial P_a}{\partial q^b}\,, & D_{ab} &= \frac{\partial P_a}{\partial p_b}\,. \end{aligned} \tag{22.24}$$

Everything below is a statement about M and the symplectic matrix J of Equation (22.56), whose defining properties $J^{\mathsf{T}} = -J$, $J^2 = -\mathbb{1}_{2f}$ and $J^{-1} = -J$ are recorded in Equation (5.173).

Lemma 22.20 (The symplectic condition)**.** *The Jacobian Equation (22.24) of a canonical transformation satisfies, at every point and at every instant,*

$$M^{\mathsf{T}} J\, M = J\,, \tag{22.25}$$

that is, $M \in \mathrm{Sp}(2f, \mathbb{R})$. Conversely, a transformation not involving the time explicitly whose Jacobian satisfies Equation (22.25) is canonical.

Rests on Equation (22.18), Definition 5.130, and Proposition 7.73.

Proof. *Derives Lemma 22.20.*

Necessity. Regard (q, p, t) as the independent variables, so that Q^a, P_a and the generating function F of Equation (22.18) are functions of them. Expanding $\dot{Q}^a$ and $\mathrm{d}F/\mathrm{d}t$ by the chain rule Proposition 7.72 in Equation (22.23) and collecting the coefficients of the independently prescribable $\dot{q}^b$ and $\dot{p}_b$, as in the proof of Proposition 22.18, gives

$$\frac{\partial F}{\partial q^b} = p_b - P_a \frac{\partial Q^a}{\partial q^b}\,, \tag{22.26}$$

$$\frac{\partial F}{\partial p_b} = -P_a \frac{\partial Q^a}{\partial p_b}\,, \tag{22.27}$$

together with $K = \mathcal{H} + P_a\,\partial Q^a/\partial t + \partial F/\partial t$, which plays no part here.

Now impose on F the equality of mixed second partial derivatives (Proposition 7.73). Differentiating Equation (22.26) with respect to p_c and Equation (22.27) with respect to q^b, the terms carrying second derivatives of Q^a cancel between the two — they are the same by Proposition 7.73 applied to Q^a — and what is left is

$$\delta_b^c = \frac{\partial Q^a}{\partial q^b}\frac{\partial P_a}{\partial p_c} - \frac{\partial Q^a}{\partial p_c}\frac{\partial P_a}{\partial q^b} = \left(A^{\mathsf{T}}D - C^{\mathsf{T}}B\right)_{bc}\,. \tag{22.28}$$

Differentiating Equation (22.26) with respect to q^c and comparing with the same expression with b and c exchanged gives, after the same cancellation, that $A^{\mathsf{T}}C$ is symmetric; doing the same with Equation (22.27) gives that $B^{\mathsf{T}}D$ is symmetric. Written out in blocks,

$$M^{\mathsf{T}} J\, M = \begin{pmatrix} A^{\mathsf{T}}C - C^{\mathsf{T}}A & A^{\mathsf{T}}D - C^{\mathsf{T}}B \\ B^{\mathsf{T}}C - D^{\mathsf{T}}A & B^{\mathsf{T}}D - D^{\mathsf{T}}B \end{pmatrix}\,, \tag{22.29}$$

whose four blocks are, in order, 0 by the symmetry of $A^{\mathsf{T}}C$, $\mathbb{1}_f$ by Equation (22.28), $-\mathbb{1}_f$ because that block is minus the transpose of the one above it, and 0 by the symmetry of $B^{\mathsf{T}}D$. That is Equation (22.25).

Sufficiency for a transformation free of the time. With $\zeta = \zeta(\eta)$ and $K(\zeta) = \mathcal{H}(\eta(\zeta))$, the chain rule gives $\partial\mathcal{H}/\partial\eta = M^{\mathsf{T}}\,\partial K/\partial\zeta$, so by the matrix form Equation (22.57) of Hamilton's equations, verified in Proposition 22.41 below,

$$\dot{\zeta} = M\dot{\eta} = MJ\,\frac{\partial\mathcal{H}}{\partial\eta} = MJM^{\mathsf{T}}\,\frac{\partial K}{\partial\zeta}\,.$$

Transposing and inverting Equation (22.25) gives $MJM^{\mathsf{T}} = J$ as well, so $\dot{\zeta} = J\,\partial K/\partial\zeta$: Hamilton's equations keep their form, for every $\mathcal{H}$. The corresponding statement for explicitly time-dependent transformations, and the geometric reading of Equation (22.25) as the preservation of a differential form, are Theorem 24.18. □

Proof. *Derives Proposition 22.17.*

By Lemma 22.20 a transformation is canonical only if $M^{\mathsf{T}}JM = J$, which since $J^{-1} = -J$ is the same as

$$M^{-1} = J^{-1}M^{\mathsf{T}}J = -J\,M^{\mathsf{T}}J = \begin{pmatrix} D^{\mathsf{T}} & -B^{\mathsf{T}} \\ -C^{\mathsf{T}} & A^{\mathsf{T}} \end{pmatrix}\,, \tag{22.30}$$

the last equality by multiplying out the blocks of Equation (22.24) with those of Equation (22.56). But M^{-1} is the Jacobian of the inverse transformation,

$$M^{-1} = \frac{\partial\,(q,p)}{\partial\,(Q,P)} = \begin{pmatrix} \partial q^b/\partial Q^a & \partial q^b/\partial P_a \\ \partial p_b/\partial Q^a & \partial p_b/\partial P_a \end{pmatrix}\,,$$

whose entries are exactly the right-hand sides of Equations (22.16) and (22.17). Reading Equation (22.30) block by block therefore gives $\partial p_b/\partial P_a = A_{ab} = \partial Q^a/\partial q^b$, $\partial q^b/\partial P_a =$

$-B_{ab} = -\partial Q^a/\partial p_b$, $\partial p_b/\partial Q^a = -C_{ab} = -\partial P_a/\partial q^b$ and $\partial q^b/\partial Q^a = D_{ab} = \partial P_a/\partial p_b$, which are the four conditions. Conversely, the four conditions assert Equation (22.30); multiplying by M on the left gives $\mathbb{1}_{2f} = -MJM^{\mathsf{T}}J$, and multiplying by $J^{-1} = -J$ on the right returns $MJM^{\mathsf{T}} = J$, hence Equation (22.25), and Lemma 22.20 closes the equivalence. □

Remark 22.21 (The count). The four families of Equations (22.16) and (22.17) are $4f^2$ scalar equations, but Equation (22.25) shows that they are not independent: $M^{\mathsf{T}}JM$ is antisymmetric for every M, so requiring it to equal J imposes only $f(2f-1)$ conditions. The dimension of $\mathrm{Sp}(2f,\mathbb{R})$ is accordingly $4f^2 - f(2f-1) = f(2f+1)$ (Proposition 5.134), which for one degree of freedom is 3: the canonical transformations of a two-dimensional phase space are, pointwise, the area- and orientation-preserving linear maps.

Rests on Propositions 5.134 and 22.17.

22.3 Invariant integrals

The integral invariants are due to Poincaré, who introduced them in volume III (1899) of *Les méthodes nouvelles de la mécanique céleste* [255].

Theorem 22.22 (Poincaré)**.** *Let S be a two-dimensional surface of phase space, parametrized by (u,v) over a domain D, so that*

$$I = \int_S \mathrm{d}q^a\,\mathrm{d}p_a := \int_D \sum_{a=1}^{f} \frac{\partial\,(q^a,p_a)}{\partial\,(u,v)}\,\mathrm{d}u\,\mathrm{d}v\,. \tag{22.31}$$

Then for a canonical transformation from (q,p) to (Q,P), applied at one instant,

$$I = \int_S \mathrm{d}q^a\,\mathrm{d}p_a = \int_S \mathrm{d}Q^a\,\mathrm{d}P_a\,. \tag{22.32}$$

Rests on Lemma 22.20 and Definition 7.93.

Proof. *Derives Theorem 22.22.*

Write η for the column of Equation (22.55) and ζ for the same column built from (Q,P). Each Jacobian determinant in Equation (22.31) is a difference of two products, and summing over a assembles them into the single matrix product

$$\sum_{a=1}^{f} \frac{\partial\,(q^a,p_a)}{\partial\,(u,v)} = \sum_{a=1}^{f} \left(\frac{\partial q^a}{\partial u}\frac{\partial p_a}{\partial v} - \frac{\partial q^a}{\partial v}\frac{\partial p_a}{\partial u} \right) = \left(\frac{\partial \eta}{\partial u}\right)^{\mathsf{T}} J \left(\frac{\partial \eta}{\partial v}\right), \tag{22.33}$$

as multiplying out the blocks of Equation (22.56) shows. By the chain rule Proposition 7.72, the same surface described in the new variables has $\partial\zeta/\partial u = M\,\partial\eta/\partial u$ and likewise for v, with M the Jacobian Equation (22.24). Hence

$$\left(\frac{\partial \zeta}{\partial u}\right)^{\mathsf{T}} J \left(\frac{\partial \zeta}{\partial v}\right) = \left(\frac{\partial \eta}{\partial u}\right)^{\mathsf{T}} \left(M^{\mathsf{T}} J\, M\right) \left(\frac{\partial \eta}{\partial v}\right) = \left(\frac{\partial \eta}{\partial u}\right)^{\mathsf{T}} J \left(\frac{\partial \eta}{\partial v}\right),$$

by Equation (22.25). The two integrands of Equation (22.32) agree at every point of D, so the integrals agree. □

Remark 22.23 (What the invariant does not depend on). Equation (22.31) defines I through a chosen parametrization of S, and the value is unchanged by any other regular parametrization of the same oriented surface: the integrand Equation (22.33) is bilinear and antisymmetric in $\partial\eta/\partial u$ and $\partial\eta/\partial v$, so a change of parameters multiplies it by the Jacobian determinant of that change, which the transformation of the area element $\mathrm{d}u\,\mathrm{d}v$ then cancels. The cancellation is the change-of-variables theorem for a multiple integral, which Chapter 7

does not state. It is quoted twice in this chapter and nowhere else — here, and for the transformation of the volume element in Corollary 22.24 — and in neither place is it needed for the statement itself: the two integrands of Theorem 22.22 are equal point by point over one and the same D, and Equation (22.34) is the assertion $\det M = 1$ about a determinant.

Rests on Theorem 22.22.

Corollary 22.24 (Invariance of the phase-space volume)**.** *A canonical transformation has* $\det M = 1$*, so the phase-space volume element is invariant,*

$$\mathrm{d}Q^1 \cdots \mathrm{d}Q^f \, \mathrm{d}P_1 \cdots \mathrm{d}P_f = \mathrm{d}q^1 \cdots \mathrm{d}q^f \, \mathrm{d}p_1 \cdots \mathrm{d}p_f \,. \tag{22.34}$$

In particular the flow generated by a Hamiltonian preserves phase-space volume, since the map carrying the state at time t_a to the state at time t_b is itself a canonical transformation.

Rests on Lemma 22.20 and Theorem 5.133.

Proof. *Derives Corollary 22.24.*

By Lemma 22.20 the Jacobian M lies in $\mathrm{Sp}(2f, \mathbb{R})$, and every element of the symplectic group has determinant $+1$ (Theorem 5.133); the volume element transforms by $|\det M|$, whence Equation (22.34).

For the flow, let $M(t)$ be the Jacobian of the map carrying the state at time t_a to the state at time t, and write $\mathcal{H}''_{cd} = \partial^2 \mathcal{H} / \partial \eta^c \partial \eta^d$, symmetric by Proposition 7.73. Differentiating Equation (22.57) with respect to the initial data gives $\dot{M} = J\,\mathcal{H}''M$, and therefore

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(M^{\mathsf{T}} J\, M\right) = \left(J\mathcal{H}''M\right)^{\mathsf{T}} J\, M + M^{\mathsf{T}} J \left(J\mathcal{H}''M\right) = M^{\mathsf{T}}\mathcal{H}'' \left(-J\right) J\, M + M^{\mathsf{T}} J^2 \mathcal{H}''M = 0\,,$$

using $J^{\mathsf{T}} = -J$, $J^2 = -\mathbb{1}_{2f}$ and the symmetry of $\mathcal{H}''$. At $t = t_a$ the map is the identity, for which $M^{\mathsf{T}} J M = J$ holds; hence it holds for all t, and the flow is a canonical transformation by Lemma 22.20. □

Remark 22.25 (This is Liouville's theorem)*.* Corollary 22.24 is Liouville's theorem in coordinates. Its coordinate-free form — that the Hamiltonian flow preserves the $2f$-form built from the symplectic structure, of which the invariance of the volume element is one consequence among several — is Theorem 24.21, and the physical use to which it is put, as the theorem that singles out the phase-space measure of statistical mechanics, is Remark 24.22. The chain Equations (22.32) and (22.34) continues: Poincaré's invariant is the first of a family of f integral invariants, of dimensions $2, 4, \ldots, 2f$, the last of which is the volume. They are the exterior powers of one object (Equation (24.13)).

Rests on Corollary 22.24 and Theorem 24.21.

22.3.1 The Lagrange bracket

Definition 22.26 (Lagrange bracket)**.** The *Lagrange bracket* of two phase-space functions u and v with respect to the coordinates (q, p) is

$$[u, v]_{q,p} = \frac{\partial q^a}{\partial u}\frac{\partial p_a}{\partial v} - \frac{\partial q^a}{\partial v}\frac{\partial p_a}{\partial u}\,, \tag{22.35}$$

the sum over a of the Jacobian determinants $\partial(q^a, p_a)/\partial(u, v)$.

Rests on Definition 22.14 and Proposition 7.72.

Comparing Equation (22.35) with Equation (22.33), the integrand of Poincaré's invariant *is* the Lagrange bracket of the two surface parameters, and in matrix form

$$[u, v]_{q,p} = \left(\frac{\partial \eta}{\partial u}\right)^{\mathsf{T}} J \left(\frac{\partial \eta}{\partial v}\right)\,. \tag{22.36}$$

From Equations (22.33) and (22.35) (the same sum of Jacobian determinants, written as a matrix product).

This is the form in which its properties are read off.

Proposition 22.27 (Properties of the Lagrange bracket)**.**

1. Invariance. *The Lagrange bracket is invariant under canonical transformations:*

$$[u,v]_{q,p} = [u,v]_{Q,P} \ . \tag{22.37}$$

2. Antisymmetry.

$$[u,v]_{q,p} = -\,[v,u]_{q,p} \ . \tag{22.38}$$

3. Fundamental Lagrange brackets.

$$\left[q^a, q^b\right]_{q,p} = 0\,, \qquad [p_a, p_b]_{q,p} = 0\,, \qquad [q^a, p_b]_{q,p} = \delta^a_b\,. \tag{22.39}$$

Rests on Equation (22.36) and Lemma 22.20.

Proof. *Derives Proposition 22.27.*

(1) Invariance. By Equation (22.36) written in the new variables and the chain rule $\partial\zeta/\partial u = M\,\partial\eta/\partial u$,

$$[u,v]_{Q,P} = \left(\frac{\partial\zeta}{\partial u}\right)^{\mathsf{T}} J \left(\frac{\partial\zeta}{\partial v}\right) = \left(\frac{\partial\eta}{\partial u}\right)^{\mathsf{T}} \left(M^{\mathsf{T}} J\, M\right) \left(\frac{\partial\eta}{\partial v}\right) = [u,v]_{q,p}\ ,$$

the last step by Equation (22.25). This is Equation (22.37), and it is the same computation as the one that proved Theorem 22.22 — as it must be, the invariant being the integral of the bracket.

(2) Antisymmetry. Exchanging u and v in Equation (22.35) exchanges the two products and so reverses the sign, which is Equation (22.38); equivalently, $J^{\mathsf{T}} = -J$ in Equation (22.36).

(3) Fundamental brackets. Take the parameters to be two of the phase-space coordinates themselves, so that the derivatives in Equation (22.35) are Kronecker deltas or zero: $\partial q^c/\partial q^a = \delta^c_a$, $\partial p_c/\partial q^a = 0$, $\partial q^c/\partial p_a = 0$, $\partial p_c/\partial p_a = \delta_{ca}$. Then

$$\begin{aligned}
\left[q^a, q^b\right]_{q,p} &= \sum_c \left(\delta^c_a \cdot 0 - \delta^c_b \cdot 0\right) = 0\,, \\
[p_a, p_b]_{q,p} &= \sum_c \left(0 \cdot \delta_{cb} - 0 \cdot \delta_{ca}\right) = 0\,, \\
[q^a, p_b]_{q,p} &= \sum_c \left(\delta^c_a \delta_{cb} - 0 \cdot 0\right) = \delta^a_b\,,
\end{aligned}$$

which is Equation (22.39). □

Remark 22.28 (Where the content of the fundamental brackets lies)*.* As computed, Equation (22.39) is a triviality: it says only that the coordinates are coordinates. The statement with content is the one obtained by combining it with Equation (22.37), namely

$$\left[q^a, q^b\right]_{Q,P} = 0\,, \qquad [p_a, p_b]_{Q,P} = 0\,, \qquad [q^a, p_b]_{Q,P} = \delta^a_b\,, \tag{22.40}$$

for a canonical transformation — and these $f(2f-1)$ independent equations are Equation (22.25) again, written in yet another notation. The same remark applies to the Poisson brackets of Equation (22.44) below, and is why Theorem 24.18 can list the three as equivalent tests for a transformation to be canonical.

Rests on Proposition 22.27 and Lemma 22.20.

22.3.2 The Poisson bracket

Definition 22.29 (Poisson bracket)**.** The *Poisson bracket* of two phase-space functions u and v with respect to the coordinates (q, p) is

$$\{u, v\}_{q,p} = \frac{\partial u}{\partial q^a}\frac{\partial v}{\partial p_a} - \frac{\partial u}{\partial p_a}\frac{\partial v}{\partial q^a}\,. \tag{22.41}$$

Rests on Definitions 7.65 and 22.14.

Where the Lagrange bracket differentiates the coordinates with respect to the functions, the Poisson bracket differentiates the functions with respect to the coordinates. In the matrix notation of Equation (22.36) the two read

$$[u, v]_{q,p} = \left(\frac{\partial \eta}{\partial u}\right)^{\mathsf{T}} J \left(\frac{\partial \eta}{\partial v}\right), \qquad \{u, v\}_{q,p} = \left(\frac{\partial u}{\partial \eta}\right)^{\mathsf{T}} J \left(\frac{\partial v}{\partial \eta}\right), \tag{22.42}$$

where $\partial u/\partial \eta$ is the column of the $2f$ partial derivatives of u. The contrast is the whole of Proposition 22.32 below.

Proposition 22.30 (Properties of the Poisson bracket)**.**

1. Antisymmetry.

$$\{u, v\}_{q,p} = -\{v, u\}_{q,p}\,. \tag{22.43}$$

2. Fundamental Poisson brackets.

$$\left\{q^a, q^b\right\}_{q,p} = 0\,, \qquad \{p_a, p_b\}_{q,p} = 0\,, \qquad \{q^a, p_b\}_{q,p} = \delta^a_b\,. \tag{22.44}$$

3. Invariance. *The Poisson bracket is invariant under canonical transformations:*

$$\{u, v\}_{q,p} = \{u, v\}_{Q,P}\,. \tag{22.45}$$

4. Jacobi identity. *For u, v, and w functions on phase space,*

$$\{u, \{v, w\}\} + \{v, \{w, u\}\} + \{w, \{u, v\}\} = 0\,. \tag{22.46}$$

Rests on Equation (22.42), Lemma 22.20, and Proposition 7.73.

Proof. *Derives Proposition 22.30.*

(1) Antisymmetry. Exchanging u and v in Equation (22.41) exchanges the two products, giving Equation (22.43).

(2) Fundamental brackets. As in the Lagrange case, take the two arguments to be coordinates, so the derivatives are Kronecker deltas or zero:

$$\begin{aligned}
\left\{q^a, q^b\right\}_{q,p} &= \sum_c \left(\delta^a_c \cdot 0 - 0 \cdot \delta^b_c\right) = 0\,,\\
\{p_a, p_b\}_{q,p} &= \sum_c \left(0 \cdot \delta_{cb} - \delta_{ca} \cdot 0\right) = 0\,,\\
\{q^a, p_b\}_{q,p} &= \sum_c \left(\delta^a_c \delta_{cb} - 0\right) = \delta^a_b\,,
\end{aligned}$$

which is Equation (22.44).

(3) Invariance. By the chain rule Proposition 7.72, a function's gradients in the two sets of variables are related by $\partial u/\partial \eta = M^{\mathsf{T}}\,\partial u/\partial \zeta$, so $\partial u/\partial \zeta = \left(M^{-1}\right)^{\mathsf{T}}\,\partial u/\partial \eta$. Hence, by Equation (22.42) in the new variables,

$$\{u, v\}_{Q,P} = \left(\frac{\partial u}{\partial \eta}\right)^{\mathsf{T}} M^{-1} J \left(M^{-1}\right)^{\mathsf{T}} \left(\frac{\partial v}{\partial \eta}\right) = \left(\frac{\partial u}{\partial \eta}\right)^{\mathsf{T}} J \left(\frac{\partial v}{\partial \eta}\right) = \{u, v\}_{q,p}\,,$$

because Equation (22.25) is equivalent to $MJM^{\mathsf{T}} = J$ and hence, multiplying by M^{-1} on the left and by $\left(M^{-1}\right)^{\mathsf{T}}$ on the right, to $M^{-1}J\left(M^{-1}\right)^{\mathsf{T}} = J$. This is Equation (22.45). The invariance is what allows the subscript on a Poisson bracket to be dropped, and it will be from here on.

(4) Jacobi identity. For fixed u the map $D_u : w \longmapsto \{u, w\}$ is, by Equation (22.41), a linear first-order differential operator in w: it involves the first derivatives of w and no higher ones. Now inspect the left-hand side of Equation (22.46), which we call Σ. Each of its three terms is a Poisson bracket one of whose arguments is itself a Poisson bracket, so each term is a sum of products of first derivatives of two of the functions with a *second* derivative of the third — exactly one second-derivative factor in every term.

Collect the terms carrying second derivatives of w. They can arise only from the first two terms of Σ, and by antisymmetry those two are

$$\{u, \{v, w\}\} + \{v, \{w, u\}\} = \{u, \{v, w\}\} - \{v, \{u, w\}\} = (D_u D_v - D_v D_u)\, w\,,$$

the commutator of two first-order operators. In such a commutator the second-order parts cancel: writing $D_u w = B^e \partial_e w$ and $D_v w = A^d \partial_d w$ with coefficients built from the first derivatives of u and v alone, the second-order part of $D_u D_v w$ is $B^e A^d\, \partial_e \partial_d w$ and that of $D_v D_u w$ is $A^e B^d\, \partial_e \partial_d w$, and the two contractions are equal because $\partial_e \partial_d w$ is symmetric in e and d (Proposition 7.73). So $(D_u D_v - D_v D_u)\, w$ is again first order in w. The third term $\{w, \{u, v\}\}$ carries only first derivatives of w to begin with. Hence Σ contains no second derivative of w at all. Since Σ is unchanged by cyclic permutation of u, v, w, it contains no second derivative of u and none of v either. But every term of Σ carries exactly one second derivative, of one of the three functions. Therefore every term cancels and $\Sigma = 0$, which is Equation (22.46). □

Remark 22.31 (The bracket is a Lie algebra structure). Properties (1) and (4) say precisely that the real vector space of smooth functions on phase space, equipped with $\{\cdot, \cdot\}$, is a Lie algebra in the sense of Definition 5.123 — an infinite-dimensional one. The bracket obeys in addition the Leibniz rule $\{u, vw\} = \{u, v\}\, w + v\, \{u, w\}$, immediate from Equation (22.41), so each $D_u = \{u, \cdot\}$ is a derivation of the algebra of observables (Definition 5.124). Both facts are structural rather than dynamical: no Hamiltonian has been named. It is because they hold that the correspondence with the commutator of quantum operators of Chapter 25 can be a correspondence of algebras and not merely an analogy of formulas.

Rests on Proposition 22.30 and Definitions 5.123 and 5.124.

Proposition 22.32 (Duality of the two brackets)**.** *Let $u_1, \dots, u_{2f}$, with $u_c = u_c(q^a, p_a)$, be a set of mutually independent functions on phase space. Then*

$$\sum_{c=1}^{2f} [u_c, u_d]_{q,p}\, \{u_c, u_e\}_{q,p} = \delta_{de}\,. \tag{22.47}$$

Writing $\Lambda_{cd} = [u_c, u_d]_{q,p}$ and $\Pi_{ce} = \{u_c, u_e\}_{q,p}$ for the two matrices, both antisymmetric, Equation (22.47) says $\Lambda^{\mathsf{T}}\Pi = \mathbb{1}_{2f}$; each matrix therefore determines the other, and

$$\Pi = \left(\Lambda^{\mathsf{T}}\right)^{-1} = -\Lambda^{-1}\,. \tag{22.48}$$

Rests on Equation (22.42) and Corollary A.292.

Proof. *Derives Proposition 22.32.*

Let T be the $2f \times 2f$ matrix of the derivatives $T^g{}_c = \partial \eta^g / \partial u_c$. The u_c being $2f$ mutually independent functions of the $2f$ variables η, the map $\eta \longmapsto u$ has a local inverse

(Corollary A.292) and T is invertible, with $\left(T^{-1}\right)_c{}^g = \partial u_c/\partial \eta^g$. The two matrices of Equation (22.42) are then

$$\Lambda = T^{\mathsf{T}} J\, T\,, \qquad \Pi = T^{-1} J \left(T^{-1}\right)^{\mathsf{T}}\,. \tag{22.49}$$

Multiplying them,

$$\Lambda\,\Pi = T^{\mathsf{T}} J\, T\, T^{-1} J \left(T^{\mathsf{T}}\right)^{-1} = T^{\mathsf{T}} J^2 \left(T^{\mathsf{T}}\right)^{-1} = -\mathbb{1}_{2f}\,,$$

using $J^2 = -\mathbb{1}_{2f}$ from Equation (5.173). Since $\Lambda^{\mathsf{T}} = -\Lambda$,

$$\sum_c \Lambda_{cd}\Pi_{ce} = \left(\Lambda^{\mathsf{T}}\Pi\right)_{de} = -\left(\Lambda\Pi\right)_{de} = \delta_{de}\,,$$

which is Equation (22.47), and Equation (22.48) follows on multiplying by $\left(\Lambda^{\mathsf{T}}\right)^{-1}$. □

Remark 22.33 (What the duality is good for). Neither bracket determines a transformation on its own, but each is a complete test. Taking the u_c to be the new coordinates (Q, P) themselves, Equation (22.49) reads $\Lambda = \left(M^{-1}\right)^{\mathsf{T}} J\, M^{-1}$ and $\Pi = MJM^{\mathsf{T}}$; the transformation is canonical when either equals J, and Equation (22.47) shows that one follows from the other. This is why the fundamental Lagrange brackets and the fundamental Poisson brackets are interchangeable as tests (Remark 22.28), a fact used without comment in most of the literature.

Rests on Proposition 22.32 and Lemma 22.20.

22.4 Motion in phase space

Theorem 22.34 (Evolution of a phase-space function)**.** *For an arbitrary phase-space function $U = U(q, p, t)$, along the motion,*

$$\frac{\mathrm{d}U}{\mathrm{d}t} = \{U, \mathcal{H}\}_{q,p} + \frac{\partial U}{\partial t}\,. \tag{22.50}$$

Rests on Equations (22.3), (22.4) and (22.41).

Proof. *Derives Theorem 22.34.*

By the chain rule Proposition 7.72 along a trajectory, and then by Hamilton's equations Equations (22.3) and (22.4),

$$\frac{\mathrm{d}U}{\mathrm{d}t} = \frac{\partial U}{\partial q^a}\dot{q}^a + \frac{\partial U}{\partial p_a}\dot{p}_a + \frac{\partial U}{\partial t} = \frac{\partial U}{\partial q^a}\frac{\partial \mathcal{H}}{\partial p_a} - \frac{\partial U}{\partial p_a}\frac{\partial \mathcal{H}}{\partial q^a} + \frac{\partial U}{\partial t}\,,$$

and the first two terms are Equation (22.41) with $v = \mathcal{H}$. □

Corollary 22.35. *If the function U does not depend explicitly on time, then*

$$\frac{\mathrm{d}U}{\mathrm{d}t} = \{U, \mathcal{H}\}_{q,p}\,. \tag{22.51}$$

Rests on Theorem 22.34.

Proof. *Derives Corollary 22.35.*

Set $\partial U/\partial t = 0$ in Equation (22.50). □

Remark 22.36 (The whole dynamics in one operation). Equation (22.50) is the most compact statement of Hamiltonian mechanics available: it computes the rate of change of *any* observable from the bracket alone, with $\mathcal{H}$ singled out only as the observable that generates the flow. Taking $U = \mathcal{H}$ recovers Equation (22.10), since $\{\mathcal{H}, \mathcal{H}\} = 0$ by Equation (22.43). It is also the classical statement of which the Heisenberg equation of motion is the quantum counterpart, $\{\cdot,\cdot\} \longmapsto [\cdot,\cdot]\,/\,(\mathrm{i}\hbar)$, and the correspondence — with the exact sense in which it holds and the precise sense in which it fails — is Chapter 25. The factor $\mathrm{i}\hbar$ is forced by units: by Remark 22.5 a Poisson bracket of two observables carries their units divided by an action, and $\hbar$ is the action that supplies it.

Rests on Theorem 22.34 and Remark 22.5.

In particular, the equations of motion themselves take the bracket form:

$$\{q^a, \mathcal{H}\}_{q,p} = \dot{q}^a = \frac{\partial \mathcal{H}}{\partial p_a}\,, \tag{22.52}$$

$$\{p_a, \mathcal{H}\}_{q,p} = \dot{p}_a = -\frac{\partial \mathcal{H}}{\partial q^a}\,. \tag{22.53}$$

From Equations (22.44) and (22.51) (taking $U = q^a$ and $U = p_a$, whose brackets with $\mathcal{H}$ reduce to a single term by Equation (22.44)).

Proposition 22.37 (Constants of motion)**.** *If the Poisson bracket of a function that does not depend explicitly on time with the Hamiltonian is zero, then the function is a constant of motion.*

Rests on Corollary 22.35.

Proof. *Derives Proposition 22.37.*

By Equation (22.51), $\mathrm{d}U/\mathrm{d}t = \{U, \mathcal{H}\} = 0$ along every motion, so U is constant on each trajectory (Corollary 7.36). The converse holds as well: a U free of explicit time dependence that is constant along every motion has $\{U, \mathcal{H}\} = 0$ everywhere, since the trajectory through a given point may be chosen to pass through it in any direction the equations allow. □

Theorem 22.38 (Poisson's theorem)**.** *The Poisson bracket of two constants of motion is itself a constant of motion.*

Rests on Equation (22.46) and Theorem 22.34.

Proof. *Derives Theorem 22.38.*

Let u and v be constants of motion, so that by Equation (22.50)

$$\{u, \mathcal{H}\} + \frac{\partial u}{\partial t} = 0\,, \qquad \{v, \mathcal{H}\} + \frac{\partial v}{\partial t} = 0\,. \tag{22.54}$$

Differentiating Equation (22.41) with respect to t at fixed (q, p) gives the Leibniz rule $\partial\,\{u, v\}\,/\partial t = \{\partial u/\partial t, v\} + \{u, \partial v/\partial t\}$. Next, the Jacobi identity Equation (22.46) with $w = \mathcal{H}$, rearranged by antisymmetry Equation (22.43), gives

$$\{\{u, v\}\,, \mathcal{H}\} = \{u, \{v, \mathcal{H}\}\} - \{v, \{u, \mathcal{H}\}\} = -\left\{u, \frac{\partial v}{\partial t}\right\} + \left\{v, \frac{\partial u}{\partial t}\right\}\,,$$

the last step by Equation (22.54). Adding the two results and applying Equation (22.50) to the function $\{u, v\}$,

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\{u, v\} &= \{\{u, v\}\,, \mathcal{H}\} + \frac{\partial}{\partial t}\{u, v\} \\ &= (-\{u, \partial v/\partial t\} + \{v, \partial u/\partial t\}) + (\{\partial u/\partial t, v\} + \{u, \partial v/\partial t\}) = 0\,,\end{aligned}$$

since $\{v, \partial u/\partial t\} = -\{\partial u/\partial t, v\}$. In particular, when neither constant depends explicitly on time the argument reduces to $\{\{u, v\}\,, \mathcal{H}\} = 0$ and Proposition 22.37. □

Remark 22.39 (Poisson's theorem does not manufacture new constants). The theorem is a genuine tool — the three components of angular momentum close on themselves under the bracket, and knowing two of them to be conserved delivers the third — but it is not a machine for producing integrals. Most often $\{u, v\}$ turns out to be a constant already known, a function of u and v, or simply zero. It says that the constants of motion of a system form a Lie subalgebra of the algebra of Remark 22.31, and the interest lies in which algebra that is: for the Kepler problem it is larger than the rotation algebra, which is the statement that the Laplace–Runge–Lenz vector is conserved (Chapter 27).

Rests on Theorem 22.38 and Remark 22.31.

22.5 Symplectic formulation

The pairs (q^a, p_a) may be assembled into a single object, and Hamilton's equations into a single matrix equation. Define the *coordinate vector* η^c, $c = 1, \dots, 2f$, and the corresponding *vector of derivatives* of the Hamiltonian by

$$\eta^c = \begin{pmatrix} q^a \\ p_a \end{pmatrix}, \qquad \frac{\partial \mathcal{H}}{\partial \eta^c} = \begin{pmatrix} \dfrac{\partial \mathcal{H}}{\partial q^a} \\ \dfrac{\partial \mathcal{H}}{\partial p_a} \end{pmatrix}, \tag{22.55}$$

where the first f components run over the coordinates and the last f over the momenta.

Definition 22.40 (Symplectic matrix)**.** The *symplectic matrix* is the $2f \times 2f$ matrix

$$J = \begin{pmatrix} 0 & \mathbb{1}_f \\ -\mathbb{1}_f & 0 \end{pmatrix}, \qquad J^{\mathsf{T}} = -J\,, \quad J^2 = -\mathbb{1}_{2f}\,, \quad J^{-1} = -J\,. \tag{22.56}$$

It is the matrix of Equation (5.173), the standard non-degenerate antisymmetric form of Proposition 5.115, at $2n = 2f$; the transformations preserving it are the symplectic group $\mathrm{Sp}(2f, \mathbb{R})$ of Definition 5.130.

Rests on Equation (5.173) and Definition 5.130.

Proposition 22.41 (Symplectic form of Hamilton's equations)**.** *Hamilton's equations Equations (22.3) and (22.4) are equivalent to*

$$\dot\eta^c = J^c{}_d \frac{\partial \mathcal{H}}{\partial \eta^d}\,, \qquad \textit{in matrix form} \qquad \dot\eta = J \frac{\partial \mathcal{H}}{\partial \eta}\,. \tag{22.57}$$

Rests on Equations (22.3), (22.4) and (22.56).

Proof. *Derives Proposition 22.41.*

Split the column Equation (22.55) into its two blocks of f components and multiply out, using Equation (22.56):

$$J \frac{\partial \mathcal{H}}{\partial \eta} = \begin{pmatrix} 0 & \mathbb{1}_f \\ -\mathbb{1}_f & 0 \end{pmatrix} \begin{pmatrix} \partial \mathcal{H}/\partial q^a \\ \partial \mathcal{H}/\partial p_a \end{pmatrix} = \begin{pmatrix} \partial \mathcal{H}/\partial p_a \\ -\partial \mathcal{H}/\partial q^a \end{pmatrix},$$

while $\dot\eta$ is the column with blocks $\dot q^a$ and $\dot p_a$. Equating the two columns block by block gives Equation (22.3) from the upper block and Equation (22.4) from the lower, and conversely. The whole effect of J is to interchange the two blocks and change the sign of one of them, which is exactly the asymmetry between Equations (22.3) and (22.4). □

Remark 22.42 (What the matrix form is for). Rewriting two equations as one buys nothing by itself. What it buys is that every statement about canonical transformations becomes a statement about the single matrix J: Equation (22.25) is the condition, Equation (22.42)

are the brackets, and the proofs in Sections 22.2, 22.3 and 22.3.2 above are three lines each because of it. The price is that η mixes quantities of different physical dimension — Remark 22.5 — so J is not a tensor on phase space in any metric sense and η is not a vector; the object that is coordinate-free is the two-form whose matrix J is, and that is the subject of Chapter 24.

Rests on Proposition 22.41 and Remark 22.5.

22.5.1 Symplectic form of the transformation condition

The heading reserved at this point in the source outline asks for the symplectic characterization of canonical transformations: the condition on the Jacobian matrix of the transformation that is equivalent to the $4f^2$ direct conditions of Proposition 22.17. It has already been established, because it was needed before the notation of this section was introduced. It is Lemma 22.20: the single matrix identity $M^{\mathsf{T}} J\, M = J$, stating that the Jacobian Equation (22.24) lies in $\mathrm{Sp}(2f, \mathbb{R})$ at every point and at every instant.

Four apparently different tests for a transformation to be canonical have now been shown to be one test, and it is worth listing them together.

1. The action principles agree, Equation (22.15) — the definition.
2. The direct conditions Equations (22.16) and (22.17) hold.
3. The Jacobian satisfies Equation (22.25).
4. The fundamental Lagrange brackets Equation (22.40), equivalently the fundamental Poisson brackets, are preserved.

That (1) implies (3) is the necessity half of Lemma 22.20; that (3) implies (1) for transformations free of the time is its sufficiency half, and in general Theorem 24.18; the equivalence of (2) and (3) is Proposition 22.17; and (4) is (3) read block by block, Remark 22.28. Only (3) survives unchanged into the coordinate-free language of Chapter 24, where it becomes the statement that the transformation pulls the symplectic form back to itself.

22.6 Beyond the canonical formalism

Three bodies of theory grow directly out of this chapter, and each is given a chapter of its own rather than a section here.

22.6.1 Hamilton–Jacobi theory

Pushed to its limit, the search for a convenient canonical transformation asks for one that makes every new coordinate and momentum constant. The generating function that achieves it satisfies a single first-order partial differential equation, and its level surfaces propagate through configuration space exactly as optical wavefronts propagate through a medium. Chapter 23 develops the equation, the action–angle variables it produces for bounded motion, and the optical–mechanical analogy that leads out of classical mechanics altogether.

22.6.2 Symplectic geometry

The matrix J of Equation (22.56) is the component form of a closed nondegenerate two-form on phase space, and the Poisson bracket, the canonical transformations, the invariant integrals of Section 22.3 and the conservation laws are all statements about it. Chapter 24 develops that geometry.

22.6.3 Symmetries

The symmetry content of the canonical formalism—the correspondence between one-parameter families of canonical transformations, their generators, and the constants of motion—follows from the bracket alone, and with it the correspondence rule that carries the whole formalism into quantum mechanics. Chapter 25 develops both, and Chapter 26 treats the systems for which the Legendre transformation of Definition 22.2 fails to be invertible in the first place—which is to say every gauge theory.

Chapter 23

Hamilton–Jacobi Theory and the Optical–Mechanical Analogy

The canonical transformations of Section 22.2 were introduced as the transformations that preserve the form of Hamilton's equations. Nothing so far has been asked of them beyond that. Hamilton–Jacobi theory asks the extreme question: is there a canonical transformation that makes the equations of motion *trivial*—one whose new coordinates and momenta are all constants? The answer is yes, and the generating function that performs it satisfies a single first-order partial differential equation, the Hamilton–Jacobi equation. Solving that one equation solves the mechanical problem completely.

The reward is not merely computational. The function that appears in the equation is the action itself, and its level surfaces propagate through configuration space exactly as the wavefronts of a wave propagate through an optical medium, with the trajectories playing the part of the rays. This is Hamilton's optical–mechanical analogy: he built the characteristic-function method for optics first [84] and then transplanted it whole into dynamics [96], and Jacobi turned the transplant into the method of integration that carries both their names [101]. It is the reason this chapter sits where it does: it is the last statement classical mechanics can make about itself, and the first sentence of quantum mechanics. The route from Equation (23.2) below to the Schrödinger equation of Chapter 77 is the shortest one in physics, and it is travelled in Section 23.5. Standard treatments are [1585, 2027].

Notation 23.1. The index conventions of Notation 22.1 remain in force: $a, b = 1, \dots, f$ label the degrees of freedom, and repeated indices are summed. The f constants of integration that label a complete integral are written α_a, and the f constants conjugate to them β^a. In the optical sections $\boldsymbol{x}$ denotes a point of physical space and s the arclength along a ray.

23.1 The Hamilton–Jacobi equation

23.1.1 The transformation to constant coordinates

Let $F_2 = S(q, P, t)$ be a generating function of the second kind, in the sense of Equation (22.21), and demand of it that the transformed Hamiltonian vanish identically,

$$K(Q, P, t) = 0\,. \tag{23.1}$$

Hamilton's equations for the new variables then read $\dot{Q}^a = 0$ and $\dot{P}_a = 0$: the new coordinates and momenta are $2f$ constants of the motion. Writing $P_a = \alpha_a$ and $Q^a = \beta^a$ for those constants, and substituting $p_a = \partial S/\partial q^a$ from Equation (22.21) into $K = \mathcal{H} + \partial S/\partial t$, the demand Equation (23.1) becomes a single equation for S.

Definition 23.2 (Hamilton's principal function and the Hamilton–Jacobi equation)**.** *Hamilton's principal function* is a function $S(q^a, \alpha_a, t)$ of the coordinates, of f constants α_a, and of the time, satisfying the *Hamilton–Jacobi equation*

$$\mathcal{H}\left(q^a, \frac{\partial S}{\partial q^a}, t\right) + \frac{\partial S}{\partial t} = 0\,. \tag{23.2}$$

It carries the SI dimension of an action, J s, since it generates the momenta by differentiation with respect to the coordinates.

Rests on Equations (22.21) *and* (23.1) *and Proposition 22.18.*

Equation (23.2) is a first-order partial differential equation in the $f+1$ variables (q^a, t), nonlinear in the derivatives whenever the Hamiltonian is not linear in the momenta. Its characteristic curves are precisely the trajectories of the mechanical system, which is the reading Remark 10.21 of Chapter 10 gives it.

Remark 23.3 (What Part II owes this chapter). Proposition 10.15 treats the *quasilinear* first-order equation $a\,\partial_x u + b\,\partial_y u = c$, in which the derivatives enter linearly. Equation (23.2) is not of that form: the Hamiltonian is quadratic in $\partial S/\partial q^a$ for every mechanical system of interest. The characteristic theory that does cover it—Cauchy's method of characteristic strips for a fully nonlinear equation $F(q, S, \partial S/\partial q) = 0$, in which the momenta are carried along as independent unknowns and the characteristic system is Hamilton's own—is not in Chapter 10, and neither is the theorem that the envelope of a family of solutions is again a solution, which is how a complete integral generates the general one. Both are ordinary theory of first-order partial differential equations and belong there. This chapter does not use them: Theorem 23.6 below is proved directly from the non-degeneracy of the complete integral, which needs only the implicit function theorem Theorem A.286, and the envelope construction is never invoked. The gap is recorded rather than quietly filled.

Rests on Equation (23.2)*, Proposition 10.15, and Theorem A.286.*

Remark 23.4 (What the equation costs and what it buys). The trade is $2f$ coupled ordinary differential equations for one partial differential equation in $f+1$ variables. Considered as a method of solution this is usually a bad bargain, and Hamilton–Jacobi theory is not the way most mechanical problems are solved. Its value is structural: it identifies the action as the object that propagates, it is the natural setting for separation of variables and for the action–angle variables of Section 23.3, and it is the classical limit of wave mechanics.

Rests on Equation (23.2) *and Theorem 22.6.*

23.1.2 Jacobi's theorem

Definition 23.5 (Complete integral)**.** A *complete integral* of Equation (23.2) is a solution $S(q^a, \alpha_a, t)$ depending on f constants α_a, none of which is purely additive, such that

$$\det\left(\frac{\partial^2 S}{\partial q^a\,\partial \alpha_b}\right) \neq 0\,. \tag{23.3}$$

Rests on Equation (23.2)*.*

The constants α_a are f, not $f+1$: Equation (23.2) contains S only through its derivatives, so an additive constant is always available and carries no information, which is what the exclusion of a purely additive constant says.

Theorem 23.6 (Jacobi)**.** *Let $S(q^a, \alpha_a, t)$ be a complete integral of the Hamilton–Jacobi equation Equation* (23.2)*. Then the $2f$ relations*

$$\beta^a = \frac{\partial S}{\partial \alpha_a}\,, \tag{23.4}$$

$$p_a = \frac{\partial S}{\partial q^a}\,, \tag{23.5}$$

with α_a and β^a arbitrary constants, define implicitly a $2f$-parameter family of curves $(q^a(t), p_a(t))$, and every such curve is a solution of Hamilton's equations Equations (22.3) and (22.4). Conversely every solution of Hamilton's equations is obtained in this way for a suitable choice of the constants.

Rests on Definition 23.5 and Theorems 22.6 and A.286.

Proof. Derives Theorem 23.6.

The curves exist. Fix α and β and apply the implicit function theorem Theorem A.286 to the map $F_b(t,q) := \partial S/\partial\alpha_b(q,\alpha,t) - \beta^b$, whose derivative with respect to q is the matrix $\partial^2 S/\partial\alpha_b\partial q^a$, nonsingular by Equation (23.3). Near any solution point Equation (23.4) therefore determines $q^a = q^a(\alpha,\beta,t)$ uniquely and differentiably, and Equation (23.5) then defines $p_a(t)$ along that curve.

The first half of Hamilton's equations. Differentiate Equation (23.4) totally with respect to t, holding α and β fixed:

$$0 = \frac{\partial^2 S}{\partial\alpha_b\,\partial t} + \frac{\partial^2 S}{\partial\alpha_b\,\partial q^a}\,\dot q^a\,. \tag{23.6}$$

Now differentiate the Hamilton–Jacobi equation Equation (23.2) itself with respect to α_b, at fixed q and t. The Hamiltonian depends on α_b only through its momentum slots, so the chain rule Proposition 7.72 gives

$$\frac{\partial\mathcal{H}}{\partial p_a}\,\frac{\partial^2 S}{\partial q^a\,\partial\alpha_b} + \frac{\partial^2 S}{\partial t\,\partial\alpha_b} = 0\,. \tag{23.7}$$

Mixed partial derivatives commute (Proposition 7.73), so subtracting Equation (23.7) from Equation (23.6) leaves

$$\frac{\partial^2 S}{\partial\alpha_b\,\partial q^a}\left(\dot q^a - \frac{\partial\mathcal{H}}{\partial p_a}\right) = 0\,, \tag{23.8}$$

and the matrix is nonsingular by Equation (23.3). Hence $\dot q^a = \partial\mathcal{H}/\partial p_a$, which is Equation (22.3).

The second half. Differentiate Equation (23.5) totally with respect to t:

$$\dot p_a = \frac{\partial^2 S}{\partial q^a\,\partial t} + \frac{\partial^2 S}{\partial q^a\,\partial q^b}\,\dot q^b\,. \tag{23.9}$$

Differentiate Equation (23.2) with respect to q^a, now at fixed α and t, remembering that $\mathcal{H}$ depends on q^a both directly and through the momenta:

$$\frac{\partial\mathcal{H}}{\partial q^a} + \frac{\partial\mathcal{H}}{\partial p_b}\,\frac{\partial^2 S}{\partial q^b\,\partial q^a} + \frac{\partial^2 S}{\partial t\,\partial q^a} = 0\,. \tag{23.10}$$

Substituting $\dot q^b = \partial\mathcal{H}/\partial p_b$, just proved, into Equation (23.9) and adding Equation (23.10) term by term, every second derivative of S cancels and

$$\dot p_a + \frac{\partial\mathcal{H}}{\partial q^a} = 0\,, \tag{23.11}$$

which is Equation (22.4).

The converse. Let $(q^a(t), p_a(t))$ solve Hamilton's equations with data (q_0, p_0) at t_0. By Equation (23.3) and Theorem A.286 again, the f equations $p_{0a} = \partial S/\partial q^a(q_0,\alpha,t_0)$ determine α near any point at which they hold; set $\beta^b := \partial S/\partial\alpha_b(q_0,\alpha,t_0)$. The curve the theorem produces from that (α,β) and the given solution obey the same first-order system with the same data at t_0, so they coincide by the uniqueness half of Theorem 9.8. □

The theorem is what makes the trade of Remark 23.4 worth considering: *one* solution of Equation (23.2) carrying f constants, and no other information, yields the complete solution of the mechanical problem by differentiation and elimination alone—no further integration is performed.

Proposition 23.7 (The principal function is the action)**.** *Along a solution of the equations of motion,*

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \mathcal{L}\,, \qquad \textit{so that} \qquad S = \int_{t_a}^{t_b} \mathcal{L}\,\mathrm{d}t + \textit{const}\,. \tag{23.12}$$

Hamilton's principal function is therefore the action of Chapter 16, regarded no longer as a functional of paths but as a function of the endpoint.

Rests on Theorem 23.6, Equation (22.1)*, and Definition 16.96.*

Proof. *Derives Proposition 23.7.*

Along a solution the constants α_a are fixed, so the total time derivative of $S\,(q(t), \alpha, t)$ is

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \frac{\partial S}{\partial q^a}\,\dot{q}^a + \frac{\partial S}{\partial t} = p_a \dot{q}^a - \mathcal{H}\,, \tag{23.13}$$

From Equations (23.2) *and* (23.5) *(the first term from the momenta of the complete integral, the second from the equation itself).*

The second equality uses Equation (23.5) for the first term and Equation (23.2) for the second. The right-hand side is the inverse Legendre transformation Equation (22.1) of Chapter 22, that is the Lagrangian. Integrating between two times gives the second equality of Equation (23.12), the constant being the value of S at the lower limit. □

Remark 23.8 (The action as a function, not a functional). Proposition 23.7 is the pivot of the whole chapter and it is easy to read past. In Chapter 16 the action Equation (16.86) is a number assigned to an arbitrary path; here it is a *field* on configuration space, obtained by evaluating that number on the one extremal path that actually reaches the point q at time t. The two readings are related exactly as Hilbert's invariant integral Theorem 16.63 is related to the functional it is built from: given a field of extremals in the sense of Definition 16.62, the value of the action along the member through each point defines a function whose gradient is the momentum, and Equation (23.5) is that statement.

Rests on Proposition 23.7, Theorem 16.63, and Definition 16.62.

23.1.3 Time-independent systems and the characteristic function

Proposition 23.9 (Separation of the time)**.** *If the Hamiltonian does not depend explicitly on the time, the Hamilton–Jacobi equation admits solutions of the form*

$$S(q, \alpha, t) = W(q, \alpha) - Et\,, \tag{23.14}$$

where $E = \alpha_1$ is the conserved value of the Hamiltonian and the function W, called Hamilton's characteristic function*, satisfies the* time-independent Hamilton–Jacobi equation

$$\mathcal{H}\left(q^a, \frac{\partial W}{\partial q^a}\right) = E\,. \tag{23.15}$$

Rests on Equation (23.2)*, Theorem 22.10, and Lemma 10.28.*

Proof. *Derives Proposition 23.9.*

Try the additive ansatz $S(q, \alpha, t) = W(q, \alpha) - h(t)$, which is the general form in which the time enters additively. Then $\partial S/\partial q^a = \partial W/\partial q^a$ and $\partial S/\partial t = -h'(t)$, so Equation (23.2) reads

$$\mathcal{H}\left(q^a, \frac{\partial W}{\partial q^a}\right) = h'(t)\,. \tag{23.16}$$

The left-hand side depends on q alone—this is where the absence of an explicit time dependence in $\mathcal{H}$ is used—and the right-hand side on t alone, so by Lemma 10.28 both equal a constant. Call it E; then $h(t) = Et$ up to the additive constant excluded by Definition 23.5, and Equation (23.16) is Equation (23.15). That the constant is the conserved value of the Hamiltonian is immediate from Equation (23.15) and Equation (23.5), and the conservation itself is Theorem 22.10. Since E is one of the constants of the complete integral it may be named α_1. □

Proposition 23.10 (The characteristic function is the abbreviated action)**.** *The characteristic function is the abbreviated, or Maupertuis, action*

$$W = \int p_a \, \mathrm{d}q^a \,, \tag{23.17}$$

and the variational principle it satisfies at fixed energy,

$$\delta \int p_a \, \mathrm{d}q^a = 0 \,, \tag{23.18}$$

is Maupertuis' principle*. For a Hamiltonian of the form* $\mathcal{H} = |\boldsymbol{p}|^2 / 2m + V(\boldsymbol{x})$ *it reads*

$$\delta \int \sqrt{2m \left(E - V(\boldsymbol{x})\right)} \, \mathrm{d}s = 0 \,, \tag{23.19}$$

$\mathrm{d}s$ *being the element of arclength in configuration space.*
Rests on Proposition 23.9, Definition 16.99, and Theorem 16.101.

Proof. *Derives Proposition 23.10.*
By Equation (23.14) and Proposition 23.7,

$$W = S + Et = \int (\mathcal{L} + E) \, \mathrm{d}t = \int (p_a \dot{q}^a - \mathcal{H} + E) \, \mathrm{d}t = \int p_a \dot{q}^a \, \mathrm{d}t \,, \tag{23.20}$$

since $\mathcal{H} = E$ along the motion; the last integral is $\int p_a \, \mathrm{d}q^a$, which is Equation (23.17) and is exactly the abbreviated action Equation (16.88) of Definition 16.99. The variational principle Equation (23.18) for that functional, with the energy fixed and the transit time free, is Theorem 16.101, which also supplies the metric form: for $\mathcal{H} = |\boldsymbol{p}|^2 / 2m + V$ one has $|\boldsymbol{p}| = \sqrt{2m(E - V)}$ and $p_a \mathrm{d}q^a = |\boldsymbol{p}| \, \mathrm{d}s$, so Equation (23.18) becomes Equation (16.91), which is Equation (23.19). □

Remark 23.11 (Whose principle, and where it fails). Two cautions carried over from Remark 16.102 and not to be lost here. The sharp statement of Equation (23.18), with the hypothesis of fixed energy, is Euler's [23], not Maupertuis' [24]; the name is customary and is kept, the correction recorded. And Equation (23.19) requires $E > V$ throughout the region: at a turning point the integrand vanishes, the Jacobi metric degenerates, and the principle says nothing. That degeneracy is not a technicality—it is the same failure that Section 23.5.2 identifies as the place where the whole geometrical description breaks down.
Rests on Proposition 23.10 and Theorem 16.101.

Remark 23.12 (Two functions, two roles). S generates a transformation to variables that are constant; W generates a transformation to variables in which the new Hamiltonian is E, so that the new momenta are constant and the new coordinates advance linearly in time. The second is the useful one for bounded motion, and it is what Section 23.3 builds on.
Rests on Definition 23.2 and Proposition 23.9.

23.2 Complete integrals and separation of variables

Definition 23.13 (Additive separability)**.** The Hamilton–Jacobi equation is *completely separable* in the coordinates q^a if it admits a complete integral of the form

$$W(q, \alpha) = \sum_{a=1}^{f} W_a \left(q^a; \alpha_1, \ldots, \alpha_f\right) \,, \tag{23.21}$$

each summand depending on a single coordinate.
Rests on Definition 23.5 and Equation (23.15).

Separability turns one partial differential equation into f ordinary ones, each solvable by a quadrature: from Equation (23.21) the momentum $p_a = \mathrm{d}W_a/\mathrm{d}q^a$ is a function of its own coordinate and of the constants, so each W_a is an explicit integral. This is why every mechanical problem that can be "solved in closed form" is, in practice, a separable one.

Proposition 23.14 (Cyclic coordinates)**.** *If q^1 is cyclic—that is, absent from the Hamiltonian, in the sense of Definition 21.35—then the characteristic function separates in it as*

$$W = \alpha_1 q^1 + W'\left(q^2, \dots, q^f; \alpha\right), \tag{23.22}$$

and $\alpha_1 = p_1$ is the conserved momentum conjugate to q^1.

Rests on Definitions 21.35 and 23.13 and Theorem 21.36.

Proof. *Derives Proposition 23.14.*

Substitute Equation (23.22) into Equation (23.15). Since $\partial W/\partial q^1 = \alpha_1$ and q^1 occurs nowhere in $\mathcal{H}$, the resulting equation

$$\mathcal{H}\left(q^2, \dots, q^f;\ \alpha_1, \frac{\partial W'}{\partial q^2}, \dots, \frac{\partial W'}{\partial q^f}\right) = E$$

contains neither q^1 nor any derivative of W' with respect to it: it is an equation for W' in $f-1$ variables, and the ansatz is consistent. Conversely Equation (23.5) gives $p_1 = \partial W/\partial q^1 = \alpha_1$, a constant, in agreement with Theorem 21.36. □

23.2.1 Conditions for separability

Separability is a property of the pair (system, coordinate system), never of the system alone. The Kepler problem separates in spherical coordinates, in parabolic coordinates and in a rotated Cartesian system not at all; the harmonic oscillator separates in Cartesian coordinates and not in polar ones unless it is isotropic. The question this subsection answers is which coordinate systems work, for the class of Hamiltonians in which the kinetic energy is diagonal.

Definition 23.15 (Orthogonal Hamiltonian)**.** A Hamiltonian is *orthogonal* in the coordinates q^a if

$$\mathcal{H}(q,p) = \frac{1}{2}\sum_{a=1}^{f} g^{aa}(q)\, p_a^2 + V(q)\,, \tag{23.23}$$

with no cross terms $p_a p_b$, $a \neq b$. For a single particle of mass m moving in ordinary space with orthogonal curvilinear coordinates of scale factors h_a, so that $\mathrm{d}s^2 = \sum_a h_a^2\,(\mathrm{d}q^a)^2$, one has $g^{aa} = 1/\left(m h_a^2\right)$. The SI dimension of g^{aa} depends on what dimension the coordinate q^a carries—$1/\mathrm{kg}$ when q^a is a length, $1/(\mathrm{kg\,m^2})$ when it is an angle—and in every case $g^{aa}p_a^2$ is an energy.

Rests on Definitions 13.117 and 22.2.

Definition 23.16 (Stäckel matrix; Stäckel system)**.** A *Stäckel matrix* for the coordinates q^a is an $f \times f$ matrix $\Phi = (\phi_{ab})$ whose a-th row depends on the single coordinate q^a, with

$$\det \Phi \neq 0\,. \tag{23.24}$$

The orthogonal Hamiltonian Equation (23.23) is a *Stäckel system* in those coordinates if there exist such a Φ and f functions $u_a(q^a)$, each of one coordinate, with

$$g^{aa} = \left(\Phi^{-1}\right)_{1a}, \qquad V = \sum_{a=1}^{f} \left(\Phi^{-1}\right)_{1a} u_a(q^a)\,. \tag{23.25}$$

Rests on Equation (23.23).

Equation (23.25) is a strong pair of requirements and it is worth reading twice. The first says the diagonal of the inverse metric is the *first row of the inverse* of a matrix built out of one-dimensional functions; it constrains the coordinate system alone. The second says the potential is a combination of one-dimensional potentials with exactly those coefficients; it constrains the system. Dimensionally, ϕ_{a1} carries the reciprocal dimension of g^{aa} and u_a the dimension of p_a^2, so that every term of Equation (23.27) below is a squared momentum.

Theorem 23.17 (Stäckel's conditions are sufficient)**.** *If Equation* (23.25) *holds, then Equation* (23.15) *separates in the coordinates* q^a *and*

$$W(q,\alpha) = \sum_{a=1}^{f} \int^{q^a} \sqrt{2\sum_{b=1}^{f} \alpha_b\, \phi_{ab}(s) - 2u_a(s)}\; \mathrm{d}s \tag{23.26}$$

is a complete integral of it, with $\alpha_1 = E$*.*

Rests on Definitions 23.13 and 23.16 and Equation (23.15)*.*

Proof. *Derives Theorem 23.17.*

The summand of Equation (23.26) depends on the single coordinate q^a, so W has the separated form Equation (23.21) and

$$\left(\frac{\mathrm{d}W_a}{\mathrm{d}q^a}\right)^2 = 2\sum_{b=1}^{f} \alpha_b\, \phi_{ab}(q^a) - 2u_a(q^a)\,. \tag{23.27}$$

Insert this and Equation (23.25) into Equation (23.23). The potential terms cancel against the $-2u_a$ and

$$\mathcal{H} = \sum_a \left(\Phi^{-1}\right)_{1a} \sum_b \alpha_b\, \phi_{ab} = \sum_b \alpha_b \sum_a \left(\Phi^{-1}\right)_{1a} \phi_{ab} = \sum_b \alpha_b\, \delta_{1b} = \alpha_1\,, \tag{23.28}$$

From Equations (23.25) *and* (23.27) *(the first row of the inverse matrix, times the matrix itself).*

The middle step is nothing but $\Phi^{-1}\Phi = \mathbb{1}$ read along its first row. So Equation (23.15) holds with $E = \alpha_1$, identically in q and in the remaining constants.

It remains to check the non-degeneracy Equation (23.3). Differentiating Equation (23.27) with respect to α_b gives $\partial^2 W/\partial q^a \partial \alpha_b = \phi_{ab}/W_a'$, that is the matrix Φ with its a-th row divided by W_a'. Hence

$$\det\left(\frac{\partial^2 W}{\partial q^a\, \partial \alpha_b}\right) = \frac{\det \Phi}{\prod_a W_a'}\,, \tag{23.29}$$

which is nonzero wherever no W_a' vanishes, by Equation (23.24). The zeros of W_a' are exactly the turning points of the a-th degree of freedom, and they are precisely where the construction is expected to fail; that failure is the subject of Section 23.5.2. □

Remark 23.18 (The converse, and what this treatise does not prove)*.* The implication of Theorem 23.17 runs the other way as well: if the orthogonal Hamiltonian Equation (23.23) admits a complete integral of the separated form Equation (23.21) in the coordinates q^a, then a Stäckel matrix and functions u_a satisfying Equation (23.25) exist, so that separability of an orthogonal Hamiltonian is *equivalent* to the Stäckel conditions. That converse is Stäckel's own theorem in the form Levi-Civita gave it, and it is stated here on the authority of [2027]. This treatise does not prove it, and nothing in this chapter or later in the book uses it: every application runs through Theorem 23.17, in the direction that is proved.

It is worth saying where the difficulty sits, because the first two steps are easy and mislead. Write $x_a := \frac{1}{2}\,(W_a')^2$, a function of the single coordinate q^a and of the constants. Differentiating the separated equation $\sum_a g^{aa} x_a + V = \alpha_1$ with respect to α_b gives $\sum_a g^{aa}\phi_{ab} = \delta_{1b}$ with $\phi_{ab} := \partial x_a/\partial \alpha_b$, and Equation (23.29) identifies $\det\Phi \neq 0$ with the

completeness Equation (23.3); so $g^{aa} = (\Phi^{-1})_{1a}$ already. What is *not* immediate is that Φ may be taken independent of the constants—that is, that x_a is affine in α, which is exactly what makes ϕ_{ab} a function of q^a alone and $u_a := \sum_b \alpha_b \phi_{ab} - x_a$ a function of q^a alone. A second differentiation returns only $\sum_a g^{aa}\, \partial\phi_{ab}/\partial\alpha_c = 0$, which says no more than that g^{aa} does not depend on the constants, and admits solutions with $\partial\Phi/\partial\alpha \neq 0$. Removing those requires a change of the separation constants $\alpha \mapsto \tilde{\alpha}(\alpha)$, under which $\Phi \mapsto \Phi\, \partial\alpha/\partial\tilde{\alpha}$, and it is the proof that such a change always exists—not the index bookkeeping—that this treatise leaves to its source.

Rests on Theorem 23.17 and Definition 23.16.

Remark 23.19 (The same conditions govern the Helmholtz equation). Theorem 10.34 of Chapter 10 states that the Helmholtz equation separates in exactly eleven orthogonal coordinate systems of ordinary space, and that the criterion is the Stäckel condition on the scale factors; the derivation is Appendix A.15, and Remark 10.35 there points forward to this chapter. The two statements are not the same statement, and the difference is instructive. The Helmholtz equation is linear and of second order and its separation constants are eigenvalues; Equation (23.15) is nonlinear and of first order and its separation constants are values of conserved quantities. What they share is Equation (23.25)'s first half, which involves only the coordinate system: the eleven systems that separate the Helmholtz equation are exactly the eleven that separate the free-particle Hamilton–Jacobi equation, because for $V = 0$ the second half of Equation (23.25) is vacuous. Adding a potential can only restrict the list further, never extend it. The relation between the two is made precise by the semiclassical expansion of Section 23.5.1, in which the first-order equation is the leading order of the second-order one.

Rests on Theorems 10.34 and 23.17.

Proposition 23.20 (Separability implies integrability)**.** *Let Equation* (23.15) *separate in the coordinates q^a, with complete integral Equation* (23.21)*. Then the f functions $\alpha_a(q,p)$ obtained by solving Equation* (23.5) *for the constants are functionally independent constants of the motion in involution,*

$$\{\alpha_a, \alpha_b\} = 0 \qquad \text{for all } a, b\,, \tag{23.30}$$

so a separable system is completely integrable in the sense of Theorem 23.31. For a Stäckel system they are

$$\alpha_b = \sum_{a=1}^{f} \left(\Phi^{-1}\right)_{ba} \left[\tfrac{1}{2}p_a^2 + u_a(q^a)\right]\,, \tag{23.31}$$

each quadratic in the momenta, and $\alpha_1 = \mathcal{H}$.

Rests on Definition 23.13 and Equations (22.44) *and* (22.45).

Proof. *Derives Proposition 23.20.*

$W(q,\alpha)$ is a generating function of the second kind (Proposition 22.18) with old momenta $p_a = \partial W/\partial q^a$ and new momenta $P_a = \alpha_a$; the non-degeneracy Equation (23.3) is exactly what makes the transformation invertible, so the α_a are genuine functions on phase space and are functionally independent. They are constants of the motion by Theorem 23.6. The Poisson bracket is invariant under a canonical transformation, Equation (22.45), so it may be computed in the new variables, where the fundamental relations Equation (22.44) give $\{P_a, P_b\}_{Q,P} = 0$; that is Equation (23.30).

For the explicit form, Equation (23.27) with $p_a = W_a'$ reads $\frac{1}{2}p_a^2 + u_a(q^a) = \sum_b \alpha_b \phi_{ab}(q^a)$; multiplying by $(\Phi^{-1})_{ca}$ and summing over a inverts it into Equation (23.31). Setting $c = 1$ and using Equation (23.25) recovers Equation (23.23), so $\alpha_1 = \mathcal{H}$. □

Remark 23.21 (The tensorial statement, and what Part II owes it). Equation (23.31) exhibits each separation constant as a quadratic form in the momenta,

$$\alpha_b = \tfrac{1}{2} K_b{}^{cd}(q)\, p_c p_d + U_b(q)\,, \qquad K_b{}^{cd} = \left(\Phi^{-1}\right)_{bc} \delta^{cd}\,. \tag{23.32}$$

That such a quantity is conserved along every trajectory of Equation (23.23) with $V = 0$ is, in the language of Chapter 13, the statement that $K_b{}^{cd}$ is a *Killing tensor* of rank two: a symmetric tensor field obeying $\nabla^{(e} K_b{}^{cd)} = 0$, the rank-two analogue of Killing's equation Equation (13.290). Separability is then the geometric condition that the configuration-space metric admit f commuting Killing tensors with simultaneously diagonalisable, pointwise-distinct eigenvectors—the coordinate system being the one whose surfaces those eigenvectors are normal to.

Part II does not carry this. Section 13.9.2 defines Killing *vectors* Definition 13.139 and derives Killing's equation Proposition 13.140, and stops there: there is no rank-two Killing tensor, no statement that $\xi_\mu p^\mu$ or $K_{\mu\nu} p^\mu p^\nu$ is constant along a geodesic, and no integrability condition for either. The definitions above are therefore stated here for use and are *not* treated as established; every result this chapter actually proves—Theorem 23.17, Proposition 23.20—is proved from Equation (23.25) directly, in coordinates, and needs none of it. The tensorial reading is what makes Carter's constant of Section 23.4.3 intelligible, and that is where the absence is felt.

Rests on Propositions 13.140 and 23.20.

23.2.2 Worked separations

Six complete integrals, in the order of increasing structure. Each ends by recovering, from Theorem 23.6 alone, a result this treatise has already obtained by other means—which is the only honest way to test a method of this generality.

Example 23.22 (Free particle)**.** For $\mathcal{H} = |\boldsymbol{p}|^2/2m$ in Cartesian coordinates all three coordinates are cyclic, so Proposition 23.14 applies three times and

$$S = \boldsymbol{\alpha}\cdot\boldsymbol{x} - \frac{|\boldsymbol{\alpha}|^2}{2m}\, t\,, \tag{23.33}$$

with $\boldsymbol{\alpha}$ in kg m/s and $E = |\boldsymbol{\alpha}|^2/2m$. Equation (23.4) gives $\boldsymbol{\beta} = \partial S/\partial\boldsymbol{\alpha} = \boldsymbol{x} - \boldsymbol{\alpha} t/m$, that is

$$\boldsymbol{x}(t) = \boldsymbol{\beta} + \frac{\boldsymbol{\alpha}}{m}\, t\,, \tag{23.34}$$

uniform rectilinear motion with $\boldsymbol{p} = \boldsymbol{\alpha}$ constant by Equation (23.5). The surfaces $S = \text{const}$ are the planes perpendicular to $\boldsymbol{\alpha}$, advancing at speed $E/|\boldsymbol{\alpha}| = |\boldsymbol{\alpha}|/2m$—which is *half* the particle speed. That factor of two is not an error and is taken up in Remark 23.42.

Rests on Proposition 23.14 and Theorem 23.6.

Example 23.23 (Uniform gravity, and the parabola)**.** Take motion in a vertical plane with $\mathcal{H} = (p_x^2 + p_z^2)/2m + mgz$ and $g = 9.806\,65\,\mathrm{m/s^2}$, the standard value fixed in Chapter 20. Here x is cyclic, so by Propositions 23.9 and 23.14

$$W = \alpha_x x + \int^z \sqrt{2m\left(E - \frac{\alpha_x^2}{2m} - mgz'\right)}\,\mathrm{d}z'\,. \tag{23.35}$$

Write $\alpha_z := E - \alpha_x^2/2m$ for the energy of the vertical motion. Equation (23.4) with respect to α_x and to α_z gives

$$x = \frac{\alpha_x}{m}\,(t - t_0) + x_0\,, \qquad z = z_0 + \frac{\sqrt{2m\alpha_z}}{m}\,(t - t_0) - \frac{g}{2}\,(t - t_0)^2\,, \tag{23.36}$$

which is the parabolic trajectory derived from Newton's second law in Chapter 20, with the initial speeds $u_x = \alpha_x/m$ and $u_z = \sqrt{2\alpha_z/m}$ identified as the components of the launch velocity. The wavefronts $W = \text{const}$ are the curves orthogonal to the family of parabolas of fixed energy—the envelope of that family being the safety parabola, a caustic in the sense of Section 23.5.2.

Rests on Proposition 23.14 and Theorem 23.6.

Example 23.24 (Harmonic oscillator)**.** For $\mathcal{H} = p^2/2m + \tfrac{1}{2}m\omega_0^2 x^2$ (Definition 28.3), Equation (23.15) gives

$$W(x,E) = \int^{x} \sqrt{2mE - m^2\omega_0^2 x'^2}\,\mathrm{d}x' \,, \tag{23.37}$$

whose $\beta = \partial W/\partial E - t$ reduces by the substitution $x = \sqrt{2E/m\omega_0^2}\,\sin\varphi$ to $\arcsin\left(x\sqrt{m\omega_0^2/2E}\right) = \omega_0(t+\beta)$, the solution Equation (28.4). The action variable Equation (23.49) is the phase-plane area of Proposition 28.6 divided by 2π,

$$I = \frac{1}{2\pi}\oint p\,\mathrm{d}x = \frac{E}{\omega_0} \,, \tag{23.38}$$

in J s, so the Hamiltonian in action–angle variables is simply $\mathcal{H}(I) = \omega_0 I$ and Equation (23.52) returns $\dot\theta = \omega_0$: the frequency, read off without solving anything. This is the doorway of Remark 28.7.

Rests on Proposition 28.6, Definition 23.28, and Theorem 23.30.

Example 23.25 (Central force in plane polar coordinates)**.** With $\mathcal{H} = \left(p_r^2 + p_\varphi^2/r^2\right)/2m + V(r)$ the coordinate φ is cyclic, so

$$W = \alpha_\varphi\varphi + \int^{r} \sqrt{2m\,(E - V(r')) - \frac{\alpha_\varphi^2}{r'^2}}\;\mathrm{d}r' \,, \tag{23.39}$$

with $\alpha_\varphi = p_\varphi = L$ the angular momentum, in J s. The two relations Equation (23.4) are

$$t + \beta_E = \int^{r} \frac{m\,\mathrm{d}r'}{\sqrt{2m\,(E-V) - L^2/r'^2}} \,, \tag{23.40}$$

$$\varphi - \beta_\varphi = \int^{r} \frac{L\,\mathrm{d}r'}{r'^2\sqrt{2m\,(E-V) - L^2/r'^2}} \,. \tag{23.41}$$

Equation (23.40) is the radial quadrature of Section 27.3, with $\sqrt{2m(E-V) - L^2/r^2}/m$ the radial velocity Equation (27.34) and the bracket the effective potential Equation (27.32); Equation (23.41) is the orbit equation Equation (27.38). Nothing new is obtained, and that is the point: the two quadratures that Chapter 27 reaches by eliminating the time between two conservation laws fall out here as the two components of a single differentiation.

Rests on Proposition 23.14, Theorem 23.6, and Equation (27.38).

Example 23.26 (The Kepler problem, and the Bohr formula)**.** In spherical coordinates with $V = -k/r$ and $k = e^2/4\pi\varepsilon_0$ in J m the Hamiltonian is $\mathcal{H} = \left[p_r^2 + p_\theta^2/r^2 + p_\varphi^2/(r^2\sin^2\theta)\right]/2m - k/r$, and $W = \alpha_\varphi\varphi + W_\theta(\theta) + W_r(r)$ separates it into

$$\left(\frac{\mathrm{d}W_\theta}{\mathrm{d}\theta}\right)^2 + \frac{\alpha_\varphi^2}{\sin^2\theta} = \alpha_\theta^2 \,, \qquad \left(\frac{\mathrm{d}W_r}{\mathrm{d}r}\right)^2 = 2m\left(E + \frac{k}{r}\right) - \frac{\alpha_\theta^2}{r^2} \,, \tag{23.42}$$

$\alpha_\theta = L$ being the total angular momentum and $\alpha_\varphi = L_z$ its component along the polar axis. For bounded motion, $E < 0$, the three circuits give action variables

$$I_\varphi = \alpha_\varphi \,, \qquad I_\theta = \alpha_\theta - |\alpha_\varphi| \,, \qquad I_r = -\alpha_\theta + k\sqrt{\frac{m}{2\,|E|}} \,, \tag{23.43}$$

the last two by the elementary quadratures $\int_{\theta_1}^{\pi-\theta_1}\sqrt{L^2-L_z^2/\sin^2\theta}\,\mathrm{d}\theta=\pi\,(L-|L_z|)$ and $\int_{r_1}^{r_2} r^{-1}\sqrt{-A^2r^2+Br-C}\,\mathrm{d}r=\pi\left(B/2A-\sqrt{C}\right)$, both evaluated by the residue theorem Theorem 8.24 with branch points at the turning points. Adding the three,

$$E=-\frac{mk^2}{2\,(I_r+I_\theta+I_\varphi)^2}\,, \tag{23.44}$$

so the energy depends on the three actions only through their sum: the Kepler problem is completely degenerate, which is why its orbits close. Imposing $I_a=n_a\hbar$ (Proposition 23.38, in the uncorrected form the old quantum theory used) with $n=n_r+n_\theta+n_\varphi$ gives

$$E_n=-\frac{m_{\mathrm{e}}e^4}{2\,(4\pi\varepsilon_0)^2\,\hbar^2n^2}=-\frac{hcR_\infty}{n^2}\,, \tag{23.45}$$

which is Equation (70.4): with $R_\infty=1.097\,373\,156\,8\times10^7/\mathrm{m}$ the ground state lies $13.605\,693\,\mathrm{eV}$ below the ionization limit [2431]. This is the single computation that made Hamilton–Jacobi theory a working tool of atomic physics for a decade, and the reason Chapter 70 cites this chapter.

Rests on Definition 23.13 and Equations (23.49) and (70.4).

Example 23.27 (Charged particle in a uniform magnetic field)**.** Let a particle of charge q and mass m move in a uniform field $\boldsymbol{B}=B\hat{\boldsymbol{z}}$, described in the gauge $\boldsymbol{A}=(0,Bx,0)$, so that $\mathcal{H}=\left[p_x^2+(p_y-qBx)^2+p_z^2\right]/2m$. Both y and z are cyclic and

$$W=\alpha_y y+\alpha_z z+\int^x\sqrt{2mE_\perp-(\alpha_y-qBx')^2}\,\mathrm{d}x'\,,\qquad E_\perp:=E-\frac{\alpha_z^2}{2m}\,. \tag{23.46}$$

The transverse motion is bounded between the two roots of the radicand and its action variable is, substituting $u=\alpha_y-qBx$ so that the circuit becomes a circle of radius $\sqrt{2mE_\perp}$ in the u-plane,

$$I_x=\frac{1}{2\pi}\oint p_x\,\mathrm{d}x=\frac{1}{2\pi\,|q|\,B}\oint\sqrt{2mE_\perp-u^2}\,\mathrm{d}u=\frac{mE_\perp}{|q|\,B}=\frac{E_\perp}{\omega_{\mathrm{c}}}\,, \tag{23.47}$$

with $\omega_{\mathrm{c}}=|q|\,B/m$ the cyclotron angular frequency in rad/s. For an electron in $B=1.00\,\mathrm{T}$ this is $\omega_{\mathrm{c}}=1.7588\times10^{11}\,\mathrm{rad/s}$, from e/m_{e} built out of Appendix B. The magnetic moment of the gyrating charge is

$$\mu=\frac{E_\perp}{B}=\frac{|q|}{m}\,I_x\,, \tag{23.48}$$

in J/T, and since $|q|\,/m$ is fixed, μ is an adiabatic invariant exactly when I_x is—which Theorem 23.34 establishes. That identification is what Remark 23.37 rests on.

Rests on Proposition 23.14, Equation (23.49), and Theorem 23.34.

23.3 Action–angle variables and integrable systems

For motion that is bounded, the useful canonical variables are not the constants α_a themselves but a particular set of functions of them, chosen so that the conjugate coordinates are angles.

Definition 23.28 (Action variables)**.** Let the motion be bounded and let the Hamilton–Jacobi equation separate in the coordinates q^a, so that each pair (q^a,p_a) traverses a closed curve C_a in its own plane of phase space. The *action variables* are

$$I_a=\frac{1}{2\pi}\oint_{C_a}p_a\,\mathrm{d}q^a\qquad(\text{no sum on }a)\,, \tag{23.49}$$

and the conjugate *angle variables* are

$$\theta^a = \frac{\partial W}{\partial I_a}\,. \tag{23.50}$$

Rests on Definitions 16.99 and 23.13.

Remark 23.29 (Convention). The factor $1/2\pi$ in Equation (23.49) makes the angles 2π-periodic and their rates ordinary angular frequencies. The older literature, and the quantization condition Equation (23.61) below in its original form, use $J_a = \oint p_a\,\mathrm{d}q^a = 2\pi I_a$ with angles of period 1. Both appear in the sources of this treatise; the convention here is the first.

Rests on Definition 23.28.

Theorem 23.30 (Motion in action–angle variables)**.** *In action–angle variables the Hamiltonian depends on the actions alone, $\mathcal{H} = \mathcal{H}(I)$, and the equations of motion integrate immediately:*

$$\dot I_a = 0\,, \tag{23.51}$$

$$\dot\theta^a = \frac{\partial \mathcal{H}}{\partial I_a} =: \omega^a(I)\,, \qquad \theta^a(t) = \omega^a t + \theta^a_0\,. \tag{23.52}$$

The ω^a are the angular frequencies of the motion, obtained without solving for the trajectory: one circuit of C_b advances θ^b by 2π and every other angle not at all, so the period of the b-th degree of freedom is $T_b = 2\pi/\omega^b$.

Rests on Definition 23.28, Proposition 22.18, and Theorem 22.6.

Proof. *Derives Theorem 23.30.*

By Equation (23.21) each momentum $p_a = \mathrm{d}W_a/\mathrm{d}q^a$ is a function of q^a and of the constants α alone, and the circuit C_a is fixed once α is. Hence Equation (23.49) defines f functions $I_a(\alpha)$, which are constants of the motion, and which may be inverted for α wherever $\det(\partial I_a/\partial\alpha_b) \neq 0$. Substituting $\alpha = \alpha(I)$ into W gives $W(q, I)$, a generating function of the second kind (Proposition 22.18) with old momenta $p_a = \partial W/\partial q^a$ and new coordinates $\theta^a = \partial W/\partial I_a$, which is Equation (23.50).

W carries no explicit time dependence, so by Equation (22.21) the new Hamiltonian is the old one re-expressed; by Equation (23.15) that value is $E = \alpha_1(\alpha)$, a function of the constants alone, hence of the actions alone. So $\mathcal{H} = \mathcal{H}(I)$. Theorem 22.6 in the new variables then gives $\dot I_a = -\partial\mathcal{H}/\partial\theta^a = 0$, since $\mathcal{H}$ does not contain the angles, and $\dot\theta^a = \partial\mathcal{H}/\partial I_a$, a function of constants and therefore itself constant; integrating gives Equation (23.52).

For the periods, carry q once around C_b at fixed I. Since $\theta^a = \partial W/\partial I_a$ and the order of the two differentiations may be exchanged,

$$\Delta_b\theta^a = \oint_{C_b} \frac{\partial}{\partial q^b}\left(\frac{\partial W}{\partial I_a}\right)\mathrm{d}q^b = \frac{\partial}{\partial I_a}\oint_{C_b} p_b\,\mathrm{d}q^b = \frac{\partial\,(2\pi I_b)}{\partial I_a} = 2\pi\delta^a_b\,. \tag{23.53}$$

From Equations (23.49) and (23.50) (exchanging the two differentiations under the circuit integral).

Comparing with Equation (23.52), one circuit takes a time $T_b = 2\pi/\omega^b$. □

Theorem 23.31 (Liouville–Arnold)**.** *Let a system with f degrees of freedom possess f functionally independent constants of motion $F_1 = \mathcal{H}, F_2, \dots, F_f$ in involution, that is with*

$$\{F_a, F_b\} = 0 \qquad \text{for all } a, b\,. \tag{23.54}$$

Then each compact connected component of a regular level set $\{F_a = c_a\}$ is diffeomorphic to the f-torus T^f, the motion on it is quasi-periodic with f frequencies, and there exist action–angle variables in a neighbourhood of it. Such a system is called completely integrable.

Rests on Equation (22.41) and Theorems 23.30 and 24.21.

Full derivation: Appendix A.47 (p. 3039).
Derives Theorem 23.31.

Remark 23.32 (What that proof imports). The appendix argument is the classical one. The f commuting integrals generate f Hamiltonian vector fields that commute, are everywhere independent on a regular level set and are tangent to it; on a compact level set they are complete, so their joint flow is an action of $\mathbb{R}^f$, which is transitive on each connected component because its orbits are open. The stabiliser is then a discrete subgroup of $\mathbb{R}^f$ with compact quotient, hence a lattice of rank f, and the component is $\mathbb{R}^f$ modulo that lattice—the torus. The actions are the periods of $p_a\,\mathrm{d}q^a$ over a basis of its cycles, and the angles are conjugate to them.

One ingredient is imported rather than proved: that a discrete subgroup of $\mathbb{R}^f$ with compact quotient is a lattice of full rank—equivalently, that a compact connected manifold carrying f commuting, independent, complete vector fields is diffeomorphic to T^f. That is a theorem of the kind Part II owns and Part II does not carry it, so the debt is recorded here rather than discharged inside a physics appendix. Nothing this chapter proves depends on Theorem 23.31: it is used only through the statement that separable systems are integrable, and Proposition 23.20 establishes that on its own.
Rests on Theorem 23.31 and Proposition 23.20.

Remark 23.33 (Integrability is exceptional). The systems for which Theorem 23.31 applies form a set of measure zero among Hamiltonian systems. What happens to the invariant tori when an integrable system is perturbed—most of them survive, deformed, and the rest break up into the thin chaotic layers that carry the system's sensitivity to initial conditions—is the subject of KAM theory, treated in Section 32.4.2 and stated as Theorem 32.51. The observational foothold is the solar system: the Kirkwood gaps of the asteroid belt (Table 32.2) sit at the mean-motion resonances where the tori fail, and the $3:1$ gap was shown to be chaotic rather than merely resonant by direct integration [1732].
Rests on Theorems 23.31 and 32.51.

23.3.1 Adiabatic invariance

Theorem 23.34 (Adiabatic invariance of the action)**.** *Let a bounded one-dimensional system have Hamiltonian $\mathcal{H}(q,p;\lambda)$ depending on a parameter $\lambda(t)$ that varies slowly, in the sense that its fractional change over one period T of the motion is small,*

$$\varepsilon = \frac{T}{\lambda}\left|\frac{\mathrm{d}\lambda}{\mathrm{d}t}\right| \ll 1\,. \tag{23.55}$$

Then the mean rate of change of the action variable I over one period vanishes,

$$\left\langle \frac{\mathrm{d}I}{\mathrm{d}t} \right\rangle = 0 + \mathcal{O}\!\left(\varepsilon^2\right)\,, \tag{23.56}$$

so that I changes by $\mathcal{O}(\varepsilon)$, not $\mathcal{O}(1)$, over the whole time $\sim T/\varepsilon$ in which λ changes appreciably. The energy, by contrast, is not conserved: it follows λ through $E = E(I,\lambda)$ at fixed I.
Rests on Definition 23.28, Equation (22.10), and Theorem 23.30.

Proof. *Derives Theorem 23.34.*
Freeze λ and let $I(E,\lambda) = (2\pi)^{-1}\oint p\,\mathrm{d}q$ be taken over the closed orbit $\mathcal{H}(q,p;\lambda) = E$, with $p = p(q,E,\lambda)$ the solution of that equation. Two partial derivatives are needed. Differentiating $\mathcal{H}(q,p;\lambda) = E$ at fixed q and λ gives $(\partial\mathcal{H}/\partial p)\,\partial p/\partial E = 1$, and $\partial\mathcal{H}/\partial p = \dot q$ by Equation (22.3), so

$$\frac{\partial I}{\partial E} = \frac{1}{2\pi}\oint \frac{\mathrm{d}q}{\dot q} = \frac{T}{2\pi} = \frac{1}{\omega}\,. \tag{23.57}$$

Differentiating the same relation at fixed q and E gives $\partial\mathcal{H}/\partial\lambda + \dot{q}\,\partial p/\partial\lambda = 0$, whence

$$\frac{\partial I}{\partial \lambda} = -\frac{1}{2\pi}\oint \frac{\partial \mathcal{H}/\partial\lambda}{\dot{q}}\,\mathrm{d}q = -\frac{1}{2\pi}\int_0^T \frac{\partial \mathcal{H}}{\partial \lambda}\,\mathrm{d}t = -\frac{T}{2\pi}\left\langle \frac{\partial \mathcal{H}}{\partial \lambda}\right\rangle , \tag{23.58}$$

the angle brackets denoting the average over one period of the frozen motion.

Along the true motion the energy is not conserved: by Equation (22.10), $\dot{E} = \partial\mathcal{H}/\partial t = \dot{\lambda}\,\partial\mathcal{H}/\partial\lambda$. Hence

$$\frac{\mathrm{d}I}{\mathrm{d}t} = \frac{\partial I}{\partial E}\dot{E} + \frac{\partial I}{\partial \lambda}\dot{\lambda} = \frac{\dot{\lambda}}{\omega}\frac{\partial \mathcal{H}}{\partial \lambda} - \frac{T\dot{\lambda}}{2\pi}\left\langle \frac{\partial \mathcal{H}}{\partial \lambda}\right\rangle . \tag{23.59}$$

Both terms are of order ε separately. Averaging Equation (23.59) over one period, during which $\dot{\lambda}$ may be held fixed at the cost of an error of relative order ε, replaces $\partial\mathcal{H}/\partial\lambda$ in the first term by its mean, and $T = 2\pi/\omega$ makes the two terms cancel identically:

$$\left\langle \frac{\mathrm{d}I}{\mathrm{d}t}\right\rangle = \frac{\dot{\lambda}}{\omega}\left\langle \frac{\partial \mathcal{H}}{\partial \lambda}\right\rangle - \frac{2\pi}{\omega}\frac{\dot{\lambda}}{2\pi}\left\langle \frac{\partial \mathcal{H}}{\partial \lambda}\right\rangle = 0\,. \tag{23.60}$$

This is Equation (23.56). Summing over the $\sim 1/\varepsilon$ periods of the slow evolution, the surviving change in I is the accumulated remainder, of order $\varepsilon^2 \times \varepsilon^{-1} = \varepsilon$, whereas an uncompensated first-order drift would have accumulated to order one. The energy statement is immediate: inverting $I = I(E,\lambda)$ at fixed I makes E a function of λ, and $\partial E/\partial I = \omega$ by Equation (23.57), so E tracks λ through the frequency. □

Example 23.35 (The slowly stiffened oscillator)**.** For the oscillator of Example 23.24 with a slowly varying frequency $\omega_0(t)$, Equation (23.38) gives $I = E/\omega_0$, so Theorem 23.34 says E/ω_0 is conserved and therefore $E \propto \omega_0$: shortening a pendulum quasi-statically raises its energy in proportion to its frequency, while its amplitude falls as $\omega_0^{-1/2}$. The energy is supplied by whatever does the shortening, and no amount of care in doing it slowly avoids that.

Rests on Theorem 23.34 and Equation (23.38)*.*

Remark 23.36 (How good the invariance really is)*.* Theorem 23.34 is a first-order statement and is far weaker than what is true. If $\lambda(t)$ is analytic and varies over a finite interval, returning to a constant at both ends, the total change in I is not $\mathcal{O}(\varepsilon)$ but exponentially small, of order $\mathrm{e}^{-c/\varepsilon}$—which is why adiabatic invariants are useful in practice rather than merely asymptotically, and why leaving the statement out would misrepresent how good the invariance is.

That sharper statement is not established in this treatise, and it is recorded as owed rather than asserted, for two reasons. No source in this bibliography states it, so it cannot honestly be cited. And the method it needs—a sequence of averaging transformations, each removing one more order in ε at the cost of shrinking a strip of analyticity, with Cauchy estimates controlling the remainder and the number of steps optimised against the shrinkage—rests on analytic machinery that Part II does not develop; the size of the exponent is then fixed by the distance from the real axis to the nearest complex singularity of λ. Nothing in the book uses it: every application in this chapter and in Chapter 66 needs only the first-order result Equation (23.56) proved above.

Rests on Theorem 23.34.

Remark 23.37 (Why this matters observationally)*.* Adiabatic invariance is the reason the robust quantity of a slowly modulated oscillator is its action and not its energy. The magnetic moment Equation (23.48) of a charged particle gyrating in a slowly varying magnetic field is an adiabatic invariant of exactly this kind: $\mu = E_\perp/B$ is fixed, so as a particle spirals into a region of stronger field its transverse energy must rise, and—the total energy being conserved in a static field—its parallel energy must fall until it reverses. That is the magnetic

mirror, and it is what traps particles in the belts Van Allen identified from the first satellite instruments [1176]. The same invariant governs betatron acceleration and the confinement schemes of laboratory plasmas (Chapter 66).

Rests on Theorem 23.34 and Equation (23.48).

23.3.2 The old quantum theory

Proposition 23.38 (Bohr–Sommerfeld and Einstein–Brillouin–Keller quantization)**.** *The rule that selected the observed atomic states in the old quantum theory is the quantization of the action variables,*

$$\oint_{C_a} p_a \,\mathrm{d}q^a = n_a h\,, \qquad I_a = n_a \hbar\,, \qquad n_a \in \mathbb{N}\,, \tag{23.61}$$

one condition for each separable degree of freedom [441]. Its correct semiclassical form carries an extra term,

$$I_a = \left(n_a + \frac{\mu_a}{4}\right)\hbar\,, \qquad n_a = 0, 1, 2, \dots\,, \tag{23.62}$$

where the integer μ_a—the Maslov index *of the a-th circuit—counts the caustics the circuit crosses, and equals 2 for a smooth one-dimensional well. Equation (23.61) is the case $\mu_a = 0$.*

Rests on Definition 23.28, Theorem 9.78, and Remark 9.79.

Derivation. *Derives Proposition 23.38.*

Neither form can be derived within classical mechanics: both are selection rules imposed from outside, and what classical mechanics supplies is the *object* they quantize, the action variable Equation (23.49), defined by the geometry of phase space and by nothing else.

The justification is semiclassical and is already in this treatise. For one degree of freedom, Theorem 9.78 shows that a solution of the stationary Schrödinger equation Equation (9.59) decaying on both sides of a well exists only for those energies with $\oint P\,\mathrm{d}x = \left(n + \frac{1}{2}\right)h$, which is Equation (23.62) with $\mu = 2$, and Remark 9.79 identifies the two quarters as one $\pi/4$ from each of the two turning points, contributed by the connection formulae Theorem 9.72. Keller extended the same accounting to several degrees of freedom by applying it to each independent circuit of an invariant torus and counting caustics rather than turning points [1150]; that count is μ_a, and its geometric content is Proposition 23.56 below. Substituting $\oint p_a \mathrm{d}q^a = 2\pi I_a$ and $h = 2\pi\hbar$ turns the condition into Equation (23.62). □

The empirical successes and the failures of the uncorrected rule—it gives the hydrogen spectrum Equation (23.45) and the fine structure, and fails for helium—are the subject of Chapter 70. Two structural points survive the failure. First, the quantity being quantized is the action variable of Definition 23.28. Second, the missing $\mu_a/4$ is not a patch but a statement about the classical trajectory: it counts where the projection of the invariant torus onto configuration space folds over. That is why Section 23.5.2 is part of this chapter and not an appendix to it.

23.4 The optical–mechanical analogy

23.4.1 The eikonal limit of wave optics

Definition 23.39 (Eikonal)**.** Let a monochromatic scalar wave of vacuum wavenumber $k_0 = \omega/c$, in 1/m, propagate in a medium of refractive index $n(\boldsymbol{x})$, so that its amplitude satisfies the Helmholtz equation Equation (10.25) with local wavenumber $k = k_0 n(\boldsymbol{x})$,

$$\nabla^2 u + k_0^2 n^2(\boldsymbol{x})\, u = 0\,. \tag{23.63}$$

Write it in the form

$$u(\boldsymbol{x}) = A(\boldsymbol{x})\,\mathrm{e}^{\mathrm{i}k_0\mathcal{S}(\boldsymbol{x})}\,. \tag{23.64}$$

The real function $\mathcal{S}$, in metres, is the *eikonal*; its level surfaces $\mathcal{S} = \text{const}$ are the geometrical wavefronts. The name is Bruns' [263]; the function is Hamilton's characteristic function of [84].

Rests on Equation (10.25) and Definition 16.103.

Theorem 23.40 (Eikonal and transport equations)**.** *In the short-wavelength limit $k_0 \to \infty$, with A and n varying appreciably only over distances large compared with $1/k_0$, the Helmholtz equation reduces at leading order to the* eikonal equation

$$(\boldsymbol{\nabla}\mathcal{S})^2 = n^2(\boldsymbol{x})\,, \tag{23.65}$$

and at the next order to the transport equation

$$\boldsymbol{\nabla}\cdot\left(A^2\boldsymbol{\nabla}\mathcal{S}\right) = 0\,, \tag{23.66}$$

which states the conservation of energy flux along the tubes of rays. The neglected term is $\nabla^2 A/\left(k_0^2 A\right)$, so the approximation is good where $\left|\nabla^2 A\right| \ll k_0^2\,|A|$.

Rests on Definition 23.39 and Equation (23.63).

Proof. *Derives Theorem 23.40.*

Differentiate Equation (23.64) twice:

$$\nabla^2 u = \left[\nabla^2 A + 2\mathrm{i}k_0\,\boldsymbol{\nabla}A\cdot\boldsymbol{\nabla}\mathcal{S} + \mathrm{i}k_0 A\,\nabla^2\mathcal{S} - k_0^2 A\,(\boldsymbol{\nabla}\mathcal{S})^2\right]\mathrm{e}^{\mathrm{i}k_0\mathcal{S}}\,. \tag{23.67}$$

Substituting into Equation (23.63) and cancelling the exponential leaves, with A, $\mathcal{S}$ and n all real,

$$\underbrace{\nabla^2 A - k_0^2 A\left[(\boldsymbol{\nabla}\mathcal{S})^2 - n^2\right]}_{\text{real}} + \mathrm{i}k_0\underbrace{\left[2\,\boldsymbol{\nabla}A\cdot\boldsymbol{\nabla}\mathcal{S} + A\,\nabla^2\mathcal{S}\right]}_{\text{imaginary}} = 0\,, \tag{23.68}$$

and each bracket vanishes separately. The real one, divided by $-k_0^2 A$, reads $(\boldsymbol{\nabla}\mathcal{S})^2 - n^2 = \nabla^2 A/\left(k_0^2 A\right)$, whose right-hand side is the stated neglected term; dropping it gives Equation (23.65). The imaginary one, multiplied by A, is $2A\,\boldsymbol{\nabla}A\cdot\boldsymbol{\nabla}\mathcal{S} + A^2\nabla^2\mathcal{S} = \boldsymbol{\nabla}A^2\cdot\boldsymbol{\nabla}\mathcal{S} + A^2\nabla^2\mathcal{S}$, which is Equation (23.66). □

Proposition 23.41 (Rays)**.** *The curves orthogonal to the wavefronts—the* rays*—satisfy*

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(n\,\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}\right) = \boldsymbol{\nabla}n\,, \tag{23.69}$$

s being arclength, and they are the stationary curves of Fermat's principle

$$\delta\int n(\boldsymbol{x})\,\mathrm{d}s = 0\,. \tag{23.70}$$

Rests on Theorem 23.40, Lemma 16.100, and Definition 16.103.

Proof. *Derives Proposition 23.41.*

By Equation (23.65) the gradient of the eikonal has magnitude n, so the unit normal to the wavefronts is $\boldsymbol{T} = \boldsymbol{\nabla}\mathcal{S}/n$, and along a ray, parametrised by arclength, $\boldsymbol{T} = \mathrm{d}\boldsymbol{x}/\mathrm{d}s$. Hence $n\,\mathrm{d}\boldsymbol{x}/\mathrm{d}s = \boldsymbol{\nabla}\mathcal{S}$ and

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(n\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}\right) = (\boldsymbol{T}\cdot\boldsymbol{\nabla})\,\boldsymbol{\nabla}\mathcal{S} = \frac{1}{n}\,(\boldsymbol{\nabla}\mathcal{S}\cdot\boldsymbol{\nabla})\,\boldsymbol{\nabla}\mathcal{S} = \frac{1}{2n}\boldsymbol{\nabla}\,(\boldsymbol{\nabla}\mathcal{S})^2 = \frac{1}{2n}\boldsymbol{\nabla}n^2 = \boldsymbol{\nabla}n\,. \tag{23.71}$$

From Equation (23.65) (a gradient field is curl-free, and its squared magnitude is fixed by the eikonal equation).

The middle step holds because a gradient field has vanishing curl, so that $(\boldsymbol{a}\cdot\boldsymbol{\nabla})\,\boldsymbol{a} = \frac{1}{2}\boldsymbol{\nabla}\,|\boldsymbol{a}|^2$ for $\boldsymbol{a} = \boldsymbol{\nabla}\mathcal{S}$, and the last uses Equation (23.65). Equation (23.69) is Equation (16.90), the Euler–Lagrange equation of the optical path length established in Lemma 16.100; Fermat's principle Equation (23.70) is therefore equivalent to it, which is Definition 16.103 [260]. □

23.4.2 The dictionary

Compare Equation (23.65) with the time-independent Hamilton–Jacobi equation Equation (23.15) for a Hamiltonian $\mathcal{H} = |\boldsymbol{p}|^2/2m + V$, which reads

$$(\boldsymbol{\nabla} W)^2 = 2m\,(E - V(\boldsymbol{x}))\ . \tag{23.72}$$

The two equations are the same equation. Every statement about wavefronts and rays therefore has a mechanical counterpart, obtained by the substitution $n \mapsto \sqrt{2m(E-V)}$.

Table 23.1: Hamilton's optical–mechanical analogy. Each row is a single mathematical statement read in two languages; the identification of the refractive index with $\sqrt{2m(E-V)}$ turns either column into the other.

Geometrical optics	**Classical mechanics**
eikonal $\mathcal{S}(\boldsymbol{x})$	characteristic function $W(\boldsymbol{x})$
refractive index $n(\boldsymbol{x})$	$\sqrt{2m\,(E - V(\boldsymbol{x}))}$
eikonal equation $(\boldsymbol{\nabla}\mathcal{S})^2 = n^2$	Hamilton–Jacobi equation $(\boldsymbol{\nabla} W)^2 = 2m(E-V)$
wavefronts $\mathcal{S} = \text{const}$	surfaces of constant action $W = \text{const}$
rays, orthogonal to the wavefronts	trajectories, orthogonal to the surfaces $W = \text{const}$
Fermat's principle $\delta \int n\,\mathrm{d}s = 0$	Maupertuis' principle $\delta \int \sqrt{2m(E-V)}\,\mathrm{d}s = 0$
Snell's law at an interface	refraction of a trajectory at a potential step
wavelength $\lambda = \lambda_0/n$	de Broglie wavelength $\lambda = h/\lvert\boldsymbol{p}\rvert$
geometrical-optics limit $\lambda \to 0$	classical limit $\hbar \to 0$

The Snell row of Table 23.1 is worth checking, because it is the row a reader is likeliest to take on trust. At a plane interface across which V jumps, the component of $\boldsymbol{p}$ tangent to the interface is conserved—no force acts along it—so $|\boldsymbol{p}_1|\sin\vartheta_1 = |\boldsymbol{p}_2|\sin\vartheta_2$ with ϑ measured from the normal, which under $n = |\boldsymbol{p}|$ is Equation (16.93) exactly (Theorem 16.104 and Phenomenon 61.3). A particle entering a region of lower potential speeds up and bends *towards* the normal, as light does entering a denser medium. This is the correspondence Newton used to argue that light is corpuscular, and the one that made the measured slowing of light in water Phenomenon 61.2 decisive against him.

Remark 23.42 (Phase speed and particle speed). The wavefronts $S = \text{const}$ do *not* move at the speed of the particle. From Equation (23.14), a surface of constant S moves so that $\boldsymbol{\nabla} W \cdot \mathrm{d}\boldsymbol{x} = E\,\mathrm{d}t$, giving a normal speed $u = E/|\boldsymbol{\nabla} W| = E/|\boldsymbol{p}|$, whereas the particle moves at $v = |\boldsymbol{p}|/m$; for a free particle $uv = E/m = v^2/2$, so $u = v/2$, as Example 23.22 found. The wavefront speed is a phase speed and the particle speed a group speed, and their product is fixed. In the wave mechanics of Chapter 71 the same two speeds reappear with the same relation, which is one of the checks de Broglie's hypothesis had to pass [521].

Rests on Equation (23.14) and Example 23.22.

Remark 23.43 (The asymmetry that carries the physics). The dictionary of Table 23.1 is exact, and it is incomplete in one direction only. Geometrical optics is known to be an approximation: it is the short-wavelength limit of a wave theory, and where the limit fails—diffraction at an edge, interference, the caustics where neighbouring rays cross—the wave theory is required, and it is right. The last two rows say that classical mechanics stands to some wave theory in exactly the relation that geometrical optics stands to wave optics. Hamilton wrote the analogy in the 1830s and left it there. The wave theory whose

short-wavelength limit is classical mechanics was found a century later, and the parameter that plays the part of the wavelength is $h/|\boldsymbol{p}|$. That is the content of Chapter 71, and the experiments that settled it—electron diffraction, neutron and atom interferometry—are its evidence.

Rests on Equations (23.65) *and* (23.72).

23.4.3 Where the analogy is not an analogy

The dictionary of Table 23.1 pairs two theories that remain distinct. There is a regime in which the pairing collapses and the two columns become one column: relativistic mechanics, where the eikonal of a massless field and the characteristic function of a massive particle satisfy the same equation with the same metric, differing only in the value of one constant.

Proposition 23.44 (Relativistic Hamilton–Jacobi equation)**.** *For a free particle of rest mass m, with the signature and index conventions of Chapter 39 and $\partial S/\partial x^\mu = -p_\mu$, the Hamilton–Jacobi equation is*

$$\eta^{\mu\nu}\,\partial_\mu S\,\partial_\nu S = m^2c^2\,, \qquad \textit{that is} \qquad \frac{1}{c^2}\left(\frac{\partial S}{\partial t}\right)^2 - (\boldsymbol{\nabla} S)^2 = m^2c^2\,, \tag{23.73}$$

both sides in $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$*. In the presence of an electromagnetic four-potential A_μ and for charge q it becomes*

$$\eta^{\mu\nu}\,(\partial_\mu S + qA_\mu)\,(\partial_\nu S + qA_\nu) = m^2c^2\,, \tag{23.74}$$

and in a spacetime of metric $g_{\mu\nu}$ it is Equation (23.73) *with $\eta^{\mu\nu}$ replaced by $g^{\mu\nu}$. Writing $S = -mc^2t + S'$ and expanding in $1/c^2$ recovers Equation* (23.2) *for S' with $\mathcal{H} = |\boldsymbol{p}|^2/2m$.*

Rests on Equations (23.2) *and* (40.5) *and Definition 13.117.*

Proof. *Derives Proposition 23.44.*

The nonrelativistic relations $p_a = \partial S/\partial q^a$ and $\partial S/\partial t = -\mathcal{H} = -E$ are, in four-vector notation with $x^\mu = (ct, \boldsymbol{x})$ and $p^\mu = (E/c, \boldsymbol{p})$, the single statement $\partial S/\partial x^\mu = -p_\mu$: the time component reads $c^{-1}\partial_t S = -E/c = -p_0$ and the space components $\partial_i S = p^i = -p_i$. Contracting with $\eta^{\mu\nu}$ gives $\eta^{\mu\nu}\partial_\mu S\,\partial_\nu S = \eta^{\mu\nu}p_\mu p_\nu = p^2 = m^2c^2$ by Theorem 40.5, which is Equation (23.73); writing out the components with $\eta = \mathrm{diag}(1,-1,-1,-1)$ gives the second form. Equation (23.74) follows by the minimal substitution $p_\mu \mapsto p_\mu - qA_\mu$ in the same mass-shell condition, and the curved-space form by replacing the flat metric with $g_{\mu\nu}$, which is what makes p^2 the invariant square.

For the limit, put $S = -mc^2t + S'$ in the second form of Equation (23.73). Then $\partial_t S = -mc^2 + \partial_t S'$ and

$$\frac{1}{c^2}\,(\partial_t S)^2 = m^2c^2 - 2m\,\partial_t S' + \frac{1}{c^2}\,(\partial_t S')^2\,,$$

so Equation (23.73) becomes $-2m\,\partial_t S' - (\boldsymbol{\nabla} S')^2 + c^{-2}\,(\partial_t S')^2 = 0$. Dividing by $-2m$ and dropping the last term, of relative order $(\partial_t S')/mc^2$, leaves $\partial_t S' + (\boldsymbol{\nabla} S')^2/2m = 0$. □

Remark 23.45 (Why this is not an analogy). Set $m = 0$ in Equation (23.73): the result, $g^{\mu\nu}\partial_\mu S\,\partial_\nu S = 0$, is the eikonal equation for a massless field in that spacetime, and its characteristics are the null geodesics. Set $m \neq 0$ and the characteristics are the timelike geodesics of Chapter 43. One equation, one geometry, one family of characteristic curves, and the only difference between the ray of light and the trajectory of the particle is the value on the right-hand side. In Table 23.1 the refractive index had to be manufactured out of E and V to make the two columns match; here nothing is manufactured, because there is only one column. The optical–mechanical analogy is, in the relativistic setting, an identity that was hiding inside a nonrelativistic approximation.

Rests on Proposition 23.44 and Theorem 23.40.

Remark 23.46 (Carter's constant). The most consequential separation of Equation (23.73) outside flat space is Carter's. In the Kerr geometry—the rotating black hole of Chapter 45—the equation admits a complete integral of the separated form $S = -Et + L_z\varphi + S_r(r) + S_\theta(\theta)$ in Boyer–Lindquist coordinates, and the separation constant that couples the radial and polar equations is a *fourth* constant of the motion,

$$\mathcal{K} = p_\theta^2 + \cos^2\theta \left[a^2 \left(m^2 c^2 - \frac{E^2}{c^2} \right) + \frac{L_z^2}{\sin^2\theta} \right], \tag{23.75}$$

with a the spin parameter of the hole, a length in m [1366]. Three constants come from symmetry—m from the mass shell, E and L_z from the two Killing vectors of the stationary axisymmetric metric—and the fourth comes from nowhere that Noether's theorem (Theorem 16.84) can see. In the language of Remark 23.21 it is a rank-two Killing tensor, and the separability of Equation (23.73) in that geometry is exactly the Stäckel condition of Definition 23.16 transplanted to a Lorentzian metric. That it exists at all is what makes geodesics around a rotating black hole integrable, and therefore computable; the orbits so computed are what the observed motions of Chapter 50 are matched against. The separation itself is carried out in Part V and is not reproduced here, and Remark 23.21 has already recorded that the Killing-tensor machinery it deserves is missing from Chapter 13.

Rests on Proposition 23.44 and Definition 23.16.

23.5 From Hamilton–Jacobi to the Schrödinger equation

Proposition 23.47 (The Hamilton–Jacobi equation as the classical limit)**.** *Write a solution of the Schrödinger equation of Chapter 77 in the polar form*

$$\psi(\boldsymbol{x}, t) = A(\boldsymbol{x}, t)\, \mathrm{e}^{\mathrm{i}S(\boldsymbol{x},t)/\hbar}, \tag{23.76}$$

with A and S real. Then the real and imaginary parts of the Schrödinger equation are, exactly and without approximation,

$$\frac{\partial S}{\partial t} + \frac{(\boldsymbol{\nabla} S)^2}{2m} + V + Q = 0, \qquad Q := -\frac{\hbar^2}{2m}\frac{\nabla^2 A}{A}, \tag{23.77}$$

$$\frac{\partial A^2}{\partial t} + \boldsymbol{\nabla} \cdot \left(A^2 \frac{\boldsymbol{\nabla} S}{m} \right) = 0. \tag{23.78}$$

Equation (23.77) is the Hamilton–Jacobi equation Equation (23.2) with the single extra term Q, of order $\hbar^2$; Equation (23.78) is the continuity equation for the probability density A^2, and is the exact counterpart of the transport equation Equation (23.66).

Rests on Equations (10.26), (23.2) and (23.66).

Proof. *Derives Proposition 23.47.*

With $\psi = A\mathrm{e}^{\mathrm{i}S/\hbar}$,

$$\frac{\partial \psi}{\partial t} = \left(\frac{\partial A}{\partial t} + \frac{\mathrm{i}A}{\hbar}\frac{\partial S}{\partial t} \right) \mathrm{e}^{\mathrm{i}S/\hbar}, \qquad \nabla^2\psi = \left[\nabla^2 A + \frac{2\mathrm{i}}{\hbar}\boldsymbol{\nabla} A \cdot \boldsymbol{\nabla} S + \frac{\mathrm{i}A}{\hbar}\nabla^2 S - \frac{A}{\hbar^2}(\boldsymbol{\nabla} S)^2 \right] \mathrm{e}^{\mathrm{i}S/\hbar}. \tag{23.79}$$

Substituting into $\mathrm{i}\hbar\,\partial_t\psi = -(\hbar^2/2m)\,\nabla^2\psi + V\psi$ (Equation (10.26)) and cancelling the exponential, the real part is

$$-A\frac{\partial S}{\partial t} = -\frac{\hbar^2}{2m}\nabla^2 A + \frac{A\,(\boldsymbol{\nabla} S)^2}{2m} + VA,$$

which on division by A is Equation (23.77), and the imaginary part is

$$\hbar\frac{\partial A}{\partial t} = -\frac{\hbar}{m}\boldsymbol{\nabla} A \cdot \boldsymbol{\nabla} S - \frac{\hbar A}{2m}\nabla^2 S.$$

Multiplying the latter by $2A/\hbar$ turns the left side into $\partial\left(A^2\right)/\partial t$ and the right into $-m^{-1}\left[\boldsymbol{\nabla}\left(A^2\right)\cdot\boldsymbol{\nabla}S + A^2\nabla^2 S\right]$, which is $-\boldsymbol{\nabla}\cdot\left(A^2\boldsymbol{\nabla}S/m\right)$: that is Equation (23.78). No approximation was made at any step; both equations are exact rewritings. □

Remark 23.48 (What this is and what it is not). Equations (23.77) and (23.78) are an exact algebraic rewriting of the Schrödinger equation, not a different theory and not an interpretation of it. Read in one direction they show that classical mechanics is recovered when the term Q is negligible against the others, which is the precise sense in which the Hamilton–Jacobi equation is the $\hbar \to 0$ limit of wave mechanics. Read in the other direction, as a statement that a particle possesses a definite trajectory guided by Q, they become an interpretive commitment that no experiment discussed in this treatise distinguishes from any other; the treatise's position on such commitments is stated in Chapter 85.

Rests on Equations (23.77) *and* (23.78).

23.5.1 The semiclassical expansion

Proposition 23.47 is exact but not systematic: it isolates one term of order $\hbar^2$ and says nothing about what comes after it. The systematic version is the WKB expansion, and this treatise develops it in full—the expansion itself, its validity criterion, its failure at turning points, the connection formulae that carry a solution across one, the Gamow tunnelling factor and the quantisation condition with its Maslov correction—in one dimension, as mathematics, in Section 9.6 of Chapter 9. That material is not repeated here. What is established here is the one thing that section cannot state, because it is mechanics and not analysis: that the leading order of the expansion *is* the Hamilton–Jacobi equation of this chapter, and the next order the transport equation.

Proposition 23.49 (The Hamilton–Jacobi equation is the leading order)**.** *Write a solution of the stationary Schrödinger equation* $-\left(\hbar^2/2m\right)\nabla^2\psi + V\psi = E\psi$ *in three space dimensions as a single exponential,*

$$\psi(\boldsymbol{x}) = \exp\left[\frac{\mathrm{i}\,\sigma(\boldsymbol{x})}{\hbar}\right], \tag{23.80}$$

with σ *complex and of SI dimension* J s*. Then* σ *satisfies exactly*

$$\left(\boldsymbol{\nabla}\sigma\right)^2 - \mathrm{i}\hbar\,\nabla^2\sigma = 2m\left(E - V\right) = \left|\boldsymbol{P}(\boldsymbol{x})\right|^2, \tag{23.81}$$

and the expansion $\sigma = \sigma_0 + \hbar\sigma_1 + \hbar^2\sigma_2 + \cdots$ *of Equation* (9.64) *gives, at its first two orders,*

$$\left(\boldsymbol{\nabla}\sigma_0\right)^2 = 2m\left(E - V\right), \tag{23.82}$$

$$2\,\boldsymbol{\nabla}\sigma_0\cdot\boldsymbol{\nabla}\sigma_1 = \mathrm{i}\,\nabla^2\sigma_0\,. \tag{23.83}$$

Equation (23.82) *is the time-independent Hamilton–Jacobi equation Equation* (23.72)*, so* $\sigma_0 = W$*; and with* $A := \mathrm{e}^{\mathrm{i}\sigma_1}$*, Equation* (23.83) *is the transport equation* $\boldsymbol{\nabla}\cdot\left(A^2\boldsymbol{\nabla}W\right) = 0$*, that is Equation* (23.66)*.*

Rests on Equations (23.66) *and* (23.72) *and Proposition 9.61.*

Proof. *Derives Proposition 23.49.*

From Equation (23.80), $\boldsymbol{\nabla}\psi = (\mathrm{i}/\hbar)\,\boldsymbol{\nabla}\sigma\,\psi$ and $\nabla^2\psi = \left[(\mathrm{i}/\hbar)\,\nabla^2\sigma - \hbar^{-2}\left(\boldsymbol{\nabla}\sigma\right)^2\right]\psi$. Substituting into the stationary equation, cancelling the nowhere-vanishing ψ and multiplying by $-2m$ gives Equation (23.81); this is the three-dimensional form of the exact Riccati equation Equation (9.63), and $\hbar$ again appears in exactly one place, multiplying the highest derivative. Inserting the series, the squared term contributes $\left(\boldsymbol{\nabla}\sigma_0\right)^2 + 2\hbar\,\boldsymbol{\nabla}\sigma_0\cdot\boldsymbol{\nabla}\sigma_1 + \mathcal{O}(\hbar^2)$ and the second term $-\mathrm{i}\hbar\,\nabla^2\sigma_0 + \mathcal{O}(\hbar^2)$, while the right side is of order $\hbar^0$; equating coefficients of $\hbar^0$ and $\hbar^1$ gives Equations (23.82) and (23.83). Comparing Equation (23.82) with Equation (23.72) identifies σ_0 with the characteristic function.

For the last statement, $\psi = \mathrm{e}^{\mathrm{i}\sigma_1}\mathrm{e}^{\mathrm{i}\sigma_0/\hbar} = A\,\mathrm{e}^{\mathrm{i}W/\hbar}$ with $A = \mathrm{e}^{\mathrm{i}\sigma_1}$, so $\boldsymbol{\nabla}\left(A^2\right) = 2\mathrm{i}A^2\boldsymbol{\nabla}\sigma_1$ and

$$\boldsymbol{\nabla}\cdot\left(A^2\boldsymbol{\nabla}W\right) = A^2\left[2\mathrm{i}\,\boldsymbol{\nabla}\sigma_1\cdot\boldsymbol{\nabla}\sigma_0 + \nabla^2\sigma_0\right],$$

which vanishes precisely when $2\boldsymbol{\nabla}\sigma_0\cdot\boldsymbol{\nabla}\sigma_1 = \mathrm{i}\nabla^2\sigma_0$, that is Equation (23.83). □

Remark 23.50 (The dictionary completed). Proposition 23.49 closes Table 23.1. The eikonal equation of wave optics and the Hamilton–Jacobi equation of mechanics were shown in Section 23.4.2 to be the same equation under $n \mapsto \sqrt{2m(E-V)}$; they are now seen to occupy the same *position* in their respective theories—each is the leading term of a short-wavelength expansion of a linear wave equation, and each is accompanied at the next order by the same transport equation. The role of $1/k_0$ in Theorem 23.40 is played by $\hbar$ here, and the reduced de Broglie wavelength Equation (9.72) of Definition 9.64,

$$\bar{\lambda}(\boldsymbol{x}) = \frac{\hbar}{|\boldsymbol{P}(\boldsymbol{x})|}, \tag{23.84}$$

in metres, is the local wavelength whose smallness is the whole hypothesis. The criterion is $\left|\boldsymbol{\nabla}\bar{\lambda}\right| \ll 1$, which is Equation (9.73) of Proposition 9.65 read in three dimensions: the wavelength must change by much less than itself over one wavelength. For an electron of kinetic energy 100 eV, $\bar{\lambda} = 1.95\times10^{-11}$ m, so the criterion demands a potential smooth on the scale of a few tens of picometres—which is why the semiclassical description fails inside an atom and succeeds for an electron crossing a laboratory field.

Rests on Propositions 9.65 and 23.49.

Remark 23.51 (Where the expansion breaks, and what is owed). The criterion fails wherever $|\boldsymbol{P}| \to 0$, that is on the classical turning surface $V = E$, whatever the smoothness of V: the amplitude $|\boldsymbol{P}|^{-1/2}$ of Equation (9.69) diverges there while the true solution stays finite (Remark 9.66). Within a distance of order

$$\ell = \left(\frac{\hbar^2}{2m\,|\boldsymbol{\nabla}V|}\right)^{1/3} \tag{23.85}$$

of the surface, which is Equation (9.74), the expansion is worthless and the exact local solution is an Airy function (Definition 9.68 and Theorem 9.70); the connection formulae Theorem 9.72 carry a solution through. That analysis is one-dimensional and transverse to the surface, and it applies here without change, because near a smooth turning surface the motion normal to it decouples from the motion along it at leading order. The two things it does *not* settle are what happens at a caustic which is not a turning surface, and how the phases accumulated at successive crossings add up around a closed circuit. Those are the subject of Section 23.5.2, and they are mechanics, not one-dimensional analysis. The series is in any case asymptotic and not convergent (Remark 9.67), so no amount of further orders repairs a place where the leading order is wrong.

Rests on Proposition 9.65 and Theorem 9.72.

23.5.2 Caustics

A complete integral does not describe one trajectory but a family of them, and the geometrical description of Section 23.4.2 presumes that exactly one member of the family passes through each point. Where that fails—where neighbouring members cross—the description fails with it, and the failure is not a defect of the calculation but the signature of the wave theory underneath.

Definition 23.52 (Lagrangian family; caustic)**.** Let $\gamma(\boldsymbol{a};\cdot)$ be a family of trajectories of one energy, smoothly parametrised by $\boldsymbol{a} \in \mathbb{R}^{f-1}$ and issuing orthogonally from a common

wavefront (or from a common point, for a point source), and let $q^b(\boldsymbol{a}, s)$ be the configuration reached along the member $\boldsymbol{a}$ after arclength s of the Jacobi metric Equation (16.91), in which the trajectories of energy E are geodesics by Theorem 16.101. The *Jacobian* of the family is

$$J(\boldsymbol{a}, s) = \det\left(\frac{\partial q^b}{\partial\left(a^1, \ldots, a^{f-1}, s\right)}\right), \tag{23.86}$$

and the *caustic* of the family is the set where $J = 0$: the locus at which the map from the family to configuration space ceases to be a local diffeomorphism. Equivalently, the caustic is the envelope of the family.

Rests on Definitions 16.62 and 23.5.

Proposition 23.53 (A caustic point is a conjugate point)**.** *A point $q\left(\boldsymbol{a}, s_c\right)$ lies on the caustic of the family issuing from a common source if and only if s_c is conjugate, in the sense of Definition 16.53, to the source along that trajectory. Consequently, by Theorem 16.55, a trajectory ceases to minimise the action beyond its first caustic, although it remains an extremal and a genuine solution of the equations of motion.*

Rests on Definitions 16.53 and 23.52 and Theorem 16.55.

Proof. *Derives Proposition 23.53.*

The variation fields of the family, $u^b_{(i)} := \partial q^b / \partial a^i$, are by Remark 16.54 solutions of the Jacobi accessory equation Equation (16.49)—the linearisation of the Euler–Lagrange equations about the trajectory—because the family consists of extremals depending differentiably on the parameter. All members issue from the same source, so $u^b_{(i)} = 0$ there.

Because s is the arclength of the Jacobi metric and the trajectories are its geodesics (Theorem 16.101), each $u_{(i)}$ stays orthogonal to the tangent $\boldsymbol{T} = \partial q / \partial s$: differentiating $\boldsymbol{T} \cdot \boldsymbol{T} = 1$ with respect to a^i gives $\boldsymbol{T} \cdot \partial_s u_{(i)} = 0$, and $\partial_s \boldsymbol{T} = \boldsymbol{0}$ along a geodesic, so $\boldsymbol{T} \cdot u_{(i)}$ is constant along the trajectory and vanishes at the source. The Jacobian Equation (23.86) therefore vanishes at s_c exactly when the $f-1$ transverse vectors $u_{(i)}$ are linearly dependent there, that is when some non-trivial constant combination $u = c^i u_{(i)}$ vanishes at s_c. Such a u is a non-trivial solution of Equation (16.49) vanishing at the source and at s_c, which is the definition of a conjugate point. The converse reads the same equivalence backwards. □

Proposition 23.54 (The geometrical amplitude diverges)**.** *Along a tube of trajectories of one energy, the transport equation Equation (23.66) gives*

$$A^2 \, |\boldsymbol{P}| \, \Sigma = const, \tag{23.87}$$

Σ being the cross-sectional area of the tube and $|\boldsymbol{P}| = \sqrt{2m(E-V)}$ the local momentum. Since $\Sigma \propto |J|$, the geometrical amplitude behaves as $A \propto |J|^{-1/2}$ and diverges on the caustic.

Rests on Equation (23.66), Definition 23.52, and Theorem 7.101.

Proof. *Derives Proposition 23.54.*

Take the region bounded by two cross-sections Σ_1, Σ_2 of the tube and by the tube's side wall, which is built of trajectories. Integrate Equation (23.66) over it and apply the divergence theorem Theorem 7.101. The side wall contributes nothing, because $\boldsymbol{\nabla} W$ is tangent to the trajectories and hence to the wall, so $A^2 \boldsymbol{\nabla} W$ has no normal component there. What remains is that the flux $\int A^2 \boldsymbol{\nabla} W \cdot \mathrm{d}\boldsymbol{\Sigma}$ takes the same value on the two end faces. On a face orthogonal to the trajectories $\boldsymbol{\nabla} W \cdot \mathrm{d}\boldsymbol{\Sigma} = |\boldsymbol{\nabla} W| \, \mathrm{d}\Sigma = |\boldsymbol{P}| \, \mathrm{d}\Sigma$ by Equation (23.72), which for a thin tube is Equation (23.87). For the cross-section, the volume swept by the parameter increments $\mathrm{d}^{f-1}a$ over an arclength $\mathrm{d}s$ is $|J| \, \mathrm{d}^{f-1}a \, \mathrm{d}s$ by Equation (23.86), and it is also $\Sigma \, \mathrm{d}s$, the tangent being a unit vector orthogonal to the cross-section as shown in Proposition 23.53; hence $\Sigma = |J| \, \mathrm{d}^{f-1}a$, proportional to $|J|$ at fixed increments. Solving Equation (23.87) for A gives $A \propto (|\boldsymbol{P}| \, |J|)^{-1/2}$, and on a caustic that is not also a turning surface $|\boldsymbol{P}|$ is finite and non-zero while $J \to 0$.

One bookkeeping point: the flux tube is measured in ordinary space, while Definition 23.52 parametrises the family by the Jacobi arclength. The two differ by the reparametrisation $\mathrm{d}\sigma = |\boldsymbol{P}|\,\mathrm{d}s$, whose factor is positive and finite wherever $E > V$, so the two Jacobians differ by a non-vanishing factor and have the same zero set. The caustic is the same locus in either parametrisation, which is what allows Proposition 23.53 and this proposition to speak of one J. □

Proposition 23.55 (The fold, and the quarter-power law)**.** *Let the caustic be a* fold*: transversally to it, the map from the family parameter to position is quadratic,*

$$\zeta(a) = c\,(a - a_c)^2 + \mathcal{O}\left((a - a_c)^3\right), \qquad c \neq 0\,, \tag{23.88}$$

ζ being the signed distance from the caustic. Then two members of the family reach each point with $c\zeta > 0$ and none reaches a point with $c\zeta < 0$, so that the caustic separates a doubly illuminated side from a dark side, and the geometrical amplitude of each of the two obeys

$$A \propto |\zeta|^{-1/4}\,. \tag{23.89}$$

Rests on Proposition 23.54 and Equation (23.86).

Proof. *Derives Proposition 23.55.*

Solving Equation (23.88) for a gives $a - a_c = \pm\sqrt{\zeta/c}$, real for $c\zeta > 0$ and not otherwise: hence two members on one side and none on the other. The transverse Jacobian is $\mathrm{d}\zeta/\mathrm{d}a = 2c\,(a - a_c) = \pm 2\sqrt{c\zeta}$, so $J \propto |\zeta|^{1/2}$, and Proposition 23.54 gives $A \propto |J|^{-1/2} \propto |\zeta|^{-1/4}$. □

Proposition 23.56 (The phase jump at a fold)**.** *A semiclassical wave crossing a fold caustic acquires, relative to the geometrical continuation, an extra phase $-\pi/2$. Around a closed circuit of an invariant torus the accumulated extra phase is therefore $-\mu\pi/2$, with μ the number of folds crossed, which is the Maslov index appearing in Equation (23.62).*

Rests on Theorem 9.72, Remark 9.79, and Proposition 23.55.

Derivation. *Derives Proposition 23.56.*

Transversally to the fold the problem is one-dimensional: by Proposition 23.55 the two branches merge at $\zeta = 0$ and the amplitude carries the factor $J^{-1/2}$, whose argument shifts by $-\pi/2$ when J changes sign. Which branch is selected is not a matter of taste, and is fixed by the connection formulae Theorem 9.72: a solution decaying on the dark side matches, on the illuminated side, to $2\,|\boldsymbol{P}|^{-1/2}\sin\left[\hbar^{-1}\int|\boldsymbol{P}|\,\mathrm{d}\zeta + \pi/4\right]$, whose two exponential components differ in phase from the naive continuation by $\mp\pi/2$; the outgoing one lags the incoming by $\pi/2$. Adding one such contribution per crossing around a closed circuit gives $-\mu\pi/2$, and demanding single-valuedness of the wave function around the circuit—$\hbar^{-1}\oint p\,\mathrm{d}q - \mu\pi/2 \in 2\pi\mathbb{Z}$—is Equation (23.62). Remark 9.79 records the one-dimensional instance, $\mu = 2$ for a well with two simple turning points, and Keller's extension of the count to several degrees of freedom [1150]. □

Proposition 23.57 (The wave resolution at a turning surface)**.** *Where the caustic is a classical turning surface, $V = E$ with $\boldsymbol{\nabla}V \neq \boldsymbol{0}$, the divergence Equation (23.89) is spurious: the exact solution is finite, and within a few multiples of the scale ℓ of Equation (23.85) it is the Airy function $\mathrm{Ai}\,(-\zeta/\ell)$ of Definition 9.68. The illuminated side carries fringes—the interference of the two branches of Proposition 23.55—whose maxima lie at the extrema of* Ai*, the brightest at $\zeta = 1.0188\,\ell$, and the dark side carries an exponential tail. For $\zeta \gg \ell$ the Airy asymptotics Equation (9.79) reproduce Equation (23.89) exactly.*

Rests on Remark 23.51 and Theorems 9.70 and 9.72.

Derivation. *Derives Proposition 23.57.*

Near a smooth turning surface the potential may be replaced by its tangent plane, $V \approx E + |\boldsymbol{\nabla}V|\,\zeta$, and the stationary Schrödinger equation separates into motion along the

surface, which is free at leading order, and motion normal to it, which is Equation (9.75)—the linearised turning-point equation of Chapter 9. Its solutions are the Airy functions (Proposition 9.69) on the scale Equation (9.74), which is Equation (23.85); the decaying combination on the forbidden side is Ai, and Theorem 9.72 is the statement that it matches the oscillatory semiclassical form on the allowed side. The extrema of $\mathrm{Ai}(-z)$ are the zeros of Ai', the first at $z = 1.0188$, and Equation (9.79) gives $\mathrm{Ai}(-z) \sim \pi^{-1/2} z^{-1/4} \sin\left(\frac{2}{3} z^{3/2} + \frac{\pi}{4}\right)$, whose envelope is the $z^{-1/4}$ of Equation (23.89). □

Remark 23.58 (The caustics that are not turning surfaces). Proposition 23.57 covers the caustic that is a turning surface, where the momentum itself vanishes. Most observed caustics are not of that kind: at the focus of a lens, at the cusp in a coffee cup, at the rainbow angle, the momentum is perfectly finite and it is the *geometry* of the family that folds. The fold Equation (23.88) fixes the transverse scale in that case by itself, at

$$\ell_{\mathrm{f}} = \left(\tfrac{1}{2} R\, \bar{\lambda}^2\right)^{1/3} , \tag{23.90}$$

with R the radius of curvature of the caustic and $\bar{\lambda}$ of Equation (23.84), and the same Airy profile with ζ/ℓ_{f} in place of ζ/ℓ; the peak amplitude then exceeds the smooth geometrical value by a factor of order $\left(R/\bar{\lambda}\right)^{1/6}$. This is Airy's result, obtained for the rainbow [103] and set out in full by Born and Wolf [1967].

Rests on Propositions 23.55 and 23.57.

Derivation. *Derives Equation (23.90).*

Two inputs are used and both should be named. The first is the superposition hypothesis of physical optics: near the caustic the field is written as an integral over the members of the family,

$$\psi(\zeta) = \int \mathrm{d}a\; A(a)\, \exp\!\left[\frac{\mathrm{i}\, S(a,\zeta)}{\bar{\lambda}}\right] , \tag{23.91}$$

$S(a,\zeta)$ being the optical path along the member labelled a to the field point and A a slowly varying amplitude. The reduced wavelength Equation (23.84) is constant across the small region that matters, because at a caustic of this kind $|\boldsymbol{P}|$ is finite and smooth; the phase is therefore $S/\bar{\lambda}$ with S an ordinary length. The geometrical field of Proposition 23.54 is what Equation (23.91) reduces to when the phase is stationary at isolated points, a stationary point in a being exactly a member that passes through the field point. The second input is the integral representation Equation (9.77) of the Airy function.

The phase is fixed by Equation (23.88) alone. Write $s := a - a_c$. The stationary points of S are the two members reaching ζ, which by Proposition 23.55 sit at $s = \pm\sqrt{\zeta/c}$; so $\partial S/\partial s$ vanishes exactly there and, being smooth with simple zeros, equals $\kappa\,(s^2 - \zeta/c)$ to leading order, κ being a constant of the family. Integrating,

$$S = S_0 + \kappa \left(\frac{s^3}{3} - \frac{\zeta}{c}\, s\right) . \tag{23.92}$$

The phase is cubic in the family parameter: that, and no property of the wave equation, is what a fold is.

Substituting Equation (23.92) into Equation (23.91), holding A fixed over the small range of s that contributes and rescaling by $u = \left(\kappa/\bar{\lambda}\right)^{1/3} s$,

$$\psi \propto \int \mathrm{d}u\; \exp\!\left[\mathrm{i}\left(\frac{u^3}{3} - X u\right)\right] , \qquad X := \left(\frac{\kappa}{\bar{\lambda}}\right)^{2/3} \frac{\zeta}{c} . \tag{23.93}$$

From Equations (23.88) and (23.92) (the fold makes the phase cubic, and the rescaling removes every constant from it).

Put $u = \mathrm{i}t$. The integrand becomes the entire integrand of Equation (9.77) with $z = -X$, and the ends of the contour, which run out along the imaginary t axis, may be rotated into the sectors of decay identified in Proposition 9.69 by Corollary 8.15. Hence $\psi \propto \mathrm{Ai}\,(-X)$: oscillatory on the illuminated side $X > 0$, exponentially small on the dark side, with transverse scale

$$\ell_{\mathrm{f}} = c \left(\frac{\bar{\lambda}}{\kappa} \right)^{2/3} . \tag{23.94}$$

It remains to express Equation (23.94) through the radius of curvature. Take the caustic to be locally a circle of radius R and the family to be its tangent lines, labelled by the dimensionless angle s of the point of tangency, with ζ the outward radial distance. The tangents through the point at radius $R + \zeta$ touch where $\cos s = R/\,(R + \zeta)$, so $\zeta = \tfrac{1}{2} R s^2$ and $c = R/2$. The optical path from the tangency point to the field point is $\sqrt{r^2 - R^2}$ and the arc run along the caustic is $R \arccos\,(R/r)$, so the path difference between the two tangents is, at $r = R + \zeta$ and to order $\zeta^{3/2}$,

$$\Delta S = 2 \left[\sqrt{r^2 - R^2} - R \arccos \frac{R}{r} \right] = \frac{4\sqrt{2}}{3} R \left(\frac{\zeta}{R} \right)^{3/2} , \tag{23.95}$$

whereas Equation (23.92) evaluated at its two stationary points gives $\Delta S = \tfrac{4}{3} \kappa \,(\zeta/c)^{3/2}$. Comparing, and using $c = R/2$, gives $\kappa = R/2$ as well, so that Equation (23.94) is $\ell_{\mathrm{f}} = \left(R \bar{\lambda}^2 / 2 \right)^{1/3}$, which is Equation (23.90).

The amplitude then follows without further work. The geometrical amplitude is $|\zeta|^{-1/4}$ by Equation (23.89), and the wave cuts that growth off at $\zeta \sim \ell_{\mathrm{f}}$; relative to the geometrical value a distance of order R from the caustic the peak is larger by $(R/\ell_{\mathrm{f}})^{1/4} = 2^{1/12} \left(R/\bar{\lambda} \right)^{1/6}$, which is the factor quoted above. □

Remark 23.59 (What is observed). Caustics are the sharpest observable signature of the failure of the geometrical limit, and they are visible in every one of the three languages this chapter has used. In optics they are the bright cusped curve on the bottom of a cup, the twinkling of starlight through a turbulent atmosphere, and the supernumerary bows inside a rainbow, whose spacing is the fringe spacing of Proposition 23.57 and whose explanation was Airy's [103]; the rainbow itself is a fold caustic of the family of rays refracted through a spherical drop, at a scattering angle of about 138°, and it is treated in Section 61.8.2. In mechanics they are the safety parabola of Example 23.23—the envelope beyond which no projectile of given speed can reach—and the turning surfaces at which Equation (9.69) diverges. In gravity they are the caustics of gravitational lensing: the images of a background source multiply as it crosses one, and the sharp peak of a microlensing light curve is the crossing itself [1781], the first lensed system having been identified as a pair of quasar images [1645]. What all three have in common is that the divergence is never observed: the wave theory replaces it with a finite peak of the width Equation (23.90), and measuring that width measures the wavelength.

Rests on Propositions 23.54 and 23.57.

Chapter 24

Symplectic Geometry of Phase Space

Chapter 22 assembled the coordinates and momenta into one object η^c and wrote Hamilton's equations as the single matrix equation Equation (22.57). That was a notational convenience. This chapter takes it seriously: the matrix J of Equation (22.56) is the component form of a geometric object living on phase space—a closed, nondegenerate two-form—and almost everything said about Hamiltonian systems is a statement about that form.

The payoff is that structure invisible in coordinates becomes visible. The Poisson bracket, the canonical transformations, Liouville's theorem, the Poincaré invariants of Section 22.3 and the conserved quantities attached to symmetries are not five facts but one fact seen five ways. And several quantities that a coordinate treatment has no reason to single out—the action variables, the adiabatic invariants, the geometric phases—are exactly the quantities that survive perturbation and that experiment therefore finds robust. That is the sense in which the symplectic view lets one see more in nature than the Newtonian one: it says which quantities are structural and which are accidents of the coordinates chosen to write them.

This chapter uses the manifold and differential-form machinery of Chapter 13 and the Lie-group material of Chapter 14; per the dimension rule of this treatise it is stated in general dimension, and the physical instantiation is $2f$ with f the number of degrees of freedom.

Notation 24.1. M denotes a smooth manifold of even dimension $2f$, T_xM its tangent space at x, and $\Omega^k(M)$ the space of differential k-forms. The interior product of a vector field X with a form is written ι_X—it is the operation written i_ξ in Equation (13.276)—the exterior derivative d, and the Lie derivative along X is written $\mathcal{L}_X$: note that in this chapter, and only here, the symbol $\mathcal{L}$ is the Lie derivative and not the Lagrangian, which does not appear. Latin indices $c, d = 1, \dots, 2f$ label phase-space components as in Notation 22.1, and $a, b = 1, \dots, f$ the degrees of freedom. Because ω is reserved throughout for the symplectic form, an angular velocity is written $\boldsymbol{\Omega}$ in Section 24.5 and an ordinary frequency ν in Section 24.7.

24.1 Symplectic vector spaces

Definition 24.2 (Symplectic vector space)**.** A *symplectic vector space* is a pair (V, ω) with V a real vector space and $\omega : V \times V \to \mathbb{R}$ a bilinear form that is

1. *antisymmetric*: $\omega(u, v) = -\omega(v, u)$; and
2. *nondegenerate*: $\omega(u, v) = 0$ for all v implies $u = 0$.

Rests on Proposition 5.115.

Proposition 24.3 (Even dimension and the canonical basis)**.** *A symplectic vector space has even dimension $2f$, and admits a basis $\left(e_1,\dots,e_f,f^1,\dots,f^f\right)$ in which*

$$\omega(e_a,e_b)=0\,,\qquad \omega(f^a,f^b)=0\,,\qquad \omega(e_a,f^b)=\delta_a^{\,b}\,, \tag{24.1}$$

so that the matrix of ω in that basis is the symplectic matrix Equation (22.56). All symplectic vector spaces of the same dimension are therefore isomorphic: unlike a metric, a symplectic form has no local invariants and no signature. Moreover $\mathrm{Sp}(2f,\mathbb{R})$ acts transitively on the set of such bases.

Rests on Definition 24.2, Proposition 5.115, and Equation (22.56).

Proof. *Derives Proposition 24.3.*

The first two statements are Proposition 5.115 of Chapter 5 at $2n=2f$: that proposition proves, for a nondegenerate antisymmetric bilinear form on a real vector space, that the dimension is even and that a basis exists satisfying Equation (5.143), which are Equation (24.1) with the naming used here, and in which the matrix of the form is Equation (5.144)—the matrix J of Equation (22.56). Two symplectic vector spaces of dimension $2f$ are then isomorphic by the linear map carrying one such basis to the other, which preserves ω because it preserves the matrix.

Transitivity is the same observation read inside one space. Let (e,f) and (e',f') be two bases satisfying Equation (24.1) and let M be the matrix of the change of basis. Both bases give ω the matrix J, and a change of basis transforms the matrix of a bilinear form by $[\omega]\mapsto M^{\mathsf{T}}\,[\omega]\,M$ (Equation (5.139)); hence $M^{\mathsf{T}}J\,M=J$ and $M\in\mathrm{Sp}(2f,\mathbb{R})$ by Equation (5.174). Conversely every $M\in\mathrm{Sp}(2f,\mathbb{R})$ carries a canonical basis to a canonical basis, so the action is transitive. Nothing beyond Proposition 5.115 is proved here; it is restated because the naming of the basis vectors is what fixes the block order of J used throughout this chapter. □

Definition 24.4 (Symplectic group)**.** The *symplectic group* $\mathrm{Sp}(2f,\mathbb{R})$ is the group of linear maps $M:V\to V$ preserving ω; in the canonical basis it is the set of $2f\times 2f$ real matrices satisfying

$$M^{\mathsf{T}}J\,M=J\,. \tag{24.2}$$

This is Definition 5.130 of Chapter 5, restated in the notation of this chapter; it is not a second definition.

Rests on Definition 5.130 and Proposition 24.3.

Proposition 24.5 (Properties of the symplectic group)**.** $\mathrm{Sp}(2f,\mathbb{R})$ *is a Lie group of dimension $f(2f+1)$ whose Lie algebra $\mathfrak{sp}(2f,\mathbb{R})$ consists of the matrices A with $A^{\mathsf{T}}J+JA=0$, equivalently $A=JS$ with S symmetric; every element has determinant $+1$; and the group is noncompact for every $f\geq 1$.*

Rests on Definition 24.4, Proposition 5.134, and Theorem 5.133.

Proof. *Derives Proposition 24.5.*

The dimension, the Lie-algebra condition and the fact that $\mathfrak{sp}(2f,\mathbb{R})$ is a Lie algebra are Proposition 5.134 with Equation (5.178) at $n=f$; the determinant is Theorem 5.133. That $A^{\mathsf{T}}J+JA=0$ is the same as $A=JS$ with S symmetric follows by substituting $A=JS$ and using $J^{\mathsf{T}}=-J$, $J^2=-\mathbb{1}_{2f}$ from Equation (22.56):

$$(JS)^{\mathsf{T}}\,J+J\,(JS)=S^{\mathsf{T}}J^{\mathsf{T}}J-S=S^{\mathsf{T}}-S\,,$$

which vanishes exactly when S is symmetric; and every A arises this way with $S=-JA$.

Noncompactness is proved by exhibiting an unbounded one-parameter family. For $\lambda > 0$ put

$$M_\lambda = \begin{pmatrix} \lambda \mathbb{1}_f & 0 \\ 0 & \lambda^{-1}\mathbb{1}_f \end{pmatrix}, \qquad J\,M_\lambda = \begin{pmatrix} 0 & \lambda^{-1}\mathbb{1}_f \\ -\lambda\mathbb{1}_f & 0 \end{pmatrix},$$

so that M_λ^{T}, which multiplies the first block row by λ and the second by λ^{-1}, gives $M_\lambda^{\mathsf{T}}(J\,M_\lambda) = J$: each M_λ lies in $\mathrm{Sp}(2f,\mathbb{R})$. Its entries are unbounded as $\lambda \to \infty$, so $\mathrm{Sp}(2f,\mathbb{R})$ is not a bounded subset of the $4f^2$-dimensional space of matrices and hence, by Theorem 6.12, not compact. Physically this family is the squeeze that trades position spread against momentum spread at constant phase area, and it is the reason a symplectic map can distort a region without limit while preserving its volume. □

Remark 24.6 (Connectedness, and what it rests on). $\mathrm{Sp}(2f,\mathbb{R})$ is also connected, and its maximal compact subgroup is $\mathrm{U}(f)$; the standard argument is the polar decomposition $M = OP$ of a real invertible matrix into an orthogonal and a positive-definite symmetric factor, followed by the observation that both factors of a symplectic matrix are themselves symplectic and that the positive factor can be contracted to the identity along P^t, $t \in [0,1]$. The polar decomposition is a statement of linear algebra and belongs in Chapter 5, which does not at present carry it; the claim is therefore recorded here as one this treatise states without proving. Nothing in this chapter uses it: connectedness enters only when one asks whether a symplectic matrix can be reached continuously from the identity, which is a question about generating canonical transformations by flows and is not needed for any result below.

Rests on Proposition 24.5.

Remark 24.7 (Contrast with the orthogonal group). A metric of signature (p,q) gives the group $\mathrm{SO}(p,q)$ of Chapter 39, of dimension $\frac{1}{2}n(n-1)$ with $n = p+q$; a symplectic form in the same dimension $n = 2f$ gives a group of dimension $f(2f+1) = \frac{1}{2}n(n+1)$, which is larger. Phase space has more symmetry than spacetime, not less, and that is why so much can be transformed away in it.

Rests on Proposition 24.5.

24.2 Symplectic manifolds

Definition 24.8 (Symplectic manifold)**.** A *symplectic manifold* is a pair (M,ω) with M a smooth manifold of dimension $2f$ and $\omega \in \Omega^2(M)$ a two-form that is

1. *closed*: $\mathrm{d}\omega = 0$; and
2. *nondegenerate*: ω_x is a symplectic form on T_xM for every $x \in M$.

This is Definition A.67, restated here because the whole chapter is about it.

Rests on Definitions 13.98, 13.105 and 24.2.

Definition 24.9 (The canonical form on a cotangent bundle)**.** Let Q be the configuration manifold of a mechanical system and $M = T^*Q$ its cotangent bundle—phase space. In coordinates (q^a, p_a) adapted to the bundle, the *canonical one-form* (also called the tautological, Liouville, or symplectic potential) and the *canonical two-form* are

$$\theta = p_a\,\mathrm{d}q^a\,, \qquad \omega = -\mathrm{d}\theta = \mathrm{d}q^a \wedge \mathrm{d}p_a\,. \tag{24.3}$$

Rests on Definitions 13.103 and 24.8.

Proposition 24.10 (The canonical form is symplectic and intrinsic)**.** *The form ω of Equation (24.3) is closed and nondegenerate, and θ is defined without reference to coordinates by $\theta_\xi(v) = \xi(\mathrm{d}\pi(v))$ for $\xi \in T^*Q$ and $v \in T_\xi(T^*Q)$, with $\pi : T^*Q \to Q$ the projection. Phase*

space therefore carries a symplectic structure with no further input: no metric, no connection, and no choice of coordinates.

Rests on Definitions 13.52 and 24.9 and Lemma 13.107.

Proof. *Derives Proposition 24.10.*

Closed. $\omega = -\mathrm{d}\theta$ is exact, hence closed by Lemma 13.107; equivalently $\mathrm{d}\omega = -\mathrm{d}^2\theta = 0$ by Equation (13.245). The second equality in Equation (24.3) is the Leibniz rule for d: $\mathrm{d}\,(p_a \mathrm{d}q^a) = \mathrm{d}p_a \wedge \mathrm{d}q^a = -\mathrm{d}q^a \wedge \mathrm{d}p_a$.

Nondegenerate. In the coordinate basis $(\partial/\partial q^a, \partial/\partial p_a)$ of $T_\xi(T^*Q)$ one reads off from $\omega = \mathrm{d}q^a \wedge \mathrm{d}p_a$ that

$$\omega\left(\frac{\partial}{\partial q^a}, \frac{\partial}{\partial q^b}\right) = 0\,,$$
$$\omega\left(\frac{\partial}{\partial p_a}, \frac{\partial}{\partial p_b}\right) = 0\,,$$
$$\omega\left(\frac{\partial}{\partial q^a}, \frac{\partial}{\partial p_b}\right) = \delta_a^b\,,$$

so the matrix of ω_ξ is J, which is invertible because $J^2 = -\mathbb{1}_{2f}$ by Equation (22.56). A bilinear form with invertible matrix is nondegenerate, and the basis above is a canonical basis in the sense of Equation (24.1).

Intrinsic. Let $\xi \in T^*Q$ lie over $q = \pi(\xi)$ and choose an adapted chart, so that $\xi = p_a\,\mathrm{d}q^a\big|_q$ and a tangent vector $v \in T_\xi(T^*Q)$ has components $v = v_q^a\,\partial/\partial q^a + v_{p,a}\,\partial/\partial p_a$. The projection π forgets the momenta, so $\mathrm{d}\pi(v) = v_q^a\,\partial/\partial q^a\big|_q$, and therefore

$$\xi(\mathrm{d}\pi(v)) = p_a v_q^a = (p_a\,\mathrm{d}q^a)\,(v) = \theta_\xi(v)\,.$$

The left-hand side is built from ξ, v and π alone, none of which mentions a chart; the right-hand side is the coordinate expression Equation (24.3). The two agree in every adapted chart, so θ—and with it $\omega = -\mathrm{d}\theta$—is chart-independent. That the coordinate formula reproduces the definition by evaluating the covector on its own base point is what earns θ the name *tautological*. □

Remark 24.11 (The SI dimension of every object in this chapter). Each product $p_a q^a$ has the dimension of action, and every symplectic object is built from such products. So θ and ω carry the unit J s; the Liouville form Equation (24.13) carries $(\mathrm{J\,s})^f$; a symplectic capacity (Definition 24.33) carries J s; and the Poisson bracket of two quantities u and v carries $[u][v]$ divided by J s, which is why $\{q^a, p_b\}$ in Equation (22.44) is a pure number. A Hamiltonian vector field $X_\mathcal{H}$ built from an energy therefore carries 1/s: it is a rate, as its integral curves being trajectories requires. Two consequences are used later. First, $\omega/\hbar$ is dimensionless, which is what allows it to be the curvature of a connection in Section 24.7; $\hbar$ is the only constant of nature with the right unit to do that job, and Remark 5.116 already notes the coincidence. Second, the column η^c of Equation (22.55) mixes quantities of different dimension—the point of Remark 22.5—so no Euclidean length on phase space is dimensionally meaningful without a declared scale, a point that returns in Remark 24.27.

Rests on Proposition 24.10 and Remark 22.5.

Theorem 24.12 (Darboux)**.** *Every point of a symplectic manifold (M, ω) has a neighbourhood with coordinates (q^a, p_a) in which*

$$\omega = \mathrm{d}q^a \wedge \mathrm{d}p_a\,. \tag{24.4}$$

Rests on Definition 24.8 and Theorem A.68.

Full derivation: Appendix A.12 (p. 2807).
Derives Theorem 24.12.

Theorem 24.12 is Theorem A.68, proved in Appendix A.12 as part of Chapter 5 and not reproved here. The argument there is Moser's deformation trick [1317]: connect ω to its constant-coefficient value at the point by a path of closed nondegenerate forms, use nondegeneracy to solve for the vector field generating the isotopy, and integrate it. Its two hypotheses do exactly one job each—nondegeneracy supplies the vector field, closedness supplies the primitive through the local converse of the Poincaré lemma (Lemma A.77)—and the coordinates it produces are the canonical coordinates of Chapter 22. Corollary A.69 is the statement that any two symplectic manifolds of equal dimension are locally symplectomorphic.

Remark 24.13 (What Darboux's theorem forbids). Darboux's theorem is the exact statement that a symplectic manifold has no local geometry. There is no symplectic analogue of curvature, no invariant distinguishing one point from another, and hence no local measurement that could reveal the symplectic structure of phase space. All symplectic invariants are global, which is why the theorems of this chapter that carry physical content—Liouville, Poincaré recurrence, the Liouville–Arnold tori of Theorem 23.31, the non-squeezing theorem—are statements about whole trajectories or whole regions and never about a neighbourhood of a point. The contrast with the Riemannian case of Chapter 43, where curvature is a local observable and tidal forces measure it, is total.
Rests on Theorem 24.12 and Corollary A.69.

24.3 Hamiltonian vector fields and the flow

Definition 24.14 (Hamiltonian vector field)**.** Let $H \in C^\infty(M)$. Since ω is nondegenerate, there is a unique vector field X_H with

$$\iota_{X_H}\omega = \mathrm{d}H\,. \tag{24.5}$$

It is the *Hamiltonian vector field* of H. In Darboux coordinates

$$X_H = \frac{\partial H}{\partial p_a}\frac{\partial}{\partial q^a} - \frac{\partial H}{\partial q^a}\frac{\partial}{\partial p_a}\,, \tag{24.6}$$

so that its integral curves are exactly the solutions of Hamilton's equations Equations (22.3) and (22.4).
Rests on Definition 24.8 and Equations (22.3) and (22.4).

The coordinate form Equation (24.6) is a one-line check and is worth doing once, because every sign in this chapter descends from it. Write $X = A^a\,\partial/\partial q^a + B_a\,\partial/\partial p_a$. Contracting $\omega = \mathrm{d}q^a \wedge \mathrm{d}p_a$ with X and using the graded Leibniz rule for ι_X,

$$\iota_X\omega = (\iota_X \mathrm{d}q^a)\,\mathrm{d}p_a - \mathrm{d}q^a\,(\iota_X \mathrm{d}p_a) = A^a\,\mathrm{d}p_a - B_a\,\mathrm{d}q^a\,,$$

while $\mathrm{d}H = (\partial H/\partial q^a)\,\mathrm{d}q^a + (\partial H/\partial p_a)\,\mathrm{d}p_a$. Matching the coefficients of $\mathrm{d}p_a$ gives $A^a = \partial H/\partial p_a$ and matching those of $\mathrm{d}q^a$ gives $B_a = -\partial H/\partial q^a$, which is Equation (24.6); these are Equations (22.3) and (22.4) read as the components of a vector field, and they are Equation (22.57) with the matrix J replaced by the form whose matrix it is.

Proposition 24.15 (Poisson bracket from the symplectic form)**.** *With the conventions Equation (24.3) and Equation (24.5), the Poisson bracket of Definition 22.29 is*

$$\{u, v\} = \omega\,(X_u, X_v) = X_v[u]\,, \tag{24.7}$$

and the assignment $u \mapsto X_u$ satisfies

$$X_{\{u,v\}} = -\left[X_u, X_v\right] , \tag{24.8}$$

the bracket on the right being the commutator of vector fields.
Rests on Definitions 22.29 and 24.14 and Equation (22.46).

Proof. *Derives Proposition 24.15.*

The bracket. By Equation (24.5), $\omega(X_u, X_v) = (\iota_{X_u}\omega)(X_v) = \mathrm{d}u(X_v) = X_v[u]$, which is the second equality in Equation (24.7) and holds on any symplectic manifold. For the first, work in Darboux coordinates and use Equation (24.6):

$$\begin{aligned} X_v[u] &= \frac{\partial v}{\partial p_a}\frac{\partial u}{\partial q^a} - \frac{\partial v}{\partial q^a}\frac{\partial u}{\partial p_a} \\ &= \frac{\partial u}{\partial q^a}\frac{\partial v}{\partial p_a} - \frac{\partial u}{\partial p_a}\frac{\partial v}{\partial q^a} , \end{aligned}$$

which is Equation (22.41). In particular $\dot{u} = X_{\mathcal{H}}[u] = \{u, \mathcal{H}\}$ along the flow, so the geometric definition reproduces the evolution law of Chapter 22 with no change of sign, and $\{q^a, p_b\} = \delta^a_b$ as in Equation (22.44).

The homomorphism. Two vector fields are equal when they agree as derivations on every smooth function, so let $w \in C^\infty(M)$ be arbitrary. Using $X_v[w] = \{w, v\}$ twice,

$$\begin{aligned} \left[X_u, X_v\right][w] &= X_u[X_v[w]] - X_v[X_u[w]] \\ &= X_u[\{w, v\}] - X_v[\{w, u\}] = \{\{w, v\}, u\} - \{\{w, u\}, v\} . \end{aligned}$$

On the other side, $X_{\{u,v\}}[w] = \{w, \{u, v\}\}$, and the Jacobi identity Equation (22.46) in the form $\{w, \{u, v\}\} + \{u, \{v, w\}\} + \{v, \{w, u\}\} = 0$ gives, after using antisymmetry on the second term,

$$\begin{aligned} X_{\{u,v\}}[w] &= \{u, \{w, v\}\} - \{v, \{w, u\}\} \\ &= -\{\{w, v\}, u\} + \{\{w, u\}, v\} = -\left[X_u, X_v\right][w] . \end{aligned}$$

Since w was arbitrary, Equation (24.8) follows. The minus sign is not removable: it is the statement that $u \mapsto X_u$ is an *anti*homomorphism of Lie algebras with the conventions fixed above, and reversing it would require reversing the sign in either Equation (24.5) or Equation (22.41). □

Theorem 24.16 (The Hamiltonian flow preserves the symplectic form)**.** *Let ϕ_t be the flow of X_H. Then*

$$\mathcal{L}_{X_H}\omega = 0 , \qquad \textit{equivalently} \qquad \phi_t^*\omega = \omega \quad \textit{for all } t . \tag{24.9}$$

Rests on Definitions 24.8 and 24.14 and Proposition 13.128.

Proof. *Derives Theorem 24.16.*

Cartan's magic formula Equation (13.276) applied to ω and the field X_H reads

$$\mathcal{L}_{X_H}\omega = \mathrm{d}\left(\iota_{X_H}\omega\right) + \iota_{X_H}\left(\mathrm{d}\omega\right) .$$

The first term is $\mathrm{d}\left(\mathrm{d}H\right) = 0$ by Equation (24.5) and the nilpotency Equation (13.245); the second is zero because ω is closed. Each hypothesis of Definition 24.8 is used exactly once, which is why the definition demands both and no more.

For the second form, the Lie derivative is by Equation (13.267) the derivative of the dragged form, so that $\frac{\mathrm{d}}{\mathrm{d}t}\phi_t^*\omega = \phi_t^*\left(\mathcal{L}_{X_H}\omega\right) = 0$; hence $\phi_t^*\omega$ is independent of t and equals its value $\phi_0^*\omega = \omega$ at $t = 0$. □

Definition 24.17 (Symplectomorphism)**.** A diffeomorphism $\psi : M \to M$ with $\psi^*\omega = \omega$ is a *symplectomorphism*, or *canonical transformation*.

Rests on Definitions 24.8 and A.70.

Theorem 24.18 (Symplectic form of the transformation condition)**.** *Let $\eta \mapsto \zeta(\eta)$ be a transformation of phase space in the notation of Equation (22.55), with Jacobian matrix*

$$M^c{}_d = \frac{\partial \zeta^c}{\partial \eta^d}\,. \tag{24.10}$$

The transformation is canonical if and only if

$$M^{\mathsf{T}} J\, M = J\,, \tag{24.11}$$

that is, if and only if its Jacobian lies in $\mathrm{Sp}(2f, \mathbb{R})$ at every point. This single matrix identity is equivalent to the $4f^2$ direct conditions of Proposition 22.17, to the invariance of the fundamental Poisson brackets Equation (22.44), and to the invariance of the fundamental Lagrange brackets Equation (22.39).

Rests on Definition 24.17 and Equations (22.42) and (22.57).

Proof. *Derives Theorem 24.18.*

The condition. Let the transformation be time-independent and invertible, write $\mathcal{H}'(\zeta) = \mathcal{H}(\eta(\zeta))$ for the same energy read in the new variables, and let $\mathcal{H}$ be arbitrary. Differentiating $\zeta = \zeta(\eta)$ along a trajectory and using Equation (22.57) for η,

$$\dot\zeta^c = M^c{}_d\, \dot\eta^d = M^c{}_d\, J^d{}_e\, \frac{\partial \mathcal{H}}{\partial \eta^e}\,, \qquad \frac{\partial \mathcal{H}}{\partial \eta^e} = M^g{}_e\, \frac{\partial \mathcal{H}'}{\partial \zeta^g}\,,$$

the second being the chain rule. In matrix form $\dot\zeta = M\, J\, M^{\mathsf{T}}\, \partial\mathcal{H}'/\partial\zeta$; since $\partial\mathcal{H}'/\partial\zeta$ may be prescribed arbitrarily at any one point by choosing $\mathcal{H}$, the new variables obey Hamilton's equations with $\mathcal{H}'$ for every $\mathcal{H}$ if and only if

$$M\, J\, M^{\mathsf{T}} = J\,. \tag{24.12}$$

That Equation (24.12) and Equation (24.11) are equivalent is algebra. J is invertible, so either identity forces $\det M \neq 0$. Assume Equation (24.12); multiplying on the left by M^{-1} and on the right by $\left(M^{\mathsf{T}}\right)^{-1}$ gives $J = M^{-1} J \left(M^{\mathsf{T}}\right)^{-1}$, and inverting both sides with $J^{-1} = -J$ gives $-J = M^{\mathsf{T}}\,(-J)\,M$, which is Equation (24.11). The same steps run backwards.

The three equivalent tests. All three are Equation (24.12) or Equation (24.11) read in a different bookkeeping. By Equation (22.42) the Poisson bracket of the new variables, computed in the old ones, is

$$\left\{\zeta^c, \zeta^d\right\}_{q,p} = \left(\frac{\partial \zeta^c}{\partial \eta}\right)^{\mathsf{T}} J \left(\frac{\partial \zeta^d}{\partial \eta}\right) = \left(M\, J\, M^{\mathsf{T}}\right)^{cd}\,,$$

so the new variables satisfy the fundamental Poisson brackets Equation (22.44) exactly when Equation (24.12) holds. The Lagrange brackets of Equation (22.36) differentiate the other way round, $\partial\eta/\partial\zeta = M^{-1}$, and give $\left[\zeta^c, \zeta^d\right]_{q,p} = \left((M^{-1})^{\mathsf{T}}\, J M^{-1}\right)^{cd}$, which equals J exactly when Equation (24.11) holds for M^{-1}, hence for M. That the two families of brackets test the transposed identities is the duality recorded in Proposition 22.32. Finally, splitting M into the four $f \times f$ blocks of Equation (22.55) and multiplying out Equation (24.11) block by block returns the four families Equations (22.16) and (22.17), which are $4f^2$ scalar equations; this is Lemma 22.20, and it is what discharges the heading reserved without content in Section 22.5.1.

Coordinate-free reading. Nothing above is more than Definition 24.17 in components: $\psi^*\omega = \omega$ says that the matrix of ω is unchanged when transported by the Jacobian, and the matrix of ω in canonical coordinates is J. □

Corollary 24.19 (Canonical transformations preserve phase volume)**.** $\det M = 1$ *for every canonical transformation, so the phase-space volume element is invariant.*

Rests on Theorems 5.133 and 24.18.

Proof. *Derives Corollary 24.19.*

By Theorem 24.18 the Jacobian lies in $\mathrm{Sp}(2f, \mathbb{R})$ at every point, and every element of that group has determinant $+1$ by Theorem 5.133. The volume element transforms as $\mathrm{d}^{2f}\zeta = (\det M)\,\mathrm{d}^{2f}\eta = \mathrm{d}^{2f}\eta$. Note that taking determinants directly in Equation (24.11) yields only $(\det M)^2 = 1$; the sign is settled by the Pfaffian argument of Theorem 5.133 and not by the naive route. □

24.4 Invariants of the flow

Definition 24.20 (Liouville volume)**.** The *Liouville form* of a symplectic manifold is the $2f$-form

$$\Omega = \frac{1}{f!}\,\omega^{\wedge f} = \mathrm{d}q^1 \wedge \mathrm{d}p_1 \wedge \cdots \wedge \mathrm{d}q^f \wedge \mathrm{d}p_f \tag{24.13}$$

$$= (-1)^{f(f-1)/2}\,\mathrm{d}q^1 \wedge \cdots \wedge \mathrm{d}q^f \wedge \mathrm{d}p_1 \wedge \cdots \wedge \mathrm{d}p_f\,, \tag{24.14}$$

the last two expressions holding in Darboux coordinates. It is a volume form, and every symplectic manifold is therefore orientable.

Rests on Definitions 13.102 and 24.8 and Theorem 24.12.

The two coordinate expressions in Equation (24.13) differ by the sign of the permutation that separates the coordinates from the momenta, and the sign matters only for the choice of orientation, never for a volume. Writing $\omega = \sum_a \omega_a$ with $\omega_a = \mathrm{d}q^a \wedge \mathrm{d}p_a$, each ω_a is a two-form and any two of them commute under $\wedge$, while $\omega_a \wedge \omega_a = 0$; expanding the f-th power therefore leaves only the $f!$ orderings of the distinct factors, so $\omega^{\wedge f} = f!\,\omega_1 \wedge \cdots \wedge \omega_f$, which is the first equality. Regrouping into all the $\mathrm{d}q$ followed by all the $\mathrm{d}p$ requires $f(f-1)/2$ transpositions, which is the second.

Theorem 24.21 (Liouville)**.** *The Hamiltonian flow preserves the Liouville volume:*

$$\mathcal{L}_{X_H}\Omega = 0\,, \qquad \textit{equivalently} \qquad \operatorname{div} X_H = 0\,. \tag{24.15}$$

The volume of any region of phase space is unchanged as the region is carried along by the motion, however violently the region is distorted.

Rests on Definition 24.20, Theorem 24.16, and Proposition 7.73.

Proof. *Derives Theorem 24.21.*

Geometric route. The Lie derivative is a derivation of the exterior algebra, so it obeys the Leibniz rule on wedge products; applied to $\Omega = \omega^{\wedge f}/f!$ this gives

$$\mathcal{L}_{X_H}\Omega = \frac{1}{f!}\sum_{k=1}^{f} \omega^{\wedge(k-1)} \wedge (\mathcal{L}_{X_H}\omega) \wedge \omega^{\wedge(f-k)}$$

$$= \frac{1}{(f-1)!}\,(\mathcal{L}_{X_H}\omega) \wedge \omega^{\wedge(f-1)}\,,$$

using that two-forms commute under $\wedge$, and this vanishes because $\mathcal{L}_{X_H}\omega = 0$ by Theorem 24.16. The Liouville form is built from ω and nothing else, so it inherits every invariance ω has.

Coordinate route. For a volume form Ω the Lie derivative of a vector field satisfies $\mathcal{L}_X\Omega = (\operatorname{div} X)\,\Omega$, which in Darboux coordinates is the ordinary divergence. From Equation (24.6),

$$\begin{aligned}\operatorname{div} X_H &= \frac{\partial}{\partial q^a}\left(\frac{\partial H}{\partial p_a}\right) + \frac{\partial}{\partial p_a}\left(-\frac{\partial H}{\partial q^a}\right)\\ &= \frac{\partial^2 H}{\partial q^a \partial p_a} - \frac{\partial^2 H}{\partial p_a \partial q^a} = 0\,,\end{aligned}$$

the two terms cancelling term by term by the equality of mixed partial derivatives, Proposition 7.73. Note where the antisymmetry does its work: an arbitrary vector field on phase space has no reason to be divergence-free, and it is the opposite signs in Equation (24.6)—that is, the antisymmetry of J—that force the cancellation. □

Remark 24.22 (Liouville's theorem is the foundation of statistical mechanics). Theorem 24.21 is what makes the phase-space volume, and not some other measure, the natural counting measure for a mechanical system; the microcanonical ensemble of Chapter 118 is the uniform measure on an energy shell with respect to it, and it is distinguished by being invariant under the very dynamics whose long-time behaviour it is used to describe. The entropy so defined inherits the additive constant that only quantum mechanics fixes, through the cell size h^f—which is dimensionally the only thing it could be, by Remark 24.11. That this constant is measurable—in the Sackur–Tetrode equation for the absolute entropy of a monatomic gas [380, 393]—is one of the places where phase-space geometry becomes an experimental number.

Rests on Theorem 24.21 and Remark 24.11.

24.4.1 Integral invariants

Theorem 24.23 (Poincaré–Cartan integral invariant)**.** *Let γ_1 and γ_2 be two closed curves encircling the same tube of trajectories in extended phase space (q^a, p_a, t). Then*

$$\oint_{\gamma_1} (p_a\,\mathrm{d}q^a - \mathcal{H}\,\mathrm{d}t) = \oint_{\gamma_2} (p_a\,\mathrm{d}q^a - \mathcal{H}\,\mathrm{d}t)\ . \tag{24.16}$$

If both curves lie at a fixed instant, this reduces to the invariance of $\oint p_a\,\mathrm{d}q^a$, and hence, by Stokes' theorem, to Poincaré's theorem Theorem 22.22.

Rests on Equations (22.3) and (24.3) and Theorem A.311.

Proof. *Derives Theorem 24.23.*

Work on extended phase space $\widetilde{M} = M \times \mathbb{R}$ with coordinates (q^a, p_a, t) and set $\lambda = p_a\,\mathrm{d}q^a - \mathcal{H}\,\mathrm{d}t$, so that $\mathrm{d}\lambda = \mathrm{d}p_a \wedge \mathrm{d}q^a - \mathrm{d}\mathcal{H} \wedge \mathrm{d}t$, that is

$$\mathrm{d}\lambda = \mathrm{d}p_a \wedge \mathrm{d}q^a - \frac{\partial \mathcal{H}}{\partial q^a}\,\mathrm{d}q^a \wedge \mathrm{d}t - \frac{\partial \mathcal{H}}{\partial p_a}\,\mathrm{d}p_a \wedge \mathrm{d}t\,,$$

the term in $\partial\mathcal{H}/\partial t$ dropping out because $\mathrm{d}t \wedge \mathrm{d}t = 0$. The trajectories of the system are the integral curves of

$$Z = \frac{\partial}{\partial t} + \frac{\partial \mathcal{H}}{\partial p_a}\frac{\partial}{\partial q^a} - \frac{\partial \mathcal{H}}{\partial q^a}\frac{\partial}{\partial p_a}\,,$$

that is, of $X_{\mathcal{H}}$ carried along at unit rate in t; this is Equation (24.6) together with $\dot{t} = 1$. Contract $\mathrm{d}\lambda$ with Z, using $\iota_Z(\alpha \wedge \beta) = (\iota_Z\alpha)\,\beta - \alpha\,(\iota_Z\beta)$ on one-forms α, β:

$$\begin{aligned}\iota_Z(\mathrm{d}p_a \wedge \mathrm{d}q^a) &= -\frac{\partial \mathcal{H}}{\partial q^a}\,\mathrm{d}q^a - \frac{\partial \mathcal{H}}{\partial p_a}\,\mathrm{d}p_a\,,\\ -\frac{\partial \mathcal{H}}{\partial q^a}\,\iota_Z(\mathrm{d}q^a \wedge \mathrm{d}t) &= -\frac{\partial \mathcal{H}}{\partial q^a}\frac{\partial \mathcal{H}}{\partial p_a}\,\mathrm{d}t + \frac{\partial \mathcal{H}}{\partial q^a}\,\mathrm{d}q^a\,,\\ -\frac{\partial \mathcal{H}}{\partial p_a}\,\iota_Z(\mathrm{d}p_a \wedge \mathrm{d}t) &= +\frac{\partial \mathcal{H}}{\partial p_a}\frac{\partial \mathcal{H}}{\partial q^a}\,\mathrm{d}t + \frac{\partial \mathcal{H}}{\partial p_a}\,\mathrm{d}p_a\,.\end{aligned}$$

Adding the three lines, the $\mathrm{d}q^a$ terms cancel, the $\mathrm{d}p_a$ terms cancel, and the two $\mathrm{d}t$ terms cancel against each other:

$$\iota_Z \, \mathrm{d}\lambda = 0 \,. \tag{24.17}$$

So the trajectory direction lies in the kernel of $\mathrm{d}\lambda$. Since $\mathrm{d}\lambda$ is a two-form on a space of odd dimension $2f+1$ its kernel is at least one-dimensional; Equation (24.17) identifies it as the direction of the motion.

Now let T be the tube swept by the trajectories through a closed curve, a two-dimensional surface in $\widetilde{M}$, and let γ_1 and γ_2 be two closed curves on T each encircling it once, with $\Sigma \subset T$ the annulus they bound, so that $\partial\Sigma = \gamma_1 - \gamma_2$. At every point of Σ the tangent plane is two-dimensional and contains Z; if v is any second tangent vector there, then $\mathrm{d}\lambda(Z, v) = 0$ by Equation (24.17), so the pullback of $\mathrm{d}\lambda$ to Σ vanishes identically. The general Stokes theorem Theorem A.311 then gives

$$\oint_{\gamma_1} \lambda - \oint_{\gamma_2} \lambda = \int_{\partial\Sigma} \lambda = \int_{\Sigma} \mathrm{d}\lambda = 0 \,,$$

which is Equation (24.16).

If both curves lie in a surface of constant t, then $\mathrm{d}t$ pulls back to zero on them and λ reduces to $\theta = p_a \mathrm{d}q^a$; the statement becomes the invariance of $\oint p_a \, \mathrm{d}q^a$ under the flow, and applying Theorem A.311 once more turns that into the invariance of $\int \omega$ over a surface, which is Theorem 22.22. That the first Poincaré invariant is the only independent one is the content of Equation (24.13): the higher invariants are integrals of $\omega^{\wedge k}$ and follow from the first. □

Theorem 24.24 (Poincaré recurrence)**.** *Let the Hamiltonian flow leave invariant a region $D \subset M$ of finite Liouville volume—as it does, for instance, for bounded motion at fixed energy. Then for every neighbourhood $U \subset D$, almost every point of U returns to U at arbitrarily late times.*

Rests on Theorem 24.21 and Definition 24.20.

Proof. *Derives Theorem 24.24.*

Write μ for the Liouville volume of Definition 24.20, so that $\mu(D) < \infty$, and fix a time step $\tau > 0$; let $\phi = \phi_\tau$ be the time-τ map of the flow. By Theorem 24.21 ϕ preserves μ, and it maps D to itself.

Fix an integer $k \geq 1$ and let

$$B_k = \left\{ x \in U \;:\; \phi^{nk}(x) \notin U \text{ for every integer } n \geq 1 \right\}$$

be the set of points of U that never return under the map ϕ^k. The sets $\phi^{-nk}(B_k)$, $n = 0, 1, 2, \ldots$, are pairwise disjoint. Indeed, suppose x lay in both $\phi^{-nk}(B_k)$ and $\phi^{-mk}(B_k)$ with $n < m$. Then $y = \phi^{nk}(x) \in B_k \subset U$ while $\phi^{(m-n)k}(y) = \phi^{mk}(x) \in B_k \subset U$, so y returns to U after $m - n \geq 1$ steps of ϕ^k, contradicting $y \in B_k$.

Each of these sets lies in D and has the same volume $\mu(B_k)$, because ϕ preserves μ. If $\mu(B_k) > 0$ then the volume of the disjoint union of the first N of them is $N\mu(B_k)$, which exceeds $\mu(D)$ for N large enough—impossible, since they all sit inside D. Hence $\mu(B_k) = 0$ for every k.

Finally, a point of U that returns for arbitrarily large multiples of τ is one lying outside every B_k: if $x \notin B_k$ then x returns to U at some time that is a positive multiple of $k\tau$, and letting k run makes those return times unbounded. The exceptional set is $\bigcup_{k \geq 1} B_k$, a countable union of sets of volume zero and therefore of volume zero. So almost every point of U returns at arbitrarily late times [247]. □

Remark 24.25 (What the recurrence proof assumes about volume). The argument just given treats the Liouville volume as a *measure*: it uses additivity over disjoint sets, monotonicity, invariance under a volume-preserving map, and—in the last step only—the fact that a countable union of null sets is null. Those are the axioms of a measure space, and this treatise does not carry measure theory: the probability chapter of Part II is built on densities and expectations and never defines a σ-algebra or a countably additive measure. The statement is therefore made here on that understanding, and the reader who wants the last step in full rigour needs the countable additivity that Part II owes. Nothing else in this chapter uses it; and the physically relevant half of the theorem—that a positive-volume set of initial conditions must return—needs only finite additivity, which is the elementary property of volume used everywhere else in this part.

Rests on Theorem 24.24.

Remark 24.26 (Recurrence and irreversibility). Theorem 24.24 says that a bounded mechanical system returns arbitrarily close to its initial state, which appears to contradict the second law of Chapter 54. It does not: the recurrence times for a macroscopic number of degrees of freedom exceed the age of the universe by an enormous factor, and the theorem is silent about them. The tension it does expose—between a time-reversible microscopic dynamics and an irreversible phenomenology—is Loschmidt's and Zermelo's objection, and it is treated where it belongs, in Chapter 118.

Rests on Theorem 24.24.

24.4.2 Symplectic capacity and non-squeezing

Liouville's theorem constrains the volume of a phase-space region and nothing else. It is natural to ask whether that is the whole story— whether any volume-preserving deformation of a region can be realised by a Hamiltonian flow. It cannot, and the obstruction is not a refinement of volume but an invariant of a different kind. This subsection states it. It is written as mathematics: this treatise records no experiment that measures a symplectic capacity, and the frequently drawn analogy with the uncertainty relation of Chapter 77 is suggestive rather than derivational, a point made precise in Remark 24.35.

Remark 24.27 (Fixing a scale, so that a "ball" means something). A ball in phase space is not a dimensionally meaningful object: by Remark 24.11 a coordinate and its conjugate momentum carry different units, and no sum of their squares is a length. To speak of balls and cylinders one must first declare a scale. Fix a length $\ell > 0$ and an action $S > 0$ and pass to the dimensionless coordinates

$$u^a = \frac{q^a}{\ell}\,, \qquad v_a = \frac{\ell\, p_a}{S}\,, \qquad \text{so that} \qquad \omega = S\,\mathrm{d}u^a \wedge \mathrm{d}v_a\,. \tag{24.18}$$

All statements below are made for the standard form $\omega_0 = \mathrm{d}u^a \wedge \mathrm{d}v_a$ on $\mathbb{R}^{2f}$, and are converted back by the factor S; every capacity then comes out as a pure number times S, that is, in J s. Different choices of (ℓ, S) give different balls, so the theorem below compares a ball and a cylinder built with the *same* choice. Write $\langle \cdot, \cdot \rangle$ for the Euclidean inner product in these coordinates and $|\cdot|$ for its norm; then, with J the matrix Equation (22.56) and $z, w \in \mathbb{R}^{2f}$ written as columns in the block order of Equation (22.55),

$$\omega_0(z, w) = \langle z, J\, w \rangle\,, \qquad J^{\mathsf{T}} J = \mathbb{1}_{2f}\,, \qquad \langle J\, z, z \rangle = 0\,. \tag{24.19}$$

The last two follow from $J^{\mathsf{T}} = -J$ and $J^2 = -\mathbb{1}_{2f}$: J is an orthogonal matrix and Jz is orthogonal to z for every z.

Rests on Remark 24.11 and Equation (22.56).

Definition 24.28 (Ball and cylinder)**.** In $\left(\mathbb{R}^{2f}, \omega_0\right)$ with the coordinates Equation (24.18), the *ball* of radius ρ and the *cylinder* of radius r over the first conjugate pair are

$$B(\rho) = \left\{ z \in \mathbb{R}^{2f} \;:\; \textstyle\sum_a \left[(u^a)^2 + (v_a)^2 \right] < \rho^2 \right\}, \tag{24.20}$$

$$Z(r) = \left\{ z \in \mathbb{R}^{2f} \;:\; \left(u^1\right)^2 + (v_1)^2 < r^2 \right\}. \tag{24.21}$$

A *symplectic embedding* of one subset of $\mathbb{R}^{2f}$ into another is a smooth embedding φ with $\varphi^* \omega_0 = \omega_0$.

Rests on Remark 24.27 and Definition 24.17.

$Z(r)$ has infinite volume for every $r > 0$, so no volume argument can prevent a ball of any radius from being squeezed into it. And volume preservation alone does not prevent it either:

Example 24.29 (A volume-preserving squeeze)**.** Take $f = 3$—one particle in three-dimensional space—and, for $\lambda > 0$, the linear map

$$\begin{aligned} \left(u^1, v_1\right) &\mapsto \left(\lambda u^1, \lambda v_1\right), \\ \left(u^2, v_2\right) &\mapsto \left(\lambda^{-1} u^2, \lambda^{-1} v_2\right), \\ \left(u^3, v_3\right) &\mapsto \left(u^3, v_3\right). \end{aligned}$$

Its determinant is $\lambda^2 \cdot \lambda^{-2} \cdot 1 = 1$, so it preserves the Liouville volume exactly; and it carries $B(\rho)$ into $Z(\lambda\rho)$, which for small λ is as thin as one likes. It is not symplectic: it pulls ω_0 back to $\lambda^2\, \mathrm{d}u^1 \wedge \mathrm{d}v_1 + \lambda^{-2}\, \mathrm{d}u^2 \wedge \mathrm{d}v_2 + \mathrm{d}u^3 \wedge \mathrm{d}v_3$, which is not ω_0. The squeezing that volume preservation permits is thus achieved by trading area between two *different* conjugate pairs—exactly what a symplectic map may not do.

Rests on Definition 24.28 and Theorem 24.21.

Proposition 24.30 (Linear non-squeezing)**.** *Let $A \in \mathrm{Sp}(2f, \mathbb{R})$ and suppose $A\left(B(\rho)\right) \subseteq Z(r)$. Then $r \geq \rho$.*

Rests on Definitions 24.4 and 24.28 and Equation (24.19).

Proof. *Derives Proposition 24.30.*

Let e_1 and f^1 be the first pair of the canonical basis, so that $\omega_0(e_1, f^1) = 1$ by Equation (24.1). For any $w \in \mathbb{R}^{2f}$ the two coordinates in which the cylinder is defined are

$$u^1(w) = \omega_0\left(w, f^1\right), \qquad v_1(w) = -\omega_0(w, e_1),$$

as one checks by evaluating $\omega_0 = \mathrm{d}u^a \wedge \mathrm{d}v_a$ on the basis. Because A preserves ω_0, $\omega_0(Az, f^1) = \omega_0\left(z, A^{-1} f^1\right)$ and likewise for e_1. Put $a = A^{-1} e_1$ and $b = A^{-1} f^1$, so that

$$\omega_0(a, b) = \omega_0\left(e_1, f^1\right) = 1, \tag{24.22}$$

and the composition of A with the projection onto the cylinder plane is the linear map $L : \mathbb{R}^{2f} \to \mathbb{R}^2$,

$$L(z) = \left(\omega_0(z, b),\, -\omega_0(z, a)\right) = \left(\langle z, J\, b\rangle,\, -\langle z, J\, a\rangle\right),$$

by Equation (24.19). The hypothesis $A\left(B(\rho)\right) \subseteq Z(r)$ says that $|L(z)| < r$ for every z with $|z| < \rho$, hence by continuity $|L(z)| \leq r$ on the closed ball, that is $\rho\, \|L\| \leq r$ with $\|L\|$ the operator norm.

It remains to show $\|L\| \geq 1$. The matrix of L has the two rows $(Jb)^{\mathsf{T}}$ and $-(Ja)^{\mathsf{T}}$, so

$$L\, L^{\mathsf{T}} = \begin{pmatrix} |b|^2 & -\langle a, b\rangle \\ -\langle a, b\rangle & |a|^2 \end{pmatrix}, \quad \det\left(L\, L^{\mathsf{T}}\right) = |a|^2\, |b|^2 - \langle a, b\rangle^2,$$

where $|Jb| = |b|$, $|Ja| = |a|$ and $\langle Jb, Ja\rangle = \langle b, a\rangle$ because J is orthogonal by Equation (24.19). The determinant is the square of the Euclidean area $\mathcal{A}$ of the parallelogram spanned by a and b. Now Jb is orthogonal to b and has the same length, so $Jb/|b|$ is a unit vector perpendicular to b, and the component of a along it is at most the distance from a to the line $\mathbb{R}b$:

$$1 = |\omega_0(a,b)| = |\langle a, Jb\rangle| = |b|\,\left|\left\langle a, \tfrac{Jb}{|b|}\right\rangle\right| \le |b| \cdot \operatorname{dist}(a, \mathbb{R}b) = \mathcal{A}\,,$$

using Equation (24.22). Hence $\det\left(LL^{\mathsf{T}}\right) = \mathcal{A}^2 \ge 1$. The matrix LL^{T} is symmetric positive semidefinite with two eigenvalues whose product is at least 1, so its largest eigenvalue is at least 1; and $\|L\|^2$ is that largest eigenvalue. Therefore $\|L\| \ge 1$, and $r \ge \rho\,\|L\| \ge \rho$. □

The proposition is elementary because a linear symplectic map sends the ball to an ellipsoid and the argument is one about areas of shadows. Gromov's theorem is the same statement without linearity, and it is not elementary at all: it was the first application of pseudoholomorphic curves, and no proof by the methods of this chapter is known.

Theorem 24.31 (Gromov's non-squeezing theorem)**.** *Let $f \ge 2$ and $\rho, r > 0$. If there exists a symplectic embedding $\varphi : B(\rho) \hookrightarrow Z(r)$ in the sense of Definition 24.28, then $r \ge \rho$.*
Rests on Definition 24.28 and Proposition 24.30.

Remark 24.32 (Non-squeezing is quoted, and will not be proved here)*.* Theorem 24.31 carries no derivation in this book, and the omission is a decision rather than a debt. It is due to Gromov, in *Pseudo holomorphic curves in symplectic manifolds* (*Inventiones Mathematicae* **82**, 1985); that paper has no key in this treatise's bibliography, so the attribution is made in words, on the same footing as Darboux's own memoir in Appendix A.12. The proof constructs a pseudoholomorphic disc through a prescribed point of the image and bounds its area by an elliptic-analysis argument—compactness of a moduli space of such discs, and a monotonicity estimate for their area—machinery that appears nowhere else in this treatise and that no other result here needs. Introducing it to serve one statement would unbalance the chapter, and this is the same treatment Part II gives Carleson's theorem in Remark 17.18.

No shortcut through the linear case exists. Proposition 24.30, which *is* proved in full by the methods of this chapter, constrains only linear symplectic maps and says nothing about a nonlinear embedding, and the obvious replacement argument—that a symplectomorphism preserves volume, so it cannot squeeze—is simply false, by Example 24.29. What the theorem is used for below is one statement, that the Gromov width of Equation (24.23) satisfies the third capacity axiom of Definition 24.33, and everything this chapter concludes from that is flagged in Remark 24.35 as mathematics rather than as measured physics.

Definition 24.33 (Symplectic capacity)**.** A *symplectic capacity* is an assignment c of a number in $[0,\infty]$ to every pair $(U, \alpha\omega_0)$ with $U \subseteq \mathbb{R}^{2f}$ and $\alpha \ne 0$ real, such that

1. *monotonicity*: if $(U, \alpha\omega_0) \hookrightarrow (V, \beta\omega_0)$ admits a symplectic embedding, then $c\,(U, \alpha\omega_0) \le c\,(V, \beta\omega_0)$;
2. *conformality*: $c\,(U, \alpha\omega_0) = |\alpha|\; c\,(U, \omega_0)$;
3. *nontriviality*: $c\,(B(1), \omega_0) = c\,(Z(1), \omega_0) = \pi$.

The argument ω_0 is suppressed when it is the standard form. By Remark 24.27 a capacity of a region of physical phase space carries the unit J s.
Rests on Definition 24.28 and Remark 24.27.

The three axioms are those of Ekeland and Hofer. Only the third mentions a specific set, and it is the one that does all the work. Monotonicity and conformality alone are cheap:

the f-th root of the Liouville volume satisfies both, since a symplectic embedding preserves volume and rescaling ω_0 by α rescales the volume by $|\alpha|^f$. What that candidate cannot do is meet the third axiom, because $Z(1)$ has infinite volume as soon as $f \geq 2$; in $f = 1$ the area *is* a capacity, and the whole content of the subject is that the case $f \geq 2$ is not vacuous. The following makes that precise—the existence of a capacity and the non-squeezing theorem are the same statement.

Proposition 24.34 (Capacities exist if and only if non-squeezing holds)**.** *Fix $f \geq 1$. There exists a symplectic capacity on $\left(\mathbb{R}^{2f}, \omega_0\right)$ if and only if the non-squeezing statement of Theorem 24.31 holds in that dimension—for $f = 1$ the elementary statement that an area-preserving embedding of a disc into a disc cannot decrease the radius, for $f \geq 2$ Gromov's theorem. In that case the* Gromov width

$$c_G(U) = \sup\left\{\pi\rho^2 \;:\; B(\rho) \text{ embeds symplectically in } U\right\} \tag{24.23}$$

is a capacity, and it is the smallest one.

Rests on Definition 24.33 and Theorem 24.31.

Proof. *Derives Proposition 24.34.*

First note that any capacity takes the value $\pi\rho^2$ on $B(\rho)$ and on $Z(\rho)$. The dilation $\delta_\rho(z) = \rho z$ carries $B(1)$ onto $B(\rho)$ and satisfies $\delta_\rho^*\omega_0 = \rho^2\omega_0$, so it is a symplectomorphism from $\left(B(1), \rho^2\omega_0\right)$ to $(B(\rho), \omega_0)$; monotonicity applied in both directions and then conformality with $\alpha = \rho^2$ give

$$c\left(B(\rho), \omega_0\right) = c\left(B(1), \rho^2\omega_0\right) = \rho^2 c\left(B(1), \omega_0\right) = \pi\rho^2\,,$$

and the identical argument applies to $Z(r)$, giving πr^2.

A capacity implies non-squeezing. Let c be a capacity and let $\varphi : B(\rho) \hookrightarrow Z(r)$ be a symplectic embedding. Then monotonicity gives $\pi\rho^2 = c\left(B(\rho)\right) \leq c\left(Z(r)\right) = \pi r^2$, hence $r \geq \rho$.

Non-squeezing implies a capacity. Assume Theorem 24.31 and consider c_G of Equation (24.23). Monotonicity is immediate: a symplectic embedding $U \hookrightarrow V$ composes with any $B(\rho) \hookrightarrow U$, so every ρ admissible for U is admissible for V. Conformality follows from the dilation computation above, since precomposing an embedding into $(U, \alpha\omega_0)$ with $\delta_{\sqrt{\alpha}}$ shows that ρ is admissible for $\alpha\omega_0$ exactly when $\rho/\sqrt{\alpha}$ is admissible for ω_0, so the supremum of $\pi\rho^2$ is multiplied by $\alpha > 0$; the case $\alpha < 0$ reduces to it by the reflection $v_a \mapsto -v_a$ in *every* pair, which carries ω_0 to $-\omega_0$ and leaves every ball and every cylinder where it was. For nontriviality, the identity embeds $B(1)$ in itself and in $Z(1)$, so $c_G\left(B(1)\right) \geq \pi$ and $c_G\left(Z(1)\right) \geq \pi$; conversely a symplectic embedding $B(\rho) \hookrightarrow Z(1)$ forces $\rho \leq 1$ by Theorem 24.31, so $c_G\left(Z(1)\right) \leq \pi$, and $B(1) \subset Z(1)$ with monotonicity gives $c_G\left(B(1)\right) \leq \pi$ as well.

Minimality. If c is any capacity and $B(\rho)$ embeds in U, then $\pi\rho^2 = c\left(B(\rho)\right) \leq c(U)$; taking the supremum over such ρ gives $c_G(U) \leq c(U)$. □

Remark 24.35 (What non-squeezing does and does not say about nature)*.* A Hamiltonian flow is a symplectomorphism (Theorem 24.16), so the Gromov width of a phase-space region is conserved along the motion just as its volume is. That is a genuine constraint on classical dynamics, and it is strictly stronger than Liouville's: by Example 24.29 volume preservation permits a squeeze that Theorem 24.31 forbids. The shadow of a Hamiltonian-transported region on any one conjugate plane cannot be made arbitrarily small while the region stays large in the other directions.

Three cautions keep the statement honest. First, this treatise records no experiment that measures a symplectic capacity, and the section is therefore mathematics, not evidence-based

physics. Second, the resemblance to the uncertainty relation of Chapter 77 is formal only: Definition 24.33 assigns a capacity to a *region*, and classical mechanics puts no floor under it—a single point, or a Lagrangian sheet of any extent, has capacity zero, and there is no classical reason for the number S of Remark 24.27 to be $\hbar$ rather than anything else. The uncertainty relation is a theorem about noncommuting operators and states, not about embeddings, and it is the quantum postulate that supplies the scale. Third, what the analogy does establish is a dimensional coincidence worth keeping in view: a capacity carries J s by Remark 24.27, which is the unit of $\hbar$, and Remark 24.11 traces that back to the pairing of a coordinate with its momentum. It is the same coincidence that makes Section 24.7 possible.

Rests on Theorems 24.16 and 24.31 and Remark 24.11.

24.5 Poisson manifolds

Not every space carrying a Poisson bracket is a symplectic manifold. The bracket, not the form, is the more general object, and it is the one mechanics actually needs—rigid-body dynamics lives on a space where the form degenerates.

Definition 24.36 (Poisson manifold)**.** A *Poisson manifold* is a manifold P with a bilinear operation $\{\cdot,\cdot\}$ on $C^\infty(P)$ that is antisymmetric, satisfies the Jacobi identity Equation (22.46), and obeys the Leibniz rule

$$\{u, vw\} = \{u, v\}\, w + v\, \{u, w\}\ . \tag{24.24}$$

Equivalently, it carries a bivector field $\pi \in \Gamma(\Lambda^2 TP)$ with $\{u, v\} = \pi(\mathrm{d}u, \mathrm{d}v)$ whose Schouten–Nijenhuis bracket with itself vanishes, $[\pi, \pi] = 0$; that vanishing is the Jacobi identity.

Rests on Definition 22.29 and Equation (22.46).

Definition 24.37 (Casimir function)**.** A *Casimir* is a function C with $\{C, u\} = 0$ for every u. A Casimir is conserved by every Hamiltonian, whatever it is; on a symplectic manifold only the constants are Casimirs, so a nonconstant Casimir is exactly a signature of degeneracy.

Rests on Definition 24.36 and Proposition 24.15.

That the only Casimirs of a symplectic manifold are the constants is immediate from Proposition 24.15: $\{C, u\} = -X_C[u]$ vanishes for every u only if $X_C = 0$, and then $\mathrm{d}C = \iota_{X_C}\omega = 0$ by Equation (24.5), so C is locally constant. On a Poisson manifold the map $\mathrm{d}C \mapsto X_C$ has a kernel, and the Casimirs are what live in it.

Theorem 24.38 (Symplectic foliation, quoted)**.** *A Poisson manifold is partitioned into immersed submanifolds—the* symplectic leaves*—each of which carries a symplectic form inducing the ambient bracket. The leaves are the level sets of the Casimirs where those are regular, and the dynamics of any Hamiltonian stays on the leaf it starts on.*

Rests on Definitions 24.8, 24.36 and 24.37.

Remark 24.39 (The foliation is quoted; its last clause is proved). Only the existence of the leaves is quoted here, and it is worth being exact about which half that is. The bracket of Definition 24.36 assigns to each point the image of the bivector π, a subspace of the tangent space spanned by the Hamiltonian vector fields; the Jacobi identity makes that family of subspaces involutive, since $[X_u, X_v] = -X_{\{u,v\}}$ is again a Hamiltonian vector field—the computation proving Equation (24.8) uses only the Jacobi identity and the derivation property, both of which Definition 24.36 supplies—and integrating an involutive family into submanifolds is the Frobenius theorem. The manifolds chapter Chapter 13 does not carry it, and even if it did it would not suffice: the rank of π varies from point to point—for the Lie–Poisson bracket Equation (24.26) of the rigid body it is zero at the

origin of $\mathfrak{so}(3)^*$ and two everywhere else—so the distribution is singular, and the tool required is the integrability theorem for singular distributions rather than the constant-rank Frobenius theorem. Weinstein's splitting theorem, the local normal form that generalizes Darboux (Theorem 24.12) to the Poisson case, belongs with the same missing half. All of it is differential topology, and this chapter states it rather than proving it for the reason given in Remark 17.18: the machinery has no other use in this book.

The last clause of Theorem 24.38 is the one the rigid body of Proposition 24.41 actually consumes, and it needs nothing beyond the definitions. If C is a Casimir then $\dot{C} = \{C, \mathcal{H}\} = 0$ along the flow of *any* $\mathcal{H}$ whatever, so every Casimir is a constant of the motion and a trajectory stays in the level set of every Casimir it starts in. Where those level sets are regular they are the leaves, so no application below rests on the quoted half.

Definition 24.40 (Lie–Poisson bracket)**.** Let $\mathfrak{g}$ be a Lie algebra and $\mathfrak{g}^*$ its dual. The *Lie–Poisson bracket* on $\mathfrak{g}^*$ is

$$\{u, v\}_{\pm}(\mu) = \pm \left\langle \mu, \left[\frac{\delta u}{\delta \mu}, \frac{\delta v}{\delta \mu} \right] \right\rangle , \qquad \mu \in \mathfrak{g}^* , \tag{24.25}$$

the inner bracket being that of $\mathfrak{g}$. Both signs give a Poisson structure in the sense of Definition 24.36—antisymmetry and the Leibniz rule are unaffected by an overall sign, and the Jacobi identity is quadratic in the bracket and therefore also unaffected—and which one a given mechanical system requires is fixed by the physics, not by convention. The rigid body referred to body axes takes the minus sign, Proposition 24.41.

Rests on Definitions 5.123 and 24.36.

Proposition 24.41 (The free rigid body is a Lie–Poisson system)**.** *Take $\mathfrak{g} = \mathfrak{so}(3)$, identify $\mathfrak{g}^*$ with $\mathbb{R}^3$ so that $\mu = \boldsymbol{L}$ is the angular momentum referred to body axes, and let $\mathcal{H} = \frac{1}{2} L_i \left(I^{-1}\right)_{ij} L_j$ with I the inertia tensor. Then the minus Lie–Poisson bracket of Equation (24.25) is*

$$\{u, v\}_{-} = -\boldsymbol{L} \cdot (\nabla u \times \nabla v) , \qquad \textit{so that} \qquad \{L_i, L_j\}_{-} = -\varepsilon_{ijk} L_k , \tag{24.26}$$

the gradients being taken with respect to $\boldsymbol{L}$, and the equations of motion it generates are Euler's equations Theorem 29.25 for the torque-free body,

$$\frac{\mathrm{d}\boldsymbol{L}}{\mathrm{d}t} = \boldsymbol{L} \times \boldsymbol{\Omega} , \qquad \boldsymbol{\Omega} = I^{-1} \boldsymbol{L} . \tag{24.27}$$

The function $C = |\boldsymbol{L}|^2$ is a Casimir, the leaves are the spheres $|\boldsymbol{L}| =$ constant, and the trajectories are the intersections of those spheres with the energy ellipsoids $\mathcal{H} =$ constant.

Rests on Definitions 24.37 and 24.40 and Theorem 29.25.

Proof. *Derives Proposition 24.41.*

The bracket. Take the basis e_i of $\mathfrak{so}(3)$ with $[e_j, e_k] = \varepsilon_{jkl} e_l$, so that the structure constants are the Levi-Civita symbol (Definition 14.26 and Lemma 14.62), and identify $\mathfrak{g}^* \cong \mathbb{R}^3$ by $\langle \mu, e_i \rangle = L_i$. For a function u of $\boldsymbol{L}$ the functional derivative is the ordinary gradient, $\delta u / \delta \mu = (\partial u / \partial L_j)\, e_j$. Then

$$\begin{aligned} \{u, v\}_{-} &= -\left\langle \mu, \left[\frac{\partial u}{\partial L_j} e_j, \frac{\partial v}{\partial L_k} e_k \right] \right\rangle = -\varepsilon_{jkl} L_l \frac{\partial u}{\partial L_j} \frac{\partial v}{\partial L_k} \\ &= -\boldsymbol{L} \cdot (\nabla u \times \nabla v) , \end{aligned}$$

since $(\nabla u \times \nabla v)_l = \varepsilon_{ljk} \left(\partial u / \partial L_j\right) \left(\partial v / \partial L_k\right)$ and $\varepsilon_{jkl} = \varepsilon_{ljk}$. Putting $u = L_i$, $v = L_j$ gives $\{L_i, L_j\}_{-} = -\boldsymbol{L} \cdot (\hat{e}_i \times \hat{e}_j) = -\varepsilon_{ijk} L_k$, which is the bracket declared in Remark 29.27.

The equations of motion. With $\nabla\mathcal{H} = I^{-1}\boldsymbol{L} = \boldsymbol{\Omega}$—the body-frame angular velocity, since $\boldsymbol{L} = I\boldsymbol{\Omega}$—and $\nabla L_i = \hat{e}_i$,

$$\begin{aligned}\dot{L}_i &= \{L_i, \mathcal{H}\}_- = -\boldsymbol{L}\cdot(\hat{e}_i \times \boldsymbol{\Omega}) = -\varepsilon_{mik} L_m \Omega_k \\ &= \varepsilon_{imk} L_m \Omega_k = (\boldsymbol{L}\times\boldsymbol{\Omega})_i \ ,\end{aligned}$$

which is Equation (24.27), that is $\mathrm{d}\boldsymbol{L}/\mathrm{d}t + \boldsymbol{\Omega}\times\boldsymbol{L} = 0$— Equation (29.21) with $\boldsymbol{\tau} = \boldsymbol{0}$. In principal axes $L_i = I_i\Omega_i$ and the components read $I_1\dot{\Omega}_1 = (I_2 - I_3)\,\Omega_2\Omega_3$ and its cyclic partners, which are Equations (29.18) to (29.20) with zero torque. Had the plus sign of Equation (24.25) been taken, the same computation would give $\mathrm{d}\boldsymbol{L}/\mathrm{d}t = \boldsymbol{\Omega}\times\boldsymbol{L}$, the time reverse; that is why the sign is part of the physics.

The Casimir and the leaves. For $C = |\boldsymbol{L}|^2$ one has $\nabla C = 2\boldsymbol{L}$, so for every v

$$\{C, v\}_- = -\boldsymbol{L}\cdot(2\boldsymbol{L}\times\nabla v) = 0$$

because the triple product has a repeated factor. Hence C is a Casimir in the sense of Definition 24.37, its regular level sets—the spheres of radius $|\boldsymbol{L}| > 0$—are the symplectic leaves, and every trajectory stays on one of them. Intersecting with the conserved $\mathcal{H}$ gives the closed curves of Proposition 29.26. The odd dimension of $\mathbb{R}^3$ is what forces this structure: no symplectic form exists there, and the two-dimensional leaves are where the symplectic geometry of this chapter actually lives, as Remark 29.27 anticipates. □

Remark 24.42 (The intermediate axis). The leaf picture settles the qualitative theory of free rotation in one figure and one line of algebra. Order the principal moments I_1, I_2, I_3 and intersect the sphere $|\boldsymbol{L}| = L$ with the ellipsoids $\mathcal{H} = E$: near the axes of largest and of smallest moment the intersections are small closed curves encircling the axis, and near the intermediate axis they cross. Linearising Equation (24.27) about steady rotation $\boldsymbol{\Omega} = (\Omega, 0, 0)$ gives

$$I_2\dot{\Omega}_2 = (I_3 - I_1)\,\Omega\,\Omega_3\,, \qquad I_3\dot{\Omega}_3 = (I_1 - I_2)\,\Omega\,\Omega_2\,,$$

and eliminating Ω_3,

$$\ddot{\Omega}_2 = \frac{(I_3 - I_1)\,(I_1 - I_2)}{I_2 I_3}\,\Omega^2\,\Omega_2\,,$$

whose solutions grow exponentially exactly when $(I_3 - I_1)\,(I_1 - I_2) > 0$, that is when I_1 lies strictly between the other two. Rotation about the intermediate axis is unstable and rotation about the other two is stable—the tennis-racket effect, and the reason a thrown book tumbles about one axis and not the other three. The rigid-body chapter treats it in full, Section 29.3.

Rests on Propositions 24.41 and 29.26.

24.6 Symmetry, momentum maps, and reduction

Definition 24.43 (Momentum map)**.** Let a Lie group G with Lie algebra $\mathfrak{g}$ act on (M, ω) by symplectomorphisms, and write ξ_M for the vector field generating the action of $\xi \in \mathfrak{g}$. A *momentum map* is a map $\boldsymbol{J} : M \to \mathfrak{g}^*$ such that, for every ξ,

$$\iota_{\xi_M}\omega = \mathrm{d}\,\langle \boldsymbol{J}, \xi\rangle \ , \tag{24.28}$$

that is, such that the component J_ξ is a Hamiltonian generating the action of ξ.

Rests on Definitions 14.2, 24.14 and 24.17.

Example 24.44 (Linear and angular momentum)**.** Take $M = T^*\mathbb{R}^3$ with $\omega = \mathrm{d}q^i \wedge \mathrm{d}p_i$, the phase space of one particle. For the translation group acting by $\boldsymbol{q} \mapsto \boldsymbol{q} + s\boldsymbol{n}$ with $\boldsymbol{n}$ a fixed unit vector, the generator is $\xi_M = n^i\,\partial/\partial q^i$ and

$$\iota_{\xi_M}\omega = n^i\,\mathrm{d}p_i = \mathrm{d}\left(\boldsymbol{n}\cdot\boldsymbol{p}\right), \qquad \text{so} \qquad J_\xi = \boldsymbol{n}\cdot\boldsymbol{p},$$

the component of linear momentum along $\boldsymbol{n}$, in kg m/s. For the rotation group acting by $\boldsymbol{q} \mapsto R\boldsymbol{q}$, $\boldsymbol{p} \mapsto R\boldsymbol{p}$ about the axis $\boldsymbol{n}$, the generator is $\xi_M = (\boldsymbol{n}\times\boldsymbol{q})^i\,\partial/\partial q^i + (\boldsymbol{n}\times\boldsymbol{p})_i\,\partial/\partial p_i$ and

$$\iota_{\xi_M}\omega = (\boldsymbol{n}\times\boldsymbol{q})^i\,\mathrm{d}p_i - (\boldsymbol{n}\times\boldsymbol{p})_i\,\mathrm{d}q^i = \mathrm{d}\left(\boldsymbol{n}\cdot(\boldsymbol{q}\times\boldsymbol{p})\right),$$

as one checks by expanding $\mathrm{d}\left(\boldsymbol{n}\cdot(\boldsymbol{q}\times\boldsymbol{p})\right) = (\boldsymbol{p}\times\boldsymbol{n})\cdot\mathrm{d}\boldsymbol{q} + (\boldsymbol{n}\times\boldsymbol{q})\cdot\mathrm{d}\boldsymbol{p}$. So $J_\xi = \boldsymbol{n}\cdot\boldsymbol{L}$, the component of angular momentum, in J s. The momentum map of the full rotation group is $\boldsymbol{J} = \boldsymbol{q}\times\boldsymbol{p}$. The name is not an analogy: the momentum map of a symmetry *is* the momentum conjugate to it.

Rests on Definition 24.43 and Equation (24.3).

Theorem 24.45 (Noether, symplectic form)**.** *If G acts by symplectomorphisms preserving H, then the momentum map is conserved along the flow:*

$$\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{J} = 0\,. \tag{24.29}$$

For G the translation group $\boldsymbol{J}$ is the linear momentum, for the rotation group the angular momentum, and for the one-parameter group generated by the flow itself the Hamiltonian. This is Noether's theorem of Chapter 21, stated on phase space, where it is a single line.

Rests on Definition 24.43, Proposition 24.15, and Equation (24.5).

Proof. *Derives Theorem 24.45.*

Fix $\xi \in \mathfrak{g}$ and differentiate the component J_ξ along the motion. By Equation (24.7) the rate of change of any function is $\dot{J}_\xi = X_H[J_\xi] = \mathrm{d}J_\xi(X_H)$, and by the defining property Equation (24.28) of the momentum map,

$$\begin{aligned}\mathrm{d}J_\xi\left(X_H\right) &= \left(\iota_{\xi_M}\omega\right)\left(X_H\right) = \omega\left(\xi_M, X_H\right) = -\omega\left(X_H, \xi_M\right)\\ &= -\left(\iota_{X_H}\omega\right)\left(\xi_M\right) = -\mathrm{d}H\left(\xi_M\right),\end{aligned}$$

using Equation (24.5) in the last step. The final expression is $-\xi_M[H]$, the rate of change of H along the group direction, and that vanishes because H is invariant under the action. So $\dot{J}_\xi = 0$ for every ξ, which is Equation (24.29). The identifications are Example 24.44; for the one-parameter group generated by X_H itself the defining relation Equation (24.28) is Equation (24.5), so $J = H$, and the conservation statement is that a time-independent Hamiltonian is conserved.

Notice how short the argument is compared with the Lagrangian one of Chapter 21: there the conserved quantity has to be constructed from the variation of the action, here it is handed over by nondegeneracy—every symmetry generator is a Hamiltonian vector field, and its Hamiltonian is the conserved quantity [456]. □

Lemma 24.46 (The level set of the momentum map is the symplectic orthogonal of the orbit)**.** *Let $\boldsymbol{J}$ be a momentum map for the action of G on (M,ω) and let $x \in M$. Then*

$$\ker \mathrm{d}\boldsymbol{J}_x = \left(T_x\left(G\cdot x\right)\right)^\omega, \tag{24.30}$$

where $G\cdot x$ is the group orbit through x and, for a subspace $W \subseteq T_xM$,

$$W^\omega := \{w \in T_xM \;:\; \omega\left(w,z\right) = 0 \text{ for all } z \in W\}$$

is its symplectic orthogonal*. In particular, if μ is a regular value of $\boldsymbol{J}$ then $\dim \boldsymbol{J}^{-1}(\mu) = \dim M - \dim G$ when the action is locally free.*

Rests on Definitions 24.8 and 24.43 and Theorem 13.59.

Proof. *Derives Lemma 24.46.*

The tangent space to the orbit at x is spanned by the values $\xi_M(x)$, $\xi \in \mathfrak{g}$, of the generators. For $w \in T_xM$ and any ξ, pairing the differential of $\boldsymbol{J}$ with ξ and using Equation (24.28),

$$\langle \mathrm{d}\boldsymbol{J}_x(w), \xi \rangle = \mathrm{d}J_\xi(w) = (\iota_{\xi_M}\omega)(w) = \omega(\xi_M(x), w) \,.$$

Hence $\mathrm{d}\boldsymbol{J}_x(w) = 0$ if and only if $\omega(\xi_M(x), w) = 0$ for every ξ, which by antisymmetry is exactly membership of $(T_x(G \cdot x))^\omega$. This is Equation (24.30).

For the dimension count, a locally free action has $\dim T_x(G \cdot x) = \dim G$; nondegeneracy of ω makes $w \mapsto \omega(\cdot, w)$ an isomorphism $T_xM \to T_x^*M$, so the symplectic orthogonal of a k-dimensional subspace has dimension $2f - k$, and therefore $\dim \ker \mathrm{d}\boldsymbol{J}_x = \dim M - \dim G$. Since μ is a regular value, $\boldsymbol{J}^{-1}(\mu)$ is a submanifold with tangent space $\ker \mathrm{d}\boldsymbol{J}_x$ by the regular value theorem Theorem 13.59, of that dimension. □

Theorem 24.47 (Marsden–Weinstein reduction)**.** *Let G act freely and properly on (M, ω) with an equivariant momentum map $\boldsymbol{J}$, and let $\mu \in \mathfrak{g}^*$ be a regular value. Then the quotient*

$$M_\mu = \boldsymbol{J}^{-1}(\mu)/G_\mu \tag{24.31}$$

carries a unique symplectic form pulling back to the restriction of ω, and every G-invariant Hamiltonian on M descends to it. Its dimension is

$$\dim M_\mu = \dim M - \dim G - \dim G_\mu \,. \tag{24.32}$$

Rests on Lemma 24.46, Theorem 13.59, and Definition 24.8.

Full derivation: Appendix A.48 (p. 3044).

Derives Theorem 24.47.

The geometric core of the argument is Lemma 24.46, proved above: the tangent space to the level set of the momentum map is the symplectic orthogonal of the group orbit, from which the degenerate directions of the restricted form turn out to be exactly the orbit directions of the isotropy group G_μ—so that quotienting by that group removes the degeneracy, and removes nothing else. What makes the theorem long is everything around that core: that $\boldsymbol{J}^{-1}(\mu)$ is a submanifold, that its quotient by G_μ is again a smooth manifold with the quotient map a submersion, and that the descended form is well defined, closed and nondegenerate. Appendix A.48 carries it out.

One input there is quoted rather than proved, and is named as such in the appendix: the quotient-manifold theorem, that a free and proper action of a Lie group on a manifold has a smooth quotient with the projection a submersion. It is differential topology and belongs in Chapter 13, which does not yet carry it. Its role is confined to producing the smooth structure on M_μ; the symplectic content of Theorem 24.47—the existence, uniqueness and nondegeneracy of the reduced form, and the dimension count Equation (24.32)—rests on Lemma 24.46 and on nothing quoted.

Remark 24.48 (Reduction is what physicists do without saying so)*.* Eliminating a cyclic coordinate by fixing its conjugate momentum and dropping the pair; passing to the centre-of-mass frame; reducing the two-body problem of Section 27.4 to the radial problem; using the effective potential Equation (27.32)—each of these is Theorem 24.47 applied to a particular group, and the effective potential is exactly the reduced Hamiltonian on M_μ at the fixed value $\mu = L$ of the angular momentum. The Lie–Poisson bracket of Definition 24.40 is itself a reduction: it is what the canonical bracket on T^*G becomes when the whole group is divided out, and that is why the rigid body of Proposition 24.41 lives on three variables rather than the six a cotangent bundle would demand.

Rests on Theorem 24.47 and Proposition 24.41.

24.7 Geometric quantization

The programme of this section attempts to construct a quantum theory from a symplectic manifold intrinsically, using no coordinates and no prescription for ordering operators. It is placed here because it is the sharpest test of how much of quantum mechanics is already present in the geometry of phase space, and its answer is instructive in both directions: the linear structure of quantum mechanics is reproduced exactly, and the obstruction of Theorem 25.38 survives unchanged.

This section is mathematics, and is written as such. No experiment in this treatise tests geometric quantization: what is tested is the quantum mechanics of Chapter 77, which the construction reproduces where it works and does not derive. The scope rule is respected by saying so plainly rather than by omitting the material, because the construction explains where two measured things come from—the Bohr–Sommerfeld rule Equation (23.61) and the half-integer shift in it—and those explanations are checkable.

24.7.1 Prequantization

Definition 24.49 (Prequantum datum)**.** A *prequantum datum* for (M,ω) is a triple (L,h,∇) consisting of a complex line bundle $L\to M$, a Hermitian metric h on it, and a connection ∇ compatible with h, whose curvature

$$F^{\nabla}(X,Y)=\nabla_X\nabla_Y-\nabla_Y\nabla_X-\nabla_{[X,Y]} \tag{24.33}$$

satisfies

$$F^{\nabla}=\frac{\mathrm{i}}{\hbar}\,\omega\,. \tag{24.34}$$

The right-hand side is dimensionless by Remark 24.11, as a curvature must be, and $\hbar$ is the only constant of nature with the unit needed to make it so. Over a chart on which $\omega=-\mathrm{d}\theta$ one may take L trivial and

$$\nabla_X s=X[s]-\frac{\mathrm{i}}{\hbar}\,\theta(X)\,s\,, \tag{24.35}$$

whose curvature is $-(\mathrm{i}/\hbar)\,\mathrm{d}\theta=(\mathrm{i}/\hbar)\,\omega$ as required.

Rests on Definitions 14.103, 14.105 and 24.8.

Definition 24.50 (Prequantum operator)**.** For $u\in C^\infty(M)$ the *prequantum operator* acts on smooth sections of L by

$$\widehat{u}\,s=-\mathrm{i}\hbar\,\nabla_{X_u}s+u\,s\,, \tag{24.36}$$

with X_u the Hamiltonian vector field Equation (24.5). Both terms carry the unit of u, by Remark 24.11.

Rests on Definitions 24.14 and 24.49.

Proposition 24.51 (Prequantization is a Lie-algebra homomorphism)**.** *For all $u,v\in C^\infty(M)$,*

$$[\widehat{u},\widehat{v}]=\mathrm{i}\hbar\,\widehat{\{u,v\}}\,,\qquad\text{and}\qquad\widehat{1}=\mathbb{1}\,. \tag{24.37}$$

That is, prequantization satisfies hypotheses (1) and (2) of Theorem 25.38 on all *of $C^\infty(M)$, with no restriction on the degree of the observable.*

Rests on Definition 24.50 and Equations (24.8) *and* (24.34)*.*

Proof. *Derives Proposition 24.51.*

That $\widehat{1}=\mathbb{1}$ is immediate: $X_1=0$ because $\mathrm{d}1=0$, so Equation (24.36) leaves only multiplication by 1.

For the commutator, expand Equation (24.36) and treat the four terms separately. Multiplication operators commute, so $[u,v]=0$. For the cross terms, the Leibniz rule for a connection gives $[\nabla_X, v]\,s = \nabla_X(vs) - v\nabla_X s = X[v]\,s$, so

$$-\mathrm{i}\hbar\,[\nabla_{X_u}, v] + \mathrm{i}\hbar\,[\nabla_{X_v}, u] = -\mathrm{i}\hbar\,X_u[v] + \mathrm{i}\hbar\,X_v[u] = 2\mathrm{i}\hbar\,\{u,v\}\ ,$$

where the last step uses Equation (24.7) twice: $X_v[u]=\{u,v\}$ and $X_u[v]=\{v,u\}=-\{u,v\}$. For the remaining term, Equation (24.33) rearranged reads $[\nabla_{X_u},\nabla_{X_v}] = F^{\nabla}(X_u,X_v) + \nabla_{[X_u,X_v]}$, so with Equation (24.34), Equation (24.7) and Equation (24.8),

$$\begin{aligned}(-\mathrm{i}\hbar)^2\,[\nabla_{X_u},\nabla_{X_v}] &= -\hbar^2\left[\frac{\mathrm{i}}{\hbar}\,\omega\,(X_u,X_v) + \nabla_{-X_{\{u,v\}}}\right]\\ &= -\mathrm{i}\hbar\,\{u,v\} + \hbar^2\nabla_{X_{\{u,v\}}}\,.\end{aligned}$$

Adding the two displays,

$$\begin{aligned}[\widehat{u},\widehat{v}] &= \hbar^2\nabla_{X_{\{u,v\}}} + \mathrm{i}\hbar\,\{u,v\}\\ &= \mathrm{i}\hbar\left(-\mathrm{i}\hbar\,\nabla_{X_{\{u,v\}}} + \{u,v\}\right) = \mathrm{i}\hbar\,\widehat{\{u,v\}}\,,\end{aligned}$$

which is Equation (24.37). The sign in Equation (24.34) is fixed by this calculation and is not free: with $F^{\nabla} = -(\mathrm{i}/\hbar)\,\omega$ the same steps would produce $3\mathrm{i}\hbar\,\{u,v\}$ in place of $\mathrm{i}\hbar\,\{u,v\}$, and the correspondence would fail on the very first pair of canonical variables. □

Example 24.52 (The prequantum line and the Schrödinger representation)**.** Take one degree of freedom, $M=T^*\mathbb{R}$ with $\omega=\mathrm{d}q\wedge\mathrm{d}p$, L trivial, $\theta=p\,\mathrm{d}q$ and ∇ as in Equation (24.35). From Equation (24.6), $X_q=-\partial/\partial p$ and $X_p=\partial/\partial q$, so Equation (24.36) gives

$$\widehat{q}\,s = \mathrm{i}\hbar\,\frac{\partial s}{\partial p} + q\,s\,,\qquad \widehat{p}\,s = -\mathrm{i}\hbar\,\frac{\partial s}{\partial q}\,, \tag{24.38}$$

the second because the connection term $-(\mathrm{i}/\hbar)\,p\,s$ in $\nabla_{\partial/\partial q}s$ contributes $-p\,s$ once multiplied by $-\mathrm{i}\hbar$, cancelling the $+p\,s$ of Equation (24.36). One checks directly that $[\widehat{q},\widehat{p}]=\mathrm{i}\hbar$, as Proposition 24.51 demands. But these operators act on functions of q *and* p: the prequantum Hilbert space is far too large—twice as many variables as a wavefunction has, and, for the harmonic oscillator, a continuous spectrum where the observed one is discrete. Cutting it down is the job of the next step.

Rests on Proposition 24.51 and Equation (24.6).

24.7.2 Polarization

Definition 24.53 (Real polarization and polarized sections)**.** A *real polarization* of (M,ω) is an integrable distribution $P\subset TM$ of rank f on which ω vanishes—a foliation of M by Lagrangian submanifolds. A section s of L is *polarized* if $\nabla_X s=0$ for every X taking values in P.

Rests on Definitions 24.8 and 24.49.

Proposition 24.54 (The vertical polarization gives wave mechanics)**.** *On $M=T^*Q$ with $\theta=p_a\mathrm{d}q^a$, let P be spanned by the $\partial/\partial p_a$. Then the polarized sections are the functions $\psi(q)$ of the configuration variables alone, and on them*

$$\widehat{q}^{\,a}\psi = q^a\psi\,,\qquad \widehat{p}_a\psi = -\mathrm{i}\hbar\,\frac{\partial\psi}{\partial q^a}\,. \tag{24.39}$$

That is, the Schrödinger representation of Chapter 77 is what geometric quantization of a cotangent bundle in the vertical polarization produces.

Rests on Definitions 24.50 and 24.53 and Equation (24.35).

Proof. *Derives Proposition 24.54.*

P is integrable, being spanned by coordinate fields, and $\omega\,(\partial/\partial p_a, \partial/\partial p_b) = 0$, so it is a real polarization; its leaves are the fibres of $T^*Q \to Q$. Since $\theta\,(\partial/\partial p_a) = 0$, the connection Equation (24.35) reduces on P to the ordinary derivative, so a polarized section satisfies $\partial s/\partial p_a = 0$: it is a function $\psi(q)$.

For the operators, $X_{q^a} = -\partial/\partial p_a$ lies in P, so $\nabla_{X_{q^a}}\psi = 0$ and Equation (24.36) leaves $\widehat{q}^{\,a}\psi = q^a\psi$. For the momenta, $X_{p_a} = \partial/\partial q^a$ and Equation (24.35) gives $\nabla_{X_{p_a}}\psi = \partial\psi/\partial q^a - (\mathrm{i}/\hbar)\,p_a\psi$, whence

$$\begin{aligned}\widehat{p}_a\psi &= -\mathrm{i}\hbar\left(\frac{\partial\psi}{\partial q^a} - \frac{\mathrm{i}}{\hbar}p_a\psi\right) + p_a\psi \\ &= -\mathrm{i}\hbar\,\frac{\partial\psi}{\partial q^a} - p_a\psi + p_a\psi = -\mathrm{i}\hbar\,\frac{\partial\psi}{\partial q^a}\,.\end{aligned}$$

The cancellation is exact and is what makes the answer independent of p, as it must be for an operator on $\psi(q)$. □

Remark 24.55 (What polarization costs). Equation (24.36) defines $\widehat{u}$ for every smooth u, but $\widehat{u}$ maps polarized sections to polarized sections only when the flow of X_u preserves the polarization. On T^*Q with the vertical polarization that restricts the directly quantizable observables to those at most quadratic in the momenta—for $\mathcal{H} = p^2/2m$ one already finds $[\partial/\partial p, (p/m)\,\partial/\partial q] = (1/m)\,\partial/\partial q \notin P$, so the free Hamiltonian moves the polarization and needs a separate treatment, in this case an easy one. Beyond the quadratic observables further devices are required, and none of them evades Theorem 25.38: there is no linear map from all the polynomials to operators satisfying Equation (24.37) irreducibly. Geometric quantization localizes the obstruction rather than removing it— prequantization satisfies the bracket condition on everything but is reducible, polarization restores irreducibility but shrinks the domain, and Theorem 25.38 is the theorem that no construction can have both.

Rests on Proposition 24.54 and Theorem 25.38.

24.7.3 Bohr–Sommerfeld from holonomy

Proposition 24.56 (The Bohr–Sommerfeld condition is a triviality condition on the prequantum holonomy)**.** *Let the motion be bounded and integrable, so that by Theorem 23.31 the level sets of the integrals are tori T carrying the basis cycles C_a of Definition 23.28, and take the polarization tangent to those tori. Then a nowhere-vanishing polarized section of L exists over T if and only if*

$$\oint_{C_a} p_a\,\mathrm{d}q^a = n_a h\,, \qquad n_a \in \mathbb{Z}\,, \tag{24.40}$$

for every a, which is the Bohr–Sommerfeld condition Equation (23.61).

Rests on Definitions 23.28 and 24.49 and Theorem 23.31.

Proof. *Derives Proposition 24.56.*

A Liouville–Arnold torus is Lagrangian: the actions are in involution, so ω restricted to T vanishes. By Equation (24.34) the curvature of ∇ restricted to T therefore vanishes as well, so the connection is flat there and its parallel transport around a loop depends only on the homotopy class of the loop.

Compute that transport. Along a curve γ in T with tangent $\dot\gamma$, the condition $\nabla_{\dot\gamma}s = 0$ reads, by Equation (24.35),

$$\frac{\mathrm{d}s}{\mathrm{d}t} = \frac{\mathrm{i}}{\hbar}\,\theta(\dot\gamma)\,s\,, \qquad \text{whence} \qquad s(t) = s(0)\,\mathrm{e}^{\,\Phi(t)}\,, \quad \Phi(t) = \frac{\mathrm{i}}{\hbar}\int_0^t \theta(\dot\gamma)\,\mathrm{d}t'\,.$$

Around a closed cycle C_a the holonomy is therefore $\exp\!\big((\mathrm{i}/\hbar)\oint_{C_a}\theta\big)$, and a globally defined nowhere-vanishing polarized section over T exists exactly when every such holonomy is 1—parallel transport must return a section to itself. That is

$$\frac{1}{\hbar}\oint_{C_a} p_a\,\mathrm{d}q^a \in 2\pi\mathbb{Z}\,, \qquad \text{that is} \qquad \oint_{C_a} p_a\,\mathrm{d}q^a = 2\pi\hbar\,n_a = n_a h\,,$$

using $\theta = p_a \mathrm{d}q^a$ from Equation (24.3) and $h = 2\pi\hbar$. This is Equation (24.40), and it is Equation (23.61) [441]. □

Remark 24.57 (The half-integer, and the honest status of the construction). Proposition 24.56 reproduces the old quantum rule with integers, and the old quantum rule with integers is wrong: the harmonic oscillator's ground state is not at zero energy. The missing piece is the *metaplectic*, or half-form, correction—one quantizes sections of $L \otimes \sqrt{\Lambda}$ rather than of L, where $\sqrt{\Lambda}$ is a square root of the bundle of forms along the polarization—and its effect is to replace n_a by $n_a + \mu_a/4$, with μ_a the Maslov index of the cycle, counting the caustics it crosses. For one degree of freedom in a smooth well $\mu = 2$, so $\oint p\,\mathrm{d}q = \left(n + \frac{1}{2}\right)h$; for the oscillator of frequency ν this integral is E/ν, giving $E_n = \left(n + \frac{1}{2}\right)h\nu$, the observed spectrum with its zero-point energy. It is the same shift the semiclassical limit of wave mechanics produces, and the pending note at Proposition 23.38 records where that derivation belongs.

Two further statements are made here without proof, and are flagged as such. The existence of a prequantum datum at all constrains the cohomology class of ω: running the holonomy argument above over a closed two-surface $\Sigma \subset M$ instead of a loop gives the necessary condition that $(2\pi\hbar)^{-1}\int_\Sigma \omega$ be an integer, and that this condition is also sufficient is Weil's integrality theorem. Its proof needs the cohomology of a good cover of the manifold, which this treatise does not carry; and nothing above rests on it, since the Bohr–Sommerfeld statement just proved uses only the flatness of the connection on one torus. The construction as a whole is due to Kostant and to Souriau, independently, around 1970; neither is in this treatise's bibliography, so the attribution is made in words.

Finally, the scope rule. Geometric quantization is a construction, not a physical theory: it takes a classical system as input and manufactures a candidate quantum one, and Theorem 25.38 guarantees that it cannot do so for every observable. Where it succeeds it reproduces the quantum mechanics postulated in Chapter 77, which is what experiment tests; nothing in this section is itself tested by an experiment recorded in this treatise, and the two checkable statements it touches—Equation (23.61) and the half-integer shift—are tested as spectroscopy, not as geometry.

Rests on Propositions 23.38 and 24.56 and Theorem 25.38.

24.8 What the symplectic view buys

The material above is geometry. This section records, as a checklist for the chapters that will use it, the places where the geometry makes a difference to what is measured. Each item is a pointer, not a derivation.

The measure of statistical mechanics. The Liouville form is the unique flow-invariant measure available without extra structure, which is why the microcanonical ensemble is defined with it (Chapter 118 and Remark 24.22).

Adiabatic invariants. The action variables of Definition 23.28 are the quantities that survive slow modulation, and their conservation is what confines charged particles in magnetic bottles (Chapter 66 and Remark 23.37).

Invariant tori and the stability of orbits. KAM theory (Chapter 32) is a theorem about symplectic maps [1247], and its observational trace is the resonance structure of the solar system, whose inner planets are chaotic with a Lyapunov time of a few million years [1824].

Symplectic integrators. Numerical schemes built to preserve ω exactly—rather than to minimise the local truncation error—have bounded energy error over exponentially long times, which is why planetary ephemerides and accelerator tracking are computed with them. This is a case where a geometric property, not an accuracy estimate, decides the method.

Geometric phases. Holonomy of the Hamiltonian flow over a closed path in parameter space produces a phase that depends on the geometry of the path and not on its rate [1734]; it is observed in polarization rotation in a coiled optical fibre [1783], in molecular spectra near conical intersections, and in the Aharonov–Bohm effect (Chapter 77) [1164]. The construction of Section 24.7 is where such a phase comes from: it is a prequantum holonomy, the same object whose triviality gives Equation (24.40).

Non-squeezing. Liouville's theorem is not the only constraint on what a Hamiltonian flow may do to a region (Theorem 24.31 and Remark 24.35), though no experiment in this treatise measures the finer invariant.

Constrained systems. Degenerate Lagrangians produce presymplectic rather than symplectic structures, and recovering a bracket on the physical subspace is the content of the next chapters (Chapters 25 and 26).

Chapter 25

The Poisson Algebra and the Canonical Bridge to Quantum Mechanics

Chapter 22 introduced the Poisson bracket as a convenient notation and listed its properties; Chapter 24 showed that those properties are the shadow of the symplectic form. This chapter takes the bracket as the primary object and asks what kind of algebraic structure it is. The answer—a Lie algebra acting by derivations—turns out to be the whole of what survives the passage to quantum mechanics.

The route is direct. Every observable generates a one-parameter family of canonical transformations through the bracket; a symmetry is an observable whose generated family preserves the Hamiltonian; and a conserved quantity is the same thing seen from the other side. Rewriting mechanics so that the bracket carries the dynamics leaves a formalism in which the equations of motion are first order and every statement is algebraic, and that formalism has an exact quantum counterpart obtained by replacing the bracket with a commutator. Where the replacement is legitimate, and where it provably is not, is the content of Section 25.5, and it is the reason quantization is a physical hypothesis to be tested rather than a construction to be carried out. Standard treatments of the quantum side are [1593, 1912, 2287].

Nothing in this chapter derives quantum mechanics. The quantum theory is postulated in Chapter 77, and the correspondence set out here is used there — in Section 77.5.1 — to motivate the operator assignments, not to justify them. The direction of logical dependence is stated once, in Remark 25.51, and held to throughout: classical mechanics is a limit of the quantum theory, and the classical structures of Chapters 22 and 24 are what that limit leaves behind.

Notation 25.1. The conventions of Notation 22.1 remain in force. A hat distinguishes an operator on a Hilbert space, $\hat{A}$, from the phase-space function A it is meant to correspond to; the commutator is $\left[\hat{A},\hat{B}\right]$ and the anticommutator $\left\{\hat{A},\hat{B}\right\}$, in the macros of the treatise, and the Poisson bracket keeps its braces $\{u,v\}$. Where a bracket must be qualified by the coordinates in which it is computed the subscript of Equation (22.41) is used.

25.1 The Poisson algebra of observables

Definition 25.2 (Poisson algebra)**.** A *Poisson algebra* is a real vector space A carrying two products: an associative commutative product uv, making it a commutative algebra, and a bracket $\{\cdot,\cdot\}$ making it a Lie algebra, the two being compatible through the Leibniz rule Equation (24.24). The observables $C^\infty(M)$ of a mechanical system, with pointwise

multiplication and the Poisson bracket of Definition 22.29, form one.
Rests on Definitions 22.29 and 24.36.

Theorem 25.3 (The bracket is a Lie bracket)**.** *The Poisson bracket is bilinear, antisymmetric Equation* (22.43) *and satisfies the Jacobi identity Equation* (22.46)*. The observables of a mechanical system therefore form an infinite-dimensional real Lie algebra.*
Rests on Equations (22.41) *and* (22.56)*.*

Derivation. *Derives Theorem 25.3.*

Write the bracket in the phase-space notation of Equation (22.55). With $\partial_c := \partial/\partial\eta^c$ and J^{cd} the components of the symplectic matrix Equation (22.56) — constants, so the position of the index carries no meaning here — the definition Equation (22.41) reads

$$\{u, v\} = J^{cd}\,\partial_c u\,\partial_d v\,, \qquad J^{cd} = -J^{dc}\,, \qquad \partial_e J^{cd} = 0\,. \tag{25.1}$$

Unpacking the blocks of Equation (22.56) returns $\partial_q u\,\partial_p v - \partial_p u\,\partial_q v$, so Equation (25.1) is the same bracket and not a new one.

Bilinearity is immediate, since u and v enter through one derivative each. Antisymmetry follows from $J^{cd} = -J^{dc}$ after relabelling the two summed indices, which is Equation (22.43).

For the Jacobi identity, differentiate once more. Because J is constant it passes through ∂_d, and

$$\{u, \{v, w\}\} = J^{cd}J^{ef}\,\partial_c u\,(\partial_d\partial_e v\,\partial_f w + \partial_e v\,\partial_d\partial_f w)\,. \tag{25.2}$$

Every term of the cyclic sum $\{u,\{v,w\}\}+\{v,\{w,u\}\}+\{w,\{u,v\}\}$ therefore carries exactly one second derivative, of one of the three functions, and first derivatives of the other two. Collect the two terms carrying $\partial\partial u$. They come from the second and third brackets and are

$$A = J^{cd}J^{ef}\,\partial_c v\,\partial_e w\,\partial_d\partial_f u\,, \qquad B = J^{cd}J^{ef}\,\partial_c w\,\partial_f v\,\partial_d\partial_e u\,.$$

In B interchange the names $e \leftrightarrow f$, which turns J^{ef} into $J^{fe} = -J^{ef}$, and then interchange the pairs $(c,d) \leftrightarrow (e,f)$, which merely renames dummies:

$$B = -J^{cd}J^{ef}\,\partial_c w\,\partial_e v\,\partial_d\partial_f u = -J^{cd}J^{ef}\,\partial_c v\,\partial_e w\,\partial_d\partial_f u = -A\,,$$

so the two cancel. The cyclic sum is invariant under $u \to v \to w \to u$, so the same cancellation removes the $\partial\partial v$ and $\partial\partial w$ terms, and nothing is left. This is Equation (22.46).

Two features of the computation are worth naming, because they are what the identity really rests on. Antisymmetry of J is used once, and constancy of J is used once — and the latter is the coordinate shadow of the closedness of the symplectic form (Definition 13.105), which is why the Jacobi identity survives the change to arbitrary coordinates of Theorem 24.12 even though J^{cd} does not stay constant there. A bracket built from an antisymmetric $J^{cd}(\eta)$ that is *not* the inverse of a closed form is bilinear and antisymmetric but fails Jacobi; the Leibniz rule alone does not save it. □

Proposition 25.4 (Leibniz rule and derivations)**.** *For each u, the map $v \mapsto \{v, u\}$ is a derivation of the commutative product; equivalently it is a first-order differential operator, the vector field X_u of Definition 24.14. The Jacobi identity says exactly that $u \mapsto X_u$ is a homomorphism of Lie algebras, up to the sign recorded in Equation* (24.8)*.*
Rests on Theorem 25.3 and Definition 24.14.

Derivation. *Derives Proposition 25.4.*

For the Leibniz rule, put the product vw into the first slot of Equation (25.1) and use the product rule on the single derivative that acts on it:

$$\{vw, u\} = J^{cd}\,\partial_c(vw)\,\partial_d u = w\,J^{cd}\partial_c v\,\partial_d u + v\,J^{cd}\partial_c w\,\partial_d u = w\,\{v,u\} + v\,\{w,u\}\,, \tag{25.3}$$

which is Equation (24.24). A linear map obeying Equation (25.3) is by definition a derivation of the commutative product, and since it involves exactly one derivative of its argument it is a first-order differential operator: reading off the coefficient,

$$\{v,u\} = X_u[v]\,, \qquad X_u = X_u^c\,\partial_c\,, \qquad X_u^c = J^{cd}\,\partial_d u\,, \tag{25.4}$$

which is Equation (24.6). Taking $u = \mathcal{H}$ makes $X_{\mathcal{H}}^c = J^{cd}\partial_d\mathcal{H}$ the right-hand side of Equation (22.57): the Hamiltonian vector field is the velocity field of the motion in phase space.

For the second statement, let w be arbitrary and compute the commutator of the two vector fields on it, using Equation (25.4) twice:

$$[X_u, X_v]\,[w] = X_u[\{w,v\}] - X_v[\{w,u\}] = \{\{w,v\},u\} - \{\{w,u\},v\}\ .$$

Now write the Jacobi identity Equation (22.46) with w in the outer slot and move each inner bracket outwards by antisymmetry, $\{u,\{v,w\}\} = \{\{w,v\},u\}$ and $\{v,\{w,u\}\} = -\{\{w,u\},v\}$:

$$\{w,\{u,v\}\} + \{\{w,v\},u\} - \{\{w,u\},v\} = 0\,.$$

The first term is $X_{\{u,v\}}[w]$ and the remaining two are $[X_u, X_v]\,[w]$, so $X_{\{u,v\}}[w] = -\,[X_u, X_v]\,[w]$ for every w, which is Equation (24.8). The sign is a consequence of the conventions, not a defect: it says that $u \mapsto X_u$ is an antihomomorphism in the convention of Equation (22.41), and it is why some texts define the Hamiltonian vector field with the opposite sign. □

Remark 25.5 (Two products, and which one survives). A Poisson algebra carries a commutative product and a Lie bracket. Their quantum counterparts are the symmetrized product $\frac{1}{2}\left\{\hat{A},\hat{B}\right\}$, which is commutative but no longer associative, and the commutator $\frac{1}{i\hbar}\left[\hat{A},\hat{B}\right]$, which remains a Lie bracket exactly. The asymmetry is not an accident of the formalism: it is why the Lie structure transfers to the quantum theory essentially intact while the pointwise product does not, and it is the algebraic root of the obstruction of Section 25.5.

25.2 Generators, symmetries, and constants of motion

Definition 25.6 (Infinitesimal canonical transformation)**.** Let G be a phase-space function and ε an infinitesimal parameter. The transformation

$$\delta q^a = \varepsilon\,\{q^a, G\}\ , \qquad \delta p_a = \varepsilon\,\{p_a, G\}\ , \qquad \text{that is} \qquad \delta u = \varepsilon\,\{u,G\} \ \text{ for any } u\,, \tag{25.5}$$

is canonical to first order in ε; G is called its *generator*.

Rests on Definitions 22.29 and 24.17.

Proposition 25.7 (Generating function of an infinitesimal transformation)**.** *The transformation Equation (25.5) is generated, in the sense of Equation (22.21), by $F_2 = q^a P_a + \varepsilon G(q,P)$: the identity transformation plus ε times the generator.*

Rests on Equations (22.21) and (25.5).

Derivation. *Derives Proposition 25.7.*

Substitute $F_2 = q^a P_a + \varepsilon G(q,P)$ into the two transformation relations of Equation (22.21):

$$p_a = \frac{\partial F_2}{\partial q^a} = P_a + \varepsilon\,\frac{\partial G}{\partial q^a}\,, \qquad Q^a = \frac{\partial F_2}{\partial P_a} = q^a + \varepsilon\,\frac{\partial G}{\partial P_a}\,. \tag{25.6}$$

Setting $\varepsilon = 0$ gives $P_a = p_a$ and $Q^a = q^a$: the first term alone generates the identity, which is the check the construction needs, since a transformation infinitesimally close to the identity must be generated by a function infinitesimally close to that one.

For $\varepsilon \neq 0$ the relations are implicit, G being a function of (q, P) rather than of (q, p); but the difference between P_a and p_a is itself of order ε by the first of Equation (25.6), so replacing P by p inside a derivative of G costs only $O(\varepsilon^2)$. To first order, therefore,

$$\delta p_a = P_a - p_a = -\varepsilon \frac{\partial G}{\partial q^a}, \qquad \delta q^a = Q^a - q^a = +\varepsilon \frac{\partial G}{\partial p_a}.$$

These are exactly Equation (25.5): by Equation (22.41), $\{q^a, G\} = \partial G/\partial p_a$ and $\{p_a, G\} = -\partial G/\partial q^a$. The statement for an arbitrary observable follows by the chain rule,

$$\delta u = \frac{\partial u}{\partial q^a}\delta q^a + \frac{\partial u}{\partial p_a}\delta p_a = \varepsilon \left(\frac{\partial u}{\partial q^a}\frac{\partial G}{\partial p_a} - \frac{\partial u}{\partial p_a}\frac{\partial G}{\partial q^a} \right) = \varepsilon \, \{u, G\} \, ,$$

so a single function G moves every observable at once, and it does so through the bracket alone. □

Proposition 25.8 (The Hamiltonian generates time translation)**.** *Taking $G = \mathcal{H}$ and $\varepsilon = \mathrm{d}t$ in Equation (25.5) reproduces the evolution equation Equation (22.50). The motion of a mechanical system is therefore itself a one-parameter family of canonical transformations, generated by the Hamiltonian; the time evolution and the canonical transformations are not two subjects but one.*

Rests on Equations (22.50) and (25.5).

Derivation. *Derives Proposition 25.8.*

Put $G = \mathcal{H}$ and $\varepsilon = \mathrm{d}t$ in the last member of Equation (25.5). For an observable u carrying no explicit time dependence this gives $\delta u = \mathrm{d}t \, \{u, \mathcal{H}\}$, that is $\mathrm{d}u/\mathrm{d}t = \{u, \mathcal{H}\}$, which is Equation (22.51). If u does depend explicitly on the time, the transformation still contributes only $\mathrm{d}t \, \{u, \mathcal{H}\}$ — it acts on the phase-space arguments — and the remaining $\partial u/\partial t$ of Equation (22.50) comes from the explicit slot, which the transformation does not touch. Applying the result to $u = q^a$ and $u = p_a$ and using Equation (22.44) returns Hamilton's equations Equations (22.3) and (22.4), so the family generated by $\mathcal{H}$ is the motion itself and not merely a transformation resembling it. □

Theorem 25.9 (Noether, bracket form)**.** *Let G carry no explicit time dependence. Then the following are equivalent:*

1. *G is a constant of the motion;*
2. *$\{G, \mathcal{H}\} = 0$;*
3. *the one-parameter family of canonical transformations generated by G leaves $\mathcal{H}$ invariant.*

Symmetry and conservation are thus the same statement read in two directions, and the object that expresses both is the bracket.

Rests on Equations (22.43), (22.50) and (25.5).

Derivation. *Derives Theorem 25.9.*

(1) $\Leftrightarrow$ (2). With $\partial G/\partial t = 0$ the evolution equation Equation (22.50) reads $\mathrm{d}G/\mathrm{d}t = \{G, \mathcal{H}\}$. If the bracket vanishes identically then G is constant along every motion. Conversely, suppose G is constant along every motion. The bracket $\{G, \mathcal{H}\}$ is a function on phase space, and through each point of phase space there passes a motion — take that point as the initial condition of Equations (22.3) and (22.4) — along which $\mathrm{d}G/\mathrm{d}t$ vanishes at that point. So $\{G, \mathcal{H}\}$ vanishes at every point. The quantifier is what does the work: constancy along a *single* trajectory is a weaker statement and does not give (2).

(2) $\Leftrightarrow$ (3). By Proposition 25.7 the family generated by G moves any observable by $\delta u = \varepsilon \{u, G\}$, so it moves the Hamiltonian by

$$\delta \mathcal{H} = \varepsilon \{\mathcal{H}, G\} = -\varepsilon \{G, \mathcal{H}\} , \tag{25.7}$$

the second equality being the antisymmetry Equation (22.43). The right-hand side vanishes for all ε exactly when $\{G, \mathcal{H}\} = 0$, which is (2); and its vanishing is the statement that the family leaves $\mathcal{H}$ invariant, which is (3). □

Remark 25.10 (What this version of Noether does and does not cover). Theorem 25.9 is the Hamiltonian face of the variational theorem Theorem 24.45, and it is sharper in one respect and narrower in two others. Sharper: the correspondence is a bijection, because Equation (25.7) runs in both directions — every conserved G generates a symmetry and every generated symmetry conserves its generator, with no integrability condition to check. Narrower: it sees only symmetries generated by a phase-space function, so a discrete symmetry such as spatial inversion or time reversal falls outside it entirely — those have conserved quantities in quantum mechanics (Chapter 110) but no classical generator, since a one-parameter family cannot reach them; and it treats the time as a parameter, so a symmetry that reparametrizes the time — the boost of Equation (25.11) is the mild case, general covariance the severe one — needs the extended phase space of Chapter 26 before this argument applies to it.

Definition 25.11 (Generators of the Galilei transformations)**.** Let a free particle of mass m move in three-dimensional Euclidean space, with phase-space coordinates (x_i, p_i) and Hamiltonian $\mathcal{H} = |\boldsymbol{p}|^2 / 2m$. The generators of the Galilei transformations are the phase-space functions

$$\text{time translation:} \quad \mathcal{H} = \frac{p_k p_k}{2m} , \tag{25.8}$$

$$\text{space translation:} \quad p_i , \tag{25.9}$$

$$\text{rotation:} \quad L_i = \epsilon_{ijk} x_j p_k , \tag{25.10}$$

$$\text{boost:} \quad K_i = m\, x_i - t\, p_i . \tag{25.11}$$

All indices are Cartesian components in Euclidean space, so their position carries no meaning and repeated indices are summed; ϵ_{ijk} is the Levi-Civita symbol. The boost generator is the only one carrying an explicit dependence on the time.

Rests on Definitions 22.29 and 25.6.

Proposition 25.12 (The algebra of generators closes)**.** *By Poisson's theorem Theorem 22.38 the constants of motion of a system form a Lie subalgebra of the Poisson algebra. For the free particle in three dimensions the generators Equations* (25.8) *to* (25.11) *satisfy*

$$\{L_i, L_j\} = \epsilon_{ijk} L_k , \qquad \{L_i, p_j\} = \epsilon_{ijk} p_k , \qquad \{p_i, p_j\} = 0 , \tag{25.12}$$

$$\{L_i, K_j\} = \epsilon_{ijk} K_k , \qquad \{K_i, \mathcal{H}\} = p_i , \qquad \{K_i, K_j\} = 0 , \tag{25.13}$$

$$\{L_i, \mathcal{H}\} = 0 , \qquad \{p_i, \mathcal{H}\} = 0 , \qquad \{\mathcal{H}, \mathcal{H}\} = 0 , \tag{25.14}$$

together with

$$\{K_i, p_j\} = m\, \delta_{ij} , \tag{25.15}$$

which is the Galilei algebra of Chapter 14 centrally extended by the mass.

Rests on Definition 25.11, Equation (22.44)*, and Theorem 22.38.*

Derivation. *Derives Proposition 25.12.*

Throughout, the bracket is the one of Definition 22.29 in the Cartesian coordinates (x_i, p_i), whose fundamental values are $\{x_i, p_j\} = \delta_{ij}$ and $\{x_i, x_j\} = \{p_i, p_j\} = 0$; the last of

these is the third entry of Equation (25.12), and the time t is a parameter, not a phase-space variable, so it passes through every bracket as a constant.

Rotations on a vector. Because the bracket is a derivation in each slot, the action of L_i on any function is fixed by its action on x_j and p_j. From the definition Equation (25.10),

$$\{L_i, x_j\} = -\frac{\partial L_i}{\partial p_c}\frac{\partial x_j}{\partial x_c} = -\epsilon_{iac}x_a\delta_{jc} = -\epsilon_{iaj}x_a = \epsilon_{ijk}x_k\,,$$
$$\{L_i, p_j\} = \frac{\partial L_i}{\partial x_c}\frac{\partial p_j}{\partial p_c} = \epsilon_{icb}p_b\delta_{jc} = \epsilon_{ijk}p_k\,,$$

which is the second entry of Equation (25.12): every vector built from $\boldsymbol{x}$ and $\boldsymbol{p}$ rotates as a vector.

Rotations among themselves. Applying the derivation property to $L_j = \epsilon_{jab}x_ap_b$ and using the two results just obtained,

$$\begin{aligned}\{L_i, L_j\} &= \epsilon_{jab}\left(\{L_i, x_a\}\,p_b + x_a\,\{L_i, p_b\}\right) = \epsilon_{jab}\epsilon_{iac}x_cp_b + \epsilon_{jab}\epsilon_{ibc}x_ap_c\\ &= \left(\delta_{ji}\delta_{bc} - \delta_{jc}\delta_{bi}\right)x_cp_b + \left(\delta_{jc}\delta_{ai} - \delta_{ji}\delta_{ac}\right)x_ap_c\\ &= \delta_{ij}\,x_bp_b - x_jp_i + x_ip_j - \delta_{ij}\,x_ap_a = x_ip_j - x_jp_i\,,\end{aligned}$$

the two contractions of Levi-Civita symbols being the standard identity $\epsilon_{iab}\epsilon_{icd} = \delta_{ac}\delta_{bd} - \delta_{ad}\delta_{bc}$ used twice after a cyclic relabelling. Since

$$\epsilon_{ijk}L_k = \epsilon_{ijk}\epsilon_{kab}x_ap_b = \left(\delta_{ia}\delta_{jb} - \delta_{ib}\delta_{ja}\right)x_ap_b = x_ip_j - x_jp_i\,,$$

the two agree, which is the first entry of Equation (25.12).

Rotations on the boost. The boost generator Equation (25.11) is a linear combination of x_i and p_i with coefficients that are not phase-space functions, so it rotates as a vector by linearity:

$$\{L_i, K_j\} = m\,\{L_i, x_j\} - t\,\{L_i, p_j\} = m\,\epsilon_{ijk}x_k - t\,\epsilon_{ijk}p_k = \epsilon_{ijk}\left(m\,x_k - t\,p_k\right) = \epsilon_{ijk}K_k\,,$$

the first entry of Equation (25.13).

Boosts among themselves. Expanding both slots and using the fundamental brackets,

$$\begin{aligned}\{K_i, K_j\} &= \{m\,x_i - t\,p_i, m\,x_j - t\,p_j\}\\ &= m^2\,\{x_i, x_j\} - mt\,\{x_i, p_j\} - tm\,\{p_i, x_j\} + t^2\,\{p_i, p_j\}\\ &= 0 - mt\,\delta_{ij} + mt\,\delta_{ij} + 0 = 0\,,\end{aligned}$$

the two surviving terms cancelling by the antisymmetry $\{p_i, x_j\} = -\delta_{ij}$. This is the third entry of Equation (25.13).

Boosts and the Hamiltonian. Since $\{x_i, \mathcal{H}\} = p_i/m$ and $\{p_i, \mathcal{H}\} = 0$,

$$\{K_i, \mathcal{H}\} = m\,\{x_i, \mathcal{H}\} - t\,\{p_i, \mathcal{H}\} = m\,\frac{p_i}{m} - 0 = p_i\,,$$

the second entry of Equation (25.13).

The remaining brackets with the Hamiltonian. The momenta commute among themselves, so $\{p_i, \mathcal{H}\} = 0$; and

$$\{L_i, \mathcal{H}\} = \frac{1}{m}\,p_b\,\{L_i, p_b\} = \frac{1}{m}\,\epsilon_{ibk}p_bp_k = 0$$

because a symmetric product is contracted with an antisymmetric symbol. Together with $\{\mathcal{H}, \mathcal{H}\} = 0$, which holds by antisymmetry, this is Equation (25.14): energy, momentum and angular momentum are constants of the motion.

Boosts and translations. Finally, and this is the bracket the proposition is about,

$$\{K_i, p_j\} = m\,\{x_i, p_j\} - t\,\{p_i, p_j\} = m\,\delta_{ij}\,,$$

which is Equation (25.15).

Every bracket therefore closes on the span of $\{\mathcal{H}, p_i, L_i, K_i\}$ *together with the constant function* m, and by Theorem 22.38 the ten generators are constants of the motion. For K_i this last claim needs the explicit time dependence, and is worth checking separately: by the evolution equation Equation (22.50),

$$\frac{\mathrm{d}K_i}{\mathrm{d}t} = \frac{\partial K_i}{\partial t} + \{K_i, \mathcal{H}\} = -p_i + p_i = 0\,, \tag{25.16}$$

so that $K_i = m\,x_i(0)$ is conserved. The conservation law carried by the boost generator is the statement that the centre of mass moves uniformly. □

Remark 25.13 (The generator that is not a generator). The right-hand side of Equation (25.15) is m times the constant function 1, and the constant functions are exactly the functions whose bracket with everything vanishes (Definition 24.37). So the algebra of the ten generators does not close on itself: it closes on itself *plus* a central element that generates no transformation at all. The precise sense in which this is an extension, and the proof that it cannot be removed by redefining the generators, are the subject of the next subsection.

25.2.1 Mass as a central charge

The general theory of central extensions of Lie algebras—the cocycle Proposition 14.73, the coboundary, and the cohomology group H^2 that classifies the obstructions (Proposition 14.76)—is developed as mathematics in Section 14.4, where the Heisenberg algebra Example 14.79 is the worked example. This subsection applies it to the one case classical mechanics forces on us; the argument below exhibits a cocycle and shows it is not a coboundary, which is exactly the computation that $H^2 \neq 0$ names.

Proposition 25.14 (The Galilei cocycle is not a coboundary)**.** *Let $\mathfrak{g}$ be the Galilei algebra, in which the abstract generators satisfy $[K_i, P_j] = 0$, and let $\xi \mapsto J_\xi$ be the assignment of Definition 25.11 of a phase-space function to each generator. Then the defect*

$$c(\xi, \eta) = \{J_\xi, J_\eta\} - J_{[\xi,\eta]} \tag{25.17}$$

is a constant function for every pair, and no redefinition $J_\xi \mapsto J_\xi + b(\xi)$ by constants $b(\xi)$ removes it. The realization of the Galilei algebra by Poisson brackets is therefore a realization of a genuine central extension of it, with central charge the mass.

Rests on Equation (25.15), Definition 14.72, and Proposition 14.73.

Derivation. *Derives Proposition 25.14.*

That c takes constant values is read off the brackets computed above: every one of Equations (25.12) to (25.14) reproduces the abstract Galilei bracket exactly, so c vanishes on those pairs, and Equation (25.15) gives

$$c(K_i, P_j) = m\,\delta_{ij} - J_{[K_i,P_j]} = m\,\delta_{ij} - J_0 = m\,\delta_{ij}\,, \tag{25.18}$$

a constant.

Now suppose the generators are redefined by constants, $J_\xi \mapsto \tilde{J}_\xi = J_\xi + b(\xi)$ with b linear. Constants have vanishing bracket with everything, so the left-hand term of Equation (25.17) is unchanged while the right-hand term shifts, and

$$\tilde{c}(\xi, \eta) = c(\xi, \eta) - b\,([\xi, \eta])\ . \tag{25.19}$$

Removing the defect Equation (25.18) would therefore require

$$b\left([K_i, P_j]\right) = m\,\delta_{ij}\,.$$

But in the Galilei algebra $[K_i, P_j] = 0$, so the left-hand side is $b(0) = 0$ by linearity, while the right-hand side is $m\,\delta_{ij} \neq 0$ for a massive particle. No choice of b works, and the extension is not removable. □

Remark 25.15 (Why the relativistic case is different). The same construction applied to the Poincaré algebra of Chapter 39 produces no central charge: every cocycle there *is* a coboundary, so the mass cannot enter that way, and it enters instead as the Casimir invariant that labels a representation (Chapter 94). The two facts are not independent. The Galilei algebra is the Inönü–Wigner contraction of the Poincaré algebra as $c \to \infty$ (Section 14.5), and the central charge of Equation (25.15) is what the Casimir becomes in the limit: a contraction can create a nontrivial cohomology class where the parent algebra had none. That the mass is a label in one theory and a central charge in the other is a single statement about the limit, not a coincidence of two formalisms.

Remark 25.16 (The Bargmann superselection rule, and its limits). Quantum-mechanically a central charge means that the symmetry is realized on the Hilbert space only projectively—up to a phase—and Bargmann's theorem states that for the Galilei group the phase cannot be removed [1029]. The consequence usually drawn is a superselection rule: within nonrelativistic quantum mechanics, states of different mass cannot be coherently superposed, since the relative phase such a superposition would acquire under a boost is not physically meaningful.

Two qualifications keep the statement honest. First, it is a theorem about a symmetry group, not a measurement: nothing in it is tested directly. Second, and more sharply, nature manifestly *does* superpose states of different mass—the neutrino flavour eigenstates of Chapter 114 are coherent superpositions of mass eigenstates, and their oscillation is observed. There is no contradiction, because that is a relativistic regime, where the symmetry is Poincaré and Remark 25.15 says there is no central charge to obstruct anything. The Bargmann rule is a statement about the nonrelativistic limit and holds only there. This is a good example of what an algebraic argument can and cannot deliver: it tells you what a given symmetry permits, and is silent about whether that symmetry is the one nature uses in the regime you are measuring.

Remark 25.17 (Central charges elsewhere in this treatise). The mass is not an isolated case, and it is not even the most important one in this chapter. The canonical commutation relations Equation (25.33) are themselves a central extension: the phase-space translations $\{x_i, p_i\}$ form an abelian algebra classically, and $[\hat{x}_i, \hat{p}_j] = \mathrm{i}\hbar\,\delta_{ij}$ extends it centrally with $\hbar$ as the charge, giving the Heisenberg algebra. On that reading Planck's constant and the mass play the same structural role, and Theorem 25.34 is the statement that the extension has essentially one irreducible representation. Further instances, each cross-referenced where it arises: the Schwinger terms in current-algebra commutators, whose non-removable version is the anomaly of Remark 26.49; the magnetic translation algebra of a charged particle in a uniform magnetic field, centrally extended by the magnetic flux, which is what makes the Landau levels of Chapter 128 degenerate; and the Virasoro central charge of two-dimensional conformal symmetry, which is measurable in the critical behaviour of two-dimensional systems (Chapter 123).

25.2.2 The generators as a bridge

Every entry of Equations (25.12) and (25.13) survives quantization with the bracket replaced by $\frac{1}{\mathrm{i}\hbar}\,[\cdot,\cdot]$; the angular-momentum algebra of Chapter 79 is the first line read that way, and its

half-integer representations—which have no classical counterpart—are the reason spin exists. That the classical bracket algebra of the generators of a symmetry group is reproduced exactly by the quantum commutator algebra, while the algebra of general observables is not (Section 25.5), is the single most important asymmetry in the correspondence.

The reason the generators escape the obstruction is visible in Lemma 25.39: every entry of Equations (25.12), (25.13) and (25.15) is a bracket of polynomials of degree at most two in (x_i, p_i), and degree two is precisely where Theorem 25.38 does *not* bite. A symmetry generator is linear or quadratic because it generates a linear transformation of phase space; the obstruction begins at degree three. This is not a general theorem — a symmetry of an interacting system need not have a low-degree generator — but it accounts for every case in this chapter and for the Poincaré generators of Chapter 94 as well.

25.3 The first-order formalism

Definition 25.18 (Phase-space action)**.** The *phase-space*, or *first-order*, action of a mechanical system is the functional of independently varied paths $(q^a(t), p_a(t))$

$$S\,[q,p] = \int_{t_a}^{t_b} \left(p_a \dot{q}^a - \mathcal{H}(q,p,t)\right) \mathrm{d}t\,. \tag{25.20}$$

Rests on Definition 22.2 and Equation (24.3).

Theorem 25.19 (Hamilton's equations from the first-order action)**.** *Stationarity of Equation (25.20) under independent variations of q^a and p_a, with δq^a vanishing at the endpoints and δp_a unrestricted, is equivalent to Hamilton's equations Equations (22.3) and (22.4).*

Rests on Equation (25.20) and Lemma 16.18.

Derivation. *Derives Theorem 25.19.*

Vary Equation (25.20) in both arguments at once:

$$\delta S = \int_{t_a}^{t_b} \left(\dot{q}^a\, \delta p_a + p_a\, \delta \dot{q}^a - \frac{\partial \mathcal{H}}{\partial q^a}\, \delta q^a - \frac{\partial \mathcal{H}}{\partial p_a}\, \delta p_a \right) \mathrm{d}t\,.$$

Only one term carries a derivative of a variation. Integrating it by parts once,

$$\int_{t_a}^{t_b} p_a\, \delta \dot{q}^a\, \mathrm{d}t = \Big[p_a\, \delta q^a \Big]_{t_a}^{t_b} - \int_{t_a}^{t_b} \dot{p}_a\, \delta q^a\, \mathrm{d}t\,,$$

and the boundary term vanishes because δq^a was required to vanish at the endpoints. Collecting,

$$\delta S = \int_{t_a}^{t_b} \left[\left(\dot{q}^a - \frac{\partial \mathcal{H}}{\partial p_a} \right) \delta p_a - \left(\dot{p}_a + \frac{\partial \mathcal{H}}{\partial q^a} \right) \delta q^a \right] \mathrm{d}t\,. \tag{25.21}$$

The variations δq^a and δp_a are independent and otherwise arbitrary, so by the fundamental lemma Lemma 16.18 applied to each in turn, $\delta S = 0$ for all of them if and only if both coefficients vanish identically, which is Equations (22.3) and (22.4). The converse direction is the same computation read backwards.

The asymmetry of the endpoint conditions is not an oversight. The integrand contains $\dot{q}^a$ but no $\dot{p}_a$, so the integration by parts is needed only for the coordinates, and only they generate a boundary term to be killed. Requiring δp_a to vanish at the ends as well would be harmless but redundant; requiring it of δq^a is not optional. □

Remark 25.20 (Why "first order" matters). The Lagrangian action is second order in time derivatives and its variation needs the positions fixed at both ends; the action Equation (25.20) is first order, and the object multiplying the derivative is the canonical one-form $\theta = p_a \mathrm{d}q^a$ of Equation (24.3). Three consequences run through the rest of this treatise:

1. the symplectic form is read off the action as $\omega = -\mathrm{d}\theta$, so a theory presented in first-order form announces its own phase-space geometry;
2. the quantity exponentiated in the phase-space path integral of Chapter 106 is $\mathrm{e}^{\mathrm{i}S[q,p]/\hbar}$ with S this action, so the measure there is the Liouville measure of Definition 24.20;
3. when the Legendre transformation of Definition 22.2 fails to be invertible, the first-order action is still well defined, and it is the starting point of the constraint analysis of Chapter 26.

25.3.1 The Faddeev–Jackiw form

The action Equation (25.20) singles out a splitting of the phase-space coordinates into q's and p's. Nothing in the variational argument required that splitting: what was used was only that the integrand is linear in the velocities. Dropping the splitting gives a formalism in which the brackets are *read off* the action rather than postulated, and in which the degenerate case — the case that defeats the Legendre transformation — is not an obstacle but the object of study. The construction is due to Faddeev and Jackiw; their 1988 letter is not in this bibliography, and the presentation below is therefore self-contained rather than a report of it.

Definition 25.21 (First-order action in general coordinates)**.** Let ξ^c, $c = 1, \dots, N$, be coordinates on a phase space, let $a_c(\xi)$ be the components of a one-form on it — the *canonical potential* — and let $\mathcal{H}(\xi)$ be the Hamiltonian. The *first-order*, or *Faddeev–Jackiw*, action is

$$S[\xi] = \int_{t_a}^{t_b} \Big(a_c(\xi)\, \dot{\xi}^c - \mathcal{H}(\xi) \Big)\, \mathrm{d}t\,, \tag{25.22}$$

and its *symplectic two-form* is the antisymmetric matrix

$$f_{cd} = \partial_c a_d - \partial_d a_c\,, \qquad \partial_c = \frac{\partial}{\partial \xi^c}\,. \tag{25.23}$$

In the notation of Section 13.6.4 this is $f = \mathrm{d}a$ in components.

Rests on Equation (25.20) and Definition 13.103.

Theorem 25.22 (Faddeev–Jackiw equations and brackets)**.** *Stationarity of Equation (25.22) under variations vanishing at the endpoints is equivalent to*

$$f_{cd}(\xi)\, \dot{\xi}^d = \partial_c \mathcal{H}(\xi)\,. \tag{25.24}$$

If f_{cd} is invertible, with inverse $\left(f^{-1}\right)^{cd}$, the motion is $\dot{\xi}^c = \left(f^{-1}\right)^{cd} \partial_d \mathcal{H}$, and it is generated by the bracket

$$\{u, v\} = \Big(f^{-1}\Big)^{cd}\, \partial_c u\, \partial_d v\,, \qquad \textit{so that} \qquad \Big\{\xi^c, \xi^d\Big\} = \Big(f^{-1}\Big)^{cd}\,. \tag{25.25}$$

This bracket satisfies the Jacobi identity for every choice of a_c.

Rests on Definition 25.21, Lemma 16.18, and Theorem 25.3.

Derivation. *Derives Theorem 25.22.*

The Euler–Lagrange equation of Equation (25.22) is

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial}{\partial \dot{\xi}^c}\Big(a_d \dot{\xi}^d - \mathcal{H}\Big) - \frac{\partial}{\partial \xi^c}\Big(a_d \dot{\xi}^d - \mathcal{H}\Big) = \partial_d a_c\, \dot{\xi}^d - \partial_c a_d\, \dot{\xi}^d + \partial_c \mathcal{H} = 0\,,$$

since $\partial\left(a_d \dot{\xi}^d\right)/\partial \dot{\xi}^c = a_c$ and $\mathrm{d}a_c/\mathrm{d}t = \partial_d a_c\, \dot{\xi}^d$. Rearranged, this is Equation (25.24). Note that a_c enters the equation of motion only through the antisymmetric combination

Equation (25.23): adding a gradient, $a_c \mapsto a_c + \partial_c \chi$, changes the integrand of Equation (25.22) by a total time derivative and leaves the dynamics alone. The potential is a gauge-dependent bookkeeping device; the form is the physics.

If f is invertible, contracting Equation (25.24) with the inverse gives $\dot{\xi}^c = \left(f^{-1}\right)^{cd} \partial_d \mathcal{H}$, and for any observable $\mathrm{d}u/\mathrm{d}t = \partial_c u \, \dot{\xi}^c = \left(f^{-1}\right)^{cd} \partial_c u \, \partial_d \mathcal{H}$, which is $\{u, \mathcal{H}\}$ in the bracket Equation (25.25). The inverse of an antisymmetric matrix is antisymmetric, so the bracket is antisymmetric, and it is a derivation in each slot because it carries one derivative per slot.

For the Jacobi identity the proof of Theorem 25.3 does not apply verbatim, since $\left(f^{-1}\right)^{cd}$ is not constant; what replaces constancy is that $f = \mathrm{d}a$ is exact, hence closed (Definition 13.105), $\partial_c f_{de} + \partial_d f_{ec} + \partial_e f_{cd} = 0$ by inspection of Equation (25.23). Differentiating $\left(f^{-1}\right)^{ce} f_{ed} = \delta^c_d$ gives $\partial_b \left(f^{-1}\right)^{cd} = -\left(f^{-1}\right)^{ce} \left(f^{-1}\right)^{fd} \partial_b f_{ef}$, and substituting this into the cyclic sum turns the three second-derivative groups into three copies of the closedness relation contracted with three inverses; they cancel in the same pattern as before. □

Remark 25.23 (Why this is more than a change of variables). Three things are gained. First, the brackets are an *output*: one writes down a first-order action, inverts a matrix, and the bracket algebra follows, with no need to guess which variables are conjugate to which. Second, Jacobi is automatic — it was bought by writing f as $\mathrm{d}a$, so any theory presented in the form Equation (25.22) carries a legitimate Poisson structure by construction. Third, and this is the point of the construction, when f_{cd} is *not* invertible the equations Equation (25.24) do not determine all the velocities: contracting with a null vector z^c of f, $z^c f_{cd} = 0$, gives $z^c \partial_c \mathcal{H} = 0$, a relation among the coordinates alone — a constraint. Each null direction is either such a constraint or a gauge direction along which the motion is undetermined. Solving the constraints, substituting back into Equation (25.22) and repeating until f is invertible is the Faddeev–Jackiw reduction; it is an alternative to the Dirac algorithm of Section 26.2, and where both apply they give the same final brackets, the Dirac bracket Equation (26.25) being the inverse of f restricted to the constraint surface. The Dirac route classifies constraints first and quantizes second; the Faddeev–Jackiw route eliminates them first and never needs the classification. Neither is uniformly shorter, and the reason to know both is that the bookkeeping of one is often trivial where the other's is not.

Example 25.24 (A charged particle in a strong magnetic field)**.** Take a particle of charge e and mass m confined to the $x_1 x_2$ plane of three-dimensional space, in a uniform magnetic field $\boldsymbol{B} = B\boldsymbol{e}_3$ described in the symmetric gauge $\boldsymbol{A} = \frac{1}{2} B\,(-x_2, x_1, 0)$, with a potential $V(x_1, x_2)$. Its Lagrangian is

$$\mathcal{L} = \frac{m}{2}\left(\dot{x}_1^2 + \dot{x}_2^2\right) + \frac{eB}{2}\left(x_1 \dot{x}_2 - x_2 \dot{x}_1\right) - V\,. \tag{25.26}$$

When the field is strong enough that the cyclotron energy $\hbar eB/m$ dwarfs every other scale in the problem, the kinetic term may be dropped — the formal limit $m \to 0$ at fixed B — and what remains is already of the form Equation (25.22) in the two coordinates $\xi = (x_1, x_2)$, with no momenta at all:

$$a_1 = -\frac{eB}{2} x_2\,, \qquad a_2 = +\frac{eB}{2} x_1\,, \qquad \mathcal{H} = V\,. \tag{25.27}$$

Then $f_{12} = \partial_1 a_2 - \partial_2 a_1 = eB$, which is invertible for $B \neq 0$, and Equation (25.25) gives at once

$$\{x_1, x_2\} = -\frac{1}{eB}\,, \tag{25.28}$$

with SI unit $\mathrm{m}^2/(\mathrm{J\,s})$. The two Cartesian coordinates of the same particle are canonically conjugate to each other: the plane has become its own phase space, of half the dimension one started with, which is what the vanishing of m did to the count.

Rests on Theorem 25.22 and Equation (25.25).

Proposition 25.25 (Noncommuting coordinates and the Landau degeneracy)**.** *Applying Postulate 25.27 to Equation* (25.28) *gives*

$$[\hat{x}_1, \hat{x}_2] = -\mathrm{i}\,\frac{\hbar}{eB} = -\mathrm{i}\,\ell_B^2\,, \qquad \ell_B = \sqrt{\frac{\hbar}{eB}}\,, \tag{25.29}$$

ℓ_B *being the* magnetic length*. The number of independent states per unit area is then bounded by*

$$n = \frac{1}{2\pi\ell_B^2} = \frac{eB}{h} = \frac{B}{\Phi_0}\,, \qquad \Phi_0 = \frac{h}{e} = 4.135\,667\,696 \times 10^{-15}\,\mathrm{Wb}\,, \tag{25.30}$$

which is the observed degeneracy of a Landau level.

Rests on Equation (25.28) *and Postulate 25.27.*

Derivation. *Derives Proposition 25.25.*

Equation (25.29) is Equation (25.31) applied to Equation (25.28). Two operators obeying a commutation relation of the canonical form $\left[\hat{A}, \hat{B}\right] = \mathrm{i}\lambda$ obey the uncertainty relation $\Delta A\,\Delta B \geq |\lambda|/2$ of Section 77.6.3, so here $\Delta x_1\,\Delta x_2 \geq \ell_B^2/2$: a state cannot be localized in the plane to better than an area $2\pi\ell_B^2/2\pi$, and the count of orthogonal states per unit area is bounded by $1/2\pi\ell_B^2$. Substituting $\ell_B^2 = \hbar/eB$ and $\hbar = h/2\pi$ gives Equation (25.30), the flux quantum $\Phi_0 = h/e$ being exact in the SI, since h and e are both defining constants (Appendix B). The bound is an inequality because an uncertainty relation is one; that it is *saturated* — that a Landau level holds exactly eB/h states per unit area and not fewer — does not follow from this argument and requires the explicit eigenfunctions, which are obtained in Chapter 128. What the bracket settles here is the scale, and the scale is what the experiment measures.

Numerically, at $B = 10\,\mathrm{T}$ — a field routinely available in a superconducting laboratory magnet — $\ell_B = 8.11\,\mathrm{nm}$ and $n = 2.418 \times 10^{15}/\mathrm{m}^2$, that is $2.418 \times 10^{11}/\mathrm{cm}^2$, which is the carrier density scale at which the integer quantum Hall plateaux appear (Chapter 128). □

Remark 25.26 (What the example does and does not show)*.* The limit $m \to 0$ is a device for isolating the lowest Landau level, not a physical statement: the electron's mass is $(9.109\,383\,701\,5 \pm 0.000\,000\,002\,8) \times 10^{-31}\,\mathrm{kg}$ and does not vanish. What the Faddeev–Jackiw reading makes visible is that the projection onto one Landau level is a *reduction of phase space*, and that the noncommutativity Equation (25.29) of the surviving coordinates is the bracket of the reduced space rather than a new postulate. The same answer follows from the Dirac algorithm by treating the two momenta as second-class constraints and computing Equation (26.25); the arithmetic there is a 2×2 inversion as well, and the agreement is Remark 25.23 in action rather than a coincidence.

25.4 Canonical quantization: the correspondence rule

Postulate 25.27 (Dirac's correspondence rule)**.** To each classical observable u associate a self-adjoint operator $\hat{u}$ on a Hilbert space, in such a way that the Poisson bracket goes over into the commutator:

$$\{u, v\} \longmapsto \frac{1}{\mathrm{i}\hbar}\,[\hat{u}, \hat{v}]\ . \tag{25.31}$$

Rests on Theorem 25.3 and Equation (22.41)*.*

The status of Postulate 25.27 in this treatise is fixed by Chapter 77, where the quantum theory is set out on its own terms: the postulates there are about states, observables and measurement, and the correspondence rule is used in Section 77.5 as the heuristic that tells one *which* operator to write for a given classical quantity. It is a bridge from a theory that is a limit to the theory it is a limit of, and it is therefore expected to be imperfect. Section 25.5 shows that it is.

Remark 25.28 (The constant on the right-hand side is measured). Antisymmetry, bilinearity and the Jacobi identity are shared by the bracket and the commutator, so a map taking one to the other must carry a constant of proportionality, and dimensional analysis fixes what kind of constant. A Poisson bracket $\{u, v\}$ has the SI dimension of $[u]\,[v]$ divided by an action, since q and p pair to an action; a commutator $[\hat{u}, \hat{v}]$ has the dimension of $[u]\,[v]$ outright. The factor relating them is therefore an action, and Equation (25.31) would be dimensionally consistent for *any* action whatever. That the action in question is Planck's constant,

$$\hbar = \frac{h}{2\pi}\,, \qquad h = 6.626\,070\,15\times10^{-34}\,\mathrm{J\,s}\ \text{(exact)}\,, \qquad \hbar = 1.054\,571\,817\times10^{-34}\,\mathrm{J\,s}\,, \tag{25.32}$$

is not a mathematical statement and cannot be derived here: it is fixed by measurement — historically by the black-body spectrum and the photoelectric effect (Chapters 68 and 69), and today by the definition of the kilogram, which makes h exact and $\hbar$ exact as a defined ratio, quoted above to ten significant figures. The factor i is likewise not free: it is what makes $\hat{u}$ self-adjoint whenever u is real, since the commutator of two self-adjoint operators is anti-self-adjoint.

Proposition 25.29 (Canonical commutation relations)**.** *Applied to the fundamental brackets Equation* (22.44)*, Equation* (25.31) *gives*

$$\left[\hat{q}^a, \hat{q}^b\right] = 0\,, \qquad [\hat{p}_a, \hat{p}_b] = 0\,, \qquad [\hat{q}^a, \hat{p}_b] = \mathrm{i}\hbar\,\delta^a_b\,. \tag{25.33}$$

Rests on Postulate 25.27 and Equation (22.44)*.*

Derivation. *Derives Proposition 25.29.*

Read Equation (22.44) through Equation (25.31) term by term. The first two brackets vanish, so the corresponding commutators do. The third is $\{q^a, p_b\} = \delta^a_b$, a multiple of the constant function 1, whose operator image is $\mathbb{1}$ by the second requirement of Theorem 25.38; hence $[\hat{q}^a, \hat{p}_b] = \mathrm{i}\hbar\,\delta^a_b\,\mathbb{1}$, the identity being suppressed in Equation (25.33) as usual. Both sides carry the SI unit J s, as they must. □

Corollary 25.30 (The relation cannot be realized by matrices)**.** *No pair of operators on a finite-dimensional space, and more generally no pair of* bounded *operators on a Hilbert space, satisfies Equation* (25.33)*. Position and momentum are therefore necessarily unbounded, and necessarily defined on domains smaller than the whole space.*

Rests on Equation (25.33) *and Theorem 12.75.*

Derivation. *Derives Corollary 25.30.*

In finite dimension take the trace of Equation (25.33): the trace of a commutator vanishes, while the trace of $\mathrm{i}\hbar\mathbb{1}$ is $\mathrm{i}\hbar$ dim, which is non-zero. The general bounded statement is Theorem 12.75, and the consequences for domains are Corollary 12.76. This is the first place where the quantum theory demands more than linear algebra, and it is why the Hilbert-space apparatus of Chapter 12 is not optional decoration. □

Proposition 25.31 (The Heisenberg equation is the evolution equation)**.** *Applied to the classical evolution equation Equation* (22.50)*, Equation* (25.31) *gives the Heisenberg equation of motion*

$$\frac{\mathrm{d}\hat{A}}{\mathrm{d}t} = \frac{1}{\mathrm{i}\hbar}\left[\hat{A}, \hat{\mathcal{H}}\right] + \frac{\partial \hat{A}}{\partial t}\,, \tag{25.34}$$

and a quantum constant of motion is an observable commuting with the Hamiltonian, in exact parallel with Proposition 22.37.

Rests on Postulate 25.27 and Equation (22.50)*.*

Derivation. *Derives Proposition 25.31.*

The evolution equation Equation (22.50) reads $\mathrm{d}U/\mathrm{d}t = \{U, \mathcal{H}\} + \partial U/\partial t$. Its first term is a Poisson bracket and goes over into $\left[\hat{A}, \hat{\mathcal{H}}\right]/\mathrm{i}\hbar$ by Equation (25.31); its second is a derivative with respect to the explicit time slot, which the correspondence does not touch, since t is a parameter and not an observable. This gives Equation (25.34). Setting $\partial\hat{A}/\partial t = 0$, the operator is constant in time precisely when it commutes with $\hat{\mathcal{H}}$, which is the operator form of Proposition 22.37.

Two remarks keep the parallel honest. First, this is a transfer of a postulate, not a derivation: Equation (25.34) is equivalent to the Schrödinger equation of Section 77.1.6 and stands or falls with it. Second, the transfer is legitimate here, and not merely suggestive, because $\mathcal{H}$ enters only through a single bracket — so Theorem 25.38 has nothing to obstruct as long as $\hat{\mathcal{H}}$ has been fixed by some other means. □

Theorem 25.32 (Ehrenfest)**.** *For $\hat{\mathcal{H}} = \hat{\boldsymbol{p}}^2/2m + V(\hat{\boldsymbol{x}})$ the expectation values obey*

$$m\frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{\boldsymbol{x}}\rangle = \langle\hat{\boldsymbol{p}}\rangle\,, \qquad \frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{\boldsymbol{p}}\rangle = -\langle\boldsymbol{\nabla}V(\hat{\boldsymbol{x}})\rangle\,. \tag{25.35}$$

The expectation values satisfy the classical equations of motion with the force evaluated as the mean of the force, not *as the force at the mean; the two agree only when the potential is at most quadratic, or when the state is narrow on the scale over which $\boldsymbol{\nabla}V$ varies.*

Rests on Equations (25.33) and (25.34).

Derivation. *Derives Theorem 25.32.*

Both statements are Equation (25.34) evaluated in a state, with $\partial\hat{A}/\partial t = 0$ for $\hat{A} = \hat{x}_i$ and $\hat{A} = \hat{p}_i$. Two commutators are needed. For the first, the commutator with a fixed operator is a derivation of the operator product, $\left[\hat{A}, \hat{B}\hat{C}\right] = \hat{B}\left[\hat{A}, \hat{C}\right] + \left[\hat{A}, \hat{B}\right]\hat{C}$, so with $[\hat{x}_i, \hat{p}_j] = \mathrm{i}\hbar\delta_{ij}$ from Equation (25.33),

$$[\hat{x}_i, \hat{p}_j\hat{p}_j] = \hat{p}_j\,[\hat{x}_i, \hat{p}_j] + [\hat{x}_i, \hat{p}_j]\,\hat{p}_j = 2\mathrm{i}\hbar\,\hat{p}_i\,, \tag{25.36}$$

while $[\hat{x}_i, V(\hat{\boldsymbol{x}})] = 0$ because V is built from the $\hat{x}_j$, which commute among themselves. Hence $\mathrm{d}\langle\hat{x}_i\rangle/\mathrm{d}t = \left\langle\left[\hat{x}_i, \hat{\mathcal{H}}\right]\right\rangle/\mathrm{i}\hbar = \langle\hat{p}_i\rangle/m$, the first of Equation (25.35).

For the second, $[\hat{p}_i, \hat{\boldsymbol{p}}^2] = 0$, and the same derivation property applied repeatedly to a monomial $\hat{x}_{j_1}\cdots\hat{x}_{j_n}$ gives

$$[\hat{p}_i, V(\hat{\boldsymbol{x}})] = -\mathrm{i}\hbar\left(\frac{\partial V}{\partial x_i}\right)(\hat{\boldsymbol{x}})\,, \tag{25.37}$$

since each factor contributes $[\hat{p}_i, \hat{x}_j] = -\mathrm{i}\hbar\delta_{ij}$ in turn, which is exactly the product rule for $\partial/\partial x_i$. The identity therefore holds for polynomials, and extends to any V reachable from them — by a convergent power series, or in general through the functional calculus of Definition 12.60 for a self-adjoint $\hat{\boldsymbol{x}}$. Then $\mathrm{d}\langle\hat{p}_i\rangle/\mathrm{d}t = \left\langle\left[\hat{p}_i, \hat{\mathcal{H}}\right]\right\rangle/\mathrm{i}\hbar = -\langle\partial_i V\rangle$, the second of Equation (25.35).

The final sentence is the substantive one. Expand $\partial_i V$ about the mean position $\langle\hat{\boldsymbol{x}}\rangle$ and take the expectation term by term. The linear term drops, because the mean of $\hat{x}_j - \langle\hat{x}_j\rangle$ is zero by construction, and what is left is

$$\left\langle\frac{\partial V}{\partial x_i}\right\rangle = \left.\frac{\partial V}{\partial x_i}\right|_{\langle\hat{\boldsymbol{x}}\rangle} + \frac{1}{2}\left.\frac{\partial^3 V}{\partial x_i\,\partial x_j\,\partial x_k}\right|_{\langle\hat{\boldsymbol{x}}\rangle}\mathrm{cov}\,(\hat{x}_j, \hat{x}_k) + \cdots\,, \tag{25.38}$$

with $\mathrm{cov}(\hat{x}_j, \hat{x}_k) = \frac{1}{2}\langle\{\hat{x}_j, \hat{x}_k\}\rangle - \langle\hat{x}_j\rangle\langle\hat{x}_k\rangle$. If V is at most quadratic every third derivative vanishes identically and Equation (25.35) becomes the classical equation exactly, whatever the state; otherwise the leading correction is a third derivative of the potential times the variance of the position, and it is not small merely because $\hbar$ is small — it is small only while the wave packet stays narrow. □

Remark 25.33 (Ehrenfest's theorem is not the classical limit). Equation (25.38) is the reason Theorem 25.32 does not, by itself, establish that quantum mechanics reproduces classical mechanics. In an anharmonic potential a packet spreads, the variance in Equation (25.38) grows, and the expectation values then follow no classical trajectory at all; the theorem remains true and says nothing useful. What is needed in addition is a mechanism that keeps the state narrow, and for a macroscopic body that mechanism is decoherence through coupling to an environment [2055], treated in Chapter 87. Ehrenfest's original note [573] claims no more than this: its title asks about the *approximate* validity of classical mechanics within quantum mechanics.

Theorem 25.34 (Stone–von Neumann)**.** *For a system with finitely many degrees of freedom, every irreducible representation of the canonical commutation relations in Weyl's exponentiated form*

$$\mathrm{e}^{\mathrm{i}a\hat{q}}\,\mathrm{e}^{\mathrm{i}b\hat{p}} = \mathrm{e}^{-\mathrm{i}\hbar ab}\,\mathrm{e}^{\mathrm{i}b\hat{p}}\,\mathrm{e}^{\mathrm{i}a\hat{q}} \tag{25.39}$$

is unitarily equivalent to the Schrödinger representation on $L^2(\mathbb{R}^f)$. The quantum kinematics is therefore fixed, up to equivalence, by the classical bracket algebra alone.

Rests on Equation (25.33), Theorem 12.66, and Definition 12.64.

Full derivation: Appendix A.49 (p. 3051).

Derives Theorem 25.34.

Remark 25.35 (The proof is functional analysis, and Part II owes its home). The argument written out in the appendix builds, from the Weyl operators of Equation (25.39), a Gaussian-smeared average that turns out to be a rank-one projector onto a vacuum vector, and then shows that the whole representation space is generated from that vector by the Weyl operators, so that any two irreducible representations are carried onto one another by a unitary. Nothing in it is physics: it is a statement about the Weyl algebra, and it belongs beside the Hilbert-space material of Chapter 12, next to Theorem 12.66, which is what carries the passage between the exponentiated form and the unbounded generators. That Chapter 12 does not carry it is recorded here as a debt of Part II, not as a gap of this chapter; the appendix proof is written so that moving it there would change nothing but its address.

Remark 25.36 (The exponentiated form is not a technicality). Corollary 25.30 forces $\hat{q}$ and $\hat{p}$ to be unbounded, and by Corollary 12.76 an unbounded operator carries a domain that is not the whole space. Two representations of Equation (25.33) can then agree on every vector where both sides are defined and still be inequivalent, because the relation says nothing about what happens outside the common domain. The Weyl form Equation (25.39) repairs this: $\mathrm{e}^{\mathrm{i}a\hat{q}}$ and $\mathrm{e}^{\mathrm{i}b\hat{p}}$ are *unitary*, hence bounded and everywhere defined, and Theorem 12.66 guarantees that a strongly continuous one-parameter unitary group determines a unique self-adjoint generator and conversely. Momentum on a half-line (Example 12.82) and momentum on an interval (Example 12.81) are the standard warnings: the first has no self-adjoint extension at all, the second a whole circle of them, and in neither case does the formal commutation relation notice. The exponentiated form is what makes the uniqueness statement true rather than nearly true.

The proof itself is missing from Part II, where it belongs: Section 12.4.3 establishes Stone's theorem but not the uniqueness of the Weyl representation. Nothing in this chapter rests on the proof — only on the statement, which is used in Theorem 25.38 to say that hypothesis (3) leaves no freedom in the operators of degree at most one.

Remark 25.37 (Where the theorem fails, and why that is physics). Theorem 25.34 assumes finitely many degrees of freedom. A field has infinitely many, and the theorem then fails: inequivalent irreducible representations of the canonical commutation relations exist in profusion, and the choice among them is a physical one. This is not a pathology to be

regretted; it is what allows a quantum field theory to have inequivalent vacua, and it is the origin of superselection sectors, of spontaneous symmetry breaking as a statement about representations (Chapter 104), and of Haag's theorem (Chapter 109).

25.5 The obstruction: what the correspondence cannot be

Postulate 25.27 is stated above as a postulate rather than as a definition or a theorem. That is deliberate, and this section says why: as a definition it would be inconsistent, and as a theorem it is false.

Theorem 25.38 (Groenewold–van Hove)**.** *There is no linear map $u \mapsto \hat{u}$ from the polynomials in (q^a, p_a) to self-adjoint operators satisfying all of*

1. *$\{u, v\} \mapsto \frac{1}{\mathrm{i}\hbar}[\hat{u}, \hat{v}]$ for all u, v;*
2. *$\hat{1} = \mathbb{1}$;*
3. *$\hat{q}^a$ and $\hat{p}_a$ act irreducibly on the Hilbert space.*

The obstruction appears already for polynomials of degree three and four in one degree of freedom: the requirements are consistent on the subalgebra of polynomials of degree at most two and inconsistent on any extension of it.

Rests on Equation (25.31) and Theorems 5.155 and 25.34.

The proof is elementary and takes two steps. First, the hypotheses leave no freedom at all in the images of the polynomials of degree at most three: every one of them is forced to be the symmetrized, or Weyl, ordering. Second, one single classical observable of degree four can be written as a Poisson bracket of degree-three polynomials in two different ways, and the two forced answers disagree.

Lemma 25.39 (The low-degree images are forced)**.** *Take one degree of freedom and write $\hat{q}, \hat{p}$ for the images of q, p. Under hypotheses (1)–(3) of Theorem 25.38,*

$$\widehat{q^2} = \hat{q}^2\,, \qquad \widehat{p^2} = \hat{p}^2\,, \qquad \widehat{qp} = \tfrac{1}{2}\{\hat{q}, \hat{p}\}\,, \tag{25.40}$$

$$\widehat{q^3} = \hat{q}^3\,, \qquad \widehat{p^3} = \hat{p}^3\,, \qquad \widehat{q^2p} = \tfrac{1}{2}\left\{\hat{q}^2, \hat{p}\right\}\,, \quad \widehat{qp^2} = \tfrac{1}{2}\left\{\hat{q}, \hat{p}^2\right\}\,. \tag{25.41}$$

Rests on Theorems 5.155 and 25.34.

Derivation. *Derives Lemma 25.39.*

Throughout, hypothesis (1) is applied only to the pairs written down, and $[\hat{q}, \hat{p}] = \mathrm{i}\hbar$ from Proposition 25.29. The tool used repeatedly is:

Schur step. If an operator D commutes with both $\hat{q}$ and $\hat{p}$ then $D = \lambda\mathbb{1}$ for some complex λ. This is Schur's lemma Theorem 5.155 applied to the irreducible representation of hypothesis (3); Theorem 25.34 says that representation is the Schrödinger one, in which the statement is that an operator commuting with multiplication by x and with differentiation is a constant.

Quadratics. From $\{q^2, q\} = 0$ and $\{q^2, p\} = 2q$, hypothesis (1) requires $\left[\widehat{q^2}, \hat{q}\right] = 0$ and $\left[\widehat{q^2}, \hat{p}\right] = 2\mathrm{i}\hbar\,\hat{q}$. The operator $\hat{q}^2$ satisfies both, so their difference passes the Schur step and $\widehat{q^2} = \hat{q}^2 + \lambda$. Symmetrically $\widehat{p^2} = \hat{p}^2 + \nu$. Writing $\hat{S} := \frac{1}{2}\{\hat{q}, \hat{p}\} = \hat{q}\hat{p} - \frac{1}{2}\mathrm{i}\hbar$, the same argument applied to $\{qp, q\} = -q$ and $\{qp, p\} = p$ gives $\widehat{qp} = \hat{S} + \mu$.

The three constants are removed by three more brackets. From $\{q^2, p^2\} = 4qp$ and $[\hat{q}^2, \hat{p}^2] = 2\mathrm{i}\hbar\,\{\hat{q}, \hat{p}\}$, the additive constants dropping out of a commutator,

$$\widehat{qp} = \frac{1}{4\mathrm{i}\hbar}\left[\widehat{q^2}, \widehat{p^2}\right] = \frac{1}{4\mathrm{i}\hbar}\left[\hat{q}^2, \hat{p}^2\right] = \hat{S}\,,$$

so $\mu = 0$. From $\{q^2, qp\} = 2q^2$ and $\left[\hat{q}^2, \hat{S}\right] = 2\mathrm{i}\hbar\,\hat{q}^2$,

$$\widehat{q^2} = \frac{1}{2\mathrm{i}\hbar}\left[\widehat{q^2}, \widehat{qp}\right] = \frac{1}{2\mathrm{i}\hbar}\left[\hat{q}^2, \hat{S}\right] = \hat{q}^2\,,$$

so $\lambda = 0$; and $\{p^2, qp\} = -2p^2$ with $\left[\hat{p}^2, \hat{S}\right] = -2\mathrm{i}\hbar\,\hat{p}^2$ gives $\nu = 0$ the same way. This is Equation (25.40).

Cubics. From $\{q^3, q\} = 0$ and $\{q^3, p\} = 3q^2$, and using $\widehat{q^2} = \hat{q}^2$ just established, the Schur step gives $\widehat{q^3} = \hat{q}^3 + \kappa$. Then $\{q^3, qp\} = 3q^3$ with $\left[\hat{q}^3, \hat{S}\right] = 3\mathrm{i}\hbar\,\hat{q}^3$ forces $3\hat{q}^3 = 3\,(\hat{q}^3 + \kappa)$, so $\kappa = 0$; symmetrically $\widehat{p^3} = \hat{p}^3$, using $\{p^3, qp\} = -3p^3$. The mixed cubics need no Schur step at all, being brackets of things already fixed: $\{q^3, p^2\} = 6q^2p$ and $[\hat{q}^3, \hat{p}^2] = 3\mathrm{i}\hbar\,\{\hat{q}^2, \hat{p}\}$ give

$$\widehat{q^2p} = \frac{1}{6\mathrm{i}\hbar}\left[\hat{q}^3, \hat{p}^2\right] = \tfrac{1}{2}\left\{\hat{q}^2, \hat{p}\right\}\,,$$

and $\{q^2, p^3\} = 6qp^2$ with $[\hat{q}^2, \hat{p}^3] = 2\mathrm{i}\hbar\,(\hat{q}\hat{p}^2 + \hat{p}\hat{q}\hat{p} + \hat{p}^2\hat{q}) = 6\mathrm{i}\hbar\,(\hat{q}\hat{p}^2 - \mathrm{i}\hbar\hat{p})$ gives $\widehat{qp^2} = \hat{q}\hat{p}^2 - \mathrm{i}\hbar\hat{p} = \frac{1}{2}\,\{\hat{q}, \hat{p}^2\}$. This is Equation (25.41). □

Derivation. *Derives Theorem 25.38.*

Consider the classical observable q^2p^2. It is a Poisson bracket of cubics in two ways:

$$\left\{q^3, p^3\right\} = 9\,q^2p^2\,, \qquad \left\{q^2p, qp^2\right\} = 3\,q^2p^2\,, \tag{25.42}$$

both read off Equation (22.41) directly — for the second, $\partial_q\,(q^2p)\,\partial_p\,(qp^2) - \partial_p\,(q^2p)\,\partial_q\,(qp^2) = 4q^2p^2 - q^2p^2$. Hypothesis (1) applied to each of Equation (25.42), with the images supplied by Lemma 25.39, gives two expressions for the same operator $\widehat{q^2p^2}$.

For the first route, $[\hat{q}^3, \hat{p}^3] = 3\mathrm{i}\hbar\,(\hat{q}^2\hat{p}^2 + \hat{p}\hat{q}^2\hat{p} + \hat{p}^2\hat{q}^2)$, and moving every $\hat{p}$ to the right with $\hat{p}\hat{q}^2 = \hat{q}^2\hat{p} - 2\mathrm{i}\hbar\hat{q}$,

$$\hat{p}\hat{q}^2\hat{p} = \hat{q}^2\hat{p}^2 - 2\mathrm{i}\hbar\,\hat{q}\hat{p}\,, \qquad \hat{p}^2\hat{q}^2 = \hat{q}^2\hat{p}^2 - 4\mathrm{i}\hbar\,\hat{q}\hat{p} - 2\hbar^2\,,$$

so that $[\hat{q}^3, \hat{p}^3] = 3\mathrm{i}\hbar\,(3\hat{q}^2\hat{p}^2 - 6\mathrm{i}\hbar\,\hat{q}\hat{p} - 2\hbar^2)$ and

$$\widehat{q^2p^2} = \frac{1}{9\mathrm{i}\hbar}\left[\hat{q}^3, \hat{p}^3\right] = \hat{q}^2\hat{p}^2 - 2\mathrm{i}\hbar\,\hat{q}\hat{p} - \frac{2}{3}\hbar^2\,. \tag{25.43}$$

For the second route write the two cubics in the compact form supplied by Lemma 25.39, $\widehat{q^2p} = \hat{q}^2\hat{p} - \mathrm{i}\hbar\hat{q}$ and $\widehat{qp^2} = \hat{q}\hat{p}^2 - \mathrm{i}\hbar\hat{p}$. Expanding the commutator in four pieces, and using $[\hat{q}^2\hat{p}, \hat{q}\hat{p}^2] = 3\mathrm{i}\hbar\,\hat{q}^2\hat{p}^2 + 2\hbar^2\hat{q}\hat{p}$ for the leading one,

$$\left[\widehat{q^2p}, \widehat{qp^2}\right] = 3\mathrm{i}\hbar\,\hat{q}^2\hat{p}^2 + 6\hbar^2\hat{q}\hat{p} - \mathrm{i}\hbar^3\,,$$

the three $\hbar^2\hat{q}\hat{p}$ contributions coming one from the leading piece and one from each cross term, and

$$\widehat{q^2p^2} = \frac{1}{3\mathrm{i}\hbar}\left[\widehat{q^2p}, \widehat{qp^2}\right] = \hat{q}^2\hat{p}^2 - 2\mathrm{i}\hbar\,\hat{q}\hat{p} - \frac{1}{3}\hbar^2\,. \tag{25.44}$$

Subtracting Equation (25.44) from Equation (25.43),

$$0 = -\frac{2}{3}\hbar^2 + \frac{1}{3}\hbar^2 = -\frac{\hbar^2}{3}\,\mathbb{1}\,, \tag{25.45}$$

which is false, $\hbar$ being a non-zero action Equation (25.32). No map satisfying (1)–(3) exists.

Nothing in the argument used more than hypothesis (1) on the pairs listed, all of degree at most three, so the conclusion is stronger than the statement: the correspondence already fails if it is demanded only of the polynomials of degree at most three. It does *not* fail

on the polynomials of degree at most two, which close under the bracket — the bracket of a monomial of degree m with one of degree n has degree $m+n-2$ — and on which Equation (25.40) is not merely forced but consistent, as the brackets computed in the proof of Lemma 25.39 verify. Degree two is exactly where the correspondence is exact, and one step beyond it is where it breaks. □

Remark 25.40 (Reading the defect). The mismatch Equation (25.45) is of order $\hbar^2$, not $\hbar$. That is not an accident of the example: an ordering difference of order $\hbar$ would show up already in Equation (25.41), where the two routes agree, and it is the second order that the Poisson bracket cannot see, since it is the first term of the expansion Equation (25.52). Groenewold's 1946 paper and van Hove's 1951 memoir — neither of which is in this bibliography, so the attribution here rests on the computation above and not on a source the reader can check — go further, showing that no subalgebra properly containing the quadratics can be quantized consistently, so that restricting the observables does not rescue the rule either. Note also what is *not* shown: that quantum mechanics is inconsistent, or that $\widehat{q^2p^2}$ has no sensible definition. Both routes produce perfectly good self-adjoint operators. What fails is the demand that one assignment serve every classical observable at once while respecting the bracket.

Corollary 25.41 (Quantization is not a functor)**.** *No prescription assigns operators to all classical observables while preserving the bracket. Every actual quantization therefore either restricts the class of observables it treats, or accepts an ordering ambiguity, or deforms the bracket. Consequently the classical theory does not determine its quantum counterpart: quantization is a hypothesis about nature, and the choices it leaves open are settled by experiment, not by mathematics.*

Rests on Theorem 25.38.

25.5.1 Ordering

Corollary 25.41 says that something must be given up. This subsection makes concrete what is given up when one keeps the operators and abandons the bracket: an *ordering ambiguity*, one for every classical observable in which coordinates and momenta are multiplied together.

Definition 25.42 (Ordering rule)**.** An *ordering rule* is a linear map $u \mapsto \hat{u}$ from the polynomials in (q^a, p_a) to operators which sends 1 to $\mathbb{1}$, sends q^a and p_a to $\hat{q}^a$ and $\hat{p}_a$, and sends a real polynomial to a self-adjoint operator. By Theorem 25.38 no such rule can also satisfy Equation (25.31) for all pairs, so a rule is a choice, and different choices are different physical hypotheses until an experiment separates them.

Rests on Corollary 25.41 and Postulate 25.27.

Proposition 25.43 (The size of the ambiguity)**.** *The classical monomial qp in one degree of freedom has the three obvious candidate images*

$$\hat{q}\hat{p}\,, \qquad \hat{p}\hat{q} = \hat{q}\hat{p} - \mathrm{i}\hbar\,, \qquad \tfrac{1}{2}\{\hat{q},\hat{p}\} = \hat{q}\hat{p} - \tfrac{1}{2}\mathrm{i}\hbar\,, \tag{25.46}$$

of which only the third is self-adjoint. More generally, any two orderings of a monomial $q^m p^n$ differ by a polynomial in $\hat{q},\hat{p}$ of degree at most $m+n-2$, whose coefficients are integer multiples of powers of $\mathrm{i}\hbar$. All orderings therefore agree in the limit $\hbar \to 0$, and none of them can be preferred on dimensional grounds.

Rests on Equation (25.33) and Definition 25.42.

Derivation. *Derives Proposition 25.43.*

The three entries of Equation (25.46) follow from $[\hat{q},\hat{p}] = \mathrm{i}\hbar$; and $(\hat{q}\hat{p})^\dagger = \hat{p}\hat{q} \neq \hat{q}\hat{p}$, so neither of the first two is self-adjoint while the anticommutator manifestly is. For the general statement, any ordering of $q^m p^n$ can be turned into any other by transposing adjacent

factors one at a time, and each transposition replaces $\hat{p}\hat{q}$ by $\hat{q}\hat{p}$ at the cost of an additive $-\mathrm{i}\hbar$ multiplying the remaining $m+n-2$ factors. Iterating, the accumulated difference is a polynomial of degree at most $m+n-2$ with coefficients built from integers and powers of $\mathrm{i}\hbar$. Since $\hbar$ carries the SI unit J s and qp carries the same, the correction terms are dimensionally indistinguishable from the leading one, which is why no dimensional argument can select an ordering. □

Definition 25.44 (Weyl and normal ordering)**.** *Weyl ordering* is the rule that symmetrizes: $q^m p^n$ is sent to the average of the $\binom{m+n}{m}$ distinct orderings of m factors $\hat{q}$ and n factors $\hat{p}$. Equivalently, and more usefully, it is fixed by requiring

$$\mathrm{e}^{\mathrm{i}(\alpha q+\beta p)} \longmapsto \mathrm{e}^{\mathrm{i}(\alpha \hat{q}+\beta \hat{p})} \tag{25.47}$$

for all real α of SI unit $1/\mathrm{m}$ and β of unit $\mathrm{s}/(\mathrm{kg\,m})$, and expanding both sides in powers of α and β. *Normal ordering* is the rule that writes the observable in terms of the ladder combinations $\hat{a}, \hat{a}^\dagger$ of Section 78.4.2 and moves every $\hat{a}^\dagger$ to the left of every $\hat{a}$.

Rests on Definition 25.42.

Example 25.45 (Weyl ordering collapses)**.** Weyl ordering of qp^2 is the average of the three arrangements, and it simplifies:

$$\tfrac{1}{3}\left(\hat{q}\hat{p}^2+\hat{p}\hat{q}\hat{p}+\hat{p}^2\hat{q}\right) = \hat{q}\hat{p}^2 - \mathrm{i}\hbar\hat{p} = \tfrac{1}{2}\left\{\hat{q},\hat{p}^2\right\}, \tag{25.48}$$

using $\hat{p}\hat{q} = \hat{q}\hat{p} - \mathrm{i}\hbar$ twice. This is the same operator that Lemma 25.39 obtained by an entirely different route — from the requirement that Equation (25.31) hold on cubics — and the agreement is the content of the statement that the correspondence is exact up to degree three. It stops being true at degree four, where Equations (25.43) and (25.44) disagree and Weyl ordering picks neither: the Weyl image of q^2p^2 is $\hat{q}^2\hat{p}^2 - 2\mathrm{i}\hbar\hat{q}\hat{p} - \tfrac{1}{2}\hbar^2$, which sits halfway between them.

Rests on Definition 25.44 and Lemma 25.39.

Proposition 25.46 (Normal ordering disagrees already at degree two)**.** *For the harmonic oscillator $\mathcal{H} = p^2/2m + \tfrac{1}{2}m\omega^2 q^2$, Weyl ordering gives $\hat{\mathcal{H}}_W = \hbar\omega\left(\hat{a}^\dagger\hat{a} + \tfrac{1}{2}\right)$ and normal ordering gives $\hat{\mathcal{H}}_N = \hbar\omega\,\hat{a}^\dagger\hat{a}$. The two differ by the zero-point energy*

$$\hat{\mathcal{H}}_W - \hat{\mathcal{H}}_N = \frac{\hbar\omega}{2}\,\mathbb{1}\,. \tag{25.49}$$

Normal ordering is therefore not merely a different arrangement of one monomial: it violates Equation (25.31) at degree two, where Lemma 25.39 shows the correspondence still has no freedom.

Rests on Definition 25.44 and Equation (25.40).

Derivation. *Derives Proposition 25.46.*

Write the classical amplitude $\alpha = \sqrt{m\omega/2\hbar}\,(q + \mathrm{i}p/m\omega)$, whose bracket is $\{\alpha, \bar{\alpha}\} = -\mathrm{i}/\hbar$ by direct substitution into Equation (22.41), so that Equation (25.31) gives $\left[\hat{a}, \hat{a}^\dagger\right] = \mathbb{1}$; and $\mathcal{H} = \hbar\omega\,\bar{\alpha}\alpha$ by expanding the square. Weyl ordering of q^2 and p^2 gives $\hat{q}^2$ and $\hat{p}^2$, whose combination is $\tfrac{1}{2}\hbar\omega\left\{\hat{a}^\dagger, \hat{a}\right\} = \hbar\omega\left(\hat{a}^\dagger\hat{a} + \tfrac{1}{2}\right)$; normal ordering of $\bar{\alpha}\alpha$ gives $\hat{a}^\dagger\hat{a}$ by definition. Subtracting gives Equation (25.49).

For the last sentence, express $\hat{q}^2$ in ladder operators: $\hat{q}^2 = (\hbar/2m\omega)\left(\hat{a}^2 + 2\hat{a}^\dagger\hat{a} + \mathbb{1} + \hat{a}^{\dagger 2}\right)$, while normal ordering of the classical q^2 drops the $\mathbb{1}$. So normal ordering sends q^2 to $\hat{q}^2 - \hbar/2m\omega$, contradicting Equation (25.40). The Dirac rule is not toothless below degree four: there it fixes the answer completely, additive constant included. □

Remark 25.47 (Whether the constant is observable). Equation (25.49) is a multiple of the identity, so it cancels from every transition frequency of a single oscillator and no measurement of that oscillator's spectrum alone can decide between the two rules. It is nevertheless decidable, and it has been decided, in two independent ways. Comparing *two* oscillators that share a force constant and differ in reduced mass makes the half-quantum visible as an isotope displacement of the whole vibrational ladder, which is Mulliken's measurement on the band spectrum of boron monoxide [515] and the evidence behind Phenomenon 78.6. And comparing the same field in two geometries makes the sum of the zero-point energies visible as a force, which is the Casimir effect of Section 99.8. Normal ordering survives in field theory not because it is right but because it is convenient (Section 99.2.4); the constant it discards is infinite there, and the honest statement is that only differences of it are ever used.

Proposition 25.48 (Where the ambiguity does and does not bite)**.** *For a Hamiltonian of the standard mechanical form* $\mathcal{H} = |\boldsymbol{p}|^2/2m + V(\boldsymbol{x})$ *with constant* m *there is no ordering ambiguity whatever: no term multiplies a coordinate by a momentum. The ambiguity appears in exactly three circumstances, and only the third is left open by physical requirements:*

1. Minimal coupling to a magnetic field. *The cross term of* $(\hat{\boldsymbol{p}} - e\boldsymbol{A}(\hat{\boldsymbol{x}}))^2$ *is ambiguous, but*
$$[\hat{p}_i, A_i(\hat{\boldsymbol{x}})] = -\mathrm{i}\hbar\, \boldsymbol{\nabla}\cdot\boldsymbol{A}\,, \tag{25.50}$$
so in the Coulomb gauge every ordering agrees, and in any other gauge the orderings differ by a term that a gauge transformation removes. The ambiguity is not physical.

2. Position-dependent mass. *For* $\mathcal{H} = |\boldsymbol{p}|^2/2m(\boldsymbol{x})$ *the orderings* $\hat{p}_i m^{-1}\hat{p}_i$, $\frac{1}{2}\{m^{-1}, \hat{p}_i\hat{p}_i\}$ *and their one-parameter interpolations are all self-adjoint and inequivalent, differing by terms in* $\hbar^2\boldsymbol{\nabla}^2 m^{-1}$*. Requiring that probability be conserved across a step in* m *selects* $\hat{p}_i m^{-1}\hat{p}_i$*; nothing weaker does.*

3. Curved configuration space. *Quantizing on a configuration manifold, the images of the classical kinetic energy differ by a multiple* $\xi\hbar^2 R$ *of the scalar curvature (Definition 13.153). No mathematical requirement fixes* ξ*.*

Rests on Proposition 25.43 and Equation (25.33)*.*

Derivation. *Derives Proposition 25.48.*

The first sentence is immediate: $|\hat{\boldsymbol{p}}|^2$ involves only momenta, which commute among themselves by Equation (25.33), and $V(\hat{\boldsymbol{x}})$ only coordinates, which do likewise.

(1) Equation (25.50) is Equation (25.37) with V replaced by A_i and the index summed. The two candidate cross terms $\hat{\boldsymbol{p}}\cdot\boldsymbol{A}$ and $\boldsymbol{A}\cdot\hat{\boldsymbol{p}}$ therefore differ by $-\mathrm{i}\hbar\,\boldsymbol{\nabla}\cdot\boldsymbol{A}$, which vanishes identically in the Coulomb gauge $\boldsymbol{\nabla}\cdot\boldsymbol{A} = 0$, and in a general gauge is the divergence of a field that a gauge transformation may set to zero without changing $\boldsymbol{B}$.

(2) Each candidate is self-adjoint because it is built as a symmetric product of self-adjoint factors; they differ because $m^{-1}(\hat{\boldsymbol{x}})$ does not commute with $\hat{\boldsymbol{p}}$, and the difference is computed by applying Equation (25.37) twice, each application producing one factor $\mathrm{i}\hbar$ and one derivative of m^{-1}. The selection rule quoted is the statement that $\hat{p}_i m^{-1}\hat{p}_i$ is the only member of the family whose associated probability current is continuous where m jumps; the others lose or create probability at the step, which is not a matter of taste.

(3) is quoted, not derived: the curvature term is what distinguishes the Laplace–Beltrami operator from the other second-order self-adjoint operators with the same symbol, and the coefficient is a free parameter of the quantization. The point of listing it is that it is the case in which nothing in the mathematics decides, and the honest procedure is the one stated next. □

Remark 25.49 (How the ordering is actually fixed). In every case where the choice has physical consequences, it is settled by requiring agreement with something already measured — a spectrum, a scattering cross-section, a transport coefficient — and not by any property of the classical theory. That is Corollary 25.41 delivering exactly what it promised: the classical theory underdetermines the quantum one, so the residue must be measured. It is also the reason the ambiguity is far less troublesome in practice than in principle. The Hamiltonians of atomic, molecular and nuclear physics are overwhelmingly of the form $|\boldsymbol{p}|^2/2m + V$, for which Proposition 25.48 says there is nothing to choose; the ambiguity becomes a live experimental question mainly in effective theories, where a coordinate-dependent mass or a curved configuration space has been produced by eliminating degrees of freedom, and where the eliminated degrees of freedom are what really fix the answer.

25.5.2 Deformation quantization and the Moyal bracket

Definition 25.50 (Star product and Moyal bracket)**.** For phase-space functions of one Cartesian pair (x, p), the *star product* is the formal series

$$u \star v = \sum_{n=0}^{\infty} \frac{1}{n!} \left(\frac{\mathrm{i}\hbar}{2}\right)^n \sum_{k=0}^{n} (-1)^k \binom{n}{k} \left(\partial_x^{n-k} \partial_p^{k} u\right) \left(\partial_x^{k} \partial_p^{n-k} v\right) , \tag{25.51}$$

which is associative and noncommutative and which reproduces operator multiplication on Weyl symbols: if u and v are the symbols of $\hat{u}$ and $\hat{v}$ in the sense of Definition 25.44, then $u \star v$ is the symbol of $\hat{u}\hat{v}$. The *Moyal bracket* is

$$\{u, v\}_{\mathrm{M}} = \frac{1}{\mathrm{i}\hbar} (u \star v - v \star u) = \{u, v\} + \mathcal{O}(\hbar^2) , \tag{25.52}$$

the $n = 0$ terms of Equation (25.51) cancelling in the difference, the $n = 1$ terms giving $\mathrm{i}\hbar\,\{u, v\}$, and every even n cancelling because the nth term is symmetric under $u \leftrightarrow v$ for n even and antisymmetric for n odd. The correction to the Poisson bracket is therefore of order $\hbar^2$, never $\hbar$.

Rests on Definition 25.44 and Equation (22.41).

Remark 25.51 (What deformation quantization says). Equation (25.52) exhibits the quantum bracket as a deformation of the Poisson bracket in the parameter $\hbar$, with the classical bracket as the leading term. Read that way the relation between the theories is inverted from the usual telling: the classical Poisson bracket is the $\hbar \to 0$ limit of an exact quantum structure, rather than the quantum commutator being a modification of a classical one. This is the honest logical order—quantum mechanics is not derived from classical mechanics, and classical mechanics is a limit of it—and it is the order this treatise adopts.

25.5.3 Phase-space quantum mechanics

Definition 25.50 deformed the bracket. Deforming the *state* in the same spirit gives a formulation of quantum mechanics carried out entirely on phase space, with no operators and no Hilbert space in sight: observables are functions of $(\boldsymbol{x}, \boldsymbol{p})$, the state is a function of $(\boldsymbol{x}, \boldsymbol{p})$, and the only thing that distinguishes the theory from classical statistical mechanics is that products are taken with $\star$ instead of pointwise. It is an exact rewriting, not an approximation, and its value here is that it shows precisely which classical intuition survives.

Definition 25.52 (Wigner function)**.** Let $\hat{\rho}$ be the density operator of a system of one particle in three-dimensional space, with position-representation kernel $\rho(\boldsymbol{x}, \boldsymbol{x}') = \langle \boldsymbol{x} | \, \hat{\rho} \, | \boldsymbol{x}' \rangle$. Its *Wigner function* is

$$W(\boldsymbol{x}, \boldsymbol{p}) = \frac{1}{(2\pi\hbar)^3} \int_{\mathbb{R}^3} \rho\!\left(\boldsymbol{x} + \frac{\boldsymbol{y}}{2}, \, \boldsymbol{x} - \frac{\boldsymbol{y}}{2}\right) \mathrm{e}^{-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{y}/\hbar} \, \mathrm{d}^3 y \, . \tag{25.53}$$

It is the Weyl symbol of $\hat{\rho}$ divided by $(2\pi\hbar)^3$, and carries the SI unit $1/(\mathrm{J}^3\,\mathrm{s}^3)$, the reciprocal of an action cubed, so that $W\,\mathrm{d}^3x\,\mathrm{d}^3p$ is dimensionless.

Rests on Definitions 17.29 and 25.44.

Theorem 25.53 (Properties of the Wigner function)**.** *For any density operator, W is real-valued and normalized, $\int W\,\mathrm{d}^3x\,\mathrm{d}^3p = 1$, and*

$$\int W(\boldsymbol{x},\boldsymbol{p})\,\mathrm{d}^3p = \rho(\boldsymbol{x},\boldsymbol{x})\,, \tag{25.54}$$

$$\int W(\boldsymbol{x},\boldsymbol{p})\,\mathrm{d}^3x = \tilde{\rho}(\boldsymbol{p},\boldsymbol{p})\,, \tag{25.55}$$

the two marginals being exactly the measured position and momentum distributions, $\tilde{\rho}$ denoting the kernel in the momentum representation. For any two states,

$$\operatorname{tr}(\hat{\rho}_1\hat{\rho}_2) = (2\pi\hbar)^3 \int W_1\,W_2\,\mathrm{d}^3x\,\mathrm{d}^3p\,, \tag{25.56}$$

and for a pure state $\hat{\rho} = |\psi\rangle\langle\psi|$,

$$|W(\boldsymbol{x},\boldsymbol{p})| \le \frac{1}{(\pi\hbar)^3} = 2.75\times10^{100}/(\mathrm{J}^3\,\mathrm{s}^3)\,. \tag{25.57}$$

Rests on Equation (25.53), Theorem 17.32, and Proposition 12.4.

Derivation. *Derives Theorem 25.53.*

Reality. Conjugating Equation (25.53) and substituting $\boldsymbol{y}\to-\boldsymbol{y}$ turns the kernel into $\rho(\boldsymbol{x}-\boldsymbol{y}/2,\boldsymbol{x}+\boldsymbol{y}/2)^*$, which is $\rho(\boldsymbol{x}+\boldsymbol{y}/2,\boldsymbol{x}-\boldsymbol{y}/2)$ because $\hat{\rho}$ is self-adjoint, and restores the exponential; so $W^* = W$.

Position marginal. Integrating Equation (25.53) over $\boldsymbol{p}$ and using $\int \mathrm{e}^{-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{y}/\hbar}\mathrm{d}^3p = (2\pi\hbar)^3\delta^3(\boldsymbol{y})$, which is the Fourier inversion formula of Section 17.2.1 read as an identity between tempered distributions (Definition 17.38), the delta collapses the $\boldsymbol{y}$ integral at $\boldsymbol{y}=0$ and leaves $\rho(\boldsymbol{x},\boldsymbol{x})$. This is Equation (25.54), and integrating it once more over $\boldsymbol{x}$ gives $\operatorname{tr}\hat{\rho} = 1$, the normalization.

Momentum marginal. Integrate over $\boldsymbol{x}$ and change variables to $\boldsymbol{u} = \boldsymbol{x}+\boldsymbol{y}/2$, $\boldsymbol{v} = \boldsymbol{x}-\boldsymbol{y}/2$, whose Jacobian has modulus 1 in each Cartesian pair. Then $\boldsymbol{y} = \boldsymbol{u}-\boldsymbol{v}$ and

$$\int W\,\mathrm{d}^3x = \frac{1}{(2\pi\hbar)^3}\iint \rho(\boldsymbol{u},\boldsymbol{v})\,\mathrm{e}^{-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{u}/\hbar}\mathrm{e}^{+\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{v}/\hbar}\,\mathrm{d}^3u\,\mathrm{d}^3v = \tilde{\rho}(\boldsymbol{p},\boldsymbol{p})\,,$$

the double integral being exactly the momentum-representation kernel at coincident arguments, in the convention that carries one factor $(2\pi\hbar)^{-1/2}$ per coordinate. For a pure state this is $\left|\tilde{\psi}(\boldsymbol{p})\right|^2$.

Overlap. Take the product of two Wigner functions with integration variables $\boldsymbol{y}$ and $\boldsymbol{y}'$ and integrate over $\boldsymbol{p}$ first; the same delta identity forces $\boldsymbol{y}' = -\boldsymbol{y}$ and removes one factor $(2\pi\hbar)^{-3}$, leaving

$$\int W_1W_2\,\mathrm{d}^3p = \frac{1}{(2\pi\hbar)^3}\int \rho_1\big(\boldsymbol{x}+\tfrac{\boldsymbol{y}}{2},\boldsymbol{x}-\tfrac{\boldsymbol{y}}{2}\big)\,\rho_2\big(\boldsymbol{x}-\tfrac{\boldsymbol{y}}{2},\boldsymbol{x}+\tfrac{\boldsymbol{y}}{2}\big)\,\mathrm{d}^3y\,.$$

Integrating over $\boldsymbol{x}$ and changing to $(\boldsymbol{u},\boldsymbol{v})$ as before turns this into $(2\pi\hbar)^{-3}\iint \rho_1(\boldsymbol{u},\boldsymbol{v})\rho_2(\boldsymbol{v},\boldsymbol{u})\,\mathrm{d}^3u\,\mathrm{d}^3v$, which is $(2\pi\hbar)^{-3}\operatorname{tr}(\hat{\rho}_1\hat{\rho}_2)$. This is Equation (25.56).

Bound. For a pure state the integrand of Equation (25.53) is $\psi(\boldsymbol{x}+\boldsymbol{y}/2)\psi^*(\boldsymbol{x}-\boldsymbol{y}/2)$; bounding the modulus of the integral by the integral of the modulus and applying Cauchy–Schwarz (Proposition 12.4),

$$|W| \le \frac{1}{(2\pi\hbar)^3}\left(\int\left|\psi(\boldsymbol{x}+\tfrac{\boldsymbol{y}}{2})\right|^2\mathrm{d}^3y\right)^{1/2}\left(\int\left|\psi(\boldsymbol{x}-\tfrac{\boldsymbol{y}}{2})\right|^2\mathrm{d}^3y\right)^{1/2} = \frac{8}{(2\pi\hbar)^3}\,,$$

each integral contributing $8 = 2^3$ from the substitution $\boldsymbol{u} = \boldsymbol{x}\pm\boldsymbol{y}/2$ and the normalization of ψ. That is Equation (25.57). □

Corollary 25.54 (Negativity is unavoidable)**.** *Let ψ be any normalized wavefunction that is odd, $\psi(-\boldsymbol{x}) = -\psi(\boldsymbol{x})$. Then its Wigner function attains at the phase-space origin the most negative value the bound Equation (25.57) permits:*

$$W(\mathbf{0},\mathbf{0}) = -\frac{1}{(\pi\hbar)^3}\,. \tag{25.58}$$

No function on phase space that takes negative values is a probability density, so W is a quasi-*probability, and the failure is not a defect of the construction: Equations (25.54) and (25.55) show that its marginals are genuine, measured distributions.*

Rests on Equations (25.53) and (25.57).

Derivation. *Derives Corollary 25.54.*

Put $\boldsymbol{x} = \mathbf{0}$ and $\boldsymbol{p} = \mathbf{0}$ in Equation (25.53) with $\rho = \psi\psi^*$. The exponential is 1 and the integrand is $\psi(\boldsymbol{y}/2)\psi^*(-\boldsymbol{y}/2) = -\,|\psi(\boldsymbol{y}/2)|^2$ by oddness, so

$$W(\mathbf{0},\mathbf{0}) = -\frac{1}{(2\pi\hbar)^3}\int |\psi(\boldsymbol{y}/2)|^2\,\mathrm{d}^3y = -\frac{8}{(2\pi\hbar)^3} = -\frac{1}{(\pi\hbar)^3}\,,$$

the factor 8 coming from $\mathrm{d}^3y = 8\,\mathrm{d}^3u$ under $\boldsymbol{u} = \boldsymbol{y}/2$. Odd normalized wavefunctions exist in abundance — the first excited state of the harmonic oscillator (Section 78.4) is one — so the value Equation (25.58) is attained by real states and not only permitted. □

Theorem 25.55 (Hudson: which pure states escape)**.** *A pure state has a Wigner function that is non-negative everywhere if and only if its wavefunction is Gaussian, that is of the form $\psi(\boldsymbol{x}) = \exp\left(-\boldsymbol{x}^{\mathsf{T}}A\boldsymbol{x} + \boldsymbol{b}\cdot\boldsymbol{x} + c\right)$ with A a complex symmetric matrix of positive-definite real part. Negativity of W is therefore an exact witness of departure from the Gaussian family, for pure states.*

Rests on Equation (25.53) and Corollary 25.54.

Full derivation: Appendix A.50 (p. 3060).

Derives Theorem 25.55.

Remark 25.56 (What the appendix proof imports, and what the theorem does not say)*.* The easy direction of Theorem 25.55 is a Gaussian integral: the Wigner transform of a Gaussian is a Gaussian, hence positive. The converse is the substantial half, and the appendix proof reduces it to one imported theorem — the Hadamard factorization of an entire function of order at most two, applied to the analytic continuation of ψ. Chapter 8 carries Liouville's theorem and the Cauchy estimates but no theory of the order and genus of an entire function, so that input is quoted there with its place named; the debt is Part II's and is recorded as such.

Two limits of the statement matter for how it is used. It is a theorem about *pure* states: there are mixed states whose Wigner function is non-negative everywhere and which are not mixtures of Gaussians, so "non-negative Wigner function" and "classical" are not synonyms in general, and Corollary 25.54 is a witness only within the pure family. And the 1974 paper in which Hudson proved it has no entry in this bibliography: the attribution above is reported without a source the reader of this book can check, and the appendix supplies the proof precisely so that nothing rests on the attribution.

Theorem 25.57 (The Moyal equation, and its classical limit)**.** *The Wigner function of a state evolving under $\hat{\mathcal{H}} = \hat{p}^2/2m + V(\hat{x})$, in one Cartesian pair, obeys*

$$\frac{\partial W}{\partial t} = -\frac{p}{m}\frac{\partial W}{\partial x} + \frac{\partial V}{\partial x}\frac{\partial W}{\partial p} - \frac{\hbar^2}{24}\frac{\partial^3 V}{\partial x^3}\frac{\partial^3 W}{\partial p^3} + \mathcal{O}(\hbar^4)\,, \tag{25.59}$$

whose first two terms are the classical Liouville equation Equation (24.15). If V is a polynomial of degree at most two, every correction vanishes identically and the Wigner function obeys the classical equation exactly*, for every state.*

Rests on Equations (25.51) and (25.53) and Theorem 24.21.

Derivation. *Derives Theorem 25.57.*

The von Neumann equation $\mathrm{i}\hbar\,\partial_t\hat\rho = \left[\hat{\mathcal{H}},\hat\rho\right]$ becomes, on Weyl symbols, $\partial_t W = \{\mathcal{H},W\}_{\mathrm{M}}$ by Definition 25.50. Evaluate the two pieces of $\mathcal{H}$ separately in Equation (25.51).

For the kinetic term $u = p^2/2m$, every x derivative of u vanishes, so only $k = n$ survives in $u \star W$ and only $k = 0$ in $W \star u$:

$$u\star W - W\star u = \sum_n \frac{1}{n!}\left(\frac{\mathrm{i}\hbar}{2}\right)^n \left[(-1)^n - 1\right]\left(\partial_p^n u\right)\left(\partial_x^n W\right) .$$

Even n cancel; odd n beyond 1 vanish because $\partial_p^3 u = 0$; and $n = 1$ leaves $-\mathrm{i}\hbar\,(p/m)\,\partial_x W$, giving the first term of Equation (25.59) after dividing by $\mathrm{i}\hbar$. The kinetic term is exact — it contributes no $\hbar$ correction at all.

For the potential $u = V(x)$, every p derivative vanishes, so the surviving index is the other one and the sign is reversed:

$$\frac{1}{\mathrm{i}\hbar}\left(V\star W - W\star V\right) = \frac{2}{\mathrm{i}\hbar}\sum_{n\ \text{odd}}\frac{1}{n!}\left(\frac{\mathrm{i}\hbar}{2}\right)^n \left(\partial_x^n V\right)\left(\partial_p^n W\right) .$$

The term $n = 1$ is $(\partial_x V)\,(\partial_p W)$, the classical force term. The term $n = 3$ is $\frac{2}{\mathrm{i}\hbar}\cdot\frac{1}{6}\left(\frac{\mathrm{i}\hbar}{2}\right)^3 \partial_x^3 V\,\partial_p^3 W = -\frac{\hbar^2}{24}\partial_x^3 V\,\partial_p^3 W$, and the next is $O(\hbar^4)$. This is Equation (25.59). If V has degree at most two then $\partial_x^3 V = 0$ and every surviving term of the series beyond $n = 1$ vanishes with it. □

Remark 25.58 (The same statement, three times). That quadratic potentials are the exactly classical case has now appeared three times in this chapter, and it is one fact each time. Theorem 25.32 said the expectation values follow the classical equations when V is at most quadratic; Lemma 25.39 said the correspondence Equation (25.31) is exact on polynomials of degree at most two; Theorem 25.57 says the phase-space density obeys the classical Liouville equation for such a potential. Degree two is where the Poisson algebra and the commutator algebra are isomorphic, and every statement of classicality traces back to that. It is also why the harmonic oscillator, the workhorse of every quantum textbook, is constitutionally unable to display any of the phenomena of this section.

Measuring a Wigner function

The formalism above would be a rewriting and nothing more if W were not accessible. It is, and the route is the Radon transform of Section 17.6.3.

Proposition 25.59 (Homodyne tomography inverts a Radon transform)**.** *Let a mode of frequency ω be described in the dimensionless quadratures*

$$X = x\sqrt{\frac{m\omega}{\hbar}}, \qquad P = \frac{p}{\sqrt{m\omega\hbar}}, \qquad \mathcal{H} = \frac{\hbar\omega}{2}\left(X^2 + P^2\right), \tag{25.60}$$

and let pr_θ be the measured distribution of the rotated quadrature $X_\theta = X\cos\theta + P\sin\theta$. Then

$$\mathrm{pr}_\theta(X_\theta) = (\mathcal{R}W)\left(\boldsymbol{n}(\theta), X_\theta\right), \qquad \boldsymbol{n}(\theta) = (\cos\theta, \sin\theta), \tag{25.61}$$

the Radon transform Equation (17.119) of W over the plane spanned by the two quadratures. The Wigner function is recovered from the family $\{\mathrm{pr}_\theta\}$, $0 \le \theta < \pi$, by filtered back-projection Equation (17.122).

Rests on Theorems 17.106 and 25.57 and Definition 17.103.

Derivation. *Derives Proposition 25.59.*

By Equation (25.54), the distribution of the quadrature X is the integral of W over the conjugate variable P — that is, the integral of W along the line $X = \text{const}$ in the (X, P) plane.

It remains to show that the same holds for every rotated quadrature. The Hamiltonian Equation (25.60) is quadratic, so by Theorem 25.57 the Wigner function evolves under it *exactly* by the classical Liouville flow; and the classical flow of $\mathcal{H} = \frac{1}{2}\hbar\omega(X^2 + P^2)$ in these coordinates is the rigid rotation $(X, P) \mapsto (X\cos\omega t + P\sin\omega t,\ -X\sin\omega t + P\cos\omega t)$, as substitution into Equations (22.3) and (22.4) confirms. So the Wigner function of the state at time $t = \theta/\omega$ is W rotated by θ, its X marginal is the integral of W along the line $X\cos\theta + P\sin\theta = \text{const}$, and that line integral is Equation (17.119) in two dimensions — which is Equation (25.61). In an optical realization the phase θ is set not by waiting but by the phase of a local oscillator, which is the same rotation performed at the detector rather than in the state.

Inverting is then Theorem 17.106 verbatim, with the projections P_θ of Equation (17.122) identified with pr_θ, and Corollary 17.107 says how many phases must be sampled to resolve structure of a given fineness. Nothing in the inversion is special to quantum mechanics: it is the arithmetic of a medical tomograph, applied to a quasi-probability instead of an attenuation coefficient. □

Remark 25.60 (What has been measured). Wigner functions with negative regions have been reconstructed by exactly this procedure. A single-photon state of a light mode is the first excited state of the oscillator Equation (25.60) and so is odd, which by Corollary 25.54 predicts $W(0,0) = -1/\pi\hbar$ in one degree of freedom: the deepest negative value the theory permits. Lvovsky and co-workers reconstructed it by balanced homodyne tomography and found the dip at the origin [2017]; the measured depth is smaller in magnitude than the ideal value, because detection efficiency below unity mixes vacuum into the state and a mixture of a Fock state with vacuum has a shallower dip. Deléglise and co-workers reconstructed the Wigner functions of photon number states and of superpositions of coherent states in a microwave cavity, and watched the negative regions disappear as the field decohered [2121] — which is Remark 25.33 seen directly, the environment turning a quasi-probability into a probability. The apparatus, the calibration and the error budget of these measurements belong with Chapter 122; what belongs here is that the object defined by Equation (25.53) is not a formal device.

Remark 25.61 (What phase-space quantum mechanics settles). The formulation answers, in the sharpest available way, the question this chapter began with. Quantum mechanics *can* be written on the very same phase space as classical mechanics, with the very same observables, and the entire difference is that the pointwise product is replaced by Equation (25.51). The classical limit is then not a change of arena but the vanishing of the $\hbar$-corrections in one product. What is lost in the passage is exactly what Remark 25.5 predicted at the start: the commutative product does not survive, and everything non-classical — the negativity of Corollary 25.54, the $\hbar^2$ term of Equation (25.59), the obstruction of Theorem 25.38 — is a consequence of that one replacement.

25.6 What carries over to field theory

The bracket. For a field theory the phase-space coordinates are a field $\varphi(\boldsymbol{x})$ and its conjugate momentum density $\pi(\boldsymbol{x})$ at each point of space, and the bracket acquires a functional derivative and a delta function, $\{\varphi(\boldsymbol{x}), \pi(\boldsymbol{y})\} = \delta^3(\boldsymbol{x} - \boldsymbol{y})$. The construction and its equal-time commutator counterpart are the subject of Chapters 64 and 99.

The first-order action. Equation (25.20) becomes $\int \mathrm{d}t \int \mathrm{d}^3x\,(\pi\dot{\varphi} - \mathcal{H})$, and it is this form, not the Lagrangian one, that the phase-space path integral of Chapter 106 discretizes. The Faddeev–Jackiw reading Equation (25.22) carries over with ξ^c replaced by the field components at each point of space, and the matrix inversion of Equation (25.25) by the inversion of an operator; where that operator is degenerate the theory is a gauge theory, which is the field-theoretic face of Remark 25.23.

The phase-space formulation. Equation (25.53) generalizes to a functional Wigner distribution, and the truncation of Equation (25.59) at its classical term is what a Boltzmann-equation treatment of a quantum field assumes; the $\hbar^2$ term is the leading quantum correction to it.

The obstruction, again. Theorem 25.38 has a field counterpart, and the ordering ambiguity there is one of the sources of the divergences that renormalization organizes (Chapter 100).

The failure of Stone–von Neumann. Inequivalent representations are the normal situation, per Remark 25.37.

Constraints. Gauge theories have degenerate Lagrangians, their naive brackets do not exist, and the whole apparatus above must be rebuilt on the constraint surface. That is the next chapter.

Chapter 26

Constrained Hamiltonian Systems: the Dirac–Bergmann Formalism

Every construction of Chapter 22 rests on one step: that the definition $p_a = \partial\mathcal{L}/\partial\dot{q}^a$ can be solved for the velocities. When it cannot, the Legendre transformation of Definition 22.2 is not invertible, the momenta are not independent functions on phase space, and the Hamiltonian formalism as stated does not exist. Proposition 22.3 named the condition and Remark 22.4 named the failure; this chapter is what happens next.

This is not a rare degeneracy to be noted and set aside. It is the generic situation for every theory with a gauge symmetry, and therefore for electromagnetism, for the whole Standard Model, and for general relativity. The reason is structural and is worth stating before any formalism: a gauge symmetry means that distinct sets of variables describe the same physical state, so the equations of motion cannot determine the evolution of all the variables—some of them must remain arbitrary—and a Legendre transformation that produced a well-posed evolution for all of them would be a contradiction. Degeneracy of the Lagrangian is the mechanical signature of redundancy in the description.

Dirac's constraint formalism, developed with Bergmann in the years around 1950, is the systematic treatment. It sorts the constraints into those that generate gauge transformations and those that merely restrict phase space, replaces the Poisson bracket by a modified bracket on the physical surface, counts the true degrees of freedom, and hands the result to the quantization rule of Section 25.4. It is stated here, in the classical part, because it is classical mechanics; Parts VII and XI use it rather than redevelop it.

Notation 26.1 (Weak and strong equality). Indices $a, b = 1, \dots, n$ label the configuration variables and $c, d = 1, \dots, 2n$ the phase-space variables, as in Notation 22.1. Constraints are written ϕ_m for primary constraints, χ_α for second-class constraints, γ_A for first-class constraints, and φ_j for the full set. The symbol $\approx$ denotes *weak equality*: $F \approx G$ means that F and G agree on the surface defined by the constraints, but not necessarily off it. The distinction is essential and is not pedantry — a weak equality may not be used inside a Poisson bracket, because the bracket differentiates in directions leaving the surface. Ordinary equality $=$ is called *strong* when the contrast is being drawn.

Rests on Notation 22.1 and Definition 22.29.

Remark 26.2 (The primary literature of this chapter is not yet in the bibliography). The formalism below is due to Dirac and to Bergmann and his collaborators, in papers of 1949–1951 and in Dirac's 1964 lecture notes; the modern standard reference is the monograph of Henneaux and Teitelboim. None of these works currently has an entry in this treatise's bibliography, so the attributions made in the prose of this chapter are, exceptionally, *uncited*. They are recorded in the source file as a citation debt. Every statement below is proved here or carries an explicit pending note, so nothing in the chapter rests on an unchecked appeal to those sources; what is missing is the historical credit, not the evidence.

26.1 Singular Lagrangians and primary constraints

Definition 26.3 (Singular Lagrangian)**.** A Lagrangian $\mathcal{L}(q,\dot q,t)$ is *singular*, or *degenerate*, if its Hessian with respect to the velocities

$$W_{ab}=\frac{\partial^2\mathcal{L}}{\partial\dot q^a\,\partial\dot q^b} \tag{26.1}$$

is not invertible. If $\operatorname{rank}W=R<n$, the Lagrangian is singular with $M=n-R$ degrees of degeneracy.

Rests on Equation (22.2) *and Proposition 22.3.*

Everything below assumes that $\operatorname{rank}W$ is *constant* on the region of TQ under study. This is an assumption about the system, not a triviality: the rank can drop on a lower-dimensional set, and where it does the constraint structure changes and the analysis must be redone patch by patch. All the systems worked in Section 26.6 have constant rank on the region of interest.

Remark 26.4 (The constant-rank theorem is owed by Part II). The proof of Proposition 26.5 needs the following statement, which belongs to multivariable analysis and to the manifolds chapter (Chapters 7 and 13) and is at present in neither. *Constant-rank theorem.* Let $f:U\subseteq\mathbb{R}^N\longrightarrow\mathbb{R}^{N'}$ be C^k, $k\geq1$, with $\operatorname{rank}Df=r$ at every point of U. Then about each point of U and its image there are C^k coordinate changes in which f reads $(u^1,\dots,u^N)\longmapsto(u^1,\dots,u^r,0,\dots,0)$. Consequently $f(U)$ is locally an r-dimensional embedded submanifold of $\mathbb{R}^{N'}$ (Definition 13.54), cut out near each of its points by $N'-r$ functions with linearly independent differentials. Theorem 13.59 is the codimension-one, maximal-rank special case of the last sentence, and Theorem A.286 is the analytic input from which the theorem is proved. The statement is used here and nowhere restated.

Proposition 26.5 (Primary constraints)**.** *If $\mathcal{L}$ is singular with $\operatorname{rank}W=R$ constant, the Legendre map $(q,\dot q)\mapsto(q,p)$ has image of dimension $n+R$, so the momenta satisfy $M=n-R$ independent relations*

$$\phi_m(q,p)\approx0\,,\qquad m=1,\dots,M\,, \tag{26.2}$$

identically in the velocities. These are the primary constraints*; they follow from the definition of the momenta alone, before any equation of motion is used.*

Rests on Definition 26.3 and Remark 26.4.

Proof. *Derives Proposition 26.5.*

Write the Legendre map as $\mathcal{F}:(q^a,\dot q^a)\longmapsto(q^a,\,\partial\mathcal{L}/\partial\dot q^a)$, a map between spaces of dimension $2n$. In the block ordering $(q,\dot q)$ its Jacobian is

$$D\mathcal{F}=\begin{pmatrix}\mathbb{1}_n & 0\\ \dfrac{\partial^2\mathcal{L}}{\partial q^b\,\partial\dot q^a} & W_{ab}\end{pmatrix}. \tag{26.3}$$

The first block column is already independent, and adding it to the second changes no rank, so $\operatorname{rank}D\mathcal{F}=n+\operatorname{rank}W=n+R$, constant by hypothesis. By the constant-rank theorem of Remark 26.4 the image is locally an embedded submanifold of the $2n$-dimensional space of the (q,p), of dimension $n+R$, and is cut out near each of its points by $2n-(n+R)=n-R=M$ functions with independent differentials. Those functions are the ϕ_m, and since the image is by construction the set of values the momenta actually take, $\phi_m\,(q,\partial\mathcal{L}/\partial\dot q)$ vanishes for *every* $(q,\dot q)$: the relations Equation (26.2) hold identically in the velocities, which is what distinguishes them from equations of motion. The q are untouched by the map, so no relation involves the coordinates alone. □

Proposition 26.6 (The canonical Hamiltonian is defined on the constraint surface)**.** *The function*

$$\mathcal{H}_c = p_a \dot{q}^a - \mathcal{L} \tag{26.4}$$

depends on the velocities only through the combinations that the momenta determine: it is a well-defined function of (q, p) on the primary constraint surface, and is ambiguous off it by terms proportional to the primary constraints.

Rests on Proposition 26.5 and Equation (26.4).

Proof. *Derives Proposition 26.6.*

Vary the right-hand side of Equation (26.4) with respect to the velocities at fixed q and fixed p:

$$\delta\mathcal{H}_{\mathrm{c}} = p_a\, \delta\dot{q}^a - \frac{\partial \mathcal{L}}{\partial \dot{q}^a}\, \delta\dot{q}^a = \left(p_a - \frac{\partial \mathcal{L}}{\partial \dot{q}^a} \right) \delta\dot{q}^a = 0\,, \tag{26.5}$$

the last step because $p_a = \partial\mathcal{L}/\partial\dot{q}^a$ is exactly the condition defining the point at which the variation is taken. So $\mathcal{H}_{\mathrm{c}}$ is constant along each fibre of the Legendre map, that is, along each set of velocities carried to the same momentum, and therefore descends to a function on the image — the primary constraint surface of Proposition 26.5. Off that surface it is not defined at all; any extension will do. Two extensions differ by a function vanishing on the surface, hence, by the regularity assumption of Remark 26.7, by a combination $c^m(q,p)\phi_m$. That ambiguity is not a defect to be removed but the origin of the undetermined multipliers in Definition 26.8. □

Remark 26.7 (The regularity assumption, stated once)*.* Throughout this chapter the constraint functions are assumed *regular*: at every point of the surface Σ they cut out, their differentials are linearly independent, and every smooth function vanishing on Σ is a combination $c^j(q,p)\varphi_j$ with smooth coefficients. The first half is what makes Σ a submanifold; the second is what lets "$F \approx 0$" be traded for "$F = c^j\varphi_j$", which is used in almost every proof below. A constraint set that fails regularity — $\phi = q^2$ rather than $\phi = q$ is the standard toy — must be replaced by an equivalent regular one before the formalism applies. This is an assumption about the system, and it is not free: it is exactly what fails at the points where $\operatorname{rank} W$ drops.

Definition 26.8 (Total Hamiltonian)**.** The *total Hamiltonian* is

$$\mathcal{H}_{\mathrm{T}} = \mathcal{H}_{\mathrm{c}} + u^m \phi_m\,, \tag{26.6}$$

with u^m undetermined multipliers. The evolution of any phase-space function is

$$\dot{F} \approx \{F, \mathcal{H}_{\mathrm{T}}\} = \{F, \mathcal{H}_{\mathrm{c}}\} + u^m \{F, \phi_m\}\,. \tag{26.7}$$

Rests on Proposition 26.6 and Definition 22.29.

26.2 The Dirac–Bergmann consistency algorithm

The constraints must be preserved by the motion: a system that starts on the constraint surface must stay on it.

Definition 26.9 (Consistency conditions)**.** The *consistency conditions* are

$$\dot{\phi}_m = \{\phi_m, \mathcal{H}_{\mathrm{c}}\} + u^n \{\phi_m, \phi_n\} \approx 0\,, \qquad m = 1, \dots, M\,. \tag{26.8}$$

Rests on Equations (26.2) and (26.7).

Proposition 26.10 (The four outcomes)**.** *Each condition Equation (26.8) does exactly one of four things:*

1. *it is satisfied identically on the constraint surface, and says nothing;*

2. *it reduces to a relation among the q and p alone, independent of the multipliers—a new,* secondary *constraint;*

3. *it determines some of the multipliers u^m; or*

4. *it is inconsistent, in which case the Lagrangian describes no motion at all.*

The procedure is then repeated on any new constraint, generating tertiary constraints and so on, until no new condition arises.

Rests on Definition 26.9 and Remark 26.7.

Proof. *Derives Proposition 26.10.*

Abbreviate $h_m := \{\phi_m, \mathcal{H}_c\}$ and $C_{mn} := \{\phi_m, \phi_n\}$, both evaluated on the primary constraint surface. Equation (26.8) is then the linear system

$$C_{mn}\, u^n \approx -h_m \,, \tag{26.9}$$

in the M unknowns u^n, with an antisymmetric coefficient matrix. Let $r = \operatorname{rank} C$ on the surface and let $\left\{V_m^{(k)}\right\}$, $k = 1, \dots, M - r$, be a basis of the null vectors of C, so that $V_m^{(k)} C_{mn} \approx 0$.

Decompose Equation (26.9) accordingly. Along the row space of C — r independent combinations — the system is solvable for r combinations of the multipliers, and this is outcome 3; the remaining $M - r$ combinations of the u^n are left arbitrary, which is the point taken up in Theorem 26.14. Contracting Equation (26.9) with a null vector annihilates every multiplier and leaves

$$V_m^{(k)}\, h_m = \left\{ V_m^{(k)} \phi_m, \mathcal{H}_c \right\} \approx 0 \,, \tag{26.10}$$

a condition on the phase-space point alone. There are three possibilities for it, and no others. If the left-hand side vanishes on the surface already, the condition is empty: outcome 1. If it is a function that does not vanish there, it is a new restriction on (q, p) — a secondary constraint: outcome 2. If it reduces to a nonzero constant, no phase-space point satisfies it and the theory has no solutions: outcome 4. The exhaustion is complete because Equation (26.9) is a linear system and every linear system either determines an unknown, or produces a compatibility condition, or is empty.

Repeating the argument with the enlarged constraint set gives the recursion. Note that Equation (26.10) identifies the generator of any new constraint as the bracket of a first-class *primary* combination $V_m^{(k)} \phi_m$ with the canonical Hamiltonian, which is how the algorithm is run in practice. □

Definition 26.11 (The final constraint set)**.** The algorithm terminates on a finite-dimensional phase space, since each round either adds an independent constraint—and there are at most $2n$ of them—or ends. Its output is the full set

$$\varphi_j \approx 0 \,, \qquad j = 1, \dots, J \,, \tag{26.11}$$

comprising the primary constraints and all those generated from them, and the surface $\Sigma \subset M$ they define is the *constraint surface*. The distinction primary/secondary refers to how a constraint was found and has no further significance; the classification that matters is the next one.

Rests on Proposition 26.10 and Remark 26.7.

26.3 First- and second-class constraints

Definition 26.12 (First and second class)**.** A phase-space function F is *first class* if

$$\{F, \varphi_j\} \approx 0 \qquad \text{for every } j\,, \tag{26.12}$$

and *second class* otherwise. The classification applies in particular to the constraints themselves. A *complete separation* of the constraint set is a choice of basis $\{\gamma_A, \chi_\alpha\}$ for it in which the γ_A are a maximal set of independent first-class combinations and the χ_α are the rest, so that no nonzero combination of the χ_α alone is first class.

Rests on Definitions 22.29 and 26.11.

Proposition 26.13 (The first-class functions close)**.** *The Poisson bracket of two first-class functions is first class. The first-class constraints therefore form a Lie algebra under the bracket, weakly; its structure functions need not be constants.*

Rests on Definition 26.12, Equation (22.46), and Remark 26.7.

Proof. *Derives Proposition 26.13.*

Let F and G be first class. By Equation (26.12) and the regularity assumption of Remark 26.7 there are smooth functions with

$$\{F, \varphi_j\} = f_j{}^k \varphi_k\,, \qquad \{G, \varphi_j\} = g_j{}^k \varphi_k\,. \tag{26.13}$$

The Jacobi identity Equation (22.46), rearranged, gives

$$\{\{F, G\}, \varphi_j\} = \{F, \{G, \varphi_j\}\} - \{G, \{F, \varphi_j\}\}\,. \tag{26.14}$$

Insert Equation (26.13) and expand each bracket by the Leibniz rule:

$$\{\{F, G\}, \varphi_j\} = \left\{F, g_j{}^k\right\} \varphi_k + g_j{}^k \{F, \varphi_k\} - \left\{G, f_j{}^k\right\} \varphi_k - f_j{}^k \{G, \varphi_k\}\,. \tag{26.15}$$

Every term on the right carries either an explicit φ_k or a bracket that vanishes weakly by hypothesis, so the whole expression is weakly zero. Hence $\{F, G\}$ is first class.

Applied to the first-class constraints themselves this says $\{\gamma_A, \gamma_B\} \approx 0$, so again by regularity

$$\{\gamma_A, \gamma_B\} = f_{AB}{}^C \gamma_C\,, \tag{26.16}$$

which is closure. The coefficients $f_{AB}{}^C$ are functions on phase space in general; whether they are constants is a property of the particular theory, and Sections 26.6.4 and 26.6.5 are the two cases that matter — constants for Yang–Mills, genuine functions for gravity. Where they are constants, Equation (26.16) is a Lie algebra in the sense of Theorem 25.3; where they are not, it is not, and the difference is not cosmetic. □

Theorem 26.14 (First-class constraints generate gauge transformations)**.** *Let $\gamma_k = V_m^{(k)} \phi_m$ be the first-class* primary *constraints, $V^{(k)}$ the null vectors of Proposition 26.10. Then two solutions of the equations of motion with the same initial data at time t differ at $t + \delta t$ by*

$$\delta_\varepsilon F = \varepsilon^k \{F, \gamma_k\}\,, \tag{26.17}$$

with ε^k arbitrary. The two therefore describe the same physical history, and the variables they differ in carry no physical information.

Rests on Proposition 26.10 and Definition 26.8.

Proof. *Derives Theorem 26.14.*

By Proposition 26.10 the consistency conditions fix the multipliers only up to the null space of C_{mn}: the general solution of Equation (26.9) is

$$u^m = U^m + v^k V_m^{(k)}\,, \tag{26.18}$$

with U^m any particular solution and the v^k arbitrary functions of time. Evolve the same initial point $z(t)$ through δt with two admissible choices u and u'. Both results solve the equations of motion, and by Equation (26.7) they differ by

$$\delta F = \delta t \left(u^m - u'^m\right) \{F, \phi_m\} = \delta t \left(v^k - v'^k\right) V_m^{(k)} \{F, \phi_m\} = \varepsilon^k \{F, \gamma_k\} \,, \tag{26.19}$$

writing $\varepsilon^k := \delta t \left(v^k - v'^k\right)$, which is arbitrary, and using that the $V^{(k)}$ are functions of (q, p) so that $V_m^{(k)} \{F, \phi_m\} = \left\{F, V_m^{(k)} \phi_m\right\}$ weakly. That $\gamma_k = V_m^{(k)} \phi_m$ is first class is Equation (26.10) together with $V_m^{(k)} C_{mn} \approx 0$: its bracket with every primary constraint vanishes weakly by the second, and with the canonical Hamiltonian by the first.

Two evolutions of one initial state cannot be two physical histories, on pain of the theory predicting nothing. So the difference Equation (26.19) is unphysical, and any two phase-space points related by Equation (26.17) describe the same state. □

Remark 26.15 (Dirac's conjecture, and why the theorem stops where it does). Theorem 26.14 is proved for the first-class *primary* constraints, because those are the ones whose multipliers the algorithm demonstrably leaves free. Dirac conjectured that *all* first-class constraints, secondary ones included, generate gauge transformations. The conjecture is true for every system in Section 26.6, and it is what justifies Definition 26.16; the general construction assembles the gauge generator as a chain $G = \varepsilon\gamma + \dot{\varepsilon}\gamma' + \cdots$ built from constraints of successive generations, of which Equation (26.61) below is the worked instance. It is nonetheless *false* in general: counterexamples exist in which a secondary first-class constraint generates no symmetry of the action, and they are not pathological beyond failing the regularity of Remark 26.7 at a point. This treatise does not yet carry a citable reference for either the general construction or the counterexample (Remark 26.2), so the theorem above claims only what is proved here.

Definition 26.16 (Extended Hamiltonian)**.** The *extended Hamiltonian* adds all first-class constraints, primary or not, with independent multipliers:

$$\mathcal{H}_{\mathrm{E}} = \mathcal{H}_{\mathrm{c}} + v^A \gamma_A \,. \tag{26.20}$$

It generates the same motion of gauge-invariant quantities as $\mathcal{H}_{\mathrm{T}}$, and a larger motion of gauge-variant ones.

Rests on Definition 26.8 and Theorem 26.14.

Theorem 26.17 (Counting the physical degrees of freedom)**.** *Let a system have $2n$ phase-space dimensions, F independent first-class constraints and S independent second-class constraints. Then*

$$\dim(\textit{physical phase space}) = 2n - 2F - S \,, \tag{26.21}$$

and the number of physical configuration-space degrees of freedom is half of that, $n - F - \frac{1}{2}S$. A first-class constraint removes two dimensions—itself, and the gauge direction it generates—while a second-class constraint removes one.

Rests on Theorem 26.14, Proposition 26.19, and Remark 26.18.

Proof. *Derives Theorem 26.17.*

By regularity (Remark 26.7) the $F + S$ constraints have independent differentials, so the constraint surface Σ of Equation (26.11) is an embedded submanifold (Definition 13.54) of dimension

$$\dim \Sigma = 2n - F - S \,. \tag{26.22}$$

Consider on Σ the Hamiltonian vector fields $X_A := \{\cdot, \gamma_A\}$ of the first-class constraints. Each is tangent to Σ, because $X_A \varphi_j = \{\varphi_j, \gamma_A\} = -\{\gamma_A, \varphi_j\} \approx 0$ by Equation (26.12), so the flow it generates does not leave the surface; and the F of them are pointwise

independent, because the $\mathrm{d}\gamma_A$ are independent and the symplectic form is non-degenerate. They therefore span an F-dimensional distribution on Σ. It is involutive: by Proposition 25.4 the bracket of Hamiltonian vector fields is the Hamiltonian vector field of the Poisson bracket, $[X_A, X_B] = X_{\{\gamma_A,\gamma_B\}}$, and $\{\gamma_A, \gamma_B\} = f_{AB}{}^C\gamma_C$ by Equation (26.16), whose Hamiltonian vector field on Σ is $f_{AB}{}^C X_C$ — again in the span.

By the Frobenius theorem of Remark 26.18 the distribution is integrable, and Σ is foliated by F-dimensional leaves: the *gauge orbits*. By Theorem 26.14 all points of one orbit describe one physical state, so the physical phase space is the space of leaves, of dimension

$$\dim\Sigma - F = 2n - F - S - F = 2n - 2F - S\,, \tag{26.23}$$

which is Equation (26.21). It is even, because S is even by Proposition 26.19, so half of it is an integer; and it is $2\left(n - F - \frac{1}{2}S\right)$, the doubling that a configuration space and its momenta always produce. Finally the reduced space carries a symplectic form: the pullback of ω to Σ has the X_A in its kernel and nothing else, so it descends to a non-degenerate form on the quotient — which is Theorem 24.47 in the special case where the momentum map is the constraint set. □

Remark 26.18 (The Frobenius theorem is owed by Part II). The proof of Theorem 26.17 needs the following, which belongs to the manifolds chapter (Chapter 13) and is not there. *Frobenius theorem.* A smooth distribution $D \subset TN$ of constant rank k on a manifold N is integrable — through each point there passes a k-dimensional immersed submanifold whose tangent space is D, and N is foliated by such leaves — if and only if D is involutive, that is, closed under the Lie bracket of vector fields. The theorem is invoked by name elsewhere in this part as well: the pending note of Theorem 24.38 attributes it to Part II, and Chapter 16 appeals to it to separate holonomic from nonholonomic constraints. It is stated here because it is used here, not because this is its home.

Proposition 26.19 (Second-class constraints come in pairs)**.** *For a complete separation in the sense of Definition 26.12, the number S of independent second-class constraints is even, and the matrix*

$$C_{\alpha\beta} = \{\chi_\alpha, \chi_\beta\} \tag{26.24}$$

is invertible on the constraint surface.

Rests on Definition 26.12 and Proposition 5.115.

Proof. *Derives Proposition 26.19.*

$C_{\alpha\beta}$ is antisymmetric, by antisymmetry of the Poisson bracket (Equation (22.43)). Suppose it were degenerate at a point of Σ: there would be numbers λ^α, not all zero, with $C_{\alpha\beta}\lambda^\beta \approx 0$. Put $\chi := \lambda^\alpha\chi_\alpha$. Then $\{\chi_\beta, \chi\} \approx 0$ for every β by construction, and $\{\gamma_A, \chi\} \approx 0$ for every A because the γ_A are first class. Since $\{\gamma_A, \chi_\alpha\}$ is a basis of the constraint set, χ has weakly vanishing bracket with every constraint: it is first class. But a complete separation admits no nonzero first-class combination of the χ_α alone, so $\lambda = 0$ — a contradiction. Hence C is non-degenerate on Σ, which is the second assertion.

For the first, C is then the matrix of a non-degenerate antisymmetric bilinear form on the S-dimensional real space spanned by the χ_α at that point. By Proposition 5.115 such a form exists only in even dimension, so $S = 2s$. Equivalently, and this is the one-line version, $\det C = \det\left(-C^{\mathsf{T}}\right) = (-1)^S \det C$, so $\det C = 0$ whenever S is odd. □

26.4 The Dirac bracket

Second-class constraints cannot be imposed strongly inside a Poisson bracket—setting $\chi_\alpha = 0$ in Equation (26.24) would make an invertible matrix vanish. The resolution is to change the bracket.

Definition 26.20 (Dirac bracket)**.** Let χ_α be a complete set of second-class constraints and $(C^{-1})^{\alpha\beta}$ the inverse of the matrix Equation (26.24). The *Dirac bracket* of two phase-space functions is

$$\{A,B\}_{\mathrm{D}} = \{A,B\} - \{A,\chi_\alpha\}\left(C^{-1}\right)^{\alpha\beta}\{\chi_\beta,B\}\,. \tag{26.25}$$

Rests on Proposition 26.19 and Definition 22.29.

Theorem 26.21 (Properties of the Dirac bracket)**.** *The Dirac bracket is bilinear and antisymmetric, obeys the Leibniz rule Equation (24.24) and the Jacobi identity Equation (22.46), and in addition*

$$\{A,\chi_\alpha\}_D = 0 \quad \textit{strongly, for every } A\,, \tag{26.26}$$

$$\{A,B\}_D \approx \{A,B\} \quad \textit{whenever } A \textit{ is first class}\,, \tag{26.27}$$

$$\dot F \approx \{F,\mathcal{H}_T\}_D\,. \tag{26.28}$$

Because of Equation (26.26), the second-class constraints may be set to zero strongly *once the Dirac bracket is adopted: they become identities, and the phase space is effectively reduced.*

Rests on Definitions 26.8 and 26.20 and Proposition 26.19.

Proof. *Derives Theorem 26.21.*

Bilinearity is immediate: both terms of Equation (26.25) are bilinear in (A,B). For antisymmetry, note first that the inverse of an invertible antisymmetric matrix is antisymmetric, since $C^{\mathsf T} = -C$ gives $(C^{-1})^{\mathsf T} = \left(C^{\mathsf T}\right)^{-1} = -C^{-1}$. Exchanging A and B in the correction term and using $\{B,\chi_\alpha\} = -\{\chi_\alpha,B\}$, $\{\chi_\beta,A\} = -\{A,\chi_\beta\}$ and then relabelling $\alpha \leftrightarrow \beta$,

$$-\{B,\chi_\alpha\}\left(C^{-1}\right)^{\alpha\beta}\{\chi_\beta,A\} = -\{A,\chi_\alpha\}\left(C^{-1}\right)^{\beta\alpha}\{\chi_\beta,B\} = +\{A,\chi_\alpha\}\left(C^{-1}\right)^{\alpha\beta}\{\chi_\beta,B\}\,, \tag{26.29}$$

so the correction changes sign with the leading term and $\{A,B\}_{\mathrm{D}} = -\{B,A\}_{\mathrm{D}}$. The Leibniz rule in the first slot follows because $A \longmapsto \{A,B\}$ and $A \longmapsto \{A,\chi_\alpha\}$ are both derivations (Proposition 25.4) and the second factor of the correction does not involve A; antisymmetry then gives it in the second slot.

For Equation (26.26), take $B = \chi_\gamma$:

$$\{A,\chi_\gamma\}_{\mathrm{D}} = \{A,\chi_\gamma\} - \{A,\chi_\alpha\}\left(C^{-1}\right)^{\alpha\beta}C_{\beta\gamma} = \{A,\chi_\gamma\} - \{A,\chi_\alpha\}\,\delta^\alpha_\gamma = 0\,, \tag{26.30}$$

which holds wherever C^{-1} is defined — strongly, not merely on Σ. Equation (26.27) is immediate: if A is first class then $\{A,\chi_\alpha\} \approx 0$ and the whole correction vanishes weakly. For Equation (26.28), the consistency algorithm has fixed the multipliers of the second-class primary constraints, and with that fixing $\mathcal{H}_{\mathrm{T}}$ is first class — it is precisely the statement that the motion preserves every constraint — so $\{\chi_\beta,\mathcal{H}_{\mathrm{T}}\} \approx 0$ and Equation (26.27) applies with $B = \mathcal{H}_{\mathrm{T}}$, giving $\{F,\mathcal{H}_{\mathrm{T}}\}_{\mathrm{D}} \approx \{F,\mathcal{H}_{\mathrm{T}}\} \approx \dot F$.

The Jacobi identity is the one property that is not a short computation; it is what earns the object the name bracket, and it is deferred. □

Full derivation: Appendix A.51 (p. 3069).

Derives Theorem 26.21.

Two routes are written out there. The direct one expands $\{A,\{B,C\}_{\mathrm{D}}\}_{\mathrm{D}}$ and its two cyclic partners: besides the Poisson Jacobi identity itself, this produces terms carrying derivatives of the inverse matrix, which are reduced by differentiating $C^{-1}C = \mathbb{1}$ to express $\left\{A,(C^{-1})^{\alpha\beta}\right\}$ through $\{A,C_{\gamma\delta}\}$, after which everything cancels in triples by the Poisson Jacobi identity applied to the constraints themselves. The structural one observes that the Dirac bracket is the Poisson bracket of the symplectic form induced on the second-class surface — a symplectic form precisely because C is invertible, which is Proposition 26.25 below — and reads the identity off the closure of that form.

Example 26.22 (Holonomic constraints)**.** A particle of mass m moving in $\mathbb{R}^3$ under a potential $V(\boldsymbol{x})$, with $\mathcal{H} = \boldsymbol{p}^2/2m + V$, is confined to the surface $g(\boldsymbol{x}) = 0$ of Definition 21.2. The Dirac bracket built from the resulting second-class pair reproduces exactly the reduced dynamics obtained in Chapter 21 by eliminating the constrained coordinate. The elementary treatment of holonomic constraints there and the formalism here agree, which is the check that fixes all signs.

Rests on Definitions 21.2 and 26.20.

Derivation. *Derives Example 26.22.*

Confinement to the surface is one condition on the coordinates, but a single $\chi_1 = g(\boldsymbol{x})$ is not preserved by the motion: the algorithm of Section 26.2 applied to it returns

$$\chi_2 := \{g, \mathcal{H}\} = \frac{1}{m}\, p_i\, \partial_i g\,, \tag{26.31}$$

the statement that the velocity is tangent to the surface. Their bracket is

$$\{\chi_1, \chi_2\} = \left\{g, \tfrac{1}{m} p_j \partial_j g\right\} = \frac{1}{m}\, \partial_i g\, \partial_i g = \frac{|\nabla g|^2}{m} =: w\,, \tag{26.32}$$

nonzero wherever $\nabla g \neq 0$, which is where the surface is regular. The pair is second class, $S = 2$, $F = 0$, and Equation (26.21) gives $2 \times 3 - 2 = 4$: two configuration degrees of freedom, as Definition 21.9 requires for a point on a surface. With

$$C = \begin{pmatrix} 0 & w \\ -w & 0 \end{pmatrix}, \qquad C^{-1} = \begin{pmatrix} 0 & -w^{-1} \\ w^{-1} & 0 \end{pmatrix}, \tag{26.33}$$

and the elementary brackets $\{x_i, \chi_1\} = 0$, $\{x_i, \chi_2\} = \partial_i g/m$, $\{p_i, \chi_1\} = -\partial_i g$ and $\{p_i, \chi_2\} = -p_k \partial_i \partial_k g/m$, Equation (26.25) gives

$$\{x_i, x_j\}_{\mathrm{D}} = 0\,, \tag{26.34}$$

$$\{x_i, p_j\}_{\mathrm{D}} = \delta_{ij} - \frac{\partial_i g\, \partial_j g}{|\nabla g|^2} = \delta_{ij} - n_i n_j\,, \tag{26.35}$$

$$\{p_i, p_j\}_{\mathrm{D}} = \frac{p_k}{|\nabla g|^2}\left[(\partial_i \partial_k g)\, \partial_j g - (\partial_j \partial_k g)\, \partial_i g\right], \tag{26.36}$$

with $\boldsymbol{n} = \nabla g / |\nabla g|$ the unit normal. Read these three. Equation (26.35) is the projector onto the tangent plane: the momentum conjugate to a coordinate is only the tangential part of $\boldsymbol{p}$, which is exactly what the reduced Lagrangian treatment produces when the normal coordinate is eliminated. The normal component of $\boldsymbol{p}$ has vanishing Dirac bracket with everything, so it is not an independent variable at all — it is χ_2, set strongly to zero by Equation (26.26). And Equation (26.36) says that the momenta no longer commute: the second derivatives of g are the second fundamental form of the surface, so the failure is its extrinsic curvature.

For the sphere $g = |\boldsymbol{x}| - R$ one has $\nabla g = \hat{\boldsymbol{r}}$ and $\partial_i \partial_j g = (\delta_{ij} - \hat{r}_i \hat{r}_j)/r$, and Equation (26.36) collapses on the constraint surface, where $\boldsymbol{p} \cdot \hat{\boldsymbol{r}} \approx 0$, to

$$\{p_i, p_j\}_{\mathrm{D}} \approx \frac{p_i \hat{r}_j - p_j \hat{r}_i}{R} = -\frac{\epsilon_{ijk} L_k}{R^2}\,, \qquad \boldsymbol{L} = \boldsymbol{x} \times \boldsymbol{p}\,, \tag{26.37}$$

so the momenta on a sphere close on the angular momentum. That is the bracket algebra of the free particle on S^2, whose Hamiltonian is $\boldsymbol{L}^2/2mR^2$ — precisely the reduced system obtained in Chapter 21 by writing the Lagrangian in the two angles. The two routes agree, and Equation (26.37) is the classical origin of the operator ordering problem for a particle on a curved configuration space, taken up in Section 25.5.1. □

26.5 Gauge fixing and the reduced phase space

Definition 26.23 (Gauge conditions)**.** Given F first-class constraints γ_A, a set of *gauge conditions* is a set of F functions ψ^A such that

$$\det\left\{\gamma_A, \psi^B\right\} \neq 0 \tag{26.38}$$

on the constraint surface. The combined set $\left\{\gamma_A, \psi^A\right\}$ is then second class, and the Dirac bracket built from it defines the dynamics on the *reduced phase space* of dimension $2n-2F-S$.

Rests on Theorem 26.17 and Definition 26.20.

Condition Equation (26.38) says two things at once, and both are needed. It says the gauge is *attainable*: since $\left\{\psi^B, \gamma_A\right\}$ is the change of ψ^B under the gauge transformation generated by γ_A, a non-vanishing determinant means the gauge parameters can be chosen to reach $\psi = 0$ from anywhere nearby. And it says the gauge is *complete*: no gauge freedom survives, because a residual transformation would leave ψ unchanged and make the determinant vanish. The count then follows from Theorem 26.17 with $F \to 0$ and $S \to S + 2F$.

Proposition 26.24 (The Faddeev–Popov determinant)**.** *Write $\Gamma_a = \left(\gamma_A, \psi^B\right)$ for the combined second-class set of Definition 26.23. Then*

$$\det\{\Gamma_a, \Gamma_b\} \approx \left(\det\left\{\gamma_A, \psi^B\right\}\right)^2 , \tag{26.39}$$

so that the factor $\sqrt{\det\{\Gamma_a, \Gamma_b\}}$ by which the Liouville measure of Definition 24.20 is corrected on passing to the gauge-fixed surface is $\left|\det\left\{\gamma_A, \psi^B\right\}\right|$. This is the object that appears as the Faddeev–Popov determinant in the path-integral quantization of Chapter 106 [1347]. Its exponentiation as an integral over anticommuting fields is what introduces the ghosts of gauge-fixed perturbation theory.

Rests on Definition 26.23 and Proposition 26.19.

Proof. *Derives Proposition 26.24.*

Order the combined set as $\left(\gamma_A, \psi^B\right)$ and write $D_A{}^B := \left\{\gamma_A, \psi^B\right\}$. Because the γ_A are first class, $\{\gamma_A, \gamma_B\} \approx 0$, so on Σ

$$\{\Gamma_a, \Gamma_b\} \approx \begin{pmatrix} 0 & D \\ -D^{\mathsf{T}} & E \end{pmatrix} , \qquad E^{AB} = \left\{\psi^A, \psi^B\right\} , \tag{26.40}$$

with all four blocks $F \times F$ and D invertible by Equation (26.38). Multiply on the left by $\begin{pmatrix} \mathbb{1} & -DE^{-1} \\ 0 & \mathbb{1} \end{pmatrix}$, of determinant 1, where E is invertible; the product is $\begin{pmatrix} DE^{-1}D^{\mathsf{T}} & 0 \\ -D^{\mathsf{T}} & E \end{pmatrix}$, whose determinant is $\det\left(DE^{-1}D^{\mathsf{T}}\right)\det E = (\det D)^2$, in which E has cancelled. Both sides of Equation (26.39) are polynomials in the entries of an *arbitrary* $F \times F$ matrix E — the antisymmetry of E is nowhere used — and they have just been shown equal on the dense open set of invertible E, so they are equal for every E. In particular the identity holds in the common case $E = 0$, where the gauge conditions commute among themselves, and this matters: for odd F an antisymmetric E is never invertible, so the perturbation must be taken outside the antisymmetric matrices, which is what the previous sentence does. Taking the positive square root gives the stated factor. □

The second sentence of Proposition 26.24 — that this determinant is the factor by which the Liouville measure is corrected — is a separate statement, and it is the measure-theoretic face of the Dirac bracket.

Proposition 26.25 (The Liouville measure of a second-class surface)**.** *Let χ_α, $\alpha = 1, \dots, S$, be a second-class set on a phase space of dimension $2n$, so that $C_{\alpha\beta}$ of Equation (26.24) is invertible on the surface Σ_χ they define, and write Θ for the Liouville form Equation (24.13) of the ambient space — the letter Ω being reserved in this chapter for the BRST charge Equation (26.97). Then Σ_χ carries the non-degenerate restriction ω_Σ of the symplectic form, $\det C > 0$, and the Liouville form Θ_Σ built from ω_Σ satisfies*

$$\int_{\Sigma_\chi} F\,\Theta_\Sigma = \int F\,\sqrt{\det C}\,\prod_{\alpha=1}^{S}\delta(\chi_\alpha)\,\Theta \tag{26.41}$$

for every integrable F. The reduced measure is thus the ambient one with a delta function of each constraint and the factor $\sqrt{\det C}$, which for a gauge-fixed set Γ_a is the $\sqrt{\det\{\Gamma_a,\Gamma_b\}}$ of Proposition 26.24.

Rests on Propositions 24.3 and 26.19 and Definition 24.20.

Proof. *Derives Proposition 26.25.*

Write M for the phase space, so that $\dim M = 2n$. Everything is pointwise linear algebra in the tangent space T_xM at a point $x \in \Sigma_\chi$, plus one convention about the delta functions.

The splitting. With the conventions Equations (24.5) and (24.7), $\mathrm{d}\chi_\gamma(X_{\chi_\alpha}) = \{\chi_\gamma, \chi_\alpha\} = C_{\gamma\alpha}$, which is invertible; so the S vectors X_{χ_α} are independent and span a subspace W, and the S covectors $\mathrm{d}\chi_\alpha$ are independent, with common kernel $T_x\Sigma_\chi$ of dimension $2n - S$. The map

$$P(v) = v - X_{\chi_\alpha}\left(C^{-1}\right)^{\alpha\beta}\mathrm{d}\chi_\beta(v) \tag{26.42}$$

gives $\mathrm{d}\chi_\gamma(P(v)) = \mathrm{d}\chi_\gamma(v) - C_{\gamma\alpha}\left(C^{-1}\right)^{\alpha\beta}\mathrm{d}\chi_\beta(v) = 0$, so it projects T_xM onto $T_x\Sigma_\chi$ along W, and $T_xM = W \oplus T_x\Sigma_\chi$. The two summands are ω-orthogonal: for $v \in T_x\Sigma_\chi$, $\omega(X_{\chi_\alpha}, v) = \left(\iota_{X_{\chi_\alpha}}\omega\right)(v) = \mathrm{d}\chi_\alpha(v) = 0$. On W the form has the invertible matrix $\omega\left(X_{\chi_\alpha}, X_{\chi_\beta}\right) = C_{\alpha\beta}$; and a $v \in T_x\Sigma_\chi$ annihilated by ω_Σ is by that orthogonality annihilated by ω on all of T_xM, hence zero. Both restrictions are therefore non-degenerate, $(\Sigma_\chi, \omega_\Sigma)$ is symplectic, and $S = 2s$ is even — which is Proposition 26.19 read geometrically.

The volume factorises. Write $\omega = \omega_1 + \omega_2$, where ω_1 is the pullback of $\omega|_W$ along $v \longmapsto v - P(v)$ and ω_2 the pullback of ω_Σ along P; that there is no cross term is the ω-orthogonality just proved. Two-forms commute under $\wedge$, and $\omega_1^{\wedge k} = 0$ for $k > s$ while $\omega_2^{\wedge k} = 0$ for $k > n - s$, each being pulled back from a space of that dimension. Expanding $\omega^{\wedge n}$ by the binomial theorem therefore leaves a single term:

$$\Theta = \frac{\omega^{\wedge n}}{n!} = \frac{\omega_1^{\wedge s}}{s!} \wedge \frac{\omega_2^{\wedge (n-s)}}{(n-s)!} = \Theta_W \wedge P^*\Theta_\Sigma\,, \tag{26.43}$$

with Θ_W the Liouville form of the symplectic space W.

Two evaluations. Take the adapted basis $(X_{\chi_1}, \dots, X_{\chi_S}, v_1, \dots, v_{2n-S})$ with the v_r a basis of $T_x\Sigma_\chi$. By Proposition 24.3 pick a canonical basis $E_1, \dots, E_S$ of $(W, \omega|_W)$, ordered as in Equation (24.13) so that Θ_W takes the value 1 on it, and write $X_{\chi_\alpha} = L_\alpha{}^a E_a$. Then $C = L\,J\,L^{\mathsf{T}}$ with J the matrix Equation (5.144), whose determinant is 1, so $\det C = (\det L)^2$ — positive, as claimed — while $\Theta_W(X_{\chi_1}, \dots, X_{\chi_S}) = \det L$. Since Θ_W annihilates every v_r and $P^*\Theta_\Sigma$ every X_{χ_α}, only one term of the wedge in Equation (26.43) survives on that basis:

$$\Theta\left(X_{\chi_1}, \dots, v_{2n-S}\right) = \pm\sqrt{\det C}\;\Theta_\Sigma\left(v_1, \dots, v_{2n-S}\right)\,. \tag{26.44}$$

The other top form built from the constraints evaluates on the same basis to

$$\left(\mathrm{d}\chi_1 \wedge \cdots \wedge \mathrm{d}\chi_S \wedge P^*\Theta_\Sigma\right)\left(X_{\chi_1}, \dots, v_{2n-S}\right) = \det C\;\Theta_\Sigma\left(v_1, \dots, v_{2n-S}\right)\,, \tag{26.45}$$

because $\det\big(\mathrm{d}\chi_\alpha(X_{\chi_\beta})\big) = \det C$. Two top forms on a $2n$-dimensional space that agree up to a factor on one basis agree up to that factor everywhere, so, orienting Σ_χ so that the sign in Equation (26.44) is positive,

$$\Theta = \frac{1}{\sqrt{\det C}}\,\mathrm{d}\chi_1 \wedge \cdots \wedge \mathrm{d}\chi_S \wedge P^*\Theta_\Sigma\,. \tag{26.46}$$

The convention. A delta function of a constraint means one thing: if a top form is presented as $\mathrm{d}\chi_1 \wedge \cdots \wedge \mathrm{d}\chi_S \wedge \eta$ for a $(2n-S)$-form η, then integrating $\prod_\alpha \delta(\chi_\alpha)$ against it is integrating η pulled back to Σ_χ. Applied to Equation (26.46), and using that P restricts to the identity on $T\Sigma_\chi$, so that $P^*\Theta_\Sigma$ pulls back to Θ_Σ,

$$\int F\,\sqrt{\det C}\,\prod_\alpha \delta(\chi_\alpha)\,\Theta = \int_{\Sigma_\chi} F\,\sqrt{\det C}\,\frac{\Theta_\Sigma}{\sqrt{\det C}} = \int_{\Sigma_\chi} F\,\Theta_\Sigma\,,$$

which is Equation (26.41). □

Remark 26.26 (What the factor is doing). Equation (26.41) is the reason the Faddeev–Popov determinant is not an arbitrary insertion. The delta functions alone would define a measure on Σ_χ that depends on how the constraints are written: replacing χ_α by $A_\alpha{}^\beta\chi_\beta$ for an invertible matrix of functions leaves the surface untouched but multiplies $\prod\delta(\chi_\alpha)$ by $|\det A|^{-1}$. It multiplies $\sqrt{\det C}$ by $|\det A|$ as well, since $C \mapsto A\,C\,A^{\mathsf{T}}$ on the surface, so the product is invariant — and it is invariant because it equals the intrinsic Liouville volume of the reduced symplectic manifold, which knows nothing about the presentation. The same computation, read on the tangent space rather than on the volume, is what makes the Dirac bracket of Definition 26.20 the Poisson bracket of ω_Σ.

Rests on Propositions 26.24 and 26.25.

Remark 26.27 (Gauge conditions need not exist globally). Equation (26.38) is a local condition. For non-abelian gauge theories no gauge condition satisfies it over the whole space of field configurations—the Gribov ambiguity [1623]—so the reduced phase space is not covered by one chart, and a gauge orbit meets the gauge-fixing surface more than once. This is a genuine obstruction, not a technical inconvenience: it is invisible in perturbation theory about $A = 0$, which is why the Faddeev–Popov procedure works there, and it is exactly what fails when the coupling is strong. Its consequences for the non-perturbative treatment of Chapter 102 are noted there.

26.6 Worked systems

The formalism above is worth exactly as much as the cases it settles. The following are the ones this treatise needs; each is stated with its constraint structure and its degree-of-freedom count.

Notation 26.28 (Field systems). From Section 26.6.2 onward the systems are field theories. A plain $H = \int \mathrm{d}^3x\,\mathcal{H}$ is the Hamiltonian and the script $\mathcal{H}$ the corresponding density; the index j of Equation (26.11) carries a continuous label $\boldsymbol{x}$ and the sums over constraints become integrals; and the Poisson bracket is built from functional derivatives,

$$\{F,G\} = \int \mathrm{d}^3x \left(\frac{\delta F}{\delta\varphi(\boldsymbol{x})}\frac{\delta G}{\delta\pi(\boldsymbol{x})} - \frac{\delta F}{\delta\pi(\boldsymbol{x})}\frac{\delta G}{\delta\varphi(\boldsymbol{x})}\right), \tag{26.47}$$

so that $\{\varphi(\boldsymbol{x}),\pi(\boldsymbol{y})\} = \delta^3(\boldsymbol{x}-\boldsymbol{y})$. The evolution parameter is the coordinate time t of a chosen inertial frame, and $x^0 = ct$; a dot means ∂_t. Momenta conjugate to a field are taken with respect to ∂_t of the *covariant* components A_μ, which is what makes the Gauss constraint come out as Equation (26.56) rather than with the opposite sign. The prices and the limits of the passage from finitely many degrees of freedom to a field are collected in Section 26.8.

Rests on Notation 26.1 and Definition 22.29.

26.6.1 The relativistic free particle

Proposition 26.29 (Reparametrization invariance and the mass-shell constraint)**.** *For the action of a free relativistic particle parametrized by an arbitrary parameter τ,*

$$S = -mc \int \sqrt{\eta_{\mu\nu} \frac{\mathrm{d}x^\mu}{\mathrm{d}\tau} \frac{\mathrm{d}x^\nu}{\mathrm{d}\tau}}\, \mathrm{d}\tau\,, \tag{26.48}$$

in the signature of Chapter 39, the Legendre transformation is singular of rank three, the canonical Hamiltonian vanishes identically, and the single primary constraint is the mass shell

$$\phi = \eta^{\mu\nu} p_\mu p_\nu - m^2 c^2 \approx 0\,, \tag{26.49}$$

which is first class. The count is $2 \times 4 - 2 \times 1 = 6$, that is three physical configuration degrees of freedom—the particle's position in space—as it must be.

Rests on Proposition 26.5 and Theorems 26.17 and 40.5.

Proof. *Derives Proposition 26.29.*

Write $\dot{x}^\mu = \mathrm{d}x^\mu/\mathrm{d}\tau$ and $\mathcal{L} = -mc\left(\eta_{\alpha\beta}\dot{x}^\alpha\dot{x}^\beta\right)^{1/2}$. The momenta are

$$p_\mu = \frac{\partial \mathcal{L}}{\partial \dot{x}^\mu} = -mc\, \frac{\eta_{\mu\nu}\dot{x}^\nu}{\sqrt{\eta_{\alpha\beta}\dot{x}^\alpha\dot{x}^\beta}}\,, \tag{26.50}$$

and contracting Equation (26.50) with itself the normalization cancels the denominator exactly: $\eta^{\mu\nu}p_\mu p_\nu = m^2c^2$ for *every* $\dot{x}$. That is Equation (26.49), and it holds identically in the velocities, which by Proposition 26.5 makes it a primary constraint. The Hessian

$$W_{\mu\nu} = \frac{\partial^2 \mathcal{L}}{\partial \dot{x}^\mu \partial \dot{x}^\nu} = -\frac{mc}{\sqrt{\dot{x}^2}}\left(\eta_{\mu\nu} - \frac{\dot{x}_\mu \dot{x}_\nu}{\dot{x}^2}\right) \tag{26.51}$$

is a multiple of the projector orthogonal to $\dot{x}$, of rank three, confirming $M = 4 - 3 = 1$: exactly one constraint, no more.

The canonical Hamiltonian is

$$\mathcal{H}_\mathrm{c} = p_\mu \dot{x}^\mu - \mathcal{L} = -mc\frac{\dot{x}^2}{\sqrt{\dot{x}^2}} + mc\sqrt{\dot{x}^2} = 0\,, \tag{26.52}$$

identically, so $\mathcal{H}_\mathrm{T} = u\phi$ by Equation (26.6). Consistency is automatic, $\dot{\phi} = \{\phi, u\phi\} = 0$: no secondary constraint arises and u is never determined. By Theorem 26.14 the constraint is first class — there is nothing for its bracket to fail to annihilate — and u is a gauge parameter. The equations of motion it generates,

$$\dot{x}^\mu = \{x^\mu, \mathcal{H}_\mathrm{T}\} = 2u\, p^\mu\,, \qquad \dot{p}_\mu = 0\,, \tag{26.53}$$

determine the worldline but not its parametrization: changing $u(\tau)$ reparametrizes τ and nothing else. Choosing τ to be the proper time of Definition 38.12 fixes $u = 1/2m$ and returns $p^\mu = m\,\mathrm{d}x^\mu/\mathrm{d}\tau$, the four-momentum of Definition 40.4. Finally $2n = 8$, $F = 1$, $S = 0$, so Equation (26.21) gives $8 - 2 = 6$ and three configuration degrees of freedom. □

Remark 26.30 (A sign to be read once). With the signature $(+,-,-,-)$ and the overall minus in Equation (26.48), Equation (26.50) evaluated in the parametrization $\tau = t$ gives $p_i = \gamma_u m\, u_i$ — the ordinary relativistic momentum, with its familiar sign — but $p_0 = -E/c$. The canonical momenta conjugate to the x^μ are thus the components of $-p_\mu$ in the convention of Definition 40.4. Nothing in the constraint analysis depends on this: Equation (26.49) is quadratic and blind to the overall sign, and it is the same statement as Equation (40.5). The sign is recorded because it is a standing trap in the literature, where both conventions are used without comment.

Remark 26.31 (A vanishing Hamiltonian is not a static system). That $\mathcal{H}_{\mathrm{c}} \approx 0$ says only that the evolution in the arbitrary parameter is pure gauge; the physical motion is the relation between the x^{μ}, which is unaffected. Any theory whose invariance group includes reparametrizations of the evolution parameter has this property, and the confusion it causes when the parameter is called "time" is discussed under Section 26.6.5.

26.6.2 The electromagnetic field

Proposition 26.32 (Constraint structure of the free Maxwell field)**.** *For the Maxwell Lagrangian density of Section 64.5.1,*

$$\mathcal{L} = -\frac{1}{4\mu_0} F_{\mu\nu}F^{\mu\nu} - A_{\mu}J^{\mu}\,, \qquad F_{\mu\nu} = \partial_{\mu}A_{\nu} - \partial_{\nu}A_{\mu}\,, \tag{26.54}$$

the momentum conjugate to A_0 vanishes identically, giving the primary constraint

$$\pi^{0}(\boldsymbol{x}) \approx 0\,, \tag{26.55}$$

whose consistency yields the secondary constraint—Gauss's law—

$$\partial_i \pi^{i}(\boldsymbol{x}) - \rho(\boldsymbol{x}) \approx 0\,. \tag{26.56}$$

Both are first class, and they generate the gauge transformations $A_{\mu} \mapsto A_{\mu} + \partial_{\mu}\Lambda$. The count per point of space is $2 \times 4 - 2 \times 2 = 4$, that is two *physical field degrees of freedom. The algorithm closes after two rounds if and only if the source is conserved, $\partial_{\mu}J^{\mu} = 0$.*

Rests on Propositions 26.5 and 26.10 and Theorem 26.17.

Proof. *Derives Proposition 26.32.*

Since $F_{\mu\nu}$ is antisymmetric, $\mathcal{L}$ contains no $\partial_0 A_0$ at all, and

$$\pi^{\mu} := \frac{\partial \mathcal{L}}{\partial \dot{A}_{\mu}} = -\frac{1}{\mu_0 c} F^{0\mu}\,, \qquad \text{so} \qquad \pi^{0} = 0\,, \quad \pi^{i} = \epsilon_0 E^{i}\,, \tag{26.57}$$

using $F^{0i} = -E^{i}/c$ and $\epsilon_0\mu_0 c^2 = 1$. The first is Equation (26.55), one primary constraint per point; the second identifies the field momentum with the electric displacement, of dimension $\mathrm{C/m^2}$. The Hessian in the four $\dot{A}_{\mu}$ has rank three per point, so there is exactly one.

The canonical Hamiltonian follows from Equation (26.4). Using $\dot{A}_i = E_i + \partial_i \phi$ with $\phi = cA_0$ the electrostatic potential, and integrating the term $\epsilon_0 \boldsymbol{E}\cdot\nabla\phi$ by parts,

$$H_{\mathrm{c}} = \int \mathrm{d}^3x \left[\frac{\pi^{i}\pi^{i}}{2\epsilon_0} + \frac{(\nabla \times \boldsymbol{A})^2}{2\mu_0} - c\,A_0\left(\partial_i \pi^{i} - \rho\right) - \boldsymbol{J}\cdot\boldsymbol{A} \right], \tag{26.58}$$

whose first two terms are the familiar field energy density $\tfrac{1}{2}\epsilon_0 E^2 + B^2/2\mu_0$. The potential A_0 appears *linearly and without derivatives*: it is a multiplier, not a dynamical variable. Consistency of Equation (26.55) is then

$$\dot{\pi}^{0}(\boldsymbol{x}) = \left\{ \pi^{0}(\boldsymbol{x}), H_{\mathrm{T}} \right\} = -\frac{\delta H_{\mathrm{c}}}{\delta A_0(\boldsymbol{x})} = c\left(\partial_i \pi^{i} - \rho\right) \approx 0\,, \tag{26.59}$$

which is outcome 2 of Proposition 26.10: a new constraint containing no multiplier. It is Equation (26.56), and written out it is $\epsilon_0 \nabla\cdot\boldsymbol{E} = \rho$ — Gauss's law appears here as a *constraint on initial data*, not as an equation of motion, which is the structural statement this analysis makes about Maxwell's system.

Running the algorithm once more, the remaining Hamilton equation is $\dot{\pi}^{i} = -\delta H_{\mathrm{c}}/\delta A_i = (\nabla\times\boldsymbol{B})_i/\mu_0 - J_i$, the Ampère–Maxwell law, so

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\partial_i \pi^{i} - \rho\right) = \partial_i \frac{(\nabla\times\boldsymbol{B})_i}{\mu_0} - \nabla\cdot\boldsymbol{J} - \dot{\rho} = -\left(\dot{\rho} + \nabla\cdot\boldsymbol{J}\right), \tag{26.60}$$

the divergence of a curl vanishing identically. The algorithm therefore terminates precisely when $\partial_\mu J^\mu = 0$, and otherwise reaches outcome 4 of Proposition 26.10: a Maxwell field coupled to a non-conserved source has no solutions at all.

Both constraints are first class. π^0 has vanishing bracket with everything built from $\boldsymbol{A}$ and $\boldsymbol{\pi}$; and $\{\mathcal{G}(\boldsymbol{x}), \mathcal{G}(\boldsymbol{y})\} = 0$ identically, where $\mathcal{G} = \partial_i \pi^i - \rho$, because $\mathcal{G}$ depends on the momenta alone. So $F = 2$ per point, $S = 0$, $2n = 8$, and Equation (26.21) gives $8 - 4 = 4$: two configuration degrees of freedom per point of space.

It remains to identify the gauge transformation. Take

$$G[\Lambda] = \int \mathrm{d}^3x \left[\frac{\dot{\Lambda}}{c}\, \pi^0 - \Lambda \left(\partial_i \pi^i - \rho \right) \right] , \tag{26.61}$$

a combination of the primary and secondary constraints with an arbitrary function Λ and its time derivative. Then $\{A_0, G\} = \dot{\Lambda}/c = \partial_0 \Lambda$ and, integrating the second term by parts, $\{A_i, G\} = \partial_i \Lambda$, while $\{\pi^\mu, G\} = 0$. That is $A_\mu \mapsto A_\mu + \partial_\mu \Lambda$ with $\boldsymbol{E}$ and $\boldsymbol{B}$ unchanged, as claimed. □

Remark 26.33 (The count is the observation). The two degrees of freedom of Proposition 26.32 are the two transverse polarizations of light. They are not a formal result: they are what is measured whenever the polarization of an electromagnetic wave is analysed (Chapter 67), and the absence of a third, longitudinal, mode is a statement about nature that the constraint analysis explains rather than assumes. The same count performed for a massless spin-two field gives two polarizations again—the plus and cross modes of Chapter 46, observed as such in the detections of Chapter 47 [2132].

26.6.3 The massive vector field

Proposition 26.34 (Proca constraints are second class)**.** *For the massive vector field of Section 64.6.1 [785],*

$$\mathcal{L} = -\frac{1}{4\mu_0} F_{\mu\nu} F^{\mu\nu} + \frac{1}{2\mu_0} \left(\frac{mc}{\hbar} \right)^2 A_\mu A^\mu , \tag{26.62}$$

the primary constraint is again $\pi^0 \approx 0$ but its consistency returns

$$\partial_i \pi^i + \frac{1}{\mu_0 c} \left(\frac{mc}{\hbar} \right)^2 A_0 - \rho \approx 0 , \tag{26.63}$$

and the two have the nonvanishing bracket

$$\left\{ \pi^0(\boldsymbol{x}), \cdot \right\} \longrightarrow -\frac{1}{\mu_0 c} \left(\frac{mc}{\hbar} \right)^2 \delta^3(\boldsymbol{x} - \boldsymbol{y}) , \tag{26.64}$$

proportional to the mass squared. They are second class rather than first: there is no gauge invariance. The count per point is $2 \times 4 - 2 = 6$, that is three physical degrees of freedom—the three polarizations of a massive spin-one particle.

Rests on Proposition 26.32, Definition 26.12, and Theorem 26.17.

Proof. *Derives Proposition 26.34.*

The mass term of Equation (26.62) carries no derivatives, so the momenta Equation (26.57) are unchanged and $\pi^0 = 0$ is still the only primary constraint. The canonical Hamiltonian Equation (26.58) acquires the extra density $-(2\mu_0)^{-1} (mc/\hbar)^2 (A_0^2 - A_i A_i)$, and now A_0 appears *quadratically*. Consistency of $\pi^0 \approx 0$ therefore gives

$$\dot{\pi}^0 = -\frac{\delta H_{\mathrm{c}}}{\delta A_0} = c \left[\partial_i \pi^i - \rho + \frac{1}{\mu_0 c} \left(\frac{mc}{\hbar} \right)^2 A_0 \right] \approx 0 , \tag{26.65}$$

which is Equation (26.63). Writing $\chi_1 = \pi^0$ and χ_2 for the left-hand side of Equation (26.63), the only term of χ_2 that fails to commute with π^0 is the one containing A_0, and

$$\{\chi_1(\boldsymbol{x}), \chi_2(\boldsymbol{y})\} = -\frac{1}{\mu_0 c}\left(\frac{mc}{\hbar}\right)^2 \delta^3(\boldsymbol{x}-\boldsymbol{y})\,, \tag{26.66}$$

which is Equation (26.64) and is invertible for every $m \neq 0$. By Definition 26.12 the pair is second class, so $S = 2$ and $F = 0$; consistency of χ_2 then determines the multiplier instead of producing a third constraint, and the algorithm stops. Equation (26.21) gives $8 - 0 - 2 = 6$ per point, three configuration degrees of freedom.

The content of Equation (26.63) is worth stating separately: it *determines* A_0 algebraically in terms of the momenta,

$$A_0 = -\mu_0 c\left(\frac{\hbar}{mc}\right)^2 \left(\partial_i \pi^i - \rho\right)\,, \tag{26.67}$$

so A_0 is not free, not gauge, and not dynamical — it is an auxiliary field. Combining Equation (26.67) with the equation of motion $\partial_\mu F^{\mu\nu} + (mc/\hbar)^2 A^\nu = \mu_0 J^\nu$ and taking a divergence returns $\partial_\mu A^\mu = 0$ for a conserved source: the Lorenz condition, here a consequence rather than a choice, exactly as Section 64.6.1 says. □

Remark 26.35 (Why the massive and massless counts differ). The passage from Proposition 26.32 to Proposition 26.34 changes the classification of the constraints, not their number, and that is what changes the count from two to three. Note precisely where the change enters: Equation (26.66) is proportional to m^2, so the bracket that makes the pair second class vanishes discontinuously at $m = 0$; the count is a step function of the mass, and no $m \to 0$ limit of the massive theory has two degrees of freedom. The physical content is that a mass term breaks the gauge invariance and thereby liberates the longitudinal mode. Classically this is the shadow of the van Dam–Veltman–Zakharov discontinuity [1419, 1439], where the corresponding step in the spin-two count leaves a massless limit that disagrees with general relativity. Experimentally it is why "the photon is massless" is a bound and never a measurement: the current limit is $m_\gamma < 1 \times 10^{-18}\,\mathrm{eV}/c^2$ [2427], from laboratory tests of Coulomb's law [1460] and, far more sharply, from planetary and galactic magnetic fields [2157]. And it is the mechanism behind the massive W and Z bosons of Chapter 104, with $M_W c^2 = (80.3692 \pm 0.0133)\,\mathrm{GeV}$ and $M_Z c^2 = (91.1880 \pm 0.0020)\,\mathrm{GeV}$ [2427], where the liberated modes are supplied by the scalar field rather than imposed by hand.

26.6.4 Yang–Mills fields

The non-abelian case is the one the Standard Model actually uses, and it differs from Proposition 26.32 in exactly one place: the Gauss constraints no longer commute with one another. Everything else — the vanishing time-component momentum, the secondary constraint, the count of two polarizations per generator — survives unchanged.

Notation 26.36 (Gauge fields and their SI dimensions). Let the gauge group be compact and simple of dimension N, with structure constants f^{abc} totally antisymmetric in the basis of Notation 102.18, whose conventions are used throughout. The potentials A^a_μ carry the dimension V s/m of the electromagnetic potential and the coupling g the dimension C of a charge, so that

$$\left[\frac{g}{\hbar}\right] = \mathrm{C}/(\mathrm{J\,s})\,, \qquad \left[\frac{g}{\hbar}A^a_\mu\right] = 1/\mathrm{m}\,. \tag{26.68}$$

The ratio $g/\hbar$ is the only combination in which the coupling occurs below, and by Equation (26.68) it is what turns a potential into an inverse length; it is the scalar behind the matrix-valued combination Equation (102.18). The field strength is Equation (102.24),

$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu - \frac{g}{\hbar} f^{abc} A^b_\mu A^c_\nu$, of dimension T, and the covariant derivative in the adjoint representation acts on a colour vector X^a as

$$(D_i X)^a = \partial_i X^a - \frac{g}{\hbar} f^{abc} A^b_i X^c \,. \tag{26.69}$$

Rests on Notations 26.28 and 102.18 and Equation (102.24).

Proposition 26.37 (Constraint structure of Yang–Mills theory)**.** *For* $\mathcal{L} = -(4\mu_0)^{-1} F^a_{\mu\nu} F^{a\,\mu\nu}$ *coupled to matter of colour charge density* ρ^a*, the momenta are* $\pi^0_a = 0$ *and* $\pi^i_a = \epsilon_0 E^i_a$*, so there are* N *primary constraints*

$$\pi^0_a(\boldsymbol{x}) \approx 0 \,, \qquad a = 1, \dots, N \,, \tag{26.70}$$

whose consistency yields the N *secondary constraints — the non-abelian Gauss law —*

$$\mathcal{G}^a := \left(D_i \pi^i\right)^a - \rho^a \approx 0 \,. \tag{26.71}$$

All $2N$ *are first class, and the Gauss constraints close on the Lie algebra of the gauge group,*

$$\left\{\mathcal{G}^a(\boldsymbol{x}), \mathcal{G}^b(\boldsymbol{y})\right\} = -\frac{g}{\hbar} f^{abc}\, \mathcal{G}^c(\boldsymbol{x})\, \delta^3(\boldsymbol{x} - \boldsymbol{y}) \,, \tag{26.72}$$

with genuine constants f^{abc} *where Equation (26.56) had zero. The count per point of space is* $2 \times 4N - 2 \times 2N = 4N$*: two physical degrees of freedom per generator, that is two transverse polarizations for each of the* N *gauge bosons.*

Rests on Propositions 26.13 and 26.32 and Notation 26.36.

Proof. *Derives Proposition 26.37.*

$F^a_{\mu\nu}$ is antisymmetric in $\mu\nu$ whatever the nonlinear term does, so no $\partial_0 A^a_0$ occurs in $\mathcal{L}$ and Equation (26.70) follows exactly as Equation (26.55) did. The Legendre transformation gives, by the computation of Proposition 26.32 with ∂_i replaced by D_i throughout,

$$H_{\mathrm{c}} = \int \mathrm{d}^3x \left[\frac{\pi^i_a \pi^i_a}{2\epsilon_0} + \frac{B^i_a B^i_a}{2\mu_0} - c\, A^a_0\, \mathcal{G}^a \right] , \tag{26.73}$$

with $B^i_a = -\frac{1}{2}\epsilon^{ijk} F^a_{jk}$ the chromomagnetic field, in which A^a_0 is again a multiplier, so that consistency of Equation (26.70) produces Equation (26.71). The two energy terms are the abelian ones; what the nonlinearity of Equation (102.24) adds is hidden inside B^i_a, which is cubic and quartic in A, so the free Yang–Mills Hamiltonian already describes a self-interacting field.

For the algebra, smear the constraint with a colour-valued test function, $G[\varepsilon] := \int \mathrm{d}^3x\, \varepsilon^a \mathcal{G}^a$, and take the matter contribution to ρ^a to generate the colour rotation of the matter fields, which it does by construction. Then

$$\frac{\delta G[\varepsilon]}{\delta A^b_i} = -\frac{g}{\hbar} f^{abc} \varepsilon^a \pi^i_c \,, \qquad \frac{\delta G[\varepsilon]}{\delta \pi^i_b} = -\left(D_i \varepsilon\right)^b \,, \tag{26.74}$$

the second by Equation (26.69) and the total antisymmetry of f. Substituting both into Equation (26.47),

$$\{G[\varepsilon], G[\eta]\} = \frac{g}{\hbar} \int \mathrm{d}^3x\; f^{abc} \pi^i_c \left[\varepsilon^a \left(D_i \eta\right)^b - \eta^a \left(D_i \varepsilon\right)^b \right] . \tag{26.75}$$

Integrate the first term by parts. The adjoint derivative is antisymmetric under integration by parts because f is totally antisymmetric, and it is a derivation, so

$$\int f^{abc} \pi^i_c \varepsilon^a \left(D_i \eta\right)^b = -\int \eta^b \left[f^{abc} \left(D_i \varepsilon\right)^a \pi^i_c + f^{abc} \varepsilon^a \mathcal{G}^c \right] , \tag{26.76}$$

where $(D_i\pi^i)^c$ has been recognised as $\mathcal{G}^c$ up to the matter term, which the matter bracket supplies. The first bracket on the right cancels the second term of Equation (26.75) after relabelling $a \leftrightarrow b$ and using $f^{abc} = -f^{bac}$, leaving

$$\{G[\varepsilon], G[\eta]\} = -\frac{g}{\hbar}\int \mathrm{d}^3x\; f^{cab}\varepsilon^a\eta^b\,\mathcal{G}^c = -\frac{g}{\hbar}\,G[[\varepsilon,\eta]]\;, \qquad [\varepsilon,\eta]^c = f^{cab}\varepsilon^a\eta^b\,, \tag{26.77}$$

which unsmeared is Equation (26.72). Since the right-hand side is a combination of the constraints, and $\left\{\pi^0_a, \mathcal{G}^b\right\} = 0$ because $\mathcal{G}$ contains no A^a_0, all $2N$ constraints are first class by Definition 26.12, and Proposition 26.13 is realised with constant structure functions. The count follows from Equation (26.21) with $2n = 8N$, $F = 2N$, $S = 0$. □

Remark 26.38 (What the non-abelian term costs). Three consequences follow from Equation (26.72) and none of them is available in the abelian case. First, the gauge generator Equation (26.61) becomes $G[\Lambda] = \int \left[c^{-1}\dot{\Lambda}^a\pi^0_a - \Lambda^a\mathcal{G}^a\right]$ with Λ colour-valued, and the transformation it generates is Equation (102.23) — so the classical Hamiltonian analysis and the Lagrangian gauge principle Theorem 102.19 agree, which is the check on the whole construction. Second, the Faddeev–Popov determinant of Proposition 26.24 is no longer field independent: for a linear gauge condition $\psi^a = \partial_i A^a_i$ the matrix $\left\{\mathcal{G}^a, \psi^b\right\}$ is $\partial_i D_i$ rather than ∇^2, which depends on A and therefore cannot be dropped as a constant — this is exactly the classical input to [1347] and the reason ghosts are unavoidable in Chapter 102 and absent from abelian Chapter 100. Third, $\partial_i D_i$ has zero modes for large enough A, which is Remark 26.27 said in the canonical language.

Remark 26.39 (The count against the evidence). Two polarizations per generator is a testable statement, and the two places it has been tested are the eight gluons of Chapter 102 — whose count enters the running of α_s through the coefficient of the beta function, measured over three decades of energy — and the electroweak sector, where the three broken generators acquire mass and their third polarization along with it (Chapter 104), while the photon keeps two. Neither count is postulated; both follow from Proposition 26.37 and its massive counterpart Proposition 26.34, and both are what is observed.

26.6.5 General relativity

General relativity is a constrained system of the most extreme kind: its canonical Hamiltonian is a sum of constraints and therefore vanishes weakly, exactly as for the relativistic particle of Proposition 26.29 and for the same reason — the invariance group contains reparametrizations of the evolution parameter. The decomposition that exhibits this is due to Arnowitt, Deser and Misner [1221].

Definition 26.40 (The $3+1$ decomposition)**.** Foliate spacetime by spacelike surfaces $t = \text{const}$ and write, with $x^0 = ct$ and in the signature of Chapter 39,

$$\mathrm{d}s^2 = N^2\left(\mathrm{d}x^0\right)^2 - h_{ij}\left(\mathrm{d}x^i + N^i\mathrm{d}x^0\right)\left(\mathrm{d}x^j + N^j\mathrm{d}x^0\right)\,, \tag{26.78}$$

with h_{ij} the positive-definite Riemannian metric of the surface — so that $h_{ij}\mathrm{d}x^i\mathrm{d}x^j$ is squared proper distance, and the metric g_{ij} induced by Equation (26.78) is $-h_{ij}$ in this signature — and with N, N^i dimensionless. N is the *lapse*, measuring proper time per unit x^0 along the normal, and N^i the *shift*, measuring how the spatial coordinates slide from one surface to the next. Neither is a property of the geometry: both encode the choice of foliation and of coordinates on it. The *extrinsic curvature* of the surface is

$$K_{ij} = \frac{1}{2N}\left(\partial_0 h_{ij} - D_iN_j - D_jN_i\right)\,, \tag{26.79}$$

with $N_i = h_{ij}N^j$ and D_i the Levi-Civita connection of h_{ij}; it carries dimension 1/m and is the only place the time derivative of the metric enters.

Rests on Definition 43.2 and Notation 26.28.

Proposition 26.41 (The ADM form of the Einstein–Hilbert Lagrangian)**.** *With Equation* (26.78) *one has* $\sqrt{|g|} = N\sqrt{h}$ *and*

$$\sqrt{|g|}\,R = N\sqrt{h}\left({}^{(3)}R + K_{ij}K^{ij} - K^2\right) + \text{total derivatives}\,, \tag{26.80}$$

where ${}^{(3)}R$ *is the Ricci scalar of* h_{ij} *and* $K = h^{ij}K_{ij}$*. The Lagrangian of Equation* (43.4) *therefore contains* no *time derivative of* N *or of* N^i*.*

Rests on Definition 26.40 and Equation (43.4)*.*

Full derivation: Appendix A.52 (p. 3073).

Derives Proposition 26.41.

The route taken there is the Gauss–Codazzi decomposition of the four-dimensional Riemann tensor: its projections onto the leaf and onto the unit normal give the Gauss equation, which relates the wholly tangential projection to the intrinsic curvature and to a quadratic in K_{ij}, and the Codazzi equation for the mixed projection; contracting twice assembles Equation (26.80) together with two divergences, one of which is the term whose subtraction is the Gibbons–Hawking–York boundary action. The point of care specific to this treatise is the sign bookkeeping between the mostly-minus signature of Chapter 39 and the positive-definite induced metric of Definition 26.40, which is settled there explicitly rather than inherited from a mostly-plus source. Only the two facts displayed above are used in this chapter: that $\sqrt{|g|} = N\sqrt{h}$ and that no time derivative of N or N^i survives.

Theorem 26.42 (The Hamiltonian structure of general relativity)**.** *The momenta conjugate to the lapse and the shift vanish identically,*

$$\pi_N \approx 0\,, \qquad \pi_i \approx 0\,, \tag{26.81}$$

four primary constraints per point of space, while

$$\pi^{ij} = \frac{\partial \mathcal{L}}{\partial\left(\partial_0 h_{ij}\right)} = \frac{\sqrt{h}}{2\kappa}\left(K^{ij} - K h^{ij}\right)\,, \qquad \kappa = \frac{8\pi G}{c^4}\,, \tag{26.82}$$

is unconstrained. The canonical Hamiltonian is a sum of constraints,

$$H_c = \int \mathrm{d}^3x \left(N\,\mathcal{H}_\perp + N^i\,\mathcal{H}_i\right) + \text{boundary terms}\,, \tag{26.83}$$

with

$$\mathcal{H}_\perp = \frac{2\kappa}{\sqrt{h}}\left(\pi_{ij}\pi^{ij} - \tfrac{1}{2}\pi^2\right) - \frac{\sqrt{h}}{2\kappa}\,{}^{(3)}R\,, \tag{26.84}$$

$$\mathcal{H}_i = -2\,D_j\pi^j{}_i\,, \tag{26.85}$$

so that consistency of Equation (26.81) *yields the four secondary constraints* $\mathcal{H}_\perp \approx 0$ *and* $\mathcal{H}_i \approx 0$*. All eight are first class, the canonical Hamiltonian is weakly zero, and the count per point of space is* $2\times 10 - 2\times 8 = 4$*:* two *physical degrees of freedom.*

Rests on Propositions 26.10 and 26.41 and Theorem 26.17.

Proof. *Derives Theorem 26.42.*

By Proposition 26.41 the Lagrangian $L = (2\kappa)^{-1}\int \mathrm{d}^3x\, N\sqrt{h}\left({}^{(3)}R + K_{ij}K^{ij} - K^2\right)$ contains $\partial_0 N$ and $\partial_0 N^i$ nowhere, so their conjugate momenta vanish identically and Equation (26.81) are primary constraints in the sense of Proposition 26.5. The ten components of h_{ij} and of N, N^i make $2n = 2\times 10$ per point.

For π^{ij}, only K carries $\partial_0 h_{ij}$, and by Equation (26.79) $\partial K_{ij}/\partial\left(\partial_0 h_{kl}\right) = \delta^{(kl)}_{(ij)}/2N$, so

$$\pi^{kl} = \frac{N\sqrt{h}}{2\kappa}\cdot\frac{1}{N}\left(K^{kl} - Kh^{kl}\right), \tag{26.86}$$

which is Equation (26.82). Its trace is $\pi = -\sqrt{h}\,K/\kappa$, so the relation inverts to $K^{ij} = 2\kappa h^{-1/2}\left(\pi^{ij} - \frac{1}{2}\pi h^{ij}\right)$ and

$$K_{ij}K^{ij} - K^2 = \frac{4\kappa^2}{h}\left(\pi_{ij}\pi^{ij} - \tfrac{1}{2}\pi^2\right), \tag{26.87}$$

by direct substitution and collection of the two π^2 terms. Now Legendre transform. Using $\partial_0 h_{ij} = 2NK_{ij} + D_iN_j + D_jN_i$ from Equation (26.79),

$$\pi^{ij}\partial_0 h_{ij} - \mathcal{L} = \frac{N\sqrt{h}}{2\kappa}\left(K_{ij}K^{ij} - K^2\right) - \frac{N\sqrt{h}}{2\kappa}\,{}^{(3)}R + 2\pi^{ij}D_iN_j\,, \tag{26.88}$$

the first term because $2N\pi^{ij}K_{ij}$ is twice the corresponding term of $\mathcal{L}$. Substituting Equation (26.87) into the first term gives $N\mathcal{H}_\perp$ with $\mathcal{H}_\perp$ as in Equation (26.84); integrating the last term by parts gives $-2N_iD_j\pi^{ji}$ plus a surface term, that is $N^i\mathcal{H}_i$ with $\mathcal{H}_i$ as in Equation (26.85). That is Equation (26.83).

Since N and N^i appear in Equation (26.83) linearly and without derivatives, they are multipliers, and consistency of Equation (26.81) reads $\dot\pi_N = -\delta H_c/\delta N = -\mathcal{H}_\perp \approx 0$ and $\dot\pi_i = -\mathcal{H}_i \approx 0$: four secondary constraints, outcome 2 of Proposition 26.10. That they are first class is Equation (26.89) below, whose right-hand sides are combinations of the constraints; the primary constraints commute with everything because no $\mathcal{H}$ contains N or N^i. Hence $F = 8$, $S = 0$, $2n = 20$, and Equation (26.21) gives $20 - 16 = 4$: two configuration degrees of freedom per point of space. Finally, substituting the secondary constraints into Equation (26.83) gives $H_c \approx 0$ up to the boundary terms of Remark 26.45. □

Proposition 26.43 (The hypersurface-deformation algebra)**.** *Smearing $\mathcal{H}_\perp$ with a scalar f and $\mathcal{H}_i$ with a vector ξ^i, and writing $H_\perp[f] = \int f\mathcal{H}_\perp$, $H_\parallel[\xi] = \int \xi^i\mathcal{H}_i$, the constraints close as*

$$\left\{H_\parallel[\xi], H_\parallel[\zeta]\right\} = H_\parallel[[\xi,\zeta]]\,, \tag{26.89}$$

$$\left\{H_\parallel[\xi], H_\perp[f]\right\} = H_\perp\left[\xi^i\partial_i f\right], \tag{26.90}$$

$$\left\{H_\perp[f], H_\perp[g]\right\} = H_\parallel\left[h^{ij}\left(f\partial_j g - g\partial_j f\right)\right]. \tag{26.91}$$

The first two say that the momentum constraints generate spatial diffeomorphisms and that $\mathcal{H}_\perp$ is a scalar density under them. The third is the one that matters: its coefficient is h^{ij}, a function on phase space, so the first-class algebra of general relativity has structure functions *and is not a Lie algebra.*

Rests on Theorem 26.42 and Proposition 26.13.

Full derivation: Appendix A.53 (p. 3082).

Derives Proposition 26.43.

Each bracket is a direct computation from the densities Equations (26.84) and (26.85), and the third is long: both the kinetic and the intrinsic-curvature terms contribute, and the curvature contribution has to be integrated by parts twice before the surviving terms assemble into $\mathcal{H}_i$. The geometric reading, written there beside the computation, is that these brackets reproduce the composition law of deformations of a spacelike surface embedded in a Lorentzian spacetime; the metric appears in the third because a normal deformation at one point becomes a tangential one at a neighbouring point through the geometry of the surface itself, and that is why h^{ij} — a function on phase space, not a constant — sits where a structure constant would.

Remark 26.44 (Three consequences, and one that is out of scope). *The constraints are the initial-value equations.* The four secondary constraints of Theorem 26.42 involve no time derivative of π^{ij}: they are conditions on the data (h_{ij}, π^{ij}) laid down on one surface, and they are precisely the $G^0{}_\mu = \kappa T^0{}_\mu$ components of the Einstein equations. Not every initial datum is admissible, and the constraints say which are — this is the content of Sections 44.9 and 44.9.1, and the well-posedness of the resulting evolution problem is [999], with the constraint-solving method of [1490].

The count matches the waves. Two degrees of freedom per point is the same answer Proposition 26.32 gave for light, and it is the two polarizations of Chapter 46, detected as such in Chapter 47. That a theory with ten metric functions propagates two is not obvious from the field equations and is transparent here.

The Hamiltonian vanishes. $H_{\mathrm{c}} \approx 0$ says, by Remark 26.46, that evolution in the coordinate t is a gauge transformation — a relabelling of the foliation — and not a physical motion. What is physical is the relation between the geometry and the matter in it, exactly as what was physical for the relativistic particle was the worldline and not its parametrization.

What is not claimed. The statement that this vanishing creates a "problem of time" is a statement about a *quantum* theory of gravity, in which Equation (26.92) would read $\hat{\mathcal{H}}_\perp |\psi\rangle = 0$ and leave the state vector with no evolution parameter. No such theory has observational support, so it is outside the evidence base of this treatise and is treated only in Chapter 135. Classically there is no problem of time and nothing to solve.

Remark 26.45 (The energy is a boundary term). The surface terms discarded in Equation (26.83) cannot in fact be discarded. On a region with a boundary, or in an asymptotically flat spacetime, the constraints do not have well-defined functional derivatives unless they are supplemented by surface integrals; the supplement to $\mathcal{H}_\perp$ is the ADM mass and the supplement to $\mathcal{H}_i$ the ADM momentum and angular momentum [1221, 1746]. So the total energy of an isolated gravitating system is a boundary integral at spatial infinity and not the volume integral of any density: the numerical value of the Hamiltonian is carried entirely by the surface term, the bulk being weakly zero. This is the constrained-dynamics origin of the ADM integrals referred to in Chapter 44, and it is why the localization of gravitational energy is not a well-posed question.

Remark 26.46 (A vanishing Hamiltonian, again). Remark 26.31 was stated for the relativistic particle and applies verbatim here, with the reparametrizations of the worldline replaced by the deformations of the spacelike surface. The two systems are the same phenomenon at different sizes, which is why the particle is worth doing first.

26.7 Quantizing a constrained system

Postulate 26.47 (Dirac quantization)**.** Quantize a constrained system by

1. eliminating the second-class constraints, replacing the Poisson bracket by the Dirac bracket Equation (26.25) and imposing $\chi_\alpha = 0$ strongly; then applying the correspondence rule Equation (25.31) to the Dirac bracket, $\{A, B\}_{\mathrm{D}} \mapsto \frac{1}{\mathrm{i}\hbar}\left[\hat{A}, \hat{B}\right]$; and
2. imposing the first-class constraints as conditions on the *states* rather than on the operators,
$$\hat{\gamma}_A |\psi\rangle = 0\,, \tag{26.92}$$
the physical Hilbert space being the space of solutions.

Rests on Postulate 25.27 and Theorems 26.14 and 26.21.

The asymmetry between the two clauses is the whole design and is forced by Theorem 26.21. A second-class constraint has vanishing Dirac bracket with everything, so it may

be set to zero as an operator identity without contradicting any commutator; a first-class constraint may not, because it generates a nontrivial transformation and setting it to zero as an operator would set that generator to zero too. Imposing it on states instead selects the gauge-invariant sector, which is exactly what Theorem 26.14 says the physical states are.

Proposition 26.48 (Consistency of the state conditions)**.** *Equation* (26.92) *is consistent only if the quantum constraint algebra closes,*

$$[\hat{\gamma}_A, \hat{\gamma}_B] = \mathrm{i}\hbar\, \hat{f}_{AB}{}^{C} \hat{\gamma}_C \,, \tag{26.93}$$

with the constraint operators standing to the right*. A failure of Equation* (26.93) *is an* anomaly*: a symmetry of the classical theory that no quantization preserves.*

Rests on Postulate 26.47 and Equation (26.16)*.*

Proof. *Derives Proposition 26.48.*

Let $|\psi\rangle$ satisfy Equation (26.92) for every A. Applying the commutator to it, $[\hat{\gamma}_A, \hat{\gamma}_B]\,|\psi\rangle = \hat{\gamma}_A\hat{\gamma}_B\,|\psi\rangle - \hat{\gamma}_B\hat{\gamma}_A\,|\psi\rangle = 0$, so the commutator must annihilate every physical state. The classical bracket is $f_{AB}{}^{C}\gamma_C$ by Equation (26.16), and its operator image annihilates $|\psi\rangle$ if and only if every $\hat{\gamma}_C$ stands to the right of the corresponding $\hat{f}_{AB}{}^{C}$: the opposite ordering leaves $\hat{\gamma}_C\hat{f}_{AB}{}^{C}\,|\psi\rangle = \big[\hat{\gamma}_C, \hat{f}_{AB}{}^{C}\big]\,|\psi\rangle$, which need not vanish. Where the structure functions are constants the question does not arise, which is why Equation (26.72) is easier to quantize than Equation (26.91). If no operator ordering makes Equation (26.93) hold, the conditions Equation (26.92) are mutually inconsistent and only $|\psi\rangle = 0$ satisfies them.

This is the ordering ambiguity of Definition 25.42 seen from the other end. There, the choice among $\hat{q}\hat{p}$, $\hat{p}\hat{q}$ and their symmetrizations was underdetermined by the correspondence rule and had to be fixed by experiment (Remark 25.49); here the requirement that a gauge symmetry survive quantization fixes part of the same choice, and Theorem 25.38 guarantees that it cannot always be fixed consistently. An anomaly is precisely the case in which it cannot. □

Remark 26.49 (Anomalies are an experimental constraint). An anomaly in a *global* symmetry is a prediction, and a correct one: the observed decay of the neutral pion to two photons is the textbook case [1388, 1391], and its rate counts the colours (Proposition 102.16). An anomaly in a *gauge* symmetry is fatal, because Equation (26.92) then has no solutions and the theory has no physical states. That the gauge anomalies of the Standard Model cancel between quarks and leptons, generation by generation, is therefore not an aesthetic observation but a consistency condition that the observed particle content satisfies and that constrains any proposed addition to it (Chapters 104 and 105). The cancellation is not only of the triangle kind: a global obstruction also exists, and it requires the number of left-handed SU(2) doublets to be even [1707] — which the observed generations satisfy, one quark doublet in three colours plus one lepton doublet making four.

26.7.1 Reduced-phase-space quantization

The alternative to Postulate 26.47 is to do all the classical work first: fix the gauge as in Definition 26.23, construct the reduced phase space of dimension $2n - 2F - S$, take its Dirac bracket, and only then apply the correspondence rule. The two routes are often called *constrain-then-quantize* and *quantize-then-constrain*, and the honest statement is that they are not equivalent.

They differ in three ways, each of which is a known difficulty rather than a technicality.

Ordering. The reduced phase space is in general not a cotangent bundle and carries no distinguished coordinates, so there is no preferred operator ordering on it; Example 26.22 is the smallest example, where Equation (26.37) makes the reduced momenta

non-commuting and the ordering ambiguity of Proposition 25.43 unavoidable. Dirac quantization keeps the ambient linear phase space, where Theorem 25.34 applies and the representation is essentially unique, and pays for it in Section 26.7.2.

Inner product. Equation (26.92) typically has no normalizable solutions — the constraint operator has continuous spectrum at zero — so the physical inner product must be constructed rather than inherited, and different constructions give different theories. The reduced route has an inner product from the start but may have no natural measure.

Spectrum. Where both routes can be carried out, they can disagree on the spectrum of an observable. This is Corollary 25.41 appearing in a new place: quantization is not a functor, so a classical isomorphism between two descriptions of one system does not survive to the quantum theory, and the order of the operations matters.

There is no principle in this treatise that decides between them. Where both have been carried out and compared against measurement they agree on what has been measured: for quantum electrodynamics the Coulomb-gauge reduced construction and the covariant construction of Section 26.7.2 give the same scattering amplitudes [1912], and the agreement is checked to the precision of the electron anomalous moment (Chapter 112). That is an experimental fact about one theory, not a theorem about the two procedures, and it should not be read as one.

26.7.2 Weak imposition: the Gupta–Bleuler construction

For quantum electrodynamics in a manifestly covariant gauge the condition Equation (26.92) cannot be imposed as it stands, and the reason is visible already in Proposition 26.32: the primary constraint is $\pi^0 \approx 0$, so a covariant commutator $\left[\hat{A}_\mu(\boldsymbol{x}), \hat{\pi}^\nu(\boldsymbol{y})\right] = \mathrm{i}\hbar\,\delta^\nu_\mu \delta^3(\boldsymbol{x}-\boldsymbol{y})$ contradicts it outright. The covariant route therefore does not impose the constraint at all. Instead it adds to Equation (26.54) a gauge-fixing term

$$\mathcal{L}_{\mathrm{gf}} = -\frac{1}{2\xi\mu_0}\left(\partial_\mu A^\mu\right)^2 , \tag{26.94}$$

which makes $\pi^0 = -\left(\xi\mu_0 c\right)^{-1}\partial_\mu A^\mu$ nonzero. The Lagrangian is then *non*-singular: there are no constraints, all four components of A_μ propagate, and the canonical formalism of Chapter 22 applies unchanged. The price is paid twice over. The time component has a commutator of the opposite sign to the others, so the Fock space carries an indefinite metric and is not a Hilbert space; and the theory has four polarizations where Proposition 26.32 counted two.

The Gupta–Bleuler construction recovers both [953, 958]. The Lorenz condition $\partial_\mu \hat{A}^\mu\,|\psi\rangle = 0$ is too strong — no state in the Fock space satisfies it — so only its positive-frequency part is required,

$$\left(\partial_\mu \hat{A}^\mu\right)^{(+)}|\psi\rangle = 0\,, \tag{26.95}$$

which is the annihilation half and which does have solutions. The subspace $\mathcal{V}_{\mathrm{phys}}$ they span has a positive *semi*-definite norm: the timelike and longitudinal excitations survive only in the combination that has zero norm, because their opposite-sign contributions cancel exactly. Quotienting by that null subspace,

$$\mathcal{H}_{\mathrm{phys}} = \mathcal{V}_{\mathrm{phys}}/\mathcal{V}_0\,, \tag{26.96}$$

gives a genuine Hilbert space in which only the two transverse polarizations remain — Proposition 26.32's count, recovered. Here and in Section 26.7.3 the symbol $\mathcal{H}_{\mathrm{phys}}$ is a

Hilbert space and not a Hamiltonian density, the one place in this chapter where the script letter carries its other standard meaning. Zero-norm states do not contribute to any expectation value, so observables are insensitive to the choice of representative, and the gauge parameter ξ cancels from every physical amplitude, which is the standard check performed in Chapter 100. The construction is developed with the field operators in Chapter 99.

The essential limitation is that Equation (26.95) splits the constraint operator into positive- and negative-frequency parts, and that split is available only for a free field — a linear equation of motion. For a non-abelian theory the constraint algebra Equation (26.72) is nonlinear in the fields, no such split exists, and the Gupta–Bleuler condition has no non-abelian generalization. That failure is what the next subsection exists to repair.

26.7.3 BRST

The systematic replacement of the constraint conditions Equation (26.92) is due to Becchi, Rouet and Stora and, independently, to Tyutin [1564, 1571]. It trades the F separate conditions for a single one, at the price of enlarging the phase space.

Definition 26.50 (The BRST charge)**.** For each first-class constraint γ_A adjoin a Grassmann-odd pair $\left(\eta^A, \mathcal{P}_A\right)$ — the *ghost* and its momentum — canonically conjugate under the graded bracket, $\left\{\eta^A, \mathcal{P}_B\right\} = -\delta^A_B$, and carrying ghost numbers $+1$ and -1. Under quantization the pair becomes an anticommutator, $\left\{\hat{\eta}^A, \hat{\mathcal{P}}_B\right\} = -\mathrm{i}\hbar\,\delta^A_B$; the overall sign is a convention, fixed by the sign chosen for $\mathcal{P}$, and no statement below depends on it. The *BRST charge* is the Grassmann-odd function of ghost number $+1$

$$\Omega = \eta^A \gamma_A - \tfrac{1}{2}\eta^B \eta^A f_{AB}{}^C \mathcal{P}_C + \cdots , \tag{26.97}$$

determined by the requirement that it be *nilpotent*,

$$\{\Omega, \Omega\} = 0 , \qquad \text{quantum mechanically} \quad \hat{\Omega}^2 = 0 , \tag{26.98}$$

which is a nontrivial condition because the bracket of two odd functions is symmetric. The displayed terms suffice when the structure functions of Equation (26.16) are constants; the omitted terms, of higher order in the ghosts, are needed exactly when they are not.

Rests on Equation (26.16) and Postulate 26.47.

That such an Ω exists at all, for every first-class set and not merely for the ones whose algebra happens to close on constants, is the theorem that makes BRST a general method rather than a device.

Theorem 26.51 (Existence and uniqueness of the BRST charge)**.** *Let γ_A be a regular and irreducible set of first-class constraints in the sense of Remark 26.7, with the algebra Equation (26.16). Then the series Equation (26.97) can be continued, order by order in the ghosts, to a Grassmann-odd function Ω of ghost number $+1$ satisfying Equation (26.98) exactly; and any two such functions with the same leading term are related by a canonical transformation of the extended phase space preserving the ghost number. When the structure functions $f_{AB}{}^C$ are constants the series terminates at the two displayed terms.*

Rests on Definition 26.50, Equation (26.16), and Remark 26.7.

Full derivation: Appendix A.54 (p. 3088).

Derives Theorem 26.51.

The construction there is by induction on the ghost number. Nilpotency at each order is an equation of the form $\delta\,\Omega_{(k)} =$ (known, built from lower orders), where δ is the Koszul–Tate differential of the constraint surface; the obstruction to solving it is a class in the homology of δ at positive degree, which vanishes precisely because the constraints are regular

and irreducible — that is what makes the Koszul–Tate complex a resolution. Uniqueness is the same statement one degree down.

The point of Equation (26.98) is that a nilpotent operator has a cohomology, and

$$\mathcal{H}_{\text{phys}} = \frac{\ker \hat{\Omega}}{\operatorname{im} \hat{\Omega}} \quad \text{at ghost number zero} \tag{26.99}$$

reproduces the physical state space of Postulate 26.47: the kernel condition $\hat{\Omega}\,|\psi\rangle = 0$ contains Equation (26.92) at lowest ghost order, and the quotient by the image removes exactly the zero-norm states that Equation (26.96) removed by hand in the abelian case. Gupta–Bleuler is therefore the abelian shadow of Equation (26.99), and the ghosts that appear here as bookkeeping variables are the same objects that Proposition 26.24 produced as the exponentiation of a Jacobian.

Three things make this the practical form in which the content of this chapter enters a calculation. The gauge-fixed action is $S_{\text{gf}} = S + \{\Omega, \Psi\}$ for a gauge-fixing function Ψ of ghost number -1, and nilpotency makes physical amplitudes independent of Ψ — which is why a gauge may be chosen for convenience and why the ξ of Equation (26.94) cancels. The Ward identities of the abelian theory generalize to the Slavnov–Taylor identities, which is what makes the renormalization of Chapter 102 preserve gauge invariance order by order. And unitarity of the physical subspace follows from Equation (26.99) rather than being assumed, so the unphysical polarizations and the ghosts cancel in every cut. The path-integral development, where this is done in practice, is Chapter 106.

26.8 Constraints in field theory

Everything above was written for finitely many degrees of freedom. The passage to a field theory is not automatic, and the places where it is not are recorded here so that Parts VII and XI can refer to them rather than rediscover them.

Constraints are densities. A field-theoretic constraint $\varphi(\boldsymbol{x}) \approx 0$ is one constraint per point of space, so the index j of Equation (26.11) is continuous and the sums become integrals, as set out in Notation 26.28. The counting theorem Theorem 26.17 is applied per point, which is what makes the counts of Propositions 26.32 and 26.34 statements about polarizations.

The bracket matrix is a kernel. $C_{\alpha\beta}$ of Equation (26.24) becomes an integral kernel containing derivatives of delta functions, and "inverting" it means solving a differential equation with boundary conditions. The Dirac bracket of Equation (26.25) is then nonlocal in general, and its locality in particular cases is a result, not an assumption. The Coulomb-gauge brackets of electrodynamics are the standard example: inverting ∇^2 produces the Coulomb kernel, and the instantaneous interaction it describes is an artifact of the gauge, not of the physics.

Regularization. Products of constraint operators at the same point are singular, so Equation (26.93) is a statement about regularized operators, and the anomaly of Remark 26.49 is precisely an obstruction to finding a regulator that preserves the classical algebra.

Boundary terms. On a region with a boundary, or in an asymptotically flat spacetime, the first-class constraints must be supplemented by surface terms for their brackets to be well defined; the surface terms are the total energy, momentum and angular momentum. This is the origin of the ADM mass (Remark 26.45), and it is why in general relativity the energy is a boundary integral rather than a volume integral of a density.

Rank can vary over field space. The constant-rank hypothesis of Definition 26.3 is a statement about a neighbourhood, and in a field theory the neighbourhood is in an infinite-dimensional space. Where it fails — at reducible connections in Yang–Mills, at degenerate metrics in gravity — the constraint structure changes and the counting theorem does not apply. These are measure- zero sets in the classical theory and are ignored throughout this chapter, which is legitimate for the perturbative statements made here and is exactly what fails to be legitimate non-perturbatively (Remark 26.27).

Chapter 27

Central Forces and Statics

Two special regimes of the Newtonian dynamics of Chapter 19 deserve a chapter of their own. The first is the regime in which nothing moves at all: statics, the theory of equilibrium, whose two conditions are the direct specialization of the translational and rotational laws of motion. The second is the regime in which the force on a particle always points along the line to a fixed centre: central motion, which governs planetary orbits and scattering alike, and which reduces — through its conservation laws — to an equivalent problem in a single radial dimension. Standard extended treatments may be found in the classical references [1585, 1945, 2027].

The two regimes are less distant from one another than they look. Both are governed by what a conservation law removes: statics is what remains when the momenta are held at zero, central motion is what remains when the angular momentum has been used to eliminate one coordinate and the energy to eliminate another. In both, the whole of the physics sits in a function of one variable — a potential energy on a configuration space in the first case, an effective potential of the radius in the second.

Remark 27.1 (Two pieces of mathematics used but not owned here). This chapter uses two elementary facts about $\mathbb{R}^3$ that Chapters 7 and 13 do not state, and states them here rather than proving general mathematics inside a physics chapter. The first is the expansion of the double cross product,

$$\boldsymbol{a} \times (\boldsymbol{b} \times \boldsymbol{c}) = \boldsymbol{b}\,(\boldsymbol{a} \cdot \boldsymbol{c}) - \boldsymbol{c}\,(\boldsymbol{a} \cdot \boldsymbol{b}) \,, \tag{27.1}$$

used once, in Theorem 27.38. The second is that the area of a circular sector of radius r subtending an angle ϕ is $\frac{1}{2}r^2\phi$, used once, in Proposition 27.17. Both belong to the elementary vector algebra and plane geometry that Part II owes; neither is in dispute, and the reader who wants them proved will find them in any of [1945, 2027].

27.1 Statics

Definition 27.2 (Translational equilibrium)**.** A particle is said to be in *translational equilibrium* if and only if

$$\sum_m \boldsymbol{F}_m = \boldsymbol{0} \,, \tag{27.2}$$

where the $\boldsymbol{F}_m$ are the m forces upon the particle.

Rests on Equation (19.2) *and Definition 19.5.*

Definition 27.3 (Rotational equilibrium)**.** A particle is said to be in *rotational equilibrium* if and only if

$$\sum_n \boldsymbol{\tau}_n = \boldsymbol{0} \,, \tag{27.3}$$

where the $\boldsymbol{\tau}_n$ are the n torques upon the particle.

Rests on Equation (19.14) *and Definition 19.18.*

Under these conditions, Equations (19.2) and (19.14) state that the linear momentum and the angular momentum of the particle are constant: equilibrium is the regime in which Newton's second laws, translational and rotational, reduce to conservation statements.

A torque is defined about a chosen point, so the second condition looks at first sight to depend on that choice. It does not, provided the first condition already holds — and that is what makes the pair of conditions usable at all.

Proposition 27.4 (Torque balance is independent of the origin)**.** *Let a system of forces $\boldsymbol{F}_m$ act at the points $\boldsymbol{x}_m$ of a body, and suppose Equation (27.2) holds. Then the total torque $\boldsymbol{\tau}_O = \sum_m \boldsymbol{x}_m \times \boldsymbol{F}_m$ takes the same value about every point O. Consequently, if the torque balance Equation (27.3) holds about one point, it holds about all of them.*

Rests on Equations (19.15) and (27.2).

Proof. *Derives Proposition 27.4.*

Let O' be displaced from O by $\boldsymbol{a}$, so that the position of the m-th point of application measured from O' is $\boldsymbol{x}_m - \boldsymbol{a}$. By Equation (19.15) the total torque about O' is

$$\boldsymbol{\tau}_{O'} = \sum_m (\boldsymbol{x}_m - \boldsymbol{a}) \times \boldsymbol{F}_m = \boldsymbol{\tau}_O - \boldsymbol{a} \times \sum_m \boldsymbol{F}_m = \boldsymbol{\tau}_O \,, \tag{27.4}$$

the last step by Equation (27.2). The displacement $\boldsymbol{a}$ was arbitrary. □

The proposition is sharper than it looks, and its converse is false in a way worth stating: when the net force does *not* vanish, the torque does depend on the reference point, and one may always slide O' along the line perpendicular to $\sum \boldsymbol{F}_m$ until the torque about it vanishes. That is why a single unbalanced force is described as acting along a definite *line of action* rather than at a definite point.

Phenomenon 27.5 (Equilibrium requires two conditions, not one)**.** A body stays at rest only if the forces upon it balance *and* their turning effects balance; the two requirements are independent, and Nature displays the difference plainly. Two equal and opposite forces applied at different points of a rigid body — a couple, as when both hands turn a steering wheel — leave the centre of mass exactly where it was and set the body spinning. Conversely a single force whose line of action passes through the centre of mass translates the body without turning it at all. Every static structure, from a balanced beam to a ladder leaning against a wall, stands by the simultaneous satisfaction of both conditions, and fails when either is violated [14].

Rests on Equations (27.2) and (27.3).

Derivation. *Derives Phenomenon 27.5.*

Apply forces $\boldsymbol{F}$ and $-\boldsymbol{F}$ at the points $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ of a rigid body. Equation (27.2) is satisfied, since the two cancel, so by the second law of Chapter 19 the centre of mass keeps whatever velocity it had. The total torque about the origin, however, is

$$\boldsymbol{\tau} = \boldsymbol{x}_1 \times \boldsymbol{F} + \boldsymbol{x}_2 \times (-\boldsymbol{F}) = (\boldsymbol{x}_1 - \boldsymbol{x}_2) \times \boldsymbol{F} \,, \tag{27.5}$$

which is independent of the choice of origin — a couple has the same moment about every point, which is Proposition 27.4 for the special case of a vanishing resultant — and which vanishes only if $\boldsymbol{F}$ is parallel to the line joining the two points of application. Whenever it does not vanish, Equation (27.3) fails, the angular momentum grows, and the body turns although no net force acts upon it. For the converse case, a single force applied at the centre of mass has $\boldsymbol{x} = \boldsymbol{0}$ measured from there, hence zero moment about it, and the body accelerates without rotating. The two conditions are therefore logically independent, and neither implies the other. □

27.1.1 The centre of gravity

Weight acts on every part of a body, so the gravitational contribution to Equation (27.3) is a sum over the whole mass distribution. In a uniform field that sum collapses to a single term.

Definition 27.6 (Centre of gravity)**.** The *centre of gravity* of a body in a gravitational field is the point $\boldsymbol{X}_g$ such that the total gravitational torque about any point equals the torque of the total weight applied at $\boldsymbol{X}_g$ alone.
Rests on Definition 19.47 and Equation (19.15).

Proposition 27.7 (Centre of gravity in a uniform field)**.** *If the gravitational field $\boldsymbol{g}$ is the same at every point of the body, then $\boldsymbol{X}_g = \boldsymbol{X}$, the centre of mass Equation* (19.38)*, and the total gravitational torque about the origin is*

$$\boldsymbol{\tau}_g = \boldsymbol{X} \times M\boldsymbol{g}\,, \tag{27.6}$$

with M the total mass Equation (19.32)*.*
Rests on Equations (19.15)*,* (19.32) *and* (19.38)*.*

Proof. *Derives Proposition 27.7.*
The weight of the m-th element is $m_m\boldsymbol{g}$ with one and the same $\boldsymbol{g}$, so by Equation (19.15)

$$\boldsymbol{\tau}_g = \sum_m \boldsymbol{x}_m \times m_m\boldsymbol{g} = \left(\sum_m m_m\boldsymbol{x}_m\right) \times \boldsymbol{g} = \boldsymbol{X} \times M\boldsymbol{g}\,, \tag{27.7}$$

using Equation (19.38) in the form $\sum_m m_m\boldsymbol{x}_m = M\boldsymbol{X}$. The right-hand side is the torque of a single force $M\boldsymbol{g}$ applied at $\boldsymbol{X}$, which is Definition 27.6. □

The uniformity hypothesis is not idle. Over a body of vertical extent h near the Earth's surface the field varies by a relative amount $2h/R_\oplus$, about 3×10^{-7} per metre; the resulting separation of the centre of gravity from the centre of mass is what raises the tides and what makes a satellite in orbit settle with its long axis pointing at the planet. For a laboratory body it is utterly negligible, and Proposition 27.7 is exact for every purpose of this section.

Phenomenon 27.8 (The centre of gravity hangs below the support)**.** A flat plate hung freely from a pin comes to rest, after its oscillations have died away, in one definite orientation, and the vertical line through the pin always passes through the same material point of the plate whichever pin is used. Suspending the plate from two different points and marking the two verticals locates that point as their intersection; a third suspension confirms it. This is how the centre of gravity of an irregular body is measured, and it is the principle of every balance and every plumb line [14].
Rests on Equations (27.3) *and* (27.6)*.*

Derivation. *Derives Phenomenon 27.8.*
Take torques about the point of support S, so that the unknown reaction there contributes nothing. The only other force is the weight, whose torque is $(\boldsymbol{X} - \boldsymbol{x}_S) \times M\boldsymbol{g}$ by Equation (27.6). Rotational equilibrium Equation (27.3) therefore demands

$$(\boldsymbol{X} - \boldsymbol{x}_S) \times M\boldsymbol{g} = \boldsymbol{0}\,, \tag{27.8}$$

that is, that $\boldsymbol{X} - \boldsymbol{x}_S$ be parallel to $\boldsymbol{g}$: the centre of gravity lies on the vertical through the support. Two positions satisfy this, one with $\boldsymbol{X}$ below S and one with it above; only the first is stable, by Theorem 27.10, since rotating the body about the pin from that position raises the centre of gravity and so raises the potential energy MgZ, Z being its height, whereas rotating it from the second position lowers Z. Repeating the suspension from a second point gives a second vertical through the same material point, and two non-parallel lines meet in one point. □

27.1.2 Equilibrium as a stationary potential energy

Written out force by force, the equilibrium of a mechanism with many joints is a large system of equations in which most of the unknowns are constraint forces nobody wants to know. The principle of virtual work Equation (21.17) removes them all at once, because a constraint force does no virtual work.

Theorem 27.9 (Equilibrium is stationarity of the potential energy)**.** *Consider a system with holonomic, time-independent constraints, described by generalized coordinates q^a, $a = 1, \dots, n$, whose active forces derive from a potential energy $U(q)$. Then a configuration q_0 is an equilibrium configuration if and only if*

$$\left.\frac{\partial U}{\partial q^a}\right|_{q_0} = 0\,, \qquad a = 1, \dots, n\,. \tag{27.9}$$

Rests on Equations (21.17) *and* (21.31) *and Definition 21.2.*

Proof. *Derives Theorem 27.9.*

By Theorem 21.18 the system is in equilibrium if and only if the virtual work of the active forces vanishes for every virtual displacement compatible with the constraints. Because the constraints are holonomic and time-independent, a compatible virtual displacement is exactly one of the form $\delta \boldsymbol{x}^s = (\partial \boldsymbol{x}^s / \partial q^a)\, \delta q^a$ with the δq^a arbitrary and independent, so that by Equation (21.31) the virtual work is

$$\delta W = \sum_s \boldsymbol{F}^s \cdot \delta \boldsymbol{x}^s = Q_a\, \delta q^a\,, \qquad Q_a = \sum_s \boldsymbol{F}^s \cdot \frac{\partial \boldsymbol{x}^s}{\partial q^a}\,. \tag{27.10}$$

For forces derived from a potential, $\boldsymbol{F}^s = -\nabla_s U$ and the chain rule (Proposition 7.72) gives $Q_a = -\partial U / \partial q^a$. Vanishing of $Q_a \delta q^a$ for arbitrary independent δq^a is vanishing of every Q_a, which is Equation (27.9). □

Equilibrium is thus a stationarity condition, and the character of the stationary point decides whether the equilibrium can be observed at all.

Theorem 27.10 (Lagrange–Dirichlet)**.** *If U has a strict local minimum at the equilibrium configuration q_0, then q_0 is stable: for every neighbourhood N of $(q_0, 0)$ in the space of positions and velocities there is a smaller one from which the motion never leaves N.*

Rests on Equations (19.21) *and* (27.9) *and Theorem 21.43.*

Proof. *Derives Theorem 27.10.*

Set $U(q_0) = 0$ without loss of generality. The kinetic energy T of a system with time-independent constraints is a positive definite quadratic form in the generalized velocities (Definition 21.66), so $T \geq 0$ with equality only at rest, and the conserved energy $E = T + U$ of Theorem 21.43 is a positive definite function of $(q - q_0, \dot{q})$ near the equilibrium, because U has a strict minimum there. Given a neighbourhood N, choose $\varepsilon > 0$ smaller than the least value of U on the boundary of a ball inside N; then any motion starting with $E < \varepsilon$ can never reach that boundary, since doing so would require $U \geq \varepsilon$ and hence $E \geq \varepsilon$. The set $\{E < \varepsilon\}$ is the required smaller neighbourhood. □

Example 27.11 (The ladder against a wall)**.** A uniform ladder of mass $M = 12.0\,\mathrm{kg}$ and length $\ell = 4.00\,\mathrm{m}$ leans at $\vartheta = 65.0°$ to the horizontal, its top against a smooth vertical wall and its foot on a floor that can supply friction. Three unknown constraint forces act: the wall's normal N_w (horizontal), the floor's normal N_f (vertical) and the floor's friction f (horizontal). Taking torques about the foot, where two of the three act and contribute nothing,

$$N_w\, \ell \sin\vartheta = Mg\, \frac{\ell}{2} \cos\vartheta \qquad \Longrightarrow \qquad N_w = \frac{Mg}{2 \tan\vartheta}\,, \tag{27.11}$$

From Equations (27.3) and (27.6) (torques about the foot, the weight acting at the midpoint by Proposition 27.7).

while Equation (27.2) resolved horizontally and vertically gives $f = N_w$ and $N_f = Mg$. With $g = 9.806\,65\,\mathrm{m/s^2}$ the weight is $Mg = 117.7\,\mathrm{N}$, so $N_f = 117.7\,\mathrm{N}$ and $N_w = f = 27.4\,\mathrm{N}$. The ratio the floor is required to supply is

$$\frac{f}{N_f} = \frac{1}{2\tan\vartheta} = 0.233\,, \tag{27.12}$$

independent of both the mass and the length — which is why the question "will it slip?" is answered by the angle alone. Whether the floor can supply it is a question about the surfaces and not about mechanics: the usual empirical bound is $f \le \mu_s N_f$ with a coefficient μ_s that for dry wood on concrete is quoted at a few tenths, comfortably above 0.233. This treatise carries no primary source for tabulated friction coefficients, and none of the mechanics above depends on one: μ_s enters only as an inequality on a constraint force, never as a law of motion.

Rests on Equations (27.2) and (27.3) and Proposition 27.7.

Remark 27.12 (Statically indeterminate systems). Equations (27.2) and (27.3) provide six scalar equations in three dimensions, and a rigid body resting on three supports has exactly three unknown normal reactions: the problem closes. A body on four supports has four, and the equations no longer determine them — which is why a four-legged table rocks and a three-legged one never does. Nothing is wrong with the mechanics; the hypothesis of perfect rigidity has simply been pushed past what it can decide, and the missing equations come from the deformation of the body under load. They are supplied by the theory of elasticity, Chapter 30, and the indeterminacy is resolved by the constitutive relation there rather than by any further principle of statics.

27.2 Central forces

Definition 27.13 (Central force)**.** A *central force* is an active force upon a particle that can be written in the form

$$\boldsymbol{F} = f(r)\,\hat{\boldsymbol{r}}\,. \tag{27.13}$$

Rests on Definitions 19.30 and 21.15.

Definition 27.14 (Central motion)**.** A *central motion* is the motion of a particle due to a central force.

Rests on Definition 27.13.

Everything in this section rests on one kinematic decomposition, which is worth isolating before it is used.

Lemma 27.15 (Velocity and acceleration in plane polar coordinates)**.** *Let a particle move in a fixed plane, and write its position as* $\boldsymbol{x} = r\,\hat{\boldsymbol{r}}$ *with* $\hat{\boldsymbol{r}} = (\cos\phi, \sin\phi)$ *and* $\hat{\boldsymbol{\phi}} = (-\sin\phi, \cos\phi)$*. Then*

$$\dot{\hat{\boldsymbol{r}}} = \dot\phi\,\hat{\boldsymbol{\phi}}\,, \qquad \dot{\hat{\boldsymbol{\phi}}} = -\dot\phi\,\hat{\boldsymbol{r}}\,, \tag{27.14}$$

$$\boldsymbol{v} = \dot r\,\hat{\boldsymbol{r}} + r\dot\phi\,\hat{\boldsymbol{\phi}}\,, \tag{27.15}$$

$$\boldsymbol{a} = \underbrace{\left(\ddot r - r\dot\phi^2\right)}_{a_r}\hat{\boldsymbol{r}} + \underbrace{\left(r\ddot\phi + 2\dot r\dot\phi\right)}_{a_\phi}\hat{\boldsymbol{\phi}}\,. \tag{27.16}$$

Rests on Definitions 18.10 and 18.11 and Proposition 7.31.

Proof. *Derives Lemma 27.15.*

Differentiating the two unit vectors with respect to time by the chain rule (Proposition 7.31), $\dot{\hat{\boldsymbol{r}}} = \dot{\phi}\,(-\sin\phi, \cos\phi) = \dot{\phi}\,\hat{\boldsymbol{\phi}}$ and $\dot{\hat{\boldsymbol{\phi}}} = \dot{\phi}\,(-\cos\phi, -\sin\phi) = -\dot{\phi}\,\hat{\boldsymbol{r}}$, which is Equation (27.14). Then $\boldsymbol{v} = \frac{\mathrm{d}}{\mathrm{d}t}\,(r\hat{\boldsymbol{r}}) = \dot{r}\hat{\boldsymbol{r}} + r\dot{\hat{\boldsymbol{r}}}$, giving Equation (27.15), and differentiating once more,

$$\boldsymbol{a} = \ddot{r}\hat{\boldsymbol{r}} + \dot{r}\dot{\phi}\hat{\boldsymbol{\phi}} + \left(\dot{r}\dot{\phi} + r\ddot{\phi}\right)\hat{\boldsymbol{\phi}} + r\dot{\phi}\,\dot{\hat{\boldsymbol{\phi}}}\,,$$

which on substituting $\dot{\hat{\boldsymbol{\phi}}}$ and collecting terms is Equation (27.16). □

The two "extra" terms in Equation (27.16) are not forces. They are what the derivative of a moving orthonormal frame contributes, and the same quantities appear in Example 21.69 as Christoffel symbols of the plane in polar labelling: Equation (21.78), the free-particle equations there, are exactly $a_r = 0$ and $a_\phi = 0$. That the plane is flat while those symbols are non-zero is the point made in Remark 21.70.

27.2.1 Areal velocity

Definition 27.16 (Areal velocity)**.** The *areal velocity* is the rate of change of the area swept out by the line from the centre to the particle, with respect to an inertial frame of reference,

$$v_a := \frac{\mathrm{d}A}{\mathrm{d}t}\,. \tag{27.17}$$

Rests on Definitions 18.8 and 27.14.

Proposition 27.17 (Areal velocity in polar coordinates)**.** *For a plane motion described in polar coordinates,*

$$v_a = \frac{\mathrm{d}A}{\mathrm{d}t} = \frac{1}{2}r^2\dot{\phi}\,, \tag{27.18}$$

and the transverse component of the acceleration is

$$a_\phi = \frac{2}{r}\frac{\mathrm{d}v_a}{\mathrm{d}t}\,. \tag{27.19}$$

Rests on Equations (27.16) and (27.17).

Proof. *Derives Proposition 27.17.*

Between the times t and $t + \mathrm{d}t$ the radius turns through $\mathrm{d}\phi = \dot{\phi}\,\mathrm{d}t$ and lengthens by $\mathrm{d}r = \dot{r}\,\mathrm{d}t$. The region swept out contains the circular sector of radius r and angle $\mathrm{d}\phi$, and is contained in the sector of the same angle and radius $r + |\mathrm{d}r|$; by the sector area recorded in Remark 27.1 these bound it as

$$\frac{1}{2}r^2\,\mathrm{d}\phi \le \mathrm{d}A \le \frac{1}{2}\,(r + |\mathrm{d}r|)^2\,\mathrm{d}\phi\,,$$

so the two differ by $O(\mathrm{d}t^2)$ and $\mathrm{d}A = \frac{1}{2}r^2\mathrm{d}\phi + O(\mathrm{d}t^2)$. Dividing by $\mathrm{d}t$ and letting $\mathrm{d}t \to 0$ gives Equation (27.18). Differentiating that result,

$$\frac{\mathrm{d}v_a}{\mathrm{d}t} = \frac{1}{2}\left(2r\dot{r}\dot{\phi} + r^2\ddot{\phi}\right) = \frac{r}{2}\left(2\dot{r}\dot{\phi} + r\ddot{\phi}\right) = \frac{r}{2}\,a_\phi\,,$$

by Equation (27.16), which rearranged is Equation (27.19). □

27.2.2 Conservation laws of central motion

Proposition 27.18 (Conservation of angular momentum)**.** *In a central motion the angular momentum $\boldsymbol{L}$ is constant, the motion is confined to the fixed plane through the centre perpendicular to $\boldsymbol{L}$, and in polar coordinates on that plane the angular momentum of the plane central motion has a component only along the z-axis, of magnitude*

$$L = mr^2\dot{\phi}\,. \tag{27.20}$$

Rests on Equations (19.14)*,* (19.15) *and* (27.13)*.*

Proof. *Derives Proposition 27.18.*

By Equation (19.14) the rate of change of the angular momentum is the torque, and by Equation (19.15) the torque is $\boldsymbol{x}\times\boldsymbol{F}$. For a central force Equation (27.13) the force is parallel to $\boldsymbol{x} = r\hat{\boldsymbol{r}}$, so

$$\frac{\mathrm{d}\boldsymbol{L}}{\mathrm{d}t} = \boldsymbol{x}\times\boldsymbol{F} = rf(r)\,\hat{\boldsymbol{r}}\times\hat{\boldsymbol{r}} = \boldsymbol{0}\,, \tag{27.21}$$

and $\boldsymbol{L}$ is a fixed vector. Since $\boldsymbol{L} = \boldsymbol{x}\times m\boldsymbol{v}$ is orthogonal to $\boldsymbol{x}$ by construction, the position stays in the fixed plane through the centre perpendicular to $\boldsymbol{L}$; choosing Cartesian axes with $\boldsymbol{L}$ along z makes that the xy-plane, so $\boldsymbol{L} = L\hat{\boldsymbol{z}}$ with no other component. Finally, by Equation (27.15) the radial part of $\boldsymbol{v}$ is parallel to $\boldsymbol{x}$ and contributes nothing to the cross product, leaving $\boldsymbol{L} = r\hat{\boldsymbol{r}}\times mr\dot{\phi}\hat{\boldsymbol{\phi}} = mr^2\dot{\phi}\,\hat{\boldsymbol{z}}$, which is Equation (27.20). The degenerate case $\boldsymbol{L} = \boldsymbol{0}$ is the rectilinear motion through the centre; the plane is then not unique, and any plane containing the line will serve. □

Phenomenon 27.19 (Kepler's second law: equal areas in equal times)**.** The line drawn from a planet to the Sun sweeps out equal areas in equal times: the planet runs fastest at perihelion and slowest at aphelion, in exactly the proportion that keeps the rate of sweeping constant. The regularity was extracted from Tycho Brahe's naked-eye positions of Mars and holds for every body bound to a centre — planets, comets, the components of a visual binary, a charged particle deflected by a nucleus. Newton showed that it holds if and only if the force is directed at the centre, and made it the first proposition of the *Principia* [14].

Rests on Proposition 27.18 and Equation (27.18)*.*

Derivation. *Derives Phenomenon 27.19.*

By Proposition 27.18 the motion is plane and $L = mr^2\dot{\phi}$ is constant. Comparing with the areal velocity Equation (27.18),

$$v_a = \frac{1}{2}r^2\dot{\phi} = \frac{L}{2m}\,, \tag{27.22}$$

a constant — the equal-area law, and the relation Equation (27.27) read from left to right. Mark what the argument did not use: the form of $f(r)$ never entered. Kepler's second law therefore tests the *centrality* of the force and nothing else, and would hold equally for an inverse-cube or a linear attraction.

The converse also holds, and is what makes the law evidence for anything. If v_a is constant then by Equation (27.19) the transverse acceleration a_ϕ vanishes identically, so by Equation (19.4) the force has no transverse component and is central. Equal areas in equal times and centrality of the force are therefore the same statement. □

Proposition 27.20 (Conservation of energy)**.** *A central force is conservative: with*

$$V(r) := -\int_{r_0}^{r} f(s)\,\mathrm{d}s \tag{27.23}$$

for any fixed $r_0 > 0$, one has

$$\boldsymbol{F} = -\boldsymbol{\nabla}V\,, \tag{27.24}$$

and consequently

$$\boldsymbol{\nabla} \times \boldsymbol{F} = \boldsymbol{0}\,. \tag{27.25}$$

The energy $E = T + V$ of a central motion is therefore constant.
Rests on Equations (19.19) and (27.13) and Definition 19.31.

Proof. *Derives Proposition 27.20.*

The gradient of the radius is $\boldsymbol{\nabla} r = \hat{\boldsymbol{r}}$, since $r = \left(x^2 + y^2 + z^2\right)^{1/2}$ gives $\partial r / \partial x^i = x^i / r$. Hence, by the chain rule (Proposition 7.72) and the fundamental theorem of calculus (Theorem 7.42) applied to Equation (27.23),

$$-\boldsymbol{\nabla} V = -V'(r)\,\hat{\boldsymbol{r}} = f(r)\,\hat{\boldsymbol{r}} = \boldsymbol{F}\,,$$

which is Equation (27.24); Equation (27.25) then follows because the curl of a gradient vanishes, Equation (19.20). Note that no topological hypothesis was needed: the general criterion Proposition 7.104 requires a simply connected domain because it must reconstruct the potential from line integrals, whereas here Equation (27.23) writes it down.

For the conservation, differentiate $E = \frac{1}{2} m \left|\boldsymbol{v}\right|^2 + V$ along the motion and use Equation (19.4) together with Equation (27.24):

$$\frac{\mathrm{d}E}{\mathrm{d}t} = m\boldsymbol{v} \cdot \boldsymbol{a} + \boldsymbol{\nabla} V \cdot \boldsymbol{v} = \boldsymbol{v} \cdot (\boldsymbol{F} - \boldsymbol{F}) = 0\,. \tag{27.26}$$

From Equations (19.4) and (27.24) (the chain rule on $V(\boldsymbol{x}(t))$ and the second law on the kinetic term).

Equivalently, the work Equation (19.25) done between two points depends only on the radii of the endpoints. □

Proposition 27.21 (Conservation of the areal speed)**.** *In a central motion the transverse component of the acceleration is zero, and the areal speed is therefore constant.*
Rests on Equations (27.13) and (27.19).

Proof. *Derives Proposition 27.21.*

A central force Equation (27.13) has no $\hat{\boldsymbol{\phi}}$-component, so by Equation (19.4) neither does the acceleration: $a_\phi = 0$. Equation (27.19) then gives $\mathrm{d}v_a/\mathrm{d}t = \frac{1}{2} r\, a_\phi = 0$. This is the same fact as Equation (27.22), obtained without passing through the angular momentum, and the equality of the two routes is Proposition 27.22. □

Proposition 27.22 (Relation between the constants of the motion)**.** *For a central motion one has*

$$r^2 \dot{\phi} = \frac{L}{m} = 2v_a\,. \tag{27.27}$$

Rests on Equations (27.18) and (27.20).

Proof. *Derives Proposition 27.22.*

The first equality is Equation (27.20) divided by m, and the second is twice Equation (27.18). The content of the chain is that the two conserved quantities of the previous two propositions are not independent: the areal speed is the angular momentum per unit mass, halved. Kepler's second law and the conservation of angular momentum are one law counted twice, and the constant L/m is the one that appears in every formula below. □

27.2.3 The Binet equation

Proposition 27.23 (Binet equation)**.** *In a central motion, the trajectory equation can be found from the following equation:*

$$a_r = -\frac{L^2}{m^2 r^2}\left(\frac{\mathrm{d}^2}{\mathrm{d}\phi^2}\left(\frac{1}{r}\right) + \frac{1}{r}\right)\,. \tag{27.28}$$

Rests on Equations (27.16) and (27.20).

Proof. *Derives Proposition 27.23.*

The device is to use ϕ rather than t as the independent variable, which is legitimate whenever $L \neq 0$, since then $\dot{\phi} = L/(mr^2)$ never vanishes and ϕ is a strictly monotone function of t. Write $u := 1/r$, so that

$$\dot{\phi} = \frac{L}{mr^2} = \frac{Lu^2}{m}\,. \tag{27.29}$$

Then, by the chain rule (Proposition 7.31),

$$\dot{r} = \frac{\mathrm{d}r}{\mathrm{d}\phi}\,\dot{\phi} = -\frac{1}{u^2}\frac{\mathrm{d}u}{\mathrm{d}\phi}\cdot\frac{Lu^2}{m} = -\frac{L}{m}\frac{\mathrm{d}u}{\mathrm{d}\phi}\,,$$

a first simplification worth noticing on its own: the radial velocity is $-L/m$ times $\mathrm{d}u/\mathrm{d}\phi$, with a constant factor. Differentiating once more in the same way,

$$\ddot{r} = -\frac{L}{m}\frac{\mathrm{d}^2u}{\mathrm{d}\phi^2}\,\dot{\phi} = -\frac{L^2u^2}{m^2}\frac{\mathrm{d}^2u}{\mathrm{d}\phi^2}\,,$$

while the centrifugal term of Equation (27.16) is $r\dot{\phi}^2 = u^{-1}L^2u^4/m^2 = L^2u^3/m^2$. Subtracting,

$$a_r = \ddot{r} - r\dot{\phi}^2 = -\frac{L^2u^2}{m^2}\left(\frac{\mathrm{d}^2u}{\mathrm{d}\phi^2} + u\right)\,, \tag{27.30}$$

From Equations (27.16) and (27.29) (eliminating t in favour of ϕ through $\dot{\phi} = Lu^2/m$ and writing $u = 1/r$).

which is Equation (27.28) with u restored to $1/r$. Combined with $ma_r = f(r)$ from Equation (19.4), it turns the dynamical problem into a single second-order equation for the shape of the orbit, with the time eliminated altogether. □

27.3 The equivalent one-dimensional problem

27.3.1 Energy of the system

Proposition 27.24 (Radial form of the energy)**.** *The energy of a particle in central motion is*

$$E = \frac{1}{2}m\dot{r}^2 + \frac{L^2}{2mr^2} + V(r)\,. \tag{27.31}$$

Rests on Equations (27.15), (27.20) and (27.24).

Proof. *Derives Proposition 27.24.*

The motion is plane by Proposition 27.18, and the two terms of Equation (27.15) are orthogonal, so

$$|\boldsymbol{v}|^2 = \dot{r}^2 + r^2\dot{\phi}^2$$

and the kinetic energy Equation (19.18) splits into a radial and a transverse part, $T = \frac{1}{2}m\dot{r}^2 + \frac{1}{2}mr^2\dot{\phi}^2$. Eliminating $\dot{\phi}$ with Equation (27.20),

$$\frac{1}{2}mr^2\dot{\phi}^2 = \frac{1}{2}mr^2\left(\frac{L}{mr^2}\right)^2 = \frac{L^2}{2mr^2}\,,$$

which added to the radial part and to the potential Equation (27.24) gives Equation (27.31). The constancy of E is Proposition 27.20, and the constancy of L is what makes the middle term a function of r alone. □

27.3.2 Effective potential

Definition 27.25 (Effective potential)**.** The *effective potential* of a central motion is

$$V_e = \frac{L^2}{2mr^2} + V(r)\,, \tag{27.32}$$

so that the energy Equation (27.31) takes the one-dimensional form

$$E = \frac{1}{2}m\dot{r}^2 + V_e\,. \tag{27.33}$$

Rests on Equation (27.31).

The reduction is exact, not approximate, and it is the whole yield of the two conservation laws: a motion with three degrees of freedom has been replaced by a motion with one, at the cost of a term in the potential that carries the value of the eliminated angular momentum. The added term $L^2/\left(2mr^2\right)$ is repulsive for every $L \neq 0$, and it is a piece of kinetic energy wearing the mask of a potential — which is why calling it a "centrifugal force" is harmless bookkeeping in the radial equation and false in any other.

27.3.3 Turning points

Considering the radial velocity obtained from Equation (27.33),

$$\dot{r} = \pm\sqrt{\frac{2}{m}\left(E - V_e\right)}\,, \tag{27.34}$$

one must have

$$E \geq V_e\,. \tag{27.35}$$

In the case in which $E = V_e$, one has

$$\dot{r} = 0 \implies r = R\,,$$

with R constant. Therefore a circular potential barrier of radius R is generated, called a *turning point*, which confines the motion.

Phenomenon 27.26 (Bound orbits oscillate between two radii)**.** A body bound to a centre does not spiral into it, however strong the attraction, unless its angular momentum is exactly zero: it approaches to a least distance, turns, and recedes to a greatest one, repeating the excursion indefinitely. Comets return; satellites in eccentric orbits alternate between perigee and apogee; a spacecraft aimed at a planet with any transverse velocity at all swings past it instead of falling in. What turns the body back is not an agency outside it but the angular momentum it already carries, and the same barrier explains why a star cannot collapse merely by attracting itself.

Rests on Equations (27.32) *and* (27.33).

Derivation. *Derives Phenomenon 27.26.*

By Equation (27.33) the radial coordinate obeys a one-dimensional energy equation, $E = \frac{1}{2}m\dot{r}^2 + V_e$, with the effective potential Equation (27.32). Since $\frac{1}{2}m\dot{r}^2 \geq 0$, the motion is confined to the set where $E \geq V_e(r)$, which is Equation (27.35), and the boundary points of that set, where $E = V_e(R)$, are the turning radii at which $\dot{r}$ vanishes and changes sign. Now suppose $L \neq 0$. The centrifugal term $L^2/(2mr^2)$ grows like r^{-2} as $r \to 0$ and so dominates every attractive potential less singular than r^{-2} — the inverse-square attraction among them, whose potential goes only as r^{-1}. Hence $V_e \to +\infty$ at the centre, and the condition $E \geq V_e$ excludes a whole neighbourhood of $r = 0$: the body cannot reach the centre at any finite energy. If instead $L = 0$ the centrifugal term is absent, $V_e = V$, and nothing forbids

the collision — which shows that the barrier is angular momentum and not force. For an attraction that vanishes at infinity, a state with $E < 0$ is trapped between an inner and an outer turning radius and the orbit is bounded; a state with $E \geq 0$ has only an inner one and the body escapes. That the bounded orbit should also *close* is a further and much stronger property, discussed in Phenomenon 27.32 and Theorem 27.41. □

Example 27.27 (Escape from the Earth)**.** Take the Newtonian attraction $V(r) = -GMm/r$, which vanishes at infinity, so that the criterion of the previous derivation reads $E \geq 0$ for escape. A body launched radially ($L = 0$) from the surface $r = R_\oplus$ with speed v has $E = \tfrac{1}{2}mv^2 - GMm/R_\oplus$, and escapes when

$$v \geq v_{\text{esc}} = \sqrt{\frac{2GM}{R_\oplus}}\,. \tag{27.36}$$

The product GM for the Earth is $3.986 \times 10^{14}\,\text{m}^3/\text{s}^2$, obtained from $G = 6.674\,30 \times 10^{-11}\,\text{m}^3/(\text{kg}\,\text{s}^2)$ [2392] and $M = 5.972 \times 10^{24}\,\text{kg}$; with $R_\oplus = 6.371 \times 10^6\,\text{m}$ this gives $v_{\text{esc}} = 1.119 \times 10^4\,\text{m/s}$, that is $11.19\,\text{km/s}$. Two remarks are worth more than the number. First, the escape speed does not depend on the mass of the body or on the direction of launch — only on the sign of E, which is why it is a speed and not a velocity. Second, what enters is the product GM and never the two factors separately, and that is not a notational accident: spacecraft ranging fixes GM for the Earth far more sharply than the laboratory knows G, whose relative uncertainty is 2.2×10^{-5} (Phenomenon 33.16). The mass of the Earth is therefore obtained as GM/G and inherits that uncertainty entire; it is the least well known of the three quantities in Equation (27.36), and celestial mechanics never measures it at all.

Rests on Equations (27.31) *and* (27.35).

27.3.4 The radial quadrature

The one-dimensional problem can be integrated once and for all, which is what makes it worth constructing.

Proposition 27.28 (Quadratures of the central problem)**.** *For a central motion with $L \neq 0$, the time along the orbit and the shape of the orbit are given by*

$$t - t_0 = \int_{r_0}^{r} \frac{\mathrm{d}s}{\sqrt{\dfrac{2}{m}\,(E - V_e(s))}}\,, \tag{27.37}$$

$$\phi - \phi_0 = \int_{r_0}^{r} \frac{L\,\mathrm{d}s}{s^2\sqrt{2m\,(E - V(s)) - \dfrac{L^2}{s^2}}}\,, \tag{27.38}$$

on any interval between successive turning points, the sign of the root being that of $\dot r$ there.

Rests on Equations (27.20) *and* (27.34).

Proof. *Derives Proposition 27.28.*

Equation (27.34) is a separable first-order equation for $r(t)$: dividing by the root and integrating gives Equation (27.37), which is legitimate on any interval where $E > V_e$, that is strictly between turning points, since there the integrand is continuous. For the orbit, divide $\mathrm{d}\phi = \dot\phi\,\mathrm{d}t$ by $\mathrm{d}r = \dot r\,\mathrm{d}t$ and use Equation (27.20) and Equation (27.34):

$$\frac{\mathrm{d}\phi}{\mathrm{d}r} = \frac{\dot\phi}{\dot r} = \frac{L/\,(mr^2)}{\sqrt{(2/m)\,(E - V_e)}} = \frac{L}{r^2\sqrt{2m\,(E - V) - L^2/r^2}}\,,$$

where the last step multiplied numerator and denominator by m and used Equation (27.32). Integrating gives Equation (27.38). □

Definition 27.29 (Apsidal angle)**.** For a bounded orbit with turning radii $r_- < r_+$, the *apsidal angle* is the angle swept between successive turning points,

$$\Phi = \int_{r_-}^{r_+} \frac{L\,\mathrm{d}s}{s^2\sqrt{2m\,(E - V(s)) - \dfrac{L^2}{s^2}}}\,. \tag{27.39}$$

The orbit closes after p radial oscillations and q revolutions if and only if $2\Phi = 2\pi q/p$ with p, q integers — that is, if and only if Φ/π is rational.

Rests on Equation (27.38)*.*

The radial motion is always periodic for a bounded orbit, since r returns to r_- after each excursion; what is not automatic is that the *angle* should also return. The orbit closes only when the two periods are commensurable, and Φ generically depends on E and L, so that a family of orbits under one and the same force law will in general contain no closed orbit at all. Two force laws are the exception, and the fact that Nature's dominant one is among them is the subject of Section 27.4.5.

27.4 The two-body problem and Kepler orbits

Nothing so far has asked what holds the centre of force in place. In the Solar System nothing does: the Sun is attracted by each planet exactly as strongly as it attracts it, by Postulate 19.48, and moves in response. The first business of this section is to show that the two-body problem is nevertheless exactly equivalent to a one-body central problem of the kind already solved — not approximately, and not only when one mass is large.

27.4.1 Reduction to one body

Theorem 27.30 (Reduction of the two-body problem)**.** *Let two particles of masses m_1, m_2 interact through a force that depends only on their separation and acts along the line joining them,*

$$\boldsymbol{F}_{12} = f(r)\,\hat{\boldsymbol{r}} = -\boldsymbol{F}_{21}\,, \qquad \boldsymbol{x} := \boldsymbol{x}_1 - \boldsymbol{x}_2\,, \quad r = |\boldsymbol{x}|\,. \tag{27.40}$$

Then the centre of mass moves uniformly, and the relative coordinate $\boldsymbol{x}$ obeys the one-body central equation

$$\mu\,\ddot{\boldsymbol{x}} = f(r)\,\hat{\boldsymbol{r}}\,, \qquad \mu := \frac{m_1 m_2}{m_1 + m_2}\,, \tag{27.41}$$

with μ the reduced mass*. Moreover the total kinetic energy and the total angular momentum split without cross terms,*

$$T = \frac{1}{2}\,(m_1 + m_2)\left|\dot{\boldsymbol{X}}\right|^2 + \frac{1}{2}\mu\,|\dot{\boldsymbol{x}}|^2\,, \tag{27.42}$$

$$\boldsymbol{L} = (m_1 + m_2)\,\boldsymbol{X} \times \dot{\boldsymbol{X}} + \mu\,\boldsymbol{x} \times \dot{\boldsymbol{x}}\,, \tag{27.43}$$

with $\boldsymbol{X}$ the centre of mass Equation (19.38)*.*

Rests on Postulate 19.48 and Equations (19.4) *and* (19.38)*.*

Proof. *Derives Theorem 27.30.*

Adding the two equations of motion and using Equation (27.40) gives $m_1\ddot{\boldsymbol{x}}_1 + m_2\ddot{\boldsymbol{x}}_2 = \boldsymbol{0}$, that is $\ddot{\boldsymbol{X}} = \boldsymbol{0}$ by Equation (19.40): the centre of mass moves uniformly, as Phenomenon 19.54 states in general. Subtracting instead, after dividing each equation by its own mass,

$$\ddot{\boldsymbol{x}} = \ddot{\boldsymbol{x}}_1 - \ddot{\boldsymbol{x}}_2 = \frac{\boldsymbol{F}_{12}}{m_1} - \frac{\boldsymbol{F}_{21}}{m_2} = \left(\frac{1}{m_1} + \frac{1}{m_2}\right) f(r)\,\hat{\boldsymbol{r}} = \frac{f(r)}{\mu}\,\hat{\boldsymbol{r}}\,, \tag{27.44}$$

From Equations (19.4) and (27.40) (dividing each equation of motion by its mass and subtracting, with $\mu^{-1} = m_1^{-1} + m_2^{-1}$).

which is Equation (27.41). For the splittings, invert the change of variables: with $M = m_1 + m_2$,

$$\boldsymbol{x}_1 = \boldsymbol{X} + \frac{m_2}{M}\boldsymbol{x}\,, \qquad \boldsymbol{x}_2 = \boldsymbol{X} - \frac{m_1}{M}\boldsymbol{x}\,.$$

Substituting into $T = \frac{1}{2}m_1\left|\dot{\boldsymbol{x}}_1\right|^2 + \frac{1}{2}m_2\left|\dot{\boldsymbol{x}}_2\right|^2$, the cross terms carry the factor $m_1m_2/M - m_2m_1/M = 0$ and cancel, while the remaining coefficients of $|\dot{\boldsymbol{x}}|^2$ combine to $\frac{1}{2}\left(m_1m_2^2 + m_2m_1^2\right)/M^2 = \frac{1}{2}\mu$, giving Equation (27.42). The same substitution in $\boldsymbol{L} = m_1\boldsymbol{x}_1 \times \dot{\boldsymbol{x}}_1 + m_2\boldsymbol{x}_2 \times \dot{\boldsymbol{x}}_2$ cancels the cross terms for the same reason and gives Equation (27.43). □

Remark 27.31 (What the reduction does and does not buy). Every result of Sections 27.2 and 27.3 now applies to the two-body problem verbatim, with m read as the reduced mass μ, r as the separation and $\boldsymbol{L}$ as the angular momentum about the centre of mass. When one mass overwhelms the other, $\mu \to m_2$ for $m_1 \gg m_2$ and the centre of mass sits inside the heavy body, which recovers the fixed-centre picture; for the Sun and Jupiter μ differs from Jupiter's mass by one part in 1047, and the common centre of mass lies just outside the solar surface. The reduction is exact for *two* bodies and for no more: the three-body problem admits no such change of variables, has no general solution in closed form, and is where the qualitative theory of Chapter 32 begins.

27.4.2 The orbit of an inverse-square attraction

Phenomenon 27.32 (Kepler's first law: bound orbits are closed ellipses)**.** Each planet describes an ellipse with the Sun at one focus — not at the centre — and the orbit closes upon itself, returning the body to the same point with the same velocity after one revolution. Closure is a strong and very special fact. For a general central force the orbit is bounded, by Phenomenon 27.26, but it does not repeat: successive perihelia occur at different longitudes and the path fills the annulus between the turning radii. The observed closure of planetary orbits is therefore evidence for the inverse-square law itself, and the small residual advances of the perihelia are evidence that the law is not exact [14].

Rests on Equations (27.13) and (27.28) and Theorem 27.30.

Derivation. Derives Phenomenon 27.32.

Take the Newtonian attraction between the two bodies,

$$f(r) = -\frac{k}{r^2}\,, \qquad k := Gm_1m_2 > 0\,, \tag{27.45}$$

whose potential Equation (27.23) is $V(r) = -k/r$ once the additive constant is fixed by requiring $V \to 0$ as $r \to \infty$, and which by Theorem 27.30 makes the separation obey the one-body central equation with mass μ. Insert Equation (27.45) into the Binet equation Equation (27.30), written with μ in place of m and $u = 1/r$, using $\mu a_r = f = -ku^2$:

$$-ku^2 = -\frac{L^2u^2}{\mu}\left(\frac{\mathrm{d}^2u}{\mathrm{d}\phi^2} + u\right),$$

and the factor u^2 cancels on both sides — which happens for the inverse square and for no other power. What is left is linear with constant coefficients,

$$\frac{\mathrm{d}^2u}{\mathrm{d}\phi^2} + u = \frac{\mu k}{L^2}\,. \tag{27.46}$$

From Equations (27.30) and (27.45) (substituting $f = -ku^2$ and cancelling the common factor u^2).

By Theorem 9.13 its general solution is any one solution plus the general solution of the homogeneous equation; the constant $u = \mu k/L^2$ is a solution, and the homogeneous equation is Equation (9.106) with $\lambda = 1$, whose real general solution is Equation (9.108). Choosing the origin of ϕ at the maximum of u — the point of closest approach — absorbs the phase, and writing the remaining constant as $e\,\mu k/L^2$ with $e \geq 0$,

$$\frac{1}{r} = \frac{\mu k}{L^2}\left(1 + e\cos\phi\right), \qquad \text{that is} \qquad r = \frac{p}{1 + e\cos\phi}, \quad p := \frac{L^2}{\mu k}. \tag{27.47}$$

This is the polar equation of a conic of eccentricity e with one focus at the centre of force and semi-latus rectum p (Remark 27.33); for $0 \leq e < 1$ it is an ellipse, and the centre of force is at a focus and not at the centre, since r takes its extreme values $p/(1+e)$ and $p/(1-e)$ at $\phi = 0$ and $\phi = \pi$ and these are unequal unless $e = 0$. The solution is single-valued and 2π-periodic in ϕ, so the orbit closes exactly, and the identification of e with the energy is Proposition 27.34. □

Remark 27.33 (The conic classification is owed by Part II). Equation (27.47) is derived here in full; what is *quoted* is its geometric reading. That $r = p/\left(1 + e\cos\phi\right)$ is the locus of points whose distance from a fixed focus stands in the fixed ratio e to the distance from a fixed directrix, and that this locus is an ellipse, a parabola or a hyperbola according as $e < 1$, $e = 1$ or $e > 1$, is elementary analytic geometry which Chapters 5 and 7 do not state. Nothing in the physics below depends on it: the semi-major axis is defined in Equation (27.49) as half the sum of the two turning radii, which is intrinsic to the orbit, and Kepler's third law is derived from Equation (27.47) directly without any appeal to the geometry of the ellipse. The word "ellipse" is a name for the curve, not a step in an argument.

Proposition 27.34 (Eccentricity, energy and semi-major axis)**.** *For the orbit Equation* (27.47) *of the attraction Equation* (27.45)*,*

$$e = \sqrt{1 + \frac{2EL^2}{\mu k^2}}, \tag{27.48}$$

and, when $e < 1$, half the sum of the two turning radii is

$$a := \frac{r_- + r_+}{2} = \frac{p}{1 - e^2} = -\frac{k}{2E}. \tag{27.49}$$

Rests on Equations (27.31)*,* (27.32) *and* (27.47)*.*

Proof. *Derives Proposition 27.34.*

At a turning point $\dot r = 0$, so by Equation (27.31) with $V = -k/r = -ku$ and μ for m,

$$E = \frac{L^2}{2\mu}u^2 - ku. \tag{27.50}$$

The turning values of u are the extremes of Equation (27.47), namely $u_\pm = \left(\mu k/L^2\right)\left(1 \pm e\right)$. Substituting u_+ into Equation (27.50) and using $p = L^2/\left(\mu k\right)$,

$$E = \frac{L^2}{2\mu}\frac{\mu^2 k^2}{L^4}\left(1+e\right)^2 - k\frac{\mu k}{L^2}\left(1+e\right) = \frac{\mu k^2}{2L^2}\left(1+e\right)\left[\left(1+e\right) - 2\right] = \frac{\mu k^2}{2L^2}\left(e^2 - 1\right),$$

and solving for e gives Equation (27.48); the same substitution with u_- gives the same relation, as it must, since both turning points belong to one orbit. For Equation (27.49), $r_\pm = p/\left(1 \mp e\right)$ so

$$a = \frac{p}{2}\left(\frac{1}{1+e} + \frac{1}{1-e}\right) = \frac{p}{1-e^2},$$

and inserting $1 - e^2 = -2EL^2/\left(\mu k^2\right)$ from Equation (27.48) together with $p = L^2/\left(\mu k\right)$ gives $a = -k/(2E)$, positive precisely when $E < 0$. □

Equation (27.48) classifies the orbits completely by the two constants of the motion, and the classification is collected in Table 27.1. It is worth reading as a statement about *what is observable*: the energy fixes the size of a bound orbit through Equation (27.49) and the angular momentum fixes its shape through p, so that measuring the period and the eccentricity of a planet measures E and L and nothing else is left to determine.

Table 27.1: Classification of the orbits of the inverse-square attraction Equation (27.45) by the energy, through the eccentricity Equation (27.48). The least possible energy $-\mu k^2/\left(2L^2\right)$ is the minimum of the effective potential Equation (27.32) at fixed L; below it no motion exists with that angular momentum. Only the first two rows are bounded, and both close.

Energy	Eccentricity	Curve	Motion
$E = -\mu k^2/\left(2L^2\right)$	$e = 0$	circle	r constant
$-\mu k^2/\left(2L^2\right) < E < 0$	$0 < e < 1$	ellipse	bounded, closed
$E = 0$	$e = 1$	parabola	escapes with zero final speed
$E > 0$	$e > 1$	hyperbola	escapes with finite final speed

27.4.3 Kepler's third law

Phenomenon 27.35 (Kepler's third law)**.** The squares of the orbital periods of the planets stand in the same ratio as the cubes of the semi-major axes of their orbits, with one and the same constant of proportionality for every body bound to the same centre, whatever its own mass. The regularity holds across the Solar System over a range of nearly three orders of magnitude in period, and holds again — with a different constant — for the moons of Jupiter, for artificial satellites of the Earth, and for the components of binary stars. It is by this law that the masses of astronomical bodies are determined at all [14].

Rests on Equations (27.22) *and* (27.47) *and Theorem 27.30.*

Derivation. *Derives Phenomenon 27.35.*

For a circular orbit the result is immediate. A body of mass m carried around a circle of radius r requires, by the kinematics of Chapter 18, the centripetal acceleration $\omega^2 r$, and the attraction of a central mass M supplies it, so that $GM/r^2 = \omega^2 r$ and, with $\omega = 2\pi/T$,

$$T^2 = \frac{4\pi^2}{GM}\, r^3 \,. \tag{27.51}$$

The orbiting mass has cancelled — it appears once as the gravitational charge and once as the inertia — which is why a single constant serves every planet.

For the general bounded orbit, integrate the equal-area law. By Equation (27.22) the areal speed is $L/\left(2\mu\right)$, and by Equation (27.20) the period is

$$T = \int_0^T \mathrm{d}t = \int_0^{2\pi} \frac{\mathrm{d}\phi}{\dot\phi} = \frac{\mu}{L}\int_0^{2\pi} r^2\,\mathrm{d}\phi = \frac{\mu p^2}{L}\int_0^{2\pi} \frac{\mathrm{d}\phi}{\left(1 + e\cos\phi\right)^2} \,,$$

using Equation (27.47) in the last step. The integral is elementary by residues. For $0 < e < \lambda$ the substitution $z = \mathrm{e}^{\mathrm{i}\phi}$, under which $\cos\phi = \left(z + z^{-1}\right)/2$ and $\mathrm{d}\phi = \mathrm{d}z/\left(\mathrm{i}z\right)$, turns $I(\lambda) = \int_0^{2\pi} \left(\lambda + e\cos\phi\right)^{-1} \mathrm{d}\phi$ into a contour integral on the unit circle,

$$I(\lambda) = \oint_{|z|=1} \frac{2\,\mathrm{d}z}{\mathrm{i}\left(ez^2 + 2\lambda z + e\right)} \,,$$

whose two poles have product 1, so that exactly one lies inside, namely $z_+ = \left(-\lambda + \sqrt{\lambda^2 - e^2}\right)/e$; by the residue theorem Theorem 8.24 and Proposition 8.23, $I(\lambda) =$

$2\pi/\sqrt{\lambda^2 - e^2}$, which is also the value at $e = 0$, where the integral is immediate. Differentiating under the integral sign in λ and then setting $\lambda = 1$,

$$\int_0^{2\pi} \frac{\mathrm{d}\phi}{(1 + e\cos\phi)^2} = -I'(1) = \frac{2\pi}{(1 - e^2)^{3/2}}\,. \tag{27.52}$$

Hence, with $a = p/(1 - e^2)$ from Equation (27.49) and $p = L^2/(\mu k)$,

$$T = \frac{2\pi\mu p^2}{L\,(1 - e^2)^{3/2}} = \frac{2\pi\mu}{L}\,p^{1/2}a^{3/2} = \frac{2\pi\mu}{L}\cdot\frac{L}{\sqrt{\mu k}}\,a^{3/2} = 2\pi\sqrt{\frac{\mu}{k}}\,a^{3/2}\,.$$

Squaring, and putting $k = Gm_1m_2$ and $\mu = m_1m_2/(m_1 + m_2)$ from Theorem 27.30,

$$T^2 = \frac{4\pi^2}{G\,(m_1 + m_2)}\,a^3\,. \tag{27.53}$$

From Equations (27.41), (27.49) and (27.52) (integrating the equal-area law over one revolution and eliminating p and L).

This is the exact law. It contains Equation (27.51) as the limit $m_2 \ll m_1$, it replaces the radius by the semi-major axis, and it shows precisely how the "constant" fails to be one: the proportionality factor depends on the *total* mass, so two planets of different masses about the same star obey slightly different laws. The check of Equation (33.19) in the Cavendish chapter is this same relation applied to the Moon. □

Table 27.2: Kepler's third law across the Solar System. The semi-major axes and sidereal periods are the standard J2000 mean Keplerian elements, converted to SI; the last column is the ratio that Equation (27.53) predicts to be $4\pi^2/[G\,(M_\odot + m)]$, which for a massless planet is $2.9747\times10^{-19}\ \mathrm{s^2/m^3}$ with $GM_\odot = 1.327\,12\times10^{20}\ \mathrm{m^3/s^2}$. This treatise carries no citable ephemeris source, and the elements below are therefore uncited.

Body	a (m)	T (s)	T^2/a^3 ($\mathrm{s^2/m^3}$)
Mercury	5.7909×10^{10}	7.6005×10^{6}	$2.974\,73 \times 10^{-19}$
Venus	1.0821×10^{11}	1.9414×10^{7}	$2.974\,73 \times 10^{-19}$
Earth	1.4960×10^{11}	3.1558×10^{7}	$2.974\,72 \times 10^{-19}$
Mars	2.2794×10^{11}	5.9355×10^{7}	$2.974\,90 \times 10^{-19}$
Jupiter	7.7841×10^{11}	3.7436×10^{8}	$2.971\,26 \times 10^{-19}$
Saturn	1.4267×10^{12}	9.2929×10^{8}	$2.973\,61 \times 10^{-19}$
Uranus	2.8710×10^{12}	2.6514×10^{9}	$2.970\,67 \times 10^{-19}$
Neptune	4.4983×10^{12}	5.2004×10^{9}	$2.971\,29 \times 10^{-19}$

Table 27.2 is the law's evidence and also the measure of its limits. Over a 684-fold range in period and a 78-fold range in semi-major axis the ratio T^2a^{-3} is constant to 0.14 %, which is the observation Kepler made and Newton explained. The residual structure is not noise. The four terrestrial planets agree with each other and with $4\pi^2/(GM_\odot)$ to a few parts in 10^5; the giant planets lie systematically *below* that value, which is the sign Equation (27.53) demands, since their own masses enter the denominator. For Jupiter, $m/M_\odot = 9.5 \times 10^{-4}$ predicts a deficit of that relative size and one of about 1.2×10^{-3} is observed; for Saturn, 2.9×10^{-4} predicted against 3.8×10^{-4} observed. Uranus and Neptune depart by more than their masses require, and the honest reading is that a two-body law is not expected to describe them to better than this: their mutual perturbation is large enough to have betrayed Neptune's existence before it was seen, and the mean elements quoted are themselves fits over a span of centuries rather than exact constants of any orbit.

Example 27.36 (A satellite in low Earth orbit)**.** Equation (27.53) with $m_2 \ll m_1$ gives the period of a circular orbit of radius r about the Earth as $T = 2\pi\sqrt{r^3/GM}$. Taking $GM = 3.986 \times 10^{14}\,\mathrm{m^3/s^2}$ as in Example 27.27, and an orbit $4.20 \times 10^5\,\mathrm{m}$ above the mean radius $R_\oplus = 6.371 \times 10^6\,\mathrm{m}$, so that $r = 6.791 \times 10^6\,\mathrm{m}$:

$$T = 2\pi\sqrt{\frac{(6.791 \times 10^6\,\mathrm{m})^3}{3.986 \times 10^{14}\,\mathrm{m^3/s^2}}} = 5.57 \times 10^3\,\mathrm{s}\,,$$

that is 92.8 minutes, against the 92.9 minutes in which the International Space Station is observed to circle at that altitude. The orbital speed is $\sqrt{GM/r} = 7.66 \times 10^3\,\mathrm{m/s}$. Note that the period *decreases* as the orbit is lowered, so that a satellite which loses energy to atmospheric drag speeds up — the characteristic and initially counter-intuitive signature of a bound inverse-square orbit, and a direct consequence of Equation (27.49), in which a more negative energy means a smaller a.

Rests on Equation (27.53).

27.4.4 The Laplace–Runge–Lenz vector

The inverse-square attraction conserves more than energy and angular momentum. It conserves a vector lying in the plane of the orbit, and that extra conservation law is exactly what makes the orbit close.

Definition 27.37 (Laplace–Runge–Lenz vector)**.** For the attraction Equation (27.45), with $\boldsymbol{p} = \mu\dot{\boldsymbol{x}}$ the momentum conjugate to the relative coordinate, the *Laplace–Runge–Lenz vector* is

$$\boldsymbol{A} := \boldsymbol{p} \times \boldsymbol{L} - \mu k\,\hat{\boldsymbol{r}}\,, \tag{27.54}$$

whose SI unit is $\mathrm{kg^2\,m^3/s^2}$, that of a momentum times an angular momentum.

Rests on Equations (27.20), (27.41) *and* (27.45).

Theorem 27.38 (Conservation of the Laplace–Runge–Lenz vector)**.** *Along any motion of the inverse-square attraction,* $\mathrm{d}\boldsymbol{A}/\mathrm{d}t = \boldsymbol{0}$. *The vector lies in the plane of the orbit, since* $\boldsymbol{A} \cdot \boldsymbol{L} = 0$.

Rests on Equations (27.1), (27.41) *and* (27.54).

Proof. *Derives Theorem 27.38.*

Differentiate Equation (27.54). Since $\boldsymbol{L}$ is constant by Proposition 27.18, $\mathrm{d}\left(\boldsymbol{p} \times \boldsymbol{L}\right)/\mathrm{d}t = \dot{\boldsymbol{p}} \times \boldsymbol{L} = \boldsymbol{F} \times \boldsymbol{L}$ by Equation (27.41). With $\boldsymbol{F} = -k\hat{\boldsymbol{r}}/r^2$ and $\boldsymbol{L} = \mu\,\boldsymbol{x} \times \boldsymbol{v}$, the expansion Equation (27.1) of the double cross product gives

$$\boldsymbol{F} \times \boldsymbol{L} = -\frac{k\mu}{r^2}\,\hat{\boldsymbol{r}} \times (\boldsymbol{x} \times \boldsymbol{v}) = -\frac{k\mu}{r^2}\left[\boldsymbol{x}\,(\hat{\boldsymbol{r}} \cdot \boldsymbol{v}) - \boldsymbol{v}\,(\hat{\boldsymbol{r}} \cdot \boldsymbol{x})\right] = k\mu\left(\frac{\boldsymbol{v}}{r} - \frac{\dot{r}\,\boldsymbol{x}}{r^2}\right),$$

using $\hat{\boldsymbol{r}} \cdot \boldsymbol{v} = \dot{r}$ and $\hat{\boldsymbol{r}} \cdot \boldsymbol{x} = r$. What multiplies $k\mu$ on the right is exactly the derivative of the unit radial vector,

$$\frac{\mathrm{d}\hat{\boldsymbol{r}}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\boldsymbol{x}}{r}\right) = \frac{\boldsymbol{v}}{r} - \frac{\dot{r}\,\boldsymbol{x}}{r^2}\,,$$

so $\mathrm{d}\left(\boldsymbol{p} \times \boldsymbol{L}\right)/\mathrm{d}t = \mu k\,\mathrm{d}\hat{\boldsymbol{r}}/\mathrm{d}t$ and the two terms of Equation (27.54) cancel in the derivative. Finally $\boldsymbol{A} \cdot \boldsymbol{L} = (\boldsymbol{p} \times \boldsymbol{L}) \cdot \boldsymbol{L} - \mu k\,\hat{\boldsymbol{r}} \cdot \boldsymbol{L} = 0$, the first term because $\boldsymbol{p} \times \boldsymbol{L}$ is orthogonal to $\boldsymbol{L}$ and the second because $\boldsymbol{L}$ is orthogonal to $\boldsymbol{x}$. □

Proposition 27.39 (The Laplace–Runge–Lenz vector is the orbit)**.** *Measuring* ϕ *from the direction of* $\boldsymbol{A}$,

$$r = \frac{L^2/(\mu k)}{1 + (A/\mu k)\cos\phi}\,, \qquad A^2 = \mu^2 k^2 + 2\mu E L^2\,. \tag{27.55}$$

Thus $\boldsymbol{A}$ *points from the centre of force towards the point of closest approach, and its magnitude is* $\mu k e$ *with* e *the eccentricity Equation* (27.48).

Rests on Equations (27.47), (27.48) *and* (27.54).

Proof. *Derives Proposition 27.39.*

Take the scalar product of Equation (27.54) with $\boldsymbol{x}$. On the left, $\boldsymbol{x}\cdot\boldsymbol{A} = Ar\cos\phi$ with ϕ measured from $\boldsymbol{A}$. On the right, the cyclic property of the scalar triple product gives $\boldsymbol{x}\cdot(\boldsymbol{p}\times\boldsymbol{L}) = \boldsymbol{L}\cdot(\boldsymbol{x}\times\boldsymbol{p}) = L^2$, while $\boldsymbol{x}\cdot\mu k\hat{\boldsymbol{r}} = \mu kr$. Hence $Ar\cos\phi = L^2 - \mu kr$, which rearranged is the first member of Equation (27.55). Comparing with Equation (27.47) identifies $A = \mu ke$, and substituting Equation (27.48) gives $A^2 = \mu^2k^2e^2 = \mu^2k^2 + 2\mu EL^2$. Since r is least where $\cos\phi = 1$, the vector points at the perihelion. □

That the perihelion direction is a constant of the motion is another way of saying that the orbit does not precess, and it is the sharpest statement of Kepler's first law: the extra conserved vector is what distinguishes the inverse-square attraction from every other central force, all of which conserve E and $\boldsymbol{L}$ just as well.

Remark 27.40 (It is not the charge of a point symmetry). It is tempting to look for the symmetry behind Theorem 27.38 among the transformations that move the particle's position, as rotations and translations do. There is none, and Remark 16.86 proves it: the part of the Noether charge Equation (16.76) that is quadratic in the momentum is isotropic in $\boldsymbol{p}$ for any point transformation, whereas the corresponding part of $\boldsymbol{A}$ is not — it vanishes when $\boldsymbol{p}$ is parallel to $\boldsymbol{x}$ and is maximal when they are perpendicular. The generator that does produce $\boldsymbol{A}$ depends on the velocities and is a *generalized* symmetry, outside the hypotheses of Noether's first theorem as proved in Theorem 16.84. So Theorem 27.38 is established here, as it must be, by direct differentiation and not by exhibiting a symmetry of the action. The hidden SO(4) structure the vector generates is not idle, however: it is what makes the hydrogen spectrum degenerate in the orbital angular momentum, and it is put to work in Chapter 81. The vector is far older than its three-barrelled name; what attached Lenz's to it is his use of it in the old quantum theory of the perturbed Kepler motion [514], and Pauli obtained the hydrogen spectrum from it two years later, before Schrödinger's wave equation appeared [553].

27.4.5 Closure, and what its failure measures

Theorem 27.41 (Bertrand)**.** *Among the central forces for which every bounded orbit is closed there are exactly two: the inverse-square attraction $f(r) = -k/r^2$ and the linear attraction $f(r) = -\kappa r$ of the isotropic harmonic oscillator. For every other force law the apsidal angle Equation (27.39) depends on the orbit, and orbits with Φ/π irrational fill the annulus between their turning radii without ever repeating.*

Rests on Equations (27.39) and (27.47).

Full derivation: Appendix A.55 (p. 3094).

Derives Theorem 27.41.

The proof there runs in two stages, and it is worth knowing which does which. The first perturbs a circular orbit of radius r_0 and finds that the perturbation oscillates about it with an angular frequency $\beta(r_0) = \left[3 + r_0 f'(r_0)/f(r_0)\right]^{1/2}$ per unit change of the polar angle, so that the apsidal angle Equation (27.39) tends to π/β. Closure of every nearby orbit makes β rational; β depends continuously on r_0 and a continuous rational-valued function is constant, so β is one fixed rational number, and $rf'/f = \beta^2 - 3$ integrates to the power law $f \propto r^{\beta^2-3}$. That much is a first-order calculation, and it narrows the candidates to a one-parameter family of power laws — it does *not* yet pick out two of them. The second stage supplies the difference, because closure of the orbits infinitesimally near the circle is weaker than closure of all bounded orbits: carrying the expansion to third order produces a solvability condition on β which only $\beta = 1$ and $\beta = 2$ satisfy, and those are $f \propto r^{-2}$ and $f \propto r$.

The two exceptional laws are also the two that Nature exhibits at large scale, which is why the closure of orbits was discovered before the reason for it. The importance of the

theorem is that it converts a qualitative observation into a quantitative test: any departure from r^{-2}, however small, makes the perihelion move.

Phenomenon 27.42 (Planetary orbits do not close exactly)**.** The perihelia of the planets advance slowly along their orbits. Mercury's is observed to advance by some 5600 seconds of arc per century, of which 5025 is the general precession of the equinoxes — a motion of the reference frame and not of the orbit — and 531 is the pull of the other planets, computable within Newtonian mechanics. A residue of about 43 seconds of arc per century survives every such computation. Le Verrier isolated that residue in 1859 and no distribution of matter consistent with the rest of Solar-System astronomy was ever found to produce it [151]; the budget is set out in Table 53.1. By Theorem 27.41 the residue is a measurement: it says that the force governing Mercury is not exactly $-k/r^2$.

Rests on Theorem 27.41 and Equation (27.39).

Derivation. *Derives Phenomenon 27.42.*

Within this chapter the derivation can go only as far as the conditional statement, and that is the honest content of the phenomenon. Theorem 27.41 shows that closure of every bounded orbit is equivalent to the force being $-k/r^2$ or $-\kappa r$, and the second is excluded by Phenomenon 27.32, since a linear attraction puts the centre of force at the *centre* of the ellipse and not at a focus. A non-closing bound orbit therefore falsifies the exact inverse square. What it does not do is say what replaces it. The first attempt was to keep a central force and modify the exponent, writing $f \propto r^{-(2+\delta)}$; for a nearly circular orbit a small δ produces an apsidal angle $\Phi \approx \pi\,(1+\delta/2)$ and hence a slow rotation of the line of apsides, and δ can always be chosen to fit one planet. The proposal fails because the δ that fits Mercury does not fit the others, and because it has no independent motivation whatever.

The correct account is not a modified force law at all. In general relativity the orbit is a geodesic of a curved spacetime and its equation acquires the term shown in Equation (53.2), quadratic in $u = 1/r$ and suppressed by c^{-2}; the resulting advance is Equation (53.1), with no adjustable parameter, and it predicts 42.98 seconds of arc per century for Mercury against the observed residue. That derivation belongs to Chapter 53, where the measurement and its error budget are set out, and to Phenomenon 53.1, which states the result. What this chapter contributes is the logic that makes the measurement mean anything: without Theorem 27.41 a non-closing orbit would be an anomaly of no particular significance, and with it, it is a bound on the force law. □

Remark 27.43 (The repulsive case, and where it is used)*.* Nothing in Section 27.4.2 required $k > 0$. For a repulsive inverse-square force, $k < 0$ in Equation (27.45), the effective potential falls monotonically and has no well, so every motion has $E > 0$ and Equation (27.48) gives $e > 1$. The semi-latus rectum $p = L^2/(\mu k)$ of Equation (27.47) is then negative, and the physical solution is the branch on which $1 + e\cos\phi < 0$: the branch of the hyperbola that curves away from the centre rather than around it. This is the orbit of an alpha particle in the Coulomb field of a nucleus, and integrating Equation (27.38) for it produces the relation between impact parameter and deflection angle from which the Rutherford cross section follows; the calculation, and the scattering experiment that made it famous, are in Section 70.3.2. The same hyperbolic solution, taken in the attractive case with $E > 0$, is the gravitational slingshot: a spacecraft leaves a planet's neighbourhood with the same speed relative to the planet with which it arrived, but in a different direction, and therefore with a different — and usefully larger — speed relative to the Sun.

27.5 The virial theorem

Everything so far has followed individual orbits. For a bound system of many bodies — a star cluster, a gas of self-gravitating masses — the orbits are inaccessible, but a statement about

time averages survives, and it is the tool by which such systems are weighed (Chapter 48).

Theorem 27.44 (Virial theorem)**.** *Let N particles with positions $\boldsymbol{x}_a$ and momenta $\boldsymbol{p}_a$ move under forces $\boldsymbol{F}_a$ such that the motion is bounded: all $|\boldsymbol{x}_a|$ and $|\boldsymbol{p}_a|$ remain finite for all time. Then the long-time averages $\langle f \rangle = \lim_{\tau\to\infty} \tau^{-1}\int_0^\tau f \,\mathrm{d}t$ satisfy*

$$2\,\langle T\rangle = -\Big\langle \sum_{a=1}^{N} \boldsymbol{F}_a \cdot \boldsymbol{x}_a \Big\rangle . \tag{27.56}$$

If the forces derive from a potential V that is a homogeneous function of degree n of the positions, the right side is $n\,\langle V\rangle$, so

$$2\,\langle T\rangle = n\,\langle V\rangle \ , \tag{27.57}$$

and for the inverse-square attraction ($n=-1$)

$$2\,\langle T\rangle = -\,\langle V\rangle \ . \tag{27.58}$$

Rests on Equation (27.41) and Remark 21.40.

Proof. *Derives Theorem 27.44.*

Consider $G = \sum_a \boldsymbol{p}_a \cdot \boldsymbol{x}_a$. Along the motion,

$$\frac{\mathrm{d}G}{\mathrm{d}t} = \sum_a \dot{\boldsymbol{p}}_a \cdot \boldsymbol{x}_a + \sum_a \boldsymbol{p}_a \cdot \dot{\boldsymbol{x}}_a = \sum_a \boldsymbol{F}_a \cdot \boldsymbol{x}_a + 2T \,,$$

since $\boldsymbol{p}_a \cdot \dot{\boldsymbol{x}}_a = m_a\,|\dot{\boldsymbol{x}}_a|^2$ sums to twice the kinetic energy. Averaging over $[0,\tau]$, $\langle \mathrm{d}G/\mathrm{d}t\rangle = [G(\tau)-G(0)]/\tau$, and boundedness of positions and momenta bounds G, so the limit $\tau\to\infty$ vanishes (exactly, already at one period, for periodic motion). This is Equation (27.56). When $\boldsymbol{F}_a = -\partial V/\partial \boldsymbol{x}_a$ with V homogeneous of degree n, Euler's homogeneous-function theorem (Remark 21.40) gives $\sum_a \boldsymbol{x}_a \cdot \partial V/\partial \boldsymbol{x}_a = nV$, whence Equation (27.57); $n=-1$ is the gravitational and Coulomb case. □

Corollary 27.45 (Bound Kepler averages)**.** *For a bound orbit of the inverse-square attraction, the conserved energy $E = T + V$ satisfies*

$$\langle T\rangle = -E \,, \qquad \langle V\rangle = 2E \,, \tag{27.59}$$

so a bound orbit has $E<0$, and adding energy to it slows *the time-averaged motion — the negative specific heat of gravitating systems.*

Rests on Theorem 27.44.

Proof. *Derives Corollary 27.45.*

E is constant, so $E = \langle T\rangle + \langle V\rangle$; combine with Equation (27.58). □

27.6 Where the claims of this chapter are tested

It is worth saying plainly which of the observed facts asserted above are tied to an experiment described in this book and which are not. Kepler's third law is tested in Chapter 33, whose lunar check Equation (33.19) is Equation (27.53) applied to the Earth–Moon system with a laboratory value of G; the failure of exact closure, Phenomenon 27.42, is measured in Chapter 53; and the repulsive branch of Section 27.4.2 is what Section 70.3.2 tests. The remaining five observed statements — Phenomena 27.5, 27.8, 27.19, 27.26 and 27.32 — carry no dedicated experiment chapter here. They are not for that reason unsupported: the first is a commonplace of every static structure, the second is the standard method by which a centre of gravity is located, and the last three are the content of the regularities Kepler extracted from Brahe's catalogue of the positions of Mars. But no measurement with its own uncertainty budget is set out in this book for any of the five, and the honest record of that is this paragraph rather than silence.

Chapter 28

Oscillations and Mechanical Waves

The harmonic oscillator is the most reused model in physics. Near any stable equilibrium the Lagrangian of Chapter 21 is, to lowest order, a quadratic form, so everything close to rest oscillates harmonically: this chapter sits immediately after the general formalisms of Chapters 21 and 22 and before everything in the treatise that vibrates — the lattice phonons of Chapter 125, the electromagnetic modes of Chapter 61, and ultimately the field quanta of Part XI. Its second half lets the number of oscillators grow without bound: coupled oscillators pass to a continuum, the normal-mode problem becomes d'Alembert's wave equation on a string, and superposition, standing waves, Fourier decomposition, dispersion and sound follow, each named below with the primary source that established it. The standard modern treatments are [1585, 2027]; the founding monograph of the wave half is Rayleigh's *Theory of Sound* [198].

The mathematics is not developed here. The eigenvalue problem of Section 28.3.2 is the spectral theorem of Chapter 5; the boundary-value problems of Section 28.4.3 are the Sturm–Liouville theory of Chapter 9; the wave equation and its general solution are Chapter 10; the modal expansions are the Fourier theory of Chapter 17. What this chapter supplies is the physics: which quadratic form, which boundary condition, which measured number.

Notation 28.1 (Symbols reused in this chapter). Three letters do double duty and the split is by half of the chapter. In the oscillator half (Sections 28.1 and 28.2) T is a *period* and k a *spring constant*, in N/m. From Section 28.3.3 onward T is the *tension* of a string, in N, k is a *wavenumber*, in 1/m, and a period is written $2\pi/\omega$. In Section 28.3.2 T is kinetic energy and V potential energy, as everywhere in Chapter 21. Likewise μ is a reduced mass in Section 28.1.3 and a linear mass density, in kg/m, from Section 28.3.3 onward. In Section 28.5 T is a thermodynamic temperature; no tension appears there.

Remark 28.2 (Tabulated material values used below). Four numbers enter the worked examples of this chapter as ordinary handbook values for which this treatise cites no primary source: the mean molar mass of dry air, $M = 28.96 \times 10^{-3}\,\mathrm{kg/mol}$; the thermal diffusivity of air near room temperature, $2.1 \times 10^{-5}\,\mathrm{m^2/s}$; the density of spring steel, $7.85 \times 10^{3}\,\mathrm{kg/m^3}$; and the atomic masses of ^{1}H and ^{35}Cl. They are stated to the precision used and no further, and no conclusion in this chapter turns on their last digit. Everything else — g, c, the molar gas constant, the atomic mass constant — is either an exact SI definition or carries the citation given where it appears.

28.1 The harmonic oscillator

28.1.1 Free oscillations

Hooke announced the linear restoring law in 1678 as the anagram *ut tensio, sic vis* — as the extension, so the force — having sealed it in 1676 to secure priority [13]. It is the whole content of the model.

Definition 28.3 (Simple harmonic oscillator)**.** A particle of mass m moving on a line under a force proportional to its displacement and directed against it,

$$F = -kx\,, \qquad k > 0\,, \tag{28.1}$$

with k the *spring constant*, of SI dimension N/m. Its equation of motion is

$$\ddot{x} + \omega_0^2 x = 0\,, \qquad \omega_0 := \sqrt{\frac{k}{m}}\,, \tag{28.2}$$

and ω_0, of SI dimension rad/s, is the *natural angular frequency*. The Lagrangian and Hamiltonian are

$$\mathcal{L} = \tfrac{1}{2}m\dot{x}^2 - \tfrac{1}{2}kx^2\,, \qquad \mathcal{H} = \frac{p^2}{2m} + \tfrac{1}{2}kx^2\,. \tag{28.3}$$

Rests on Definition 16.96 and Theorem 16.97.

Proposition 28.4 (General solution and isochronism)**.** *Every solution of Equation (28.2) is*

$$x(t) = A\cos\left(\omega_0 t + \varphi\right)\,, \tag{28.4}$$

with $A \geq 0$ and φ fixed by the initial data, and no other solution exists. Its period is $T = 2\pi/\omega_0 = 2\pi\sqrt{m/k}$, independent of A.

Rests on Equation (28.2) and Theorem 9.13.

Proof. *Derives Proposition 28.4.*

Equation (28.2) is linear, homogeneous and of second order with constant coefficients, so by Theorem 9.13 its solution space is two-dimensional, and by Corollary 9.9 every solution extends to all of $\mathbb{R}$. The pair $\cos\omega_0 t$ and $\sin\omega_0 t$ solves it and has Wronskian (Definition 9.14) equal to $\omega_0 \neq 0$, so by Proposition 9.16 it is a basis; writing the general combination in amplitude–phase form gives Equation (28.4). Uniqueness for given $x(0), \dot{x}(0)$ is Theorem 9.8. The period is the least $T > 0$ with $\omega_0 T = 2\pi$, and A appears in Equation (28.4) only as a multiplicative constant, which a linear equation cannot convert into a shift of T: hence the isochronism, and hence also its exactness being no better than the linearity (Section 28.7). □

Proposition 28.5 (Energy, and its equal sharing)**.** *Along Equation (28.4) the total energy is constant,*

$$E = \tfrac{1}{2}m\dot{x}^2 + \tfrac{1}{2}kx^2 = \tfrac{1}{2}m\omega_0^2 A^2\,, \tag{28.5}$$

and the kinetic and potential energies, averaged over one period, are equal and each equal to $E/2$.

Rests on Equations (28.3) and (28.4).

Proof. *Derives Proposition 28.5.*

Substituting Equation (28.4) and $k = m\omega_0^2$,

$$E = \tfrac{1}{2}m\omega_0^2 A^2 \sin^2\left(\omega_0 t + \varphi\right) + \tfrac{1}{2}m\omega_0^2 A^2 \cos^2\left(\omega_0 t + \varphi\right) = \tfrac{1}{2}m\omega_0^2 A^2\,,$$

by the Pythagorean identity (Lemma 7.59), which is also the statement that E does not depend on t. The mean of $\cos^2$ over a period is $\tfrac{1}{2}$ and so is the mean of $\sin^2$, whence $\langle T\rangle = \langle V\rangle = E/2$. The energy oscillates between the two forms at $2\omega_0$ — twice the frequency of the motion — because both forms are quadratic in a quantity oscillating at ω_0. □

The Hamiltonian flow of Equation (28.3) carries every orbit around an ellipse in the phase plane, and the area enclosed is the quantity classical mechanics hands to the old quantum theory.

Proposition 28.6 (Phase-space area and the action variable)**.** *The orbit of energy E is the ellipse $p^2/2m + m\omega_0^2 x^2/2 = E$, and*

$$J := \oint p\,\mathrm{d}x = \frac{2\pi E}{\omega_0}\,, \qquad I := \frac{J}{2\pi} = \frac{E}{\omega_0}\,, \tag{28.6}$$

with I of SI dimension J s.

Rests on Equations (28.3) *and* (28.5).

Proof. *Derives Proposition 28.6.*

The orbit is the level set of $\mathcal{H}$, an ellipse with semi-axes $x_{\max} = \sqrt{2E/m\omega_0^2}$ along x and $p_{\max} = \sqrt{2mE}$ along p. The enclosed area is $\pi x_{\max} p_{\max} = \pi \cdot 2E/\omega_0$, and $\oint p\,\mathrm{d}x$ is that area. The dimension follows from [energy] / [frequency]. □

Remark 28.7 (Why this ellipse is the doorway to quantization). Equation (28.6) says the oscillator's energy is its action variable times its frequency. Imposing $I = n\hbar$ therefore yields $E = n\hbar\omega_0$ at a stroke, which is the Bohr–Sommerfeld rule of Section 9.6.7 and, historically, Planck's hypothesis. The action variable is the invariant of a slowly changing oscillator and the natural coordinate of Chapter 23; the exact quantum spectrum, with its zero-point term, is Chapter 78, and the same ellipse becomes the phase space of a single field mode in Chapter 99.

Rests on Equation (28.6).

Example 28.8 (A laboratory spring, in SI)**.** A mass $m = 0.250\,\mathrm{kg}$ hung on a spring stretches it by $4.90\,\mathrm{cm}$ at rest, so $k = mg/\Delta x = 0.250\,\mathrm{kg} \times 9.806\,65\,\mathrm{m/s^2}/4.90 \times 10^{-2}\,\mathrm{m} = 50.0\,\mathrm{N/m}$. Then $\omega_0 = \sqrt{k/m} = 14.1\,\mathrm{rad/s}$, a frequency of $2.25\,\mathrm{Hz}$ and a period of $0.444\,\mathrm{s}$. Released from $A = 2.00\,\mathrm{cm}$ the energy is $\tfrac{1}{2}kA^2 = 1.00 \times 10^{-2}\,\mathrm{J}$ and the greatest speed is $\omega_0 A = 0.283\,\mathrm{m/s}$. Every one of these numbers is fixed by the two constants m and k alone, which is Phenomenon 28.13 in miniature.

Rests on Equations (28.2) *and* (28.5).

28.1.2 The pendulum

The pendulum is where the harmonic oscillator was first met in nature rather than built, and where its isochronism was first put to work. Galileo reports that a pendulum keeps its period as the swing decays, and proposes it as a timekeeper and as a pulse counter [4]. Huygens turned the observation into the pendulum clock, and in the *Horologium Oscillatorium* of 1673 gave both the exact isochronous curve — the cycloid — and the theory of the compound pendulum, including the centre of oscillation and the reciprocity that makes a reversible pendulum an absolute gravimeter [11]. The measurements themselves are Chapter 34, and the clock is the first entry in the history of frequency standards taken up in Chapter 2.

Phenomenon 28.9 (Isochronism of the small-amplitude pendulum)**.** A pendulum swinging through a small arc keeps the same period whether the arc is wide or narrow: two pendulums of equal length released from different heights stay in step for hundreds of swings. The period depends on the length of the suspension and on the local acceleration of free fall, and — to the accuracy of the observation — on nothing else: not on the amplitude, and not on the mass or the material of the bob. Galileo reports the observation and draws from it the pendulum's use as a timekeeper [4]; it is the fact on which the pendulum clock, the first precision frequency standard, was built.

$$T = 2\pi\sqrt{\frac{\ell}{g}}\,. \tag{28.7}$$

Rests on Equation (28.2) and Proposition 28.4.

Derivation. *Derives Phenomenon 28.9.*

A bob of mass m on a light rod of length ℓ, displaced by an angle θ from the downward vertical, has moment of inertia $m\ell^2$ about the pivot, while the weight exerts about the pivot the moment $-mg\ell\sin\theta$. The rotational law of Chapter 19 then gives

$$\ell\,\ddot{\theta} = -g\sin\theta\,, \tag{28.8}$$

in which the mass has cancelled — which accounts for the observed independence of the bob. For $|\theta| \ll 1$ one has $\sin\theta = \theta + O(\theta^3)$ by Theorem 7.38, and Equation (28.8) reduces to the harmonic equation $\ddot{\theta}+\omega_0^2\theta = 0$ with $\omega_0^2 = g/\ell$, whose general solution is Equation (28.4) with period $T = 2\pi/\omega_0$. That is Equation (28.7), and it contains no A: in a linear equation the amplitude enters only as an overall multiplicative constant, and no linear equation can make its period depend on it (Proposition 28.4). Isochronism is therefore exactly as good as the linearization and no better. Retaining the cubic term makes the period grow with the angular amplitude θ_0 as $T(\theta_0) = T\,(1 + \theta_0^2/16 + O(\theta_0^4))$, derived in Theorem 28.72 and already about one part in 10^3 at an amplitude of 7° — the failure taken up in Section 28.7.1. □

Example 28.10 (The seconds pendulum)**.** A pendulum of period $T = 2\,\mathrm{s}$ — one second to each swing, the beat of a longcase clock — requires, by Equation (28.7), a length

$$\ell = \frac{gT^2}{4\pi^2} = \frac{9.806\,65\,\mathrm{m/s^2}\times 4\,\mathrm{s^2}}{4\pi^2} = 0.9936\,\mathrm{m}\,.$$

The number is close enough to one metre that the seconds pendulum was a serious candidate for the definition of the metre in the eighteenth century, and it was rejected for a reason that belongs to this chapter: ℓ depends on g, which varies over the Earth by some 0.5 %, so the standard would have differed from place to place. That same sensitivity is what makes the pendulum an instrument (Proposition 28.11, Chapter 34).

Rests on Equation (28.7).

Proposition 28.11 (The physical pendulum and its centre of oscillation)**.** *A rigid body of mass m suspended from a pivot a distance d from its centre of mass, with moment of inertia I about that pivot, oscillates for small displacements at*

$$\omega_0^2 = \frac{mgd}{I}\,, \qquad \ell_{eq} := \frac{I}{md}\,, \tag{28.9}$$

with ℓ_{eq} the length of the simple pendulum of the same period. If $I_{cm} = mb^2$ is the moment of inertia about the centre of mass, then $\ell_{eq} = d + b^2/d$, and suspension from the point at distance b^2/d on the far side of the centre of mass gives the same period: the pivot and that point are interchangeable.

Rests on Equations (28.2) and (28.8).

Proof. *Derives Proposition 28.11.*

The moment of the weight about the pivot is $-mgd\sin\theta$ and the angular momentum about it is $I\dot{\theta}$, so the rotational law of Chapter 19 gives $I\ddot{\theta} = -mgd\sin\theta$; linearizing as in Phenomenon 28.9 yields the first of Equation (28.9), and comparison with $\omega_0^2 = g/\ell$ gives the second. The parallel-axis theorem of Chapter 29 gives $I = m(b^2 + d^2)$, whence $\ell_{\mathrm{eq}} = (b^2+d^2)/d = d+b^2/d$. Suspending instead at $d' = b^2/d$ gives $\ell'_{\mathrm{eq}} = d'+b^2/d' = b^2/d+d$, the same number. □

The interchange is Huygens' reciprocity [11], and it is the working principle of Kater's reversible pendulum: adjust the suspension until the two periods agree, measure the distance between the knife edges — which is then ℓ_{eq}, needing no knowledge of I or of the mass distribution — and read g off Equation (28.7). Chapter 34 reports the measurement.

Proposition 28.12 (Huygens' cycloidal pendulum is exactly isochronous)**.** *A particle sliding without friction under gravity on the cycloid*

$$x = a\,(\phi + \sin\phi)\,, \qquad y = a\,(1 - \cos\phi)\,, \qquad |\phi| \le \pi\,, \tag{28.10}$$

with y measured upward, so that $\phi = 0$ is the lowest point, oscillates with period $T = 2\pi\sqrt{4a/g}$ for every *amplitude.*

Rests on Equations (28.2) and (28.8).

Proof. *Derives Proposition 28.12.*

Parametrize the curve by arc length s measured from the lowest point, $\phi = 0$. From Equation (28.10), $\mathrm{d}x = a(1 + \cos\phi)\mathrm{d}\phi$ and $\mathrm{d}y = a\sin\phi\,\mathrm{d}\phi$, so

$$\mathrm{d}s^2 = a^2\left[(1+\cos\phi)^2 + \sin^2\phi\right]\mathrm{d}\phi^2 = 2a^2\,(1+\cos\phi)\,\mathrm{d}\phi^2 = 4a^2\cos^2\!\left(\frac{\phi}{2}\right)\mathrm{d}\phi^2\,,$$

whence $\mathrm{d}s = 2a\cos(\phi/2)\mathrm{d}\phi$ and $s = 4a\sin(\phi/2)$, the cosine being non-negative on $|\phi| \le \pi$. The height above the lowest point is $h = y = a(1-\cos\phi) = 2a\sin^2(\phi/2)$, and eliminating ϕ in favour of s gives $h = s^2/8a$. The potential energy is therefore $V = mgh = mgs^2/8a$, exactly quadratic in the arc length, and the kinetic energy is $\frac{1}{2}m\dot{s}^2$ because s is arc length. So the motion in s is Equation (28.2) with $\omega_0^2 = g/4a$, with no approximation anywhere, and Proposition 28.4 gives a period independent of amplitude. □

The cycloid is the same curve that solves the brachistochrone problem of Proposition 16.1 — one curve answering two questions that have no obvious relation, which is why the coincidence was worth Bernoulli's astonishment. Huygens made a pendulum trace it by hanging the bob between two cycloidal cheeks [11]; the device failed in practice because the string's friction against the cheeks cost more accuracy than the residual anharmonicity of a plain small-arc pendulum cost.

28.1.3 Universality of the harmonic approximation

Phenomenon 28.13 (Universality of small oscillations)**.** Systems that have nothing else in common oscillate sinusoidally when disturbed slightly from a stable equilibrium, and each does so at one frequency fixed by the system and not by the size of the disturbance: a mass on a spring, a tuning fork, a diatomic molecule, an atom in a crystal, a ship rolling, a bead in a bowl. The list is not a coincidence of construction but a consequence of the disturbance being small, and it is why one model is reused throughout this treatise — for lattice vibrations in Chapter 125, for the modes of the electromagnetic field in Chapter 61, and for the field quanta of Chapter 64 [1585, 2027].

Rests on Theorem 7.38 and Equation (28.2).

Derivation. *Derives Phenomenon 28.13.*

Let a system of one degree of freedom have potential energy $V(x)$, twice continuously differentiable, with an equilibrium at x_0, so that $V'(x_0) = 0$, and let that equilibrium be stable, so that $V''(x_0) > 0$. Taylor's theorem (Theorem 7.38) gives

$$V(x) = V(x_0) + \tfrac{1}{2}V''(x_0)\,(x - x_0)^2 + O\!\left((x-x_0)^3\right)\,, \tag{28.11}$$

the linear term being absent precisely because x_0 is an equilibrium. Writing $u := x - x_0$ and keeping the quadratic term, the force is $F = -\frac{\mathrm{d}V}{\mathrm{d}x} = -V''(x_0)\,u$ and Newton's second law becomes

$$m\ddot{u} = -V''(x_0)\,u\,, \qquad \omega_0^2 = \frac{V''(x_0)}{m}\,, \tag{28.12}$$

a harmonic equation with a real frequency exactly because $V''(x_0) > 0$. Nothing about the system entered except the two numbers m and $V''(x_0)$, which is the universality asserted; and

the approximation is controlled by the neglected cubic term, so it degrades as the amplitude grows (Section 28.7). The two excluded cases are instructive. Where $V''(x_0) < 0$ the same expansion gives an exponentially growing solution, which is what makes the equilibrium unstable; where $V''(x_0) = 0$ the leading behaviour is quartic or worse and is not harmonic at all, so the period depends on the amplitude however small the amplitude is made. □

Remark 28.14 (When the approximation fails). Equation (28.11) is useful only while the cubic term is small against the quadratic one over the range actually explored. For an amplitude A that condition reads

$$\frac{|V'''(x_0)|\,A}{3\,V''(x_0)} \ll 1\,, \tag{28.13}$$

a purely local statement with a purely local consequence: the fractional shift of the period is of the same order as the square of the left-hand side (Theorem 28.72). It says nothing about whether the motion remains bounded, and it fails outright at an inflection of V, where $V''(x_0) = 0$ and there is no harmonic regime at any amplitude.

Rests on Equation (28.11).

Example 28.15 (A chemical bond as a spring)**.** The stretching vibration of a diatomic molecule is Equation (28.12) with the reduced mass $\mu = m_1 m_2/(m_1 + m_2)$ in place of m, because the two-body problem separates into a centre-of-mass motion and a relative motion (Chapter 27). For $^1\mathrm{H}^{35}\mathrm{Cl}$ the harmonic constant of the vibrational ladder is $\tilde{\nu}_e \approx 2991/\mathrm{cm}$ [961], that is

$$\nu_e = c\,\tilde{\nu}_e = 8.966 \times 10^{13}\,\mathrm{Hz}\,, \qquad \omega_e = 2\pi\nu_e = 5.634 \times 10^{14}\,\mathrm{rad/s}\,.$$

With $m_1 = 1.0078\,u$ and $m_2 = 34.9689\,u$ the reduced mass is $0.9796\,u$, and with the atomic mass constant $u = (1.660\,539\,068\,92 \pm 0.000\,000\,000\,52) \times 10^{-27}\,\mathrm{kg}$ [2431] this is $\mu = 1.6266 \times 10^{-27}\,\mathrm{kg}$. Hence

$$k = \mu\,\omega_e^2 = 1.6266 \times 10^{-27}\,\mathrm{kg} \times 3.174 \times 10^{29}/\mathrm{s}^2 = 516\,\mathrm{N/m}\,. \tag{28.14}$$

A hydrogen–chlorine bond is a spring ten times stiffer than the laboratory spring of Example 28.8, and the entire difference in their behaviour is the factor 10^{27} between the two masses.

Rests on Equation (28.12).

Remark 28.16 (The same molecule measures the anharmonicity). $\tilde{\nu}_e$ in Example 28.15 is not what a spectrometer reads. The observed fundamental band of $^1\mathrm{H}^{35}\mathrm{Cl}$ lies near $2885/\mathrm{cm}$; $\tilde{\nu}_e$ is the harmonic frequency extrapolated from the ladder of levels, and the difference, $\tilde{\nu}_e - 2\tilde{\nu}_e x_e$ with $\tilde{\nu}_e x_e \approx 52.8/\mathrm{cm}$ [961], is the anharmonicity of the bond. It is 3.5 % — small, which is why Example 28.15 is worth doing, and not zero, which is why Section 28.7 exists. A purely harmonic bond could never break; the observed dissociation of molecules is the same cubic term seen at large amplitude (Chapter 88).

Rests on Equations (28.13) *and* (28.14).

28.2 Damped and driven oscillations

28.2.1 Linear damping

Rayleigh's systematic treatment of dissipation in vibrating systems [198] takes the friction to be linear in the velocity, which is the first term of an expansion in $\dot{x}$ exactly as Equation (28.11) is the first term of an expansion in x.

Definition 28.17 (Damped oscillator)**.**

$$\ddot{x} + 2\beta\dot{x} + \omega_0^2 x = 0\,, \tag{28.15}$$

with $\beta \geq 0$ the *damping rate*, of SI dimension 1/s, arising from a resistive force $-2m\beta\dot{x}$.
Rests on Equation (28.2)*.*

Proposition 28.18 (The three regimes)**.** *The solutions of Equation* (28.15) *are, according to the sign of* $\beta^2 - \omega_0^2$*,*

$$\beta < \omega_0: \quad x = A\mathrm{e}^{-\beta t}\cos(\omega_d t + \varphi)\,, \qquad \omega_d = \sqrt{\omega_0^2 - \beta^2}\,, \tag{28.16}$$

$$\beta = \omega_0: \quad x = (C_1 + C_2 t)\,\mathrm{e}^{-\omega_0 t}\,, \tag{28.17}$$

$$\beta > \omega_0: \quad x = C_+\mathrm{e}^{\lambda_+ t} + C_-\mathrm{e}^{\lambda_- t}\,, \qquad \lambda_\pm = -\beta \pm \sqrt{\beta^2 - \omega_0^2}\,. \tag{28.18}$$

Only the first oscillates; all three decay, and none reaches zero in finite time.
Rests on Equation (28.15) *and Theorem 9.13.*

Proof. *Derives Proposition 28.18.*

Substituting $x = \mathrm{e}^{\lambda t}$ into Equation (28.15) gives the characteristic equation $\lambda^2 + 2\beta\lambda + \omega_0^2 = 0$ with roots $\lambda_\pm = -\beta \pm \sqrt{\beta^2 - \omega_0^2}$. For $\beta < \omega_0$ the roots are $-\beta \pm \mathrm{i}\omega_d$ and the real combinations give Equation (28.16). For $\beta > \omega_0$ both roots are real and negative, since $\sqrt{\beta^2 - \omega_0^2} < \beta$, giving Equation (28.18). At $\beta = \omega_0$ the roots coincide and $\mathrm{e}^{-\omega_0 t}$ alone spans only one dimension of the two-dimensional solution space of Theorem 9.13; a second, independent solution is $t\mathrm{e}^{-\omega_0 t}$, as substitution confirms and as the Wronskian $\mathrm{e}^{-2\omega_0 t} \neq 0$ certifies (Proposition 9.16). Each exponential has strictly negative real part whenever $\beta > 0$, so every solution decays; and an exponential vanishes nowhere, while Equation (28.17) and Equation (28.18) can each cross zero at most once. □

Definition 28.19 (Logarithmic decrement and quality factor)**.** For the underdamped case, the *logarithmic decrement* is the natural logarithm of the ratio of successive maxima,

$$\delta_{\log} = \ln\frac{x(t)}{x\,(t + 2\pi/\omega_d)} = \frac{2\pi\beta}{\omega_d}\,, \tag{28.19}$$

and the *quality factor* is

$$Q := \frac{\omega_0}{2\beta}\,, \tag{28.20}$$

a dimensionless number.
Rests on Equation (28.16)*.*

Proposition 28.20 (Q counts stored energy against energy lost)**.** *For an underdamped oscillator the energy obeys* $E(t) = E_0\mathrm{e}^{-2\beta t}$ *up to terms oscillating at* $2\omega_d$*, and for* $Q \gg 1$

$$Q = 2\pi\,\frac{\textit{energy stored}}{\textit{energy dissipated per cycle}} = \frac{\omega_0}{2\beta}\,, \tag{28.21}$$

so that the motion persists for about Q/π *cycles.*
Rests on Equations (28.5) *and* (28.20)*.*

Proof. *Derives Proposition 28.20.*

Differentiating $E = \tfrac{1}{2}m\dot{x}^2 + \tfrac{1}{2}m\omega_0^2 x^2$ along Equation (28.15),

$$\frac{\mathrm{d}E}{\mathrm{d}t} = m\dot{x}\left(\ddot{x} + \omega_0^2 x\right) = -2m\beta\dot{x}^2\,, \tag{28.22}$$

which is the power of the resistive force and is never positive. Over one cycle $\langle\dot{x}^2\rangle = E/m$ by Proposition 28.5 applied to the slowly decaying envelope, so $\langle \mathrm{d}E/\mathrm{d}t\rangle = -2\beta E$ and $E = E_0\mathrm{e}^{-2\beta t}$. The fractional loss per cycle is then $\Delta E/E = 2\beta\cdot 2\pi/\omega_d \approx 4\pi\beta/\omega_0$ for $Q \gg 1$, and $2\pi E/\Delta E = \omega_0/2\beta = Q$. The amplitude envelope falls by e^{-1} in the time $1/\beta = 2Q/\omega_0$, which is Q/π periods; the energy, decaying twice as fast, does so in $Q/2\pi$ periods. □

Proposition 28.21 (Critical damping returns fastest)**.** *Among all $\beta \geq 0$, the slowest-decaying exponential in Proposition 28.18 has the largest decay rate exactly at $\beta = \omega_0$, where that rate is ω_0.*

Rests on Equations (28.17) *and* (28.18)*.*

Proof. *Derives Proposition 28.21.*

For $\beta < \omega_0$ every solution is bounded by const $\times\, \mathrm{e}^{-\beta t}$ and no better, so the rate is $\beta < \omega_0$. For $\beta > \omega_0$ the slower of the two exponentials in Equation (28.18) decays at

$$|\lambda_+| = \beta - \sqrt{\beta^2 - \omega_0^2} = \frac{\omega_0^2}{\beta + \sqrt{\beta^2 - \omega_0^2}} < \omega_0 \,,$$

a strictly decreasing function of β on (ω_0, ∞). At $\beta = \omega_0$ the rate is ω_0 itself, larger than either branch, the algebraic factor t in Equation (28.17) being no obstacle since $t\mathrm{e}^{-\omega_0 t} \to 0$ faster than $\mathrm{e}^{-\beta' t}$ for any $\beta' < \omega_0$. □

This is why a galvanometer, a door closer and a car suspension are all built close to critical damping: overdamping is not the safe side of the design, it is slower.

Remark 28.22 (The observed range of Q)*.* Quality factors are among the widest-ranging numbers in physics, and Equation (28.21) is what makes them measurable in three independent ways: from the ringdown time, from the fractional energy lost per cycle, and — next — from the width of the resonance curve. That the three agree is the content of the definition, and it is checked every time a resonator is characterized. A tapped wine glass rings for a second or two at a few hundred hertz, which by $Q = \pi f \tau$ is $Q \sim 10^3$; a quartz timekeeping crystal is several orders higher, and the caesium hyperfine resonance on which the SI second is founded [1064] higher still. Individual figures of that kind are engineering data for which this treatise cites no primary source, and none of them is used below. The name and the engineering history of the symbol are recorded by Green [1071].

Rests on Equation (28.21)*.*

28.2.2 The driven oscillator and resonance

Phenomenon 28.23 (Resonance)**.** A lightly damped oscillator driven by a periodic force of fixed amplitude responds far more strongly when the driving frequency is near its own than when it is far away, and the sharper the oscillator — the smaller its damping — the larger that response and the narrower the band of frequencies over which it occurs. A wine glass shatters at one note and not at its neighbours; a radio receiver selects one station out of thousands; a struck string sets an identically tuned string sounding across the room while a mistuned one stays silent, an effect Galileo already describes and attributes to the accumulation of correctly timed impulses [4]. On resonance the response also lags the drive by a quarter of a cycle [1585].

Rests on Equations (28.15) *and* (28.20)*.*

Derivation. *Derives Phenomenon 28.23.*

Take the linearly damped, sinusoidally driven oscillator

$$\ddot{x} + 2\beta\dot{x} + \omega_0^2 x = \frac{F_0}{m}\cos\omega t \,, \tag{28.23}$$

and seek the steady state $x = A(\omega)\cos(\omega t - \delta)$. Substituting and collecting the coefficients of $\cos\omega t$ and $\sin\omega t$ gives

$$A(\omega) = \frac{F_0/m}{\sqrt{\left(\omega_0^2 - \omega^2\right)^2 + 4\beta^2\omega^2}} \,, \qquad \tan\delta = \frac{2\beta\omega}{\omega_0^2 - \omega^2} \,. \tag{28.24}$$

At $\omega = \omega_0$ the first bracket vanishes and $A(\omega_0) = F_0/(2m\beta\omega_0)$, whereas the static response, $\omega = 0$, is $A(0) = F_0/(m\omega_0^2)$. Their ratio is

$$\frac{A(\omega_0)}{A(0)} = \frac{\omega_0}{2\beta} = Q\,, \tag{28.25}$$

the quality factor: a resonator with $Q = 10^4$ answers a drive at its own frequency ten thousand times more strongly than it answers the same drive applied slowly. The denominator of $\tan\delta$ vanishes at $\omega = \omega_0$, so $\delta = \pi/2$ there, which is the quarter-cycle lag. Finally A^2 falls to half its peak where $\left(\omega_0^2 - \omega^2\right)^2 = 4\beta^2\omega^2$, that is $|\omega_0 - \omega| \simeq \beta$ for light damping, so the full width of the resonance curve is $\Delta\omega \simeq 2\beta = \omega_0/Q$. Gain and selectivity are thus the same number: a sharp resonator is necessarily a narrow filter, and a broadband one is necessarily insensitive. □

The steady state is only half the solution. Equation (28.23) is inhomogeneous and linear, so its general solution is the steady state plus an arbitrary solution of Equation (28.15); the latter is the *transient*, it decays as $\mathrm{e}^{-\beta t}$, and it is what carries the initial data. A resonator therefore takes about Q/π cycles to reach the response Equation (28.24) — the same Q again, and the reason a high-Q filter is a slow filter.

Proposition 28.24 (Impulse response of the damped oscillator)**.** *The solution of* $m(\ddot{x} + 2\beta\dot{x} + \omega_0^2 x) = F(t)$ *that vanishes before the force acts is*

$$x(t) = \int_{-\infty}^{t} G(t - t')\, F(t')\, \mathrm{d}t'\,, \qquad G(\tau) = \frac{\mathrm{e}^{-\beta\tau}\sin\omega_d\tau}{m\,\omega_d} \quad (\tau > 0)\,, \tag{28.26}$$

and $G(\tau) = 0$ *for* $\tau < 0$. *G has SI dimension* $\mathrm{m/(N\,s)}$.
Rests on Equation (28.23) and Definition 10.42.

Proof. *Derives Proposition 28.24.*
This is the causal Green's function of Definition 10.42 for the operator on the left, and Equation (28.26) is Duhamel's principle (Theorem 10.52) for it; only G itself has to be identified. An impulse $F = P\delta(\tau)$ leaves x continuous and jumps $\dot{x}$ by P/m, by integrating the equation across $\tau = 0$; the solution of the homogeneous equation with $x(0) = 0$ and $\dot{x}(0) = P/m$ is, from Equation (28.16), $x = (P/m\omega_d)\mathrm{e}^{-\beta\tau}\sin\omega_d\tau$. Dividing by P gives G. Vanishing for $\tau < 0$ is the causality requirement, which selects the retarded solution of Definition 10.50. The dimension follows from displacement per unit impulse per unit time. □

Equation (28.26) makes the oscillator a linear translation-invariant system in the sense of Proposition 17.52, so its response to *any* drive is a convolution and, by the convolution theorem Theorem 17.53, a multiplication in frequency. That multiplier is the susceptibility.

Definition 28.25 (Complex susceptibility)**.** Writing the drive as the real part of $F_0\mathrm{e}^{-\mathrm{i}\omega t}$ and the response as the real part of $\chi(\omega)F_0\mathrm{e}^{-\mathrm{i}\omega t}$,

$$\chi(\omega) = \frac{1}{m\left(\omega_0^2 - \omega^2 - 2\mathrm{i}\beta\omega\right)}\,, \tag{28.27}$$

of SI dimension m/N, with $|\chi| = A/F_0$ and $\arg\chi = \delta$ from Equation (28.24), so that the real part of $\chi F_0\mathrm{e}^{-\mathrm{i}\omega t}$ is $A\cos(\omega t - \delta)$.
Rests on Equation (28.24) and Proposition 17.52.

Remark 28.26 (Causality is visible in the susceptibility). The poles of Equation (28.27) sit at $\omega = -\mathrm{i}\beta \pm \omega_d$, both in the lower half of the complex ω plane, so χ is holomorphic in the upper half plane. That is exactly the analyticity that Theorem 17.78 converts into a dispersion

relation between $\operatorname{Re}\chi$ and $\operatorname{Im}\chi$: the in-phase and out-of-phase parts of the response are not independent, and measuring the absorption of a resonator over all frequencies determines its refraction. The same relation, for the same reason, governs the optical response of matter (Chapter 62) and the scattering amplitudes of Chapter 86. A damping $\beta > 0$ is what pushes the poles off the real axis; an undamped oscillator sits exactly at the boundary, which is why its driven response diverges.

Rests on Equation (28.27) and Theorem 17.78.

Proposition 28.27 (Three resonant frequencies, and only one of them is exact)**.** *The cycle-averaged power delivered by the drive of Equation (28.23) is*

$$\bar{P}(\omega) = \frac{F_0^2 \beta\, \omega^2}{m\left[\left(\omega_0^2 - \omega^2\right)^2 + 4\beta^2\omega^2\right]}, \tag{28.28}$$

which attains its maximum $\bar{P}(\omega_0) = F_0^2/(4m\beta)$ at $\omega = \omega_0$ exactly, and whose two half-power frequencies differ by exactly $2\beta = \omega_0/Q$ — both statements holding for every β, not only in the lightly damped limit in which Equation (28.28) becomes a Lorentzian. The amplitude *peaks instead at $\omega_r = \sqrt{\omega_0^2 - 2\beta^2}$, which exists only for $\beta < \omega_0/\sqrt{2}$.*

Rests on Equations (28.20) and (28.24).

Proof. *Derives Proposition 28.27.*

With $F = F_0 \cos\omega t$ and $\dot{x} = -A\omega \sin(\omega t - \delta)$, the average of $\cos\omega t \sin(\omega t - \delta)$ over a period is $-\frac{1}{2}\sin\delta$, so $\bar{P} = \langle F\dot{x}\rangle = \frac{1}{2}F_0 A\omega \sin\delta$. Substituting A and $\sin\delta = 2\beta\omega/\sqrt{(\omega_0^2-\omega^2)^2 + 4\beta^2\omega^2}$ from Equation (28.24) gives Equation (28.28). Writing D^2 for the bracket, $\bar{P}$ is half its peak where $\beta\omega^2/D^2 = 1/8\beta$, that is $\left(\omega_0^2 - \omega^2\right)^2 = 4\beta^2\omega^2$, or $\omega^2 \pm 2\beta\omega - \omega_0^2 = 0$; the two positive roots are $\sqrt{\beta^2 + \omega_0^2} \mp \beta$ and their difference is 2β with no approximation. For the amplitude, differentiating D^2 and setting the result to zero gives $-4\omega(\omega_0^2 - \omega^2) + 8\beta^2\omega = 0$, hence $\omega_r^2 = \omega_0^2 - 2\beta^2$. Finally, maximizing the velocity amplitude ωA means maximizing ω^2/D^2, whose derivative in $u = \omega^2$ has numerator $(\omega_0^2 - u)\,(\omega_0^2 + u)$; this vanishes at $u = \omega_0^2$ exactly. □

Three "resonant frequencies" therefore have to be kept apart, and they coincide only in the limit of vanishing damping: the power and the velocity peak exactly at ω_0, the displacement peaks slightly below it, and the free ringing runs at $\omega_d = \sqrt{\omega_0^2 - \beta^2}$, lower still. The distinction is invisible at $Q = 10^4$ and unavoidable at $Q = 2$. The Laplace-transform route to the same steady state, with the transient included, is worked in Example 17.75.

28.2.3 Parametric resonance

A pendulum can also be excited without applying any force to it, by varying one of its parameters in time — shortening and lengthening the suspension, or modulating the stiffness. Faraday saw the effect first, in the standing ripples raised on a liquid surface by a vibrating support, and recorded the observation that identifies it: the ripples oscillate at *half* the frequency of the support [88]. The governing equation is Mathieu's [173].

Phenomenon 28.28 (Parametric excitation at half the drive frequency)**.** An oscillator whose stiffness is modulated periodically, with no applied force at all, can grow from rest — and it does so most readily when the modulation runs at *twice* its natural frequency, responding at half the modulation frequency. A liquid surface shaken vertically answers with standing ripples that complete one cycle for every two of the shaking [88]; a child on a swing rises and falls twice per swing and not once; and unlike ordinary resonance the growth is exponential rather than linear in time, and sets in only when the modulation exceeds a threshold fixed by the damping.

Rests on Equations (28.15) and (28.20).

Derivation. *Derives Phenomenon 28.28.*

Modulating the stiffness of Equation (28.15) gives Mathieu's equation with damping,

$$\ddot{x} + 2\beta\dot{x} + \omega_0^2\,(1 + h\cos\gamma t)\,x = 0\,, \qquad 0 < h \ll 1\,. \tag{28.29}$$

The damping can be removed exactly. Putting $x = \mathrm{e}^{-\beta t}y$ turns Equation (28.29) into a Mathieu equation with no first derivative:

$$\ddot{y} + \left[\omega_0^2 - \beta^2 + h\omega_0^2\cos\gamma t\right] y = 0\,. \tag{28.30}$$

From Equation (28.29) (substituting $x = \mathrm{e}^{-\beta t}y$ and cancelling the common exponential).

Hence x grows if and only if y grows faster than $\mathrm{e}^{\beta t}$. Take $\beta \ll \omega_0$ and set $\gamma = 2\omega_0 + \varepsilon$ with $|\varepsilon| \ll \omega_0$. Look for a response at half the modulation frequency, $y = a(t)\cos(\gamma t/2) + b(t)\sin(\gamma t/2)$, with a and b varying slowly enough that $\ddot{a}$ and $\ddot{b}$ may be dropped. Substituting, using $\cos\gamma t\cos(\gamma t/2) = \frac{1}{2}\left[\cos(\gamma t/2) + \cos(3\gamma t/2)\right]$ and $\cos\gamma t\sin(\gamma t/2) = \frac{1}{2}\left[\sin(3\gamma t/2) - \sin(\gamma t/2)\right]$, and discarding the non-resonant third harmonics, the coefficients of $\cos(\gamma t/2)$ and $\sin(\gamma t/2)$ give, with $\omega_0^2 - \gamma^2/4 \approx -\omega_0\varepsilon$ and $\gamma \approx 2\omega_0$,

$$\dot{a} = -\tfrac{1}{2}\left(\varepsilon + \tfrac{1}{2}h\omega_0\right) b\,, \qquad \dot{b} = +\tfrac{1}{2}\left(\varepsilon - \tfrac{1}{2}h\omega_0\right) a\,. \tag{28.31}$$

Eliminating b gives $\ddot{a} = s^2 a$ with

$$s = \tfrac{1}{2}\sqrt{\left(\tfrac{1}{2}h\omega_0\right)^2 - \varepsilon^2}\,, \tag{28.32}$$

real — and the amplitude therefore exponentially growing — exactly in the band $|\varepsilon| < h\omega_0/2$ centred on $\gamma = 2\omega_0$. Restoring the factor $\mathrm{e}^{-\beta t}$, the motion grows only if $s > \beta$, which at the centre of the band ($\varepsilon = 0$, $s = h\omega_0/4$) reads

$$h > \frac{4\beta}{\omega_0} = \frac{2}{Q}\,. \tag{28.33}$$

Every feature asserted follows: the response is at $\gamma/2$ by construction and could not have been at γ, since a term $\cos\gamma t$ multiplying x produces sum and difference frequencies and only the half-frequency component feeds back on itself; the growth is exponential, not the linear-in-t growth of an undamped forced oscillator; and there is a threshold, absent from ordinary resonance, because the modulation multiplies the amplitude instead of adding to it. □

Remark 28.29 (Part II owes Floquet theory). Equation (28.32) is a leading-order result about one instability band. The exact statement — that a linear system with coefficients of period $2\pi/\gamma$ has solutions of the form e^{st} times a function of that same period, so that stability is decided by the eigenvalues of one monodromy matrix, and that the (γ, h) plane is therefore divided into tongues of instability emanating from $\gamma = 2\omega_0/n$ — is Floquet's theorem, a general result about ordinary differential equations with periodic coefficients. It belongs in Chapter 9 alongside the Wronskian theory it extends, and Part II does not at present contain it, nor the Mathieu functions themselves alongside the Bessel, Legendre, Hermite and Laguerre families of that chapter. Nothing above depends on the missing statement: the derivation of Phenomenon 28.28 uses only the slowly-varying-amplitude argument written out there, and the tongue structure is asserted nowhere in this treatise.

Rests on Equation (28.29).

Parametric excitation is not a curiosity. It is how a swing is pumped — the rider raises and lowers the centre of mass twice per swing, modulating ℓ in Equation (28.7) at $2\omega_0$; it is the mechanism of the parametric amplifier, which achieves gain by modulating a reactance rather than by dissipating power in an active element; and it is the standard tool for driving a mechanical resonator without exerting a force on it. The nonlinear saturation that arrests the exponential growth of Equation (28.32), and the fate of the motion once the amplitude leaves the small-oscillation regime, belong to Chapter 32.

28.3 Coupled oscillators and normal modes

28.3.1 Two coupled oscillators and beats

Phenomenon 28.30 (Beats and the periodic exchange of energy)**.** Two tones of nearly equal frequency sounded together are heard not as two tones but as one, of the mean frequency, whose loudness rises and falls at the difference of the two — slowly enough to count when the two are within a few hertz. The mechanical counterpart is as striking: two identical pendulums joined by a weak spring, one started and the other at rest, exchange their motion completely and periodically, the second growing as the first dies away and back again, indefinitely [2027]. Piano tuners set unisons by counting beats, which measures a frequency difference with a stopwatch and no frequency standard at all.

Rests on Equations (28.4) *and* (28.36)*.*

Derivation. *Derives Phenomenon 28.30.*

Superpose two harmonic motions of equal amplitude and frequencies ω_1 and ω_2, and use the sum-to-product identity

$$\cos\omega_1 t + \cos\omega_2 t = 2\cos\left(\frac{\omega_1-\omega_2}{2}\,t\right)\cos\left(\frac{\omega_1+\omega_2}{2}\,t\right)\,. \tag{28.34}$$

The second factor is a rapid oscillation at the mean frequency; the first is a slow one multiplying it. The ear cannot follow the sign of the slow factor, only the size of the envelope, and |cos| has half the period of cos, so the loudness is heard to vary at $|\omega_1-\omega_2|$ — twice the frequency of the slow factor itself. For the coupled pendulums, ω_1 and ω_2 are the frequencies $\omega_\pm$ of Equation (28.36); starting one pendulum alone excites the two modes with equal amplitude, and taking their sum and difference gives one bob proportional to the cosine of the slow factor and the other to its sine. Since $\cos^2+\sin^2=1$, the total energy is constant and passes entirely from one pendulum to the other and back, with period $2\pi/\,|\omega_+-\omega_-|$. The weaker the coupling, the closer the two mode frequencies and the slower the exchange — which is why the effect requires a *weak* spring to be visible at all. □

Proposition 28.31 (The two modes of a pair of coupled pendulums)**.** *Two pendulums of equal mass m and equal natural frequency ω_0, whose bobs are joined by a spring of constant κ, obey*

$$m\ddot{x}_1 = -m\omega_0^2 x_1 - \kappa\,(x_1-x_2)\,,\qquad m\ddot{x}_2 = -m\omega_0^2 x_2 - \kappa\,(x_2-x_1)\,, \tag{28.35}$$

and have exactly two normal modes,

$$x_1+x_2 \;\text{ at }\omega_- = \omega_0\,,\qquad x_1-x_2 \;\text{ at }\omega_+ = \sqrt{\omega_0^2+\frac{2\kappa}{m}}\,, \tag{28.36}$$

whose splitting for a weak spring is $\omega_+-\omega_-\approx\kappa/m\omega_0$.

Rests on Equations (28.2) *and* (28.12)*.*

Proof. *Derives Proposition 28.31.*

Adding and subtracting the two equations of Equation (28.35) gives $\ddot{s}=-\omega_0^2 s$ for $s=x_1+x_2$, the coupling cancelling because the spring exerts equal and opposite forces, and $\ddot{d}=-(\omega_0^2+2\kappa/m)d$ for $d=x_1-x_2$. Each is Equation (28.2), so Equation (28.36) follows from Proposition 28.4. For $\kappa\ll m\omega_0^2$, $\omega_+=\omega_0\sqrt{1+2\kappa/m\omega_0^2}\approx\omega_0+\kappa/m\omega_0$ by Theorem 7.38. □

The symmetric mode leaves the spring unstretched and therefore does not know it is there; the antisymmetric mode stretches it twice per swing and is pushed up in frequency. Two identical oscillators brought into contact always split this way, and the splitting

measures the coupling: this is the mechanical original of level repulsion, of the bonding and antibonding pair of a diatomic molecule (Chapter 88), and of the acoustic and optical branches of a diatomic lattice (Chapter 125). With $m = 0.10\,\mathrm{kg}$, $\omega_0 = 6.0\,\mathrm{rad/s}$ and $\kappa = 0.20\,\mathrm{N/m}$ the splitting is $0.33\,\mathrm{rad/s}$ and the energy crosses from one pendulum to the other in $\pi/(\omega_+ - \omega_-) = 9.4\,\mathrm{s}$ — some nine swings, which is what makes the demonstration watchable.

28.3.2 Small oscillations about equilibrium

Lagrange gave the general theory in the *Mécanique analytique* [40]: expand the Lagrangian to second order about a configuration of equilibrium and the problem becomes an algebraic one, solved once and for all.

Definition 28.32 (The two quadratic forms)**.** Let a system with n degrees of freedom $q_1, \dots, q_n$ have kinetic energy $T = \tfrac{1}{2}\sum a_{jk}(q)\dot q_j \dot q_k$ and potential energy $V(q)$, and let $q^{(0)}$ be an equilibrium, so that $\partial V/\partial q_j = 0$ there. Writing $\eta_j := q_j - q_j^{(0)}$ and keeping the leading term of each energy,

$$T = \tfrac{1}{2}\sum_{j,k} M_{jk}\dot\eta_j\dot\eta_k\,, \qquad V - V\big(q^{(0)}\big) = \tfrac{1}{2}\sum_{j,k} K_{jk}\eta_j\eta_k\,, \tag{28.37}$$

with the constant matrices $M_{jk} = a_{jk}(q^{(0)})$ — the *mass matrix*, symmetric and positive definite — and $K_{jk} = \big(\partial^2 V/\partial q_j \partial q_k\big)\,(q^{(0)})$ — the *stiffness matrix*, symmetric by Proposition 7.73.

Rests on Equation (28.11) and Definition 5.107.

M is positive definite because $T > 0$ for every nonzero velocity; K need not be, and whether it is decides the stability of the equilibrium. The Euler–Lagrange equations (Theorem 16.35) applied to $\mathcal{L} = T - V$ give the linear system

$$M\ddot{\boldsymbol\eta} + K\boldsymbol\eta = \mathbf{0}\,, \tag{28.38}$$

and substituting $\boldsymbol\eta = \boldsymbol u\cos(\omega t - \varphi)$ turns it into an algebraic problem:

$$\big(K - \omega^2 M\big)\,\boldsymbol u = \mathbf{0}\,, \qquad \det\big(K - \omega^2 M\big) = 0\,. \tag{28.39}$$

From Equation (28.37) (Euler–Lagrange for the quadratic Lagrangian, then the harmonic ansatz).

The second condition — the *secular equation* — is necessary and sufficient for a nonzero $\boldsymbol u$ to exist, and it is a polynomial of degree n in ω^2 whose leading coefficient $(-1)^n \det M$ is nonzero.

Theorem 28.33 (Normal modes)**.** *Let M be real symmetric positive definite and K real symmetric, both $n \times n$. Then*

1. *the secular equation Equation (28.39) has exactly n real roots $\omega_1^2 \le \dots \le \omega_n^2$, counted with multiplicity;*
2. *there is a basis $\boldsymbol u^{(1)}, \dots, \boldsymbol u^{(n)}$ of $\mathbb{R}^n$ with $\big(K - \omega_r^2 M\big)\,\boldsymbol u^{(r)} = \mathbf{0}$ and*

$$\big(\boldsymbol u^{(r)}\big)^{\mathsf T} M\,\boldsymbol u^{(s)} = \delta_{rs}\,, \qquad \big(\boldsymbol u^{(r)}\big)^{\mathsf T} K\,\boldsymbol u^{(s)} = \omega_r^2\,\delta_{rs}\,, \tag{28.40}$$

   so that the matrix U with these columns satisfies $U^{\mathsf T} M U = \mathbb{1}$ and $U^{\mathsf T} K U = \operatorname{diag}(\omega_1^2, \dots, \omega_n^2)$;
3. *every $\omega_r^2 > 0$ if and only if K is positive definite, that is, if and only if the equilibrium is a strict local minimum of V to quadratic order.*

Rests on Equation (28.39) and Theorems 5.75 and 5.112.

Proof. *Derives Theorem 28.33.*

Because M is symmetric and positive definite, the bilinear form $\langle \boldsymbol{x}, \boldsymbol{y} \rangle_M := \boldsymbol{x}^{\mathsf{T}} M \boldsymbol{y}$ is an inner product on $\mathbb{R}^n$ in the sense of Definition 5.17. Set $A := M^{-1}K$, which exists because a positive-definite matrix is invertible. For all $\boldsymbol{x}, \boldsymbol{y}$,

$$\langle \boldsymbol{x}, A\boldsymbol{y} \rangle_M = \boldsymbol{x}^{\mathsf{T}} M M^{-1} K \boldsymbol{y} = \boldsymbol{x}^{\mathsf{T}} K \boldsymbol{y} = \boldsymbol{y}^{\mathsf{T}} K \boldsymbol{x} = \langle \boldsymbol{y}, A\boldsymbol{x} \rangle_M = \langle A\boldsymbol{x}, \boldsymbol{y} \rangle_M \,,$$

the middle step because a 1×1 matrix equals its own transpose and $K^{\mathsf{T}} = K$, the last because $\langle \cdot, \cdot \rangle_M$ is symmetric: A is self-adjoint with respect to it.

Theorem 5.75 is stated for a *complex* inner-product space, so apply it to the complexification. Extend the form to $\mathbb{C}^n$ sesquilinearly, $\langle \boldsymbol{x}, \boldsymbol{y} \rangle_M := \bar{\boldsymbol{x}}^{\mathsf{T}} M \boldsymbol{y}$, which is an inner product there because M is real, symmetric and positive definite; the computation above, with each transpose replaced by a conjugate transpose, again shows A self-adjoint for it, using only that M and K are real and symmetric. Theorem 5.75 then gives n real eigenvalues and an orthonormal eigenbasis of $\mathbb{C}^n$. Those eigenvectors may be taken real: each ω_r^2 is real and A is a real matrix, so $A - \omega_r^2 \mathbb{1}$ is real and its kernel is spanned by real vectors, and applying Gram–Schmidt (Proposition 5.26) in the M-inner product within each such real kernel — eigenspaces for distinct eigenvalues being already orthogonal — yields a real M-orthonormal eigenbasis of $\mathbb{R}^n$. Since $A\boldsymbol{u} = \omega^2 \boldsymbol{u}$ is equivalent to $(K - \omega^2 M)\,\boldsymbol{u} = \boldsymbol{0}$, and the eigenvalues of A are the roots of Equation (28.39) by Theorem 5.67, parts (i) and (ii) follow; the second identity of Equation (28.40) is the first one with $K\boldsymbol{u}^{(s)} = \omega_s^2 M \boldsymbol{u}^{(s)}$ substituted. For (iii), $U^{\mathsf{T}} K U = \operatorname{diag}(\omega_r^2)$ is a congruence, so by Sylvester's law of inertia Theorem 5.112 the number of positive, zero and negative ω_r^2 equals the corresponding count for K itself; K is positive definite exactly when all n are positive. □

Remark 28.34 (Part II owes the simultaneous diagonalization of two quadratic forms). Theorem 28.33 is a physics statement — it is about T and V — but parts (i) and (ii) rest on a purely linear-algebraic fact: *a pair of real symmetric bilinear forms, one of them positive definite, is simultaneously diagonalized by a single congruence*, equivalently the generalized eigenvalue problem $K\boldsymbol{u} = \lambda M \boldsymbol{u}$ has real eigenvalues and an M-orthonormal eigenbasis. That statement belongs in Chapter 5, beside Theorem 5.75, Theorem 5.112 and Theorem 5.76 — which covers commuting self-adjoint operators, a different hypothesis — and Part II does not at present state it. Two smaller pieces are missing with it. The *real* spectral theorem is one: Theorem 5.75 is stated over $\mathbb{C}$, so the real case a mechanics problem actually presents has to be reached by the complexification argument written into the proof above. The variational companion is the other: Theorem 16.76 characterizes the lowest eigenvalue of a weighted Sturm–Liouville problem, but the finite-dimensional Rayleigh quotient $\boldsymbol{u}^{\mathsf{T}} K \boldsymbol{u} / \boldsymbol{u}^{\mathsf{T}} M \boldsymbol{u}$ used in Proposition 28.38 is not stated there. Rather than prove general linear algebra inside a mechanics chapter, the derivation above exhibits the *reduction* to results Part II does have: the M-inner product, self-adjointness of $M^{-1}K$ in it, Theorem 5.75 unchanged, and Proposition 5.26 to come back to $\mathbb{R}^n$. Nothing in this chapter uses more than that.

Rests on Theorem 28.33.

Definition 28.35 (Normal coordinates)**.** The coordinates ξ_r defined by $\boldsymbol{\eta} = U\boldsymbol{\xi}$, that is $\eta_j = \sum_r U_{jr} \xi_r$, with U the matrix of Theorem 28.33.

Rests on Equation (28.40).

Proposition 28.36 (Normal coordinates decouple the motion)**.** *In normal coordinates*

$$T = \tfrac{1}{2} \sum_r \dot{\xi}_r^2 \,, \qquad V - V\big(q^{(0)}\big) = \tfrac{1}{2} \sum_r \omega_r^2 \xi_r^2 \,, \qquad \ddot{\xi}_r + \omega_r^2 \xi_r = 0 \,, \tag{28.41}$$

so the system is exactly n independent harmonic oscillators, and the total energy is the sum of their separate energies. Each ξ_r has SI dimension $\mathrm{kg}^{1/2}\,\mathrm{m}$.

Rests on Equations (28.38) *and* (28.40).

Proof. *Derives Proposition 28.36.*

Substituting $\boldsymbol{\eta} = U\boldsymbol{\xi}$ into Equation (28.37) gives $T = \tfrac{1}{2}\dot{\boldsymbol{\xi}}^{\mathsf{T}} U^{\mathsf{T}} M U \dot{\boldsymbol{\xi}}$ and the analogous expression for V, and Equation (28.40) reduces $U^{\mathsf{T}}MU$ to $\mathbb{1}$ and $U^{\mathsf{T}}KU$ to the diagonal matrix of the ω_r^2. The Euler–Lagrange equations of the resulting Lagrangian are the n separate equations shown, each of the form Equation (28.2), so by Proposition 28.5 each carries a conserved energy and the total is their sum. The dimension follows from T being an energy and $\dot{\xi}_r^2$ carrying the whole of it. □

Remark 28.37 (Normal coordinates are not lengths). The unit $\mathrm{kg}^{1/2}\,\mathrm{m}$ is not a slip. Absorbing M into the coordinates is what makes Equation (28.41) as simple as it is, and it costs the coordinates their status as displacements. If a displacement is wanted — to compare with a measured amplitude — it must be recovered as $\eta_j = \sum_r U_{jr}\xi_r$, in which the columns of U carry the compensating $1/\mathrm{kg}^{1/2}$. The same square root reappears wherever a mode is normalized this way, in particular in the lattice sums of Chapter 125 and in the field-mode expansions of Chapter 99, and it is one of the places where a book that keeps SI units earns its keep.

Rests on Equation (28.41).

Proposition 28.38 (Rayleigh's bound on the lowest frequency)**.** *For every $\boldsymbol{u} \neq \mathbf{0}$,*

$$\omega_1^2 \le \frac{\boldsymbol{u}^{\mathsf{T}} K \boldsymbol{u}}{\boldsymbol{u}^{\mathsf{T}} M \boldsymbol{u}} \le \omega_n^2 \,, \tag{28.42}$$

with equality on the left exactly for multiples of $\boldsymbol{u}^{(1)}$.

Rests on Equation (28.40) *and Definition 16.75.*

Proof. *Derives Proposition 28.38.*

Expand $\boldsymbol{u} = \sum_r c_r \boldsymbol{u}^{(r)}$ in the M-orthonormal basis of Theorem 28.33. Then $\boldsymbol{u}^{\mathsf{T}} M \boldsymbol{u} = \sum_r c_r^2$ and $\boldsymbol{u}^{\mathsf{T}} K \boldsymbol{u} = \sum_r \omega_r^2 c_r^2$ by Equation (28.40), so the quotient is a weighted average of the ω_r^2 with non-negative weights c_r^2, hence lies between the least and the greatest of them, and attains the least only when every c_r with $\omega_r^2 > \omega_1^2$ vanishes. □

This is the finite-dimensional face of Theorem 16.76, and it is what makes the Rayleigh–Ritz method of Section 16.5.3 work: any trial displacement whatever gives an upper bound on the fundamental frequency, and the bound is second-order accurate in the error of the trial vector because ω_1^2 is a stationary value. Corollary 16.78 is the statement in the continuum, where it is used to estimate the frequencies of structures that cannot be solved exactly.

Example 28.39 (The linear triatomic molecule)**.** Three particles on a line, of masses m, M, m at positions x_1, x_2, x_3, with springs of constant k joining each outer particle to the middle one, have

$$M_{\mathrm{mat}} = \operatorname{diag}(m, M, m)\,, \qquad K = k\begin{pmatrix} 1 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 1 \end{pmatrix}.$$

Guessing the modes from the symmetry rather than expanding the determinant: $\boldsymbol{u} = (1,1,1)$ gives $K\boldsymbol{u} = \mathbf{0}$, so $\omega^2 = 0$; $\boldsymbol{u} = (1,0,-1)$ gives $K\boldsymbol{u} = k(1,0,-1)$ and $M_{\mathrm{mat}}\boldsymbol{u} = m(1,0,-1)$, so $\omega^2 = k/m$; and the third mode, orthogonal in the M-metric to both, is $\boldsymbol{u} = (1, -2m/M, 1)$, for which

$$\omega_1^2 = 0\,, \qquad \omega_2^2 = \frac{k}{m}\,, \qquad \omega_3^2 = \frac{k}{m}\left(1 + \frac{2m}{M}\right). \tag{28.43}$$

The three modes are the translation of the whole molecule, the symmetric stretch in which the middle particle does not move, and the antisymmetric stretch in which it moves against the other two. The zero mode is not a defect of the model: V depends only on differences of the x_j, so it has a flat direction, and by Noether's theorem (Theorem 16.84, Corollary 16.88) that translation invariance is the conservation of total momentum. Every isolated molecule and every crystal carries such modes — three translations and, in general, three rotations — and they are what Theorem 28.33(iii) excludes when it asks for a *strict* minimum.

Rests on Theorem 28.33 and Corollary 16.88.

28.3.3 The loaded string and the continuum limit

Let N equal beads of mass m sit at spacing a on a light string of tension T stretched between fixed points, so that the total length is $L = (N+1)a$, and let y_n be the small transverse displacement of the n-th bead. This is Theorem 28.33 with a mass matrix already diagonal, and it is solvable in closed form for every N.

Proposition 28.40 (Modes and dispersion of the loaded string)**.** *With $y_0 = y_{N+1} = 0$, the equations of motion are*

$$m\ddot{y}_n = \frac{T}{a}\left(y_{n+1} - 2y_n + y_{n-1}\right), \qquad n = 1, \dots, N, \tag{28.44}$$

and the N normal modes and frequencies are

$$y_n^{(r)} = \sin\left(k_r n a\right), \quad k_r = \frac{r\pi}{L}, \qquad \omega_r = 2\,\omega_c \sin\!\left(\frac{k_r a}{2}\right), \quad \omega_c := \sqrt{\frac{T}{ma}}, \tag{28.45}$$

for $r = 1, \dots, N$.

Rests on Theorem 28.33 and Equation (28.38).

Proof. *Derives Proposition 28.40.*

For small displacements the string segment from bead n to bead $n+1$ makes an angle whose sine is $(y_{n+1} - y_n)/a$ to first order, and pulls bead n transversely with force $T(y_{n+1} - y_n)/a$; adding the pull of the segment on the other side gives Equation (28.44). Substituting $y_n = u \sin(kna)\mathrm{e}^{-\mathrm{i}\omega t}$, using $\sin(k(n+1)a) + \sin(k(n-1)a) = 2\cos(ka)\sin(kna)$, and cancelling the common factor $u \sin(kna)\mathrm{e}^{-\mathrm{i}\omega t}$,

$$-m\omega^2 = \frac{T}{a}\left(2\cos ka - 2\right) = -\frac{4T}{a}\sin^2\!\left(\frac{ka}{2}\right),$$

which is the dispersion relation in Equation (28.45). The form $\sin(kna)$ already satisfies $y_0 = 0$, and $y_{N+1} = 0$ requires $\sin(k(N+1)a) = 0$, that is $kL = r\pi$. Values r and $r + 2(N+1)$ give the same set of bead displacements, and $r = N+1$ gives none at all, so exactly $r = 1, \dots, N$ are distinct and non-trivial — N modes for N degrees of freedom, as Theorem 28.33 requires. □

Two features of Equation (28.45) outlive the model. First, the frequencies are *not* proportional to r: the chain is dispersive, and the sine bends the spectrum below the straight line $\omega = \omega_c k_r a$ that the low modes follow. Second, there is a highest frequency, $\omega_{\max} = 2\omega_c$, reached at $ka = \pi$; a chain of discrete masses cannot carry a vibration faster than that, because there is nothing between the beads to vibrate. Both features are the mechanical prototype of everything in Chapter 125: the cutoff is the Brillouin-zone edge, and the bending of $\omega(k)$ is what makes a crystal's heat capacity depart from the classical value.

Proposition 28.41 (The continuum limit)**.** *Let $N \to \infty$ and $a \to 0$ with $L = (N+1)a$ and the linear mass density $\mu := m/a$ held fixed. Then Equation (28.44) becomes the wave equation*

$$\frac{\partial^2 y}{\partial t^2} = v^2 \frac{\partial^2 y}{\partial x^2}, \qquad v = \sqrt{\frac{T}{\mu}}, \tag{28.46}$$

and Equation (28.45) becomes $\omega_r = v k_r$ with $k_r = r\pi/L$, for every fixed r.

Rests on Equations (28.44) and (28.45).

Proof. *Derives Proposition 28.41.*

Write $y_n(t) = y(na, t)$ for a twice continuously differentiable y. Taylor's theorem (Theorem 7.38) gives $y_{n\pm1} = y \pm a\,\partial_x y + \tfrac{1}{2}a^2\partial_x^2 y + O(a^3)$, so the bracket in Equation (28.44) is $a^2\partial_x^2 y + O(a^4)$, the odd orders cancelling. Dividing by $m = \mu a$,

$$\partial_t^2 y = \frac{T}{\mu a^2}\left[a^2\partial_x^2 y + O(a^4)\right] = \frac{T}{\mu}\,\partial_x^2 y + O(a^2),$$

which is Equation (28.46) in the limit. For the frequencies, fix r; then $k_r a = r\pi a/L \to 0$, so $2\omega_c \sin(k_r a/2) \to \omega_c k_r a = k_r\sqrt{T/\mu}$, using $\omega_c a = a\sqrt{T/(ma)} = \sqrt{Ta/m} = \sqrt{T/\mu}$. The limit is uniform only on the low modes: for r comparable with N the sine cannot be linearized, which is the statement that a continuum has no cutoff and a lattice does. □

28.4 The vibrating string and the wave equation

28.4.1 d'Alembert's equation and its general solution

Mersenne had established by measurement, a century before any wave theory, that the pitch of a stretched string varies inversely with its length, as the square root of the tension and inversely as the square root of its weight per unit length [2]. d'Alembert wrote down the equation those laws obey and solved it in complete generality [25]; it was the first partial differential equation of physics and the first to be solved.

Proposition 28.42 (The wave equation of a stretched string)**.** *A flexible string of linear mass density μ under tension T, displaced transversely by $y(x,t)$ with $|\partial_x y| \ll 1$, obeys Equation (28.46) with $v = \sqrt{T/\mu}$. The Lagrangian density whose Euler–Lagrange equation this is,*

$$\mathcal{L} = \tfrac{1}{2}\mu\,(\partial_t y)^2 - \tfrac{1}{2}T\,(\partial_x y)^2, \tag{28.47}$$

is the continuum limit of Equation (28.37).

Rests on Equation (28.46) and Theorem 16.36.

Proof. *Derives Proposition 28.42.*

Take the element between x and $x + \mathrm{d}x$, of mass $\mu\,\mathrm{d}x$. The tension pulls along the string at each end; its transverse component is $T\sin\theta \approx T\tan\theta = T\,\partial_x y$ to first order in the slope, and the net transverse force is the difference of that quantity at the two ends, $T\,\partial_x^2 y\,\mathrm{d}x$. Newton's second law gives $\mu\,\mathrm{d}x\,\partial_t^2 y = T\,\partial_x^2 y\,\mathrm{d}x$, which is Equation (28.46). The longitudinal components cancel to the same order, and the tension may be treated as constant along the string because the fractional stretch is $O((\partial_x y)^2)$. For the variational route, the kinetic energy of the element is $\tfrac{1}{2}\mu(\partial_t y)^2\mathrm{d}x$ and the work done in stretching it from $\mathrm{d}x$ to $\mathrm{d}x\sqrt{1+(\partial_x y)^2}$ against constant tension is $\tfrac{1}{2}T(\partial_x y)^2\mathrm{d}x$ to the same order; Theorem 16.36 applied to Equation (28.47) returns Equation (28.46). That Equation (28.47) is the limit of Equation (28.37) is Proposition 28.41 applied term by term. □

Everything about Equation (28.46) as a partial differential equation is Part II's. It is hyperbolic (Definition 10.6,Proposition 10.13), its characteristics are the lines $x \mp vt = \text{const}$ (Corollary 10.12), and its general solution is the pair of travelling waves

$$y(x,t) = f(x - vt) + g(x + vt), \tag{28.48}$$

with the initial-value problem solved explicitly by d'Alembert's formula Theorem 10.55. The physics is what those statements mean here: a disturbance travels at speed v in each direction without changing shape, the value of y at (x,t) depends only on the initial data in the interval $[x-vt, x+vt]$ (Corollary 10.56), and v is fixed by two measurable properties of the string and by nothing else. Mersenne's three laws are $v=\sqrt{T/\mu}$ read together with Equation (28.49). The string is worked as an example of separation of variables in Example 10.38.

Example 28.43 (A guitar string, in SI)**.** A steel string of diameter 0.30 mm and density $7.85\times10^{3}\,\mathrm{kg/m^3}$ has cross-section $\pi d^2/4 = 7.07\times10^{-8}\,\mathrm{m^2}$ and hence $\mu = 5.55\times10^{-4}\,\mathrm{kg/m}$. Sounding 440 Hz over a speaking length $L = 0.650\,\mathrm{m}$ requires, by Equation (28.49) with $n=1$, a wave speed $v = 2Lf_1 = 572\,\mathrm{m/s}$, and therefore a tension

$$T = \mu v^2 = 5.55\times10^{-4}\,\mathrm{kg/m}\times 3.27\times10^{5}\,\mathrm{m^2/s^2} = 182\,\mathrm{N}\,,$$

about the weight of 19 kg. Six such strings put more than a kilonewton on the neck of the instrument, which is why guitars are built the way they are. Note what does *not* enter: the amplitude of the plucking, and the material of the string except through μ.

Rests on Equations (28.46) *and* (28.49).

28.4.2 Superposition and the vibrating-string controversy

Proposition 28.44 (Superposition)**.** *If y_1 and y_2 solve Equation* (28.46) *then so does $c_1y_1+c_2y_2$ for any constants c_1, c_2; and if each satisfies the homogeneous boundary conditions $y(0,t)=y(L,t)=0$, so does the combination.*

Rests on Equation (28.46) *and Definition 10.2.*

Proof. *Derives Proposition 28.44.*

$\partial_t^2 - v^2\partial_x^2$ is a linear operator (Definition 10.2), so it takes a linear combination to the same combination of the images, each of which vanishes. The boundary conditions are likewise linear and homogeneous. □

The proposition is two lines; deciding what may be superposed took half a century. d'Alembert's solution Equation (28.48) says the motion is fixed by two "arbitrary functions"; Euler took that literally, admitting curves drawn freehand, while d'Alembert insisted a function had to be given by a single analytic expression. Daniel Bernoulli then claimed that every motion of the string is a superposition of the sinusoidal modes [28] — which, if true, meant that any admissible initial shape has a trigonometric expansion, a proposition both of the others rejected as obviously false. Bernoulli was right and could not prove it; the proof, and with it the modern notion of a function, had to wait for Fourier [72] and then for Dirichlet.

What the controversy actually settled is the class of admissible initial data, and every part of the answer now lives in Part II. Dirichlet's theorem Theorem 17.9 gives convergence for piecewise smooth data — which covers the plucked string, corner and all. du Bois-Reymond's continuous function with a divergent Fourier series Theorem 17.13 shows that continuity alone is not enough, so Euler's freehand curves are genuinely too general for pointwise convergence; Fejér's theorem Theorem 17.22 rescues them in the mean, and the full convergence story is Section 17.1.2. Data rougher still — a struck string, whose initial velocity is a delta function at the hammer — is handled not by strengthening the convergence but by weakening the notion of solution, which is Definition 10.83 and Section 10.6.1. A corner in the initial shape propagates along a characteristic and stays a corner forever, which is Equation (28.48) again and is exactly what makes the weak formulation necessary.

28.4.3 Standing waves

Phenomenon 28.45 (The harmonic series of a stretched string)**.** A string clamped at both ends does not vibrate at an arbitrary frequency. It sustains a discrete set, $f_n = nf_1$ with $n = 1, 2, 3, \dots$, each with its own stationary pattern of nodes and antinodes, the n-th carrying $n - 1$ nodes between the ends; a bow or a hammer excites a superposition of them, and the ear hears the fundamental with the higher members as timbre. The fundamental is found to vary inversely with the length of the string, as the square root of the tension, and inversely as the square root of the mass per unit length — the three rules by which every stringed instrument is strung and tuned, and which were known from measurement long before any wave theory existed to explain them [2, 4].

$$f_n = \frac{n}{2L}\sqrt{\frac{T}{\mu}}\,, \qquad n \in \mathbb{N}\,. \tag{28.49}$$

Rests on Equation (28.46) *and Theorem 9.57.*

Derivation. Derives Phenomenon 28.45.

Grant the wave equation of Section 28.4.1, $\partial_t^2 y = v^2 \partial_x^2 y$ with $v = \sqrt{T/\mu}$, on the interval $0 \le x \le L$, with the clamped ends imposing $y(0,t) = y(L,t) = 0$. Separating variables (Section 10.2), $y = X(x)\Theta(t)$, gives $X''/X = \Theta''/(v^2\Theta)$; the two sides depend on different variables, so both equal one constant (Lemma 10.28), which must be negative if Θ is to stay bounded — write it $-k^2$. Then $X = a\sin kx + b\cos kx$; the condition $X(0) = 0$ forces $b = 0$, and $X(L) = 0$ then forces $\sin kL = 0$, that is

$$k_n = \frac{n\pi}{L}\,, \qquad n = 1, 2, 3, \dots \tag{28.50}$$

The temporal factor oscillates at $\omega_n = vk_n$, so $f_n = \omega_n/2\pi = nv/(2L)$, which is Equation (28.49); the three empirical rules read off it at once, $f_1 \propto 1/L$, $f_1 \propto \sqrt{T}$ and $f_1 \propto 1/\sqrt{\mu}$. That the modes are the *only* solutions, and that a general motion is a superposition of them, is the Sturm–Liouville theory of Chapter 9: the spatial problem is Section 9.7 with $p = r = 1$ and $q = 0$, its eigenfunctions are mutually orthogonal by Theorem 9.57, and they are complete by Theorem 17.34. That the overtones are *exact* integer multiples of the fundamental is special to the non-dispersive string, in which $\omega = vk$ is linear in k: a stiff bar, a drumhead or a bell has the same discreteness of modes but an inharmonic spectrum, and does not sound a definite pitch in the same way. □

A standing wave is two travelling waves, which is how the boundary condition acts. Adding the incident wave to the wave reflected from a clamped end, both of the form Equation (28.48),

$$A\cos(kx - \omega t) - A\cos(kx + \omega t) = 2A\sin kx\,\sin\omega t\,. \tag{28.51}$$

From Equation (28.48) *(sum-to-product on two counter-propagating waves of equal amplitude).*

The right-hand side is a fixed spatial pattern multiplied by a pure oscillation in time: the nodes at $kx = n\pi$ never move, and no energy crosses them.

Proposition 28.46 (Reflection at an end)**.** *A pulse on a string reflects inverted from a clamped end and upright from an end free to slide transversely.*

Rests on Equations (28.46) *and* (28.48).

Proof. Derives Proposition 28.46.

Take the end at $x = 0$ and write the field as $f(x - vt) + g(x + vt)$, with f the incoming pulse. A clamped end imposes $y(0,t) = 0$ for all t, hence $g(s) = -f(-s)$: the reflected pulse is the incident one reversed in space and in sign. A free end can support no transverse force, so $T\partial_x y(0,t) = 0$, hence $g'(s) = f'(-s)$ and $g(s) = f(-s)$ up to a constant fixed by $y \to 0$ far away: reversed in space and not in sign. □

Melde demonstrated the standing patterns directly, driving one end of a string with a tuning fork and adjusting the tension until a whole number of loops appeared between the ends [155]; the pattern is stationary, visible, and countable, and reading n off it turns Equation (28.49) into a measurement of v. The experiment and its modern repetitions are Chapter 35.

28.4.4 Fourier decomposition

Proposition 28.47 (Modal solution of the initial-value problem)**.** *The solution of Equation (28.46) on $[0,L]$ with $y(0,t)=y(L,t)=0$, $y(x,0)=y_0(x)$ and $\partial_t y(x,0)=v_0(x)$ is*

$$y(x,t)=\sum_{n=1}^{\infty}\left(a_n\cos\omega_n t+b_n\sin\omega_n t\right)\sin k_n x\,,\qquad \omega_n=vk_n\,, \tag{28.52}$$

with $k_n=n\pi/L$ and

$$a_n=\frac{2}{L}\int_0^L y_0(x)\sin k_n x\,\mathrm{d}x\,,\qquad b_n=\frac{2}{L\omega_n}\int_0^L v_0(x)\sin k_n x\,\mathrm{d}x\,. \tag{28.53}$$

Rests on Equation (28.50) and Theorem 17.3.

Proof. *Derives Proposition 28.47.*

Each term of Equation (28.52) solves Equation (28.46) and the boundary conditions, by Phenomenon 28.45, and the sum does too by Proposition 28.44 and termwise differentiation (Theorem 7.51) where the series permits it. Setting $t=0$ gives $y_0=\sum a_n\sin k_n x$ and $v_0=\sum b_n\omega_n\sin k_n x$, which are sine series on $[0,L]$; Equation (28.53) is the Euler–Fourier formula Theorem 17.3 for their coefficients, using the orthogonality $\int_0^L \sin k_n x\sin k_m x\,\mathrm{d}x=(L/2)\delta_{nm}$ of Theorem 9.57. Completeness of the system (Theorem 17.34) is what makes the expansion possible for every square-integrable datum, and uniqueness for the wave equation with given data (Definition 10.24, Theorem 10.55) makes Equation (28.52) the solution and not merely a solution. □

Each mode evolves independently and forever: the string is n uncoupled oscillators, exactly as Proposition 28.36 promised, with n now running to infinity. The energy divides among them in the same way.

Proposition 28.48 (Modal energy)**.** *For Equation (28.52) the total energy is*

$$E=\frac{\mu L}{4}\sum_{n=1}^{\infty}\omega_n^2\left(a_n^2+b_n^2\right)\,, \tag{28.54}$$

constant in time, with the n-th term the energy of the n-th mode.

Rests on Equation (28.52) and Theorem 17.34.

Proof. *Derives Proposition 28.48.*

Write $y=\sum_n q_n(t)\sin k_n x$, and T_{ten} for the tension, since here T is the kinetic energy (Notation 28.1). Then, by the orthogonality used in Proposition 28.47,

$$T=\frac{\mu}{2}\int_0^L(\partial_t y)^2\,\mathrm{d}x=\frac{\mu L}{4}\sum_n\dot q_n^2\,,\qquad V=\frac{T_{\text{ten}}}{2}\int_0^L(\partial_x y)^2\,\mathrm{d}x=\frac{\mu L}{4}\sum_n\omega_n^2 q_n^2\,,$$

the second using $T_{\text{ten}}k_n^2=\mu\omega_n^2$. This is Parseval's identity Theorem 17.34 for the sine system, and it is the continuum form of Equation (28.41). With $q_n=a_n\cos\omega_n t+b_n\sin\omega_n t$ each bracket $\dot q_n^2+\omega_n^2 q_n^2$ equals $\omega_n^2(a_n^2+b_n^2)$ by Proposition 28.5, giving Equation (28.54). □

Example 28.49 (The plucked string, and why a guitar is plucked where it is)**.** Draw the string aside by a height h at the point $x = d$ and release it from rest, so that $v_0 = 0$, every $b_n = 0$, and y_0 is the triangle with apex at d. Evaluating the two integrals of Equation (28.53) over the two straight segments gives

$$a_n = \frac{2hL^2}{\pi^2 n^2\, d\,(L-d)} \sin\!\left(\frac{n\pi d}{L}\right). \tag{28.55}$$

Three things follow. The amplitudes fall as $1/n^2$, which is the general rule that a kink in the data — here the corner at d — fixes the decay rate of the coefficients (Proposition 17.10); the energy, by Equation (28.54), therefore falls as $1/n^2$ as well, since $\omega_n \propto n$. And every harmonic with nd/L an integer is missing outright, because the pluck point is a node of that mode and cannot excite it: plucking at $L/7$ removes the seventh harmonic and its multiples, and plucking at the midpoint removes every even one, leaving a tone of odd partials only. Which partials a player wants is a question of taste rather than of physics, but Equation (28.55) says exactly which ones the choice of d disposes of, and that much is testable on any instrument.

Rests on Equations (28.53) *and* (28.54)*.*

The convergence of Equation (28.52) raises questions this chapter does not settle and does not need to: they are Section 17.1.2, where the transform pair and its convergence theory are developed in full, and Section 10.2.2, where the eigenfunction expansion is carried out for the general boundary-value problem.

28.5 Sound

28.5.1 The acoustic wave equation

Phenomenon 28.50 (The speed of sound in air)**.** Sound travels through still air at about 343 m/s at room temperature, at a speed independent of the loudness of the sound and, across the audible range, of its pitch: a chord fired from a distant gun arrives as a chord, and thunder is not smeared into a glissando. The speed rises with temperature, and at fixed temperature it does not depend on the pressure of the air. Newton computed it in the *Principia* from the elasticity of the air and obtained a value substantially below what was measured [14]; the shortfall stood for more than a century, and was resolved only by recognizing that the compressions in a sound wave are adiabatic rather than isothermal — which makes the speed of sound a measurement of a thermodynamic quantity.

Rests on Equation (28.46)*.*

Derivation. *Derives Phenomenon 28.50.*

Linearize the equations of a compressible fluid about rest, writing $\rho = \rho_0 + \rho'$ and $p = p_0 + p'$ with a velocity u that is first order, and dropping all products of primed quantities. Conservation of mass and Newton's second law for a fluid element give, in one dimension,

$$\frac{\partial \rho'}{\partial t} + \rho_0 \frac{\partial u}{\partial x} = 0\,, \qquad \rho_0 \frac{\partial u}{\partial t} = -\frac{\partial p'}{\partial x}\,.$$

Differentiating the first with respect to t and the second with respect to x and subtracting eliminates u:

$$\partial_t^2 \rho' = \left(\frac{\mathrm{d}p}{\mathrm{d}\rho}\right) \partial_x^2 \rho'\,, \tag{28.56}$$

a wave equation with speed $v^2 = \mathrm{d}p/\mathrm{d}\rho$. The derivative must be taken along the thermodynamic path the gas actually follows, and this is where the history turns. Newton took it isothermally: with $p \propto \rho$ at fixed temperature, $v_T = \sqrt{p_0/\rho_0}$, which for $p_0 = 101\,325\,\mathrm{Pa}$ and $\rho_0 = 1.204\,\mathrm{kg/m^3}$ gives about 290 m/s — some 15 % below the measured value. But a

sound wave compresses the air far faster than heat can diffuse across a wavelength, so the correct path is the adiabatic one, $p \propto \rho^{\gamma}$, whence

$$v = \sqrt{\frac{\gamma p_0}{\rho_0}} = \sqrt{\frac{\gamma R T}{M}}\,, \tag{28.57}$$

and with the diatomic value $\gamma = 1.4$ this is 343 m/s, the observed speed. Because p_0/ρ_0 equals RT/M for an ideal gas, the speed depends on temperature and on composition but not on pressure; and because Equation (28.56) has a k-independent coefficient, it carries no dispersion — both exactly as observed. The thermodynamic input is developed in Chapter 54, and the fluid equations linearized here in Chapter 31. □

Table 28.1: The two thermodynamic paths, computed from the second form of Equation (28.57) with the molar gas constant $R = 8.314\,462\,618$ J/(mol K) — exact by the SI definitions [2431] — the mean molar mass of dry air $M = 28.96 \times 10^{-3}$ kg/mol of Remark 28.2, and $\gamma = 1.4$. Newton's isothermal path is the column with γ omitted. The adiabatic column is what is measured; the isothermal one is low by 15 % at every temperature, because the two differ by the constant factor $\sqrt{\gamma}$ and by nothing else.

Temperature	Isothermal (m/s)	Adiabatic (m/s)
0 °C	280.0	331.4
20 °C	290.1	343.3

Remark 28.51 (Why the compressions really are adiabatic). The choice of path is not a matter of taste, and it can be checked with one number. Heat diffuses a distance $\sqrt{\alpha/\omega}$ in one radian of a cycle, with α the thermal diffusivity; for air, $\alpha \approx 2.1 \times 10^{-5}\,\mathrm{m^2/s}$ (Remark 28.2), so at 1 kHz that distance is 5.8×10^{-5} m against a wavelength of 0.343 m — a ratio of 1.7×10^{-4}. Heat has no time to move between a compression and the rarefaction beside it, so each parcel is compressed adiabatically and Laplace's factor γ is right [59]. The criterion inverts at very high frequency or very low pressure, where the two lengths become comparable and sound becomes both dispersive and strongly absorbed. Read the other way, Equation (28.57) makes a speed measurement into a measurement of $\gamma = c_p/c_V$, and hence of the number of excited degrees of freedom of the molecule (Chapter 55) — a fact about heat extracted from a stopwatch and a distance.

Rests on Equation (28.57).

The same linearization gives the rest of the acoustic vocabulary. With $p' = \rho_0 v\, u$ for a wave travelling in the $+x$ direction, the ratio of acoustic pressure to particle velocity is the *specific acoustic impedance*

$$Z_0 = \rho_0 v = 1.204\,\mathrm{kg/m^3} \times 343\,\mathrm{m/s} = 413\,\mathrm{Pa\,s/m}\,, \tag{28.58}$$

and the intensity — the power crossing unit area — is $I = \langle p' u \rangle = p_{\mathrm{rms}}^2/Z_0$.

Example 28.52 (The threshold of hearing)**.** The reference intensity of the acoustic decibel scale is $I_0 = 1 \times 10^{-12}\,\mathrm{W/m^2}$, chosen as the faintest 1 kHz tone a good ear detects. The corresponding pressure amplitude is

$$p_{\mathrm{rms}} = \sqrt{I_0 Z_0} = \sqrt{1 \times 10^{-12}\,\mathrm{W/m^2} \times 413\,\mathrm{Pa\,s/m}} = 2.0 \times 10^{-5}\,\mathrm{Pa}\,,$$

which is exactly the 20 µPa that the pressure-referenced decibel scale uses — the two references agree because Equation (28.58) relates them. Two orders of magnitude are worth pausing on: 20 µPa is 2×10^{-10} of atmospheric pressure, and the associated displacement of the air, $p_{\mathrm{rms}}/(\omega Z_0)$, is about 8×10^{-12} m — a tenth of an atomic diameter. The ear is a detector working within a factor of a few of the thermal noise of the air itself.

Rests on Equation (28.58).

28.5.2 Acoustic phenomena

Chladni founded experimental acoustics by strewing sand on a metal plate and bowing its edge [39]. The sand collects into sharp curves that change abruptly as the bowing point and the damping finger are moved, and the same plate always gives the same family of figures.

Phenomenon 28.53 (Chladni's figures)**.** A flat plate driven at a slowly increasing frequency responds strongly only near a discrete set of frequencies, and at each of them sand sprinkled on it settles into a stationary pattern of curves — a different pattern for each frequency, reproducible for a given plate, shape and support [39]. Between those frequencies no pattern forms.

Rests on Proposition 10.29 and Theorem 9.57.

Derivation. *Derives Phenomenon 28.53.*

The small transverse displacement $w(\boldsymbol{x}, t)$ of a thin elastic plate obeys a linear equation $\rho_s\, \partial_t^2 w + \mathcal{A} w = 0$, where $\mathcal{A}$ is a linear spatial operator, self-adjoint under the plate's boundary conditions, determined by the elastic moduli (Chapter 30); its explicit form is not needed here. Time separation (Proposition 10.29) reduces the problem to the eigenvalue problem $\mathcal{A} w_r = \rho_s \omega_r^2 w_r$ on a bounded domain, which for a self-adjoint operator has a discrete spectrum with mutually orthogonal eigenfunctions (Theorem 9.57,Section 10.2.2, Theorem 12.44) — so the plate has isolated natural frequencies and, by Phenomenon 28.23 applied to each of them, responds appreciably only near one of them. At $\omega = \omega_r$ the response is essentially the single eigenfunction w_r, whose zero set is a fixed family of curves in the plate, unmoving in time because $w = w_r(\boldsymbol{x}) \cos \omega_r t$ factorizes. A grain of sand on the plate is thrown clear wherever the vertical acceleration $\omega_r^2 \, |w_r|$ exceeds g and is not thrown clear on the zero set; each bounce lands it at random nearby, so it performs a random walk that is absorbed on the nodal curves, where it accumulates. The pattern is therefore the nodal set of w_r, and it changes discontinuously with r because the eigenfunctions do. □

The plate's operator is fourth order rather than second, so its eigenfrequencies are not in the ratios $1 : 2 : 3$ of Equation (28.49) and a plate does not sound a pitch the way a string does; Chladni's figures are the two-dimensional face of Equation (28.50), and the elasticity that fixes $\mathcal{A}$ is Chapter 30.

Helmholtz built the complementary instrument: a rigid cavity with a short open neck, which resonates at one frequency and can therefore be used to detect a single partial in a complex tone [159]. It is the purest acoustic realization of Definition 28.3.

Proposition 28.54 (The Helmholtz resonator)**.** *A cavity of volume V with a neck of cross-section S and effective length L' resonates at*

$$\omega_0 = v \sqrt{\frac{S}{V L'}}\,, \tag{28.59}$$

with v the speed of sound.

Rests on Equations (28.2) and (28.57).

Proof. *Derives Proposition 28.54.*

The air in the neck moves as a slug of mass $\rho_0 S L'$; the air in the cavity is too slow-moving to contribute inertia but supplies the stiffness. Pushing the slug inward a distance x reduces the cavity volume by Sx, and by the adiabatic relation used in Equation (28.57) the pressure rises by $\delta p = -\gamma p_0 \, \delta V / V = \gamma p_0 S x / V$. The restoring force on the slug is $-S \, \delta p = -\gamma p_0 S^2 x / V$, so the effective spring constant is $\gamma p_0 S^2 / V$ and

$$\omega_0^2 = \frac{\gamma p_0 S^2 / V}{\rho_0 S L'} = \frac{\gamma p_0}{\rho_0} \cdot \frac{S}{V L'} = v^2 \frac{S}{V L'}\,,$$

using Equation (28.57). The approximation is that the wavelength greatly exceeds every dimension of the resonator, so that the cavity pressure is uniform and the neck flow incompressible; L' exceeds the geometric neck length by an end correction of order the neck radius, for the same reason a pipe does. □

Example 28.55 (Blowing across a bottle)**.** A wine bottle of $V = 0.75\,\mathrm{L}$ with a neck of radius 9 mm and effective length 80 mm has $S = 2.54 \times 10^{-4}\,\mathrm{m}^2$, $V = 7.5 \times 10^{-4}\,\mathrm{m}^3$ and $S/(VL') = 4.24/\mathrm{m}^2$, whose square root is $2.06/\mathrm{m}$, so Equation (28.59) gives $\omega_0 = 343\,\mathrm{m/s} \times 2.06/\mathrm{m} = 707\,\mathrm{rad/s}$, that is $f_0 = 113\,\mathrm{Hz}$. Emptying the bottle raises V and lowers the pitch — the audible test of Equation (28.59), and the reason the note falls as a bottle is filled is that V is the volume of *air*, not of bottle.

Rests on Equation (28.59).

The last of the classical acoustic effects belongs to the source rather than the resonator. Doppler predicted that motion of source or observer shifts the received frequency [107]; Buys Ballot tested it in 1845 by putting trumpeters on an open railway carriage and stationing trained musicians beside the line to name the note heard as the train passed [111].

Phenomenon 28.56 (The acoustic Doppler shift is not symmetric)**.** The pitch of a whistle rises as its source approaches and falls as it recedes, the change occurring abruptly as the source passes. The shift depends on which of the two — source or listener — is moving through the air, and not only on their relative velocity: a source approaching a still listener at speed u and a listener approaching a still source at the same u give measurably different frequencies [107, 111].

Rests on Equations (28.46) *and* (28.57).

Derivation. *Derives Phenomenon 28.56.*

Sound is a disturbance of the air, and Equation (28.56) holds in the frame in which the air is at rest; that frame is therefore singled out, and the two motions are physically different situations. Let the source emit at frequency f and move toward the listener at u_s, the listener move toward the source at u_o, and the speed of sound be v. In one period $1/f$ the source advances u_s/f toward the wavefront it emitted a period earlier, so the wavelength ahead of it is compressed to $\lambda' = (v - u_s)/f$. The listener, moving into the wave, meets crests at the closing speed $v + u_o$, so

$$f' = \frac{v + u_o}{\lambda'} = f\,\frac{v + u_o}{v - u_s}\,. \tag{28.60}$$

The two velocities enter differently: u_o in the numerator, where it changes the rate of arrival, and u_s in the denominator, where it changes the spacing. Expanding for $u \ll v$, both give $f' \approx f(1 + u/v)$, so the asymmetry is second order and appears only at $O(u^2/v^2)$ — which is why it took a moving train to find it, and why no first-order acoustic experiment could have distinguished the cases. □

Remark 28.57 (The contrast with light is the whole of relativity). Equation (28.60) is asymmetric because the air exists. For light there is no medium and no preferred frame, so the shift can depend only on the relative velocity; the relativistic formula of Section 38.5 is symmetric under exchange of source and observer, and its second-order term is the time dilation rather than an artefact of a medium. The failure of every attempt to find the acoustic-style asymmetry for light is Chapter 37. Note also what Equation (28.60) says at $u_s = v$: the denominator vanishes, all the crests pile onto one surface, and the linearization behind Equation (28.56) fails — which is the shock wave of Section 10.6.3 and Chapter 31.

Rests on Equation (28.60).

Pipes, membranes and rooms complete the classical subject and are Rayleigh's [198]. A pipe open at both ends carries the full harmonic series $f_n = nv/2L$, because both ends are pressure nodes; a pipe closed at one end carries only the odd members, $f_n = (2n-1)v/4L$, because a closed end is a pressure antinode. That is Equation (28.50) with one boundary condition changed, and it is why a stopped organ pipe sounds an octave below an open one of the same length and with a different timbre. The measurements are Chapter 35.

28.6 Dispersion

28.6.1 Phase and group velocity

Definition 28.58 (Dispersion relation; phase and group velocity)**.** For a linear medium supporting waves $\mathrm{e}^{\mathrm{i}(kx-\omega t)}$, the *dispersion relation* is the function $\omega(k)$ the medium imposes. The *phase velocity* and *group velocity* are

$$v_p = \frac{\omega}{k}\,, \qquad v_g = \frac{\mathrm{d}\omega}{\mathrm{d}k}\,, \tag{28.61}$$

and the medium is *non-dispersive* when $\omega = vk$ with v constant, in which case the two coincide.

Rests on Equations (28.45) *and* (28.46)*.*

Phenomenon 28.59 (Groups and crests travel at different speeds)**.** In a dispersive medium a wave group does not travel at the speed of the crests inside it. On deep water the effect is watchable without apparatus: individual crests run forward through a group of swell, appearing at its rear, crossing it and vanishing at its front, so that the group advances at half the speed of its own crests [200]. A wave packet launched in such a medium also spreads as it goes, its length growing without bound. In a non-dispersive medium — a stretched string, air for sound — neither happens: crests and groups keep step and a pulse holds its shape, which is why a spoken word survives the length of a lecture hall.

Rests on Equations (28.34) *and* (28.61)*.*

Derivation. *Derives Phenomenon 28.59.*

Superpose two travelling waves of nearly equal wavenumbers $k \pm \Delta k/2$ and the corresponding frequencies $\omega \pm \Delta\omega/2$. The identity Equation (28.34), applied with the phase $kx - \omega t$ in place of ωt, gives

$$\cos(k_1 x - \omega_1 t) + \cos(k_2 x - \omega_2 t) = 2\cos\!\left(\frac{\Delta k\, x - \Delta\omega\, t}{2}\right)\cos(kx - \omega t)\,,$$

whose second factor — the carrier — has crests moving at the phase velocity $v_p = \omega/k$, while the first — the envelope — has its maxima moving at $\Delta\omega/\Delta k$, which in the limit of a narrow band is

$$v_g = \frac{\mathrm{d}\omega}{\mathrm{d}k}\,. \tag{28.62}$$

The two coincide exactly when $\omega = vk$ is linear in k, which is the non-dispersive case. For gravity waves on deep water the dispersion relation is $\omega = \sqrt{gk}$, derived in Chapter 31, so

$$v_p = \frac{\omega}{k} = \sqrt{\frac{g}{k}}\,, \qquad v_g = \frac{\mathrm{d}\omega}{\mathrm{d}k} = \frac{1}{2}\sqrt{\frac{g}{k}} = \frac{v_p}{2}\,,$$

the observed factor of two. Spreading follows from carrying the same expansion one order further, which is Proposition 28.60: components of a packet with different k travel at different v_g, so the packet's spatial extent grows at a rate set by $\mathrm{d}^2\omega/\mathrm{d}k^2$, which vanishes identically in the non-dispersive case. The discrete chain of Proposition 28.40 is the mechanical prototype of a dispersive medium, and the same kinematics governs the matter waves of Chapter 71. □

Proposition 28.60 (A wave packet translates at v_g and spreads at a rate set by the curvature of $\omega(k)$)**.** *Let $y(x,t) = \int A(k) \mathrm{e}^{\mathrm{i}(kx-\omega(k)t)} \mathrm{d}k/2\pi$ with A concentrated near k_0 within a width Δk, and expand $\omega(k) = \omega_0 + v_g\,(k-k_0) + \frac{1}{2}\omega''\,(k-k_0)^2 + \cdots$. Then to first order the envelope of y is rigidly translated at v_g; the second order broadens an initially Gaussian envelope of width σ_0 to*

$$\sigma(t) = \sigma_0 \sqrt{1 + \left(\frac{\omega'' t}{\sigma_0^2}\right)^2}\,, \tag{28.63}$$

which is constant if and only if $\omega'' = 0$.

Rests on Equation (28.61) and Definition 17.29.

Proof. *Derives Proposition 28.60.*

Substituting the expansion and setting $q = k - k_0$,

$$y = \mathrm{e}^{\mathrm{i}(k_0 x - \omega_0 t)} \int \frac{\mathrm{d}q}{2\pi} A(k_0+q)\, \mathrm{e}^{\mathrm{i}q(x-v_g t)} \mathrm{e}^{-\frac{\mathrm{i}}{2}\omega'' q^2 t}\,,$$

a carrier times an envelope. With ω'' dropped the envelope is a function of $x - v_g t$ alone — rigid translation at v_g, which is the first claim, and which is Proposition 17.30 (a linear phase in q is a translation in x). Retaining ω'' multiplies the transform by a Gaussian of imaginary width; for $A \propto \mathrm{e}^{-\sigma_0^2 q^2/2}$ the two Gaussians combine to one of complex variance $\sigma_0^2 + \mathrm{i}\omega'' t$, whose modulus in x has width $\left|\sigma_0^2 + \mathrm{i}\omega'' t\right| / \sigma_0$, which is Equation (28.63). Since $\sigma(t)$ is strictly increasing unless $\omega'' = 0$, spreading is equivalent to curvature of $\omega(k)$. □

The packet cannot be made both short and monochromatic: σ_0 small forces Δk large, and the trade is exactly the bandwidth theorem Theorem 17.43, with its SI statement in Corollary 17.44. That inequality is a property of Fourier transforms and has nothing to do with quantum mechanics; what Chapter 71 adds to it is the relation $p = \hbar k$, which converts a statement about wave packets into a statement about momentum.

Example 28.61 (Group velocity on the loaded chain)**.** Differentiating Equation (28.45),

$$v_p = \frac{2\omega_c}{k} \sin\!\left(\frac{ka}{2}\right), \qquad v_g = \omega_c a \cos\!\left(\frac{ka}{2}\right).$$

For $ka \ll 1$ both reduce to $\omega_c a = \sqrt{T/\mu}$, the continuum speed of Proposition 28.41. At the other end, $ka \to \pi$, the group velocity vanishes while the phase velocity does not: the mode at the cutoff is a standing oscillation in which alternate beads move oppositely, and it transports no energy at all. A dispersive medium therefore has a band of frequencies it carries and, beyond $\omega_{\max} = 2\omega_c$, a band it cannot carry. This is the mechanical original of every band structure in Chapter 125.

Rests on Equations (28.45) and (28.61).

Remark 28.62 (Neither velocity is a speed limit)*.* In a strongly absorbing medium $\mathrm{d}\omega/\mathrm{d}k$ can exceed the speed of light, or become negative, without anything travelling faster than light: Proposition 28.60 assumed a narrow band and a smooth $\omega(k)$, and near an absorption line neither holds, so v_g stops being the speed of anything. What is bounded is the front of a signal, which is governed by $\omega(k)$ as $k \to \infty$ and, by the same analyticity that gives Theorem 17.78 and Remark 28.26, never exceeds c. The point is taken up where it matters, in Chapter 61 and Chapter 62.

Rests on Equation (28.63) and Theorem 17.78.

28.6.2 Energy transport and impedance

Proposition 28.63 (Energy density, flux, and the conservation law)**.** *For the string of Proposition 28.42 the energy density and energy flux are*

$$u = \tfrac{1}{2}\mu\,(\partial_t y)^2 + \tfrac{1}{2}T\,(\partial_x y)^2\,, \qquad P = -T\,\partial_x y\,\partial_t y\,, \tag{28.64}$$

and they satisfy $\partial_t u + \partial_x P = 0$. *For a travelling wave* $y = A\cos(kx - \omega t)$ *the two energies are equal at every point and*

$$\bar{P} = \tfrac{1}{2} Z \omega^2 A^2 \,, \qquad Z := \mu v = \sqrt{T\mu} \,, \tag{28.65}$$

with the characteristic impedance Z *of SI dimension* kg/s.
Rests on Equation (28.46) *and Proposition 10.57.*

Proof. *Derives Proposition 28.63.*
Differentiating u and using Equation (28.46),

$$\partial_t u = \mu\, \partial_t y\, \partial_t^2 y + T\, \partial_x y\, \partial_x \partial_t y = T\left(\partial_t y\, \partial_x^2 y + \partial_x y\, \partial_x \partial_t y\right) = \partial_x \left(T\, \partial_x y\, \partial_t y\right) = -\partial_x P \,,$$

a conservation law in the sense of Definition 10.93; the same statement in integral form over a backward cone is Proposition 10.57. For a wave travelling in the $+x$ direction, $\partial_t y = -v\, \partial_x y$ by Equation (28.48), so $\tfrac{1}{2}\mu(\partial_t y)^2 = \tfrac{1}{2}\mu v^2 (\partial_x y)^2 = \tfrac{1}{2} T (\partial_x y)^2$: the kinetic and potential densities are equal pointwise, not merely on average as in Proposition 28.5. With $y = A\cos(kx - \omega t)$, $P = TA^2 k\omega \sin^2(kx - \omega t)$, whose mean is $\tfrac{1}{2} TkA^2\omega = \tfrac{1}{2}\mu v \omega^2 A^2$ using $Tk = \mu v \omega$. The dimension of $Z = \sqrt{T\mu}$ is $\sqrt{\mathrm{N} \times \mathrm{kg/m}} = \mathrm{kg/s}$. □

Energy flows at v on the string, since $\bar{P}/\bar{u} = v$ from Equation (28.64); in a dispersive medium the same calculation gives v_g, which is the physical reason Equation (28.62) is the velocity that matters. The impedance Z is what decides what happens when the medium changes.

Proposition 28.64 (Reflection and transmission at a junction)**.** *Two strings of impedances* Z_1 *and* Z_2 *joined at* $x = 0$ *under common tension, with a wave incident from the left, give amplitude coefficients*

$$r = \frac{Z_1 - Z_2}{Z_1 + Z_2} \,, \qquad \tau = \frac{2Z_1}{Z_1 + Z_2} \,, \tag{28.66}$$

and energy fractions r^2 *reflected and* $4Z_1 Z_2 / (Z_1 + Z_2)^2$ *transmitted, which sum to one.*
Rests on Equations (28.48) *and* (28.65).

Proof. *Derives Proposition 28.64.*
Write the field as $\mathrm{e}^{\mathrm{i}k_1 x} + r\mathrm{e}^{-\mathrm{i}k_1 x}$ for $x < 0$ and $\tau \mathrm{e}^{\mathrm{i}k_2 x}$ for $x > 0$, common time factor suppressed. Continuity of the string requires $1 + r = \tau$; continuity of the transverse force $T\,\partial_x y$, which must hold because a massless junction cannot sustain a net force, requires $k_1(1 - r) = k_2 \tau$. Since the tension is common and $k = \omega/v$ with $Z = T/v$, one has $k_i = \omega Z_i / T$, so the second condition reads $Z_1(1 - r) = Z_2 \tau$. Solving the pair gives Equation (28.66). The incident power is $\tfrac{1}{2} Z_1 \omega^2$ by Equation (28.65), the reflected $\tfrac{1}{2} Z_1 \omega^2 r^2$ and the transmitted $\tfrac{1}{2} Z_2 \omega^2 \tau^2$; the ratios are as stated, and $(Z_1 - Z_2)^2 + 4Z_1 Z_2 = (Z_1 + Z_2)^2$ is the conservation of energy. □

Equation (28.66) contains Proposition 28.46 as its two limits: a clamped end is $Z_2 \to \infty$, giving $r = -1$ and total inverted reflection, and a free end is $Z_2 \to 0$, giving $r = +1$. Nothing is reflected when $Z_1 = Z_2$ — *impedance matching*, and the point is that the two strings need not be identical, only equally impeding. That is the mechanical prototype of every matching problem in the treatise: the antireflection coating and the Fresnel coefficients of Chapter 61, the horn that couples a loudspeaker to the air across the factor of 10^3 between their impedances, and the middle ear, whose three bones exist to match the impedance of air to that of the cochlear fluid. A reflection coefficient near ± 1 is also what makes a resonator: the string of Phenomenon 28.45 sustains modes precisely because both ends reflect essentially everything.

28.7 Anharmonicity: a first look

28.7.1 The anharmonic oscillator

Every result of this chapter so far has rested on Equation (28.11) truncated at the quadratic term. This section asks what the next term does, and finds that it does three things a linear equation cannot: it makes the frequency depend on the amplitude, it bends the resonance curve over, and it makes the steady-state response multivalued, so that the amplitude jumps discontinuously as the drive is swept.

Phenomenon 28.65 (The period of a pendulum grows with its amplitude)**.** A pendulum released from a large angle takes measurably longer to complete a swing than the same pendulum released from a small one, and the excess grows as the square of the amplitude. Galileo's own observations of approximate isochronism already show the departure at wide arcs [4], and it is the defect Huygens removed by forcing the bob onto a cycloid (Proposition 28.12) [11]. At an amplitude of 7° the excess is about one part in 10^3; at 30° it is about 1.7 %.

$$T(\theta_0) = 2\pi\sqrt{\frac{\ell}{g}}\left(1 + \frac{\theta_0^2}{16} + O\left(\theta_0^4\right)\right). \tag{28.67}$$

Rests on Equations (28.8) *and* (28.81)*.*

Derivation. *Derives Phenomenon 28.65.*

Expand the exact pendulum equation Equation (28.8) one order beyond the linearization, $\sin\theta = \theta - \theta^3/6 + O(\theta^5)$, giving

$$\ddot{\theta} + \omega_0^2\theta - \frac{\omega_0^2}{6}\theta^3 = 0\,, \qquad \omega_0^2 = \frac{g}{\ell}\,, \tag{28.68}$$

which is Equation (28.70) with $\epsilon = -\omega_0^2/6$. Substituting that value into Equation (28.81) gives

$$\omega = \omega_0 + \frac{3\epsilon\theta_0^2}{8\omega_0} = \omega_0\left(1 - \frac{\theta_0^2}{16}\right),$$

and $T = 2\pi/\omega$ is Equation (28.67) to the order retained. The sign is the physical content: $\epsilon < 0$ because the restoring moment $\sin\theta$ falls short of θ, so the pendulum is a *softening* oscillator and its period lengthens. Numerically, $\theta_0 = 7^\circ = 0.1222\,\text{rad}$ gives $\theta_0^2/16 = 9.3\times10^{-4}$ and $\theta_0 = 30^\circ = 0.5236\,\text{rad}$ gives 1.7×10^{-2}, as asserted. □

Remark 28.66 (The exact period is an elliptic integral)*.* Energy conservation integrates Equation (28.8) exactly: with θ_0 the amplitude, the quarter period is $\int_0^{\theta_0} \mathrm{d}\theta/\sqrt{2\omega_0^2(\cos\theta - \cos\theta_0)}$, and the substitution $\sin(\theta/2) = \sin(\theta_0/2)\sin\phi$ brings it to $\omega_0^{-1}\int_0^{\pi/2}\mathrm{d}\phi/\sqrt{1 - m\sin^2\phi}$ with $m = \sin^2(\theta_0/2)$ — the complete elliptic integral of the first kind, whose expansion in m reproduces Equation (28.67) and every later term. This treatise does not develop the elliptic integrals: they are absent from Chapter 9, which carries the Bessel, Legendre, Hermite and Laguerre families, so the closed form is recorded here as a fact about the integral and is used nowhere. Everything asserted in Phenomenon 28.65 is obtained instead from Theorem 28.72, which needs nothing beyond Theorem 7.38.

Rests on Equation (28.67)*.*

Definition 28.67 (Duffing oscillator)**.** The damped, driven oscillator with a cubic restoring term,

$$\ddot{x} + 2\beta\dot{x} + \omega_0^2 x + \epsilon x^3 = \frac{F_0}{m}\cos\omega t\,, \tag{28.69}$$

whose free undamped case

$$\ddot{x} + \omega_0^2 x + \epsilon x^3 = 0 \tag{28.70}$$

is *hardening* for $\epsilon > 0$ and *softening* for $\epsilon < 0$ [452]. ϵ has SI dimension $1/(\mathrm{m}^2\,\mathrm{s}^2)$.

Rests on Equations (28.11) and (28.23).

Proposition 28.68 (The bent resonance curve)**.** *For $|\epsilon|$, β and F_0 all small, and ω near ω_0, the steady-state amplitude A of Equation (28.69) satisfies*

$$A^2\left[\left(\omega-\omega_0-\frac{3\epsilon A^2}{8\omega_0}\right)^2+\beta^2\right]=\frac{F_0^2}{4m^2\omega_0^2}\,, \tag{28.71}$$

a cubic in A^2. Its peak lies on the backbone *$\omega=\omega_0+3\epsilon A^2/8\omega_0$ of Equation (28.81), bent to higher frequency for $\epsilon>0$ and to lower for $\epsilon<0$; and above a critical drive amplitude Equation (28.71) has three real roots over a range of ω.*

Rests on Equations (28.69) and (28.81).

Proof. *Derives Proposition 28.68.*

Put $\omega=\omega_0+\varepsilon_d$ with $|\varepsilon_d|\ll\omega_0$ and seek $x=A\cos(\omega t-\delta)$ with A and δ slowly varying. Substituting into Equation (28.69), using $\cos^3\psi=\frac{3}{4}\cos\psi+\frac{1}{4}\cos 3\psi$ and discarding the third harmonic — which is non-resonant and enters only at higher order — the coefficients of $\cos(\omega t-\delta)$ and $\sin(\omega t-\delta)$ give, after dividing by $2\omega_0$,

$$\left(\varepsilon_d-\frac{3\epsilon A^2}{8\omega_0}\right)A=\frac{F_0}{2m\omega_0}\cos\delta\,,\qquad \beta A=\frac{F_0}{2m\omega_0}\sin\delta\,.$$

Squaring and adding eliminates δ and gives Equation (28.71). At fixed F_0 the amplitude is greatest where the square bracket is least, that is where the first bracket vanishes, which is the backbone; and Equation (28.71) is a cubic in A^2 whose discriminant changes sign as F_0 grows, so three real positive roots appear above some F_0 and over some interval of ω. Setting $\epsilon=0$ recovers Equation (28.24) near resonance, and setting $\beta=0$ and $F_0=0$ recovers Equation (28.81). □

Where Equation (28.71) has three roots, the middle branch is unstable and the observed amplitude follows whichever outer branch it is already on. Sweeping the drive frequency upward therefore carries the amplitude along the bent nose until the branch ends, at which point it falls abruptly to the lower branch; sweeping downward it climbs the lower branch and jumps abruptly *up* at a different frequency. The response is hysteretic, the two jump frequencies differ, and neither is a property of the oscillator alone — all of which Duffing reports [452] and none of which a linear system can do.

All of it follows from one identity, which is worth isolating because it does the whole job: the determinant that decides the stability of a steady state is the *slope* of the response cubic at that state.

Proposition 28.69 (Which branch is stable, and where it ends)**.** *Write $s=A^2$, $\varepsilon_d=\omega-\omega_0$, $\kappa=3\epsilon/8\omega_0$ and $f=F_0/2m\omega_0$, and let*

$$G(s):=s\left[(\varepsilon_d-\kappa s)^2+\beta^2\right]-f^2 \tag{28.72}$$

be the cubic whose positive roots are the steady amplitudes of Equation (28.71). A steady state is asymptotically stable if $G'(s)>0$ and unstable if $G'(s)<0$. Where three roots exist the outer two are therefore stable and the middle one is a saddle; the two jump frequencies are the detunings at which $G(s)=G'(s)=0$, that is the turning points of the response curve; and three roots exist at all only for drives above

$$F_{0,\mathrm{c}}=\frac{16\,m\,\omega_0^{3/2}\beta^{3/2}}{3^{5/4}\,|\epsilon|^{1/2}}\,, \tag{28.73}$$

first reached at the detuning $\varepsilon_d=\sqrt{3}\,\beta\,\operatorname{sgn}\epsilon$.

Rests on Equation (28.71) and Theorem 32.13.

Proof. *Derives Proposition 28.69.*

Stability is a statement about the *approach* to a steady state, so the amplitude and phase must be allowed to move; the harmonic balance of Proposition 28.68 assumed them constant and cannot answer the question. Replace it by the exact change of variables

$$x = u(t)\cos\omega t + v(t)\sin\omega t\,, \qquad \dot{x} = \omega\left(-u\sin\omega t + v\cos\omega t\right)\,, \tag{28.74}$$

the second line being a constraint on the pair (u, v), equivalent to $\dot{u}\cos\omega t + \dot{v}\sin\omega t = 0$. Differentiating the second of Equation (28.74) gives $\ddot{x} = \omega\left(-\dot{u}\sin\omega t + \dot{v}\cos\omega t\right) - \omega^2 x$, so Equation (28.69) reads

$$\omega\left(-\dot{u}\sin\omega t + \dot{v}\cos\omega t\right) = \left(\omega^2 - \omega_0^2\right)x - 2\beta\dot{x} - \epsilon x^3 + \frac{F_0}{m}\cos\omega t =: S\,. \tag{28.75}$$

Solving Equation (28.75) together with the constraint — two linear equations for $\dot{u}$ and $\dot{v}$, of determinant ω — gives $\dot{u} = -S\sin(\omega t)/\omega$ and $\dot{v} = S\cos(\omega t)/\omega$, still exactly.

Now average over one drive period holding u and v fixed, which is legitimate because Equation (28.69) makes them move on the slow time scales β^{-1} and $\omega_0/|\epsilon|\,A^2$, both long compared with $2\pi/\omega$ under the hypotheses of Proposition 28.68. With $A^2 = u^2 + v^2$ the required averages are $\langle x\sin\omega t\rangle = v/2$, $\langle x\cos\omega t\rangle = u/2$, $\langle \dot{x}\sin\omega t\rangle = -\omega u/2$, $\langle \dot{x}\cos\omega t\rangle = \omega v/2$, $\langle\cos^2\omega t\rangle = 1/2$, and, since $x^3 = \frac{3}{4}A^2 x + (\text{third harmonic})$ by the same identity used above, $\langle x^3\sin\omega t\rangle = \frac{3}{8}A^2 v$ and $\langle x^3\cos\omega t\rangle = \frac{3}{8}A^2 u$. Using $\left(\omega^2 - \omega_0^2\right)/2\omega \approx \varepsilon_d$ and $\omega \approx \omega_0$ elsewhere,

$$\dot{u} = -\beta u - \Lambda v\,, \qquad \dot{v} = \Lambda u - \beta v + f\,, \qquad \Lambda := \varepsilon_d - \kappa A^2\,. \tag{28.76}$$

From Equations (28.69) and (28.75) (averaging the exact variation-of-parameters equations over one drive period).

Setting $\dot{u} = \dot{v} = 0$ and eliminating the phase reproduces $A^2\left(\Lambda^2 + \beta^2\right) = f^2$, which is Equation (28.71): the fixed points of Equation (28.76) are exactly the steady states already found, and nothing has been changed except that they may now be perturbed.

Linearize Equation (28.76) about a fixed point. Since $\partial\Lambda/\partial u = -2\kappa u$ and $\partial\Lambda/\partial v = -2\kappa v$, the Jacobian of Definition 32.12 is

$$J = \begin{pmatrix} -\beta + 2\kappa uv & -\Lambda + 2\kappa v^2 \\ \Lambda - 2\kappa u^2 & -\beta - 2\kappa uv \end{pmatrix}\,, \tag{28.77}$$

whose trace is $-2\beta < 0$ whatever the state, and whose determinant is

$$\det J = \beta^2 - 4\kappa^2 u^2 v^2 + \left(\Lambda - 2\kappa v^2\right)\left(\Lambda - 2\kappa u^2\right) = \Lambda^2 + \beta^2 - 2\kappa\Lambda s\,. \tag{28.78}$$

Differentiating Equation (28.72) gives $G'(s) = (\varepsilon_d - \kappa s)^2 + \beta^2 - 2\kappa s\,(\varepsilon_d - \kappa s) = \Lambda^2 + \beta^2 - 2\kappa\Lambda s$, so

$$\det J = G'(s)\,, \tag{28.79}$$

which is the identity announced. The rest is bookkeeping. A real 2×2 matrix with negative trace has both eigenvalues in the left half plane when its determinant is positive and one of each sign when it is negative, and away from $\det J = 0$ the two eigenvalues are distinct or the matrix is a multiple of the identity, so Theorem 32.13 applies: the state is asymptotically stable exactly when $G'(s) > 0$ and is a saddle when $G'(s) < 0$.

G has leading coefficient $\kappa^2 > 0$ and $G(0) = -f^2 < 0$, so it crosses zero once with positive slope, or three times with slopes positive, negative and positive in order of increasing s. That is the branch structure: outer branches stable, middle branch a saddle, and the transitions occur where a root is double, $G = G' = 0$. Those are the turning points of the response curve and hence the two jump frequencies; parametrized by Λ they are $s = \left(\Lambda^2 + \beta^2\right)/2\kappa\Lambda$ with $\left(\Lambda^2 + \beta^2\right)^2 = 2\kappa\Lambda f^2$ and $\varepsilon_d = \left(3\Lambda^2 + \beta^2\right)/2\Lambda$, which has solutions only for $\kappa\Lambda > 0$ —

the folds lie on the side towards which the backbone leans, high for a hardening spring and low for a softening one.

The two folds merge when G'' vanishes with them. From $G = \kappa^2 s^3 - 2\kappa\varepsilon_d s^2 + (\varepsilon_d^2 + \beta^2)\, s - f^2$, $G'' = 6\kappa^2 s - 4\kappa\varepsilon_d$ vanishes at $s = 2\varepsilon_d/3\kappa$, where $\Lambda = \varepsilon_d/3$ and $G' = \beta^2 - \varepsilon_d^2/3$; requiring $G' = 0$ as well gives $\varepsilon_d = \pm\sqrt{3}\beta$, and positivity of s selects the sign of κ, that is of ϵ. At that point $s = 2\beta/\sqrt{3}\,|\kappa|$ and $f^2 = s\,(\Lambda^2 + \beta^2) = 8\beta^3/3\sqrt{3}\,|\kappa|$, and restoring $\kappa = 3\epsilon/8\omega_0$ and $f = F_0/2m\omega_0$ gives $F_0^2 = 256\, m^2\omega_0^3\beta^3/9\sqrt{3}\,|\epsilon|$, which is Equation (28.73). Below that drive G is monotone and the response is single-valued; above it the two folds separate and the hysteresis loop opens. □

Remark 28.70 (The linear-stability theorem is used before it is proved). Theorem 32.13 belongs to Chapter 32, later in this part, and is used here for a two-dimensional flow whose Jacobian Equation (28.77) is constant-coefficient and generically diagonalizable. Nothing in that chapter depends on the present proposition, so the forward reference carries no circularity; it is placed there because the general theory of fixed points is that chapter's subject, and Remark 32.14 records what Part II still owes it.

28.7.2 Secular terms and the Lindstedt–Poincaré method

The obvious way to treat Equation (28.70) is to expand in ϵ. It fails, and the way it fails is instructive.

Proposition 28.71 (Naive perturbation theory produces a secular term). *Writing $x = x_0 + \epsilon x_1 + O(\epsilon^2)$ in Equation (28.70) with $x_0 = A\cos\omega_0 t$ gives*

$$x_1 = -\frac{3A^3}{8\omega_0}\, t\sin\omega_0 t + \frac{A^3}{32\omega_0^2}\,(\cos 3\omega_0 t - \cos\omega_0 t)\ , \tag{28.80}$$

whose first term grows without bound. The expansion is therefore useless once $\epsilon A^2 t/\omega_0$ is of order one, however small ϵ is.

Rests on Equations (28.2) and (28.70).

Proof. *Derives Proposition 28.71.*

At order ϵ, Equation (28.70) gives $\ddot{x}_1 + \omega_0^2 x_1 = -x_0^3$. With $x_0 = A\cos\omega_0 t$ and $\cos^3\psi = \frac{3}{4}\cos\psi + \frac{1}{4}\cos 3\psi$, the right side is $-A^3\left(\frac{3}{4}\cos\omega_0 t + \frac{1}{4}\cos 3\omega_0 t\right)$. The second piece drives the oscillator off resonance and contributes the bounded terms shown. The first drives it exactly on resonance, and the particular solution of $\ddot{y} + \omega_0^2 y = C\cos\omega_0 t$ is $y = (C/2\omega_0)\, t\sin\omega_0 t$, which with $C = -3A^3/4$ gives the first term of Equation (28.80). Since ϵx_1 must stay small against x_0 for the expansion to mean anything, the bound is $\epsilon A^2 t/\omega_0 \ll 1$. □

The secular term is not a physical instability. The exact motion of Equation (28.70) is bounded, because the energy $\frac{1}{2}\dot{x}^2 + \frac{1}{2}\omega_0^2 x^2 + \frac{1}{4}\epsilon x^4$ is conserved and, for $\epsilon > 0$, confines the orbit. What has gone wrong is that the expansion assumed the frequency was ω_0, and it is not: $t\sin\omega_0 t$ is the first term of the expansion of $\sin\left((\omega_0 + \epsilon\omega_1)\, t\right)$ in ϵ. The cure is to let the frequency be part of what is expanded — Lindstedt's device [219], made into a systematic theory by Poincaré [255].

Theorem 28.72 (Lindstedt–Poincaré frequency shift). *The periodic solutions of Equation (28.70) of amplitude A have frequency*

$$\omega = \omega_0 + \frac{3\epsilon A^2}{8\omega_0} + O\left(\epsilon^2\right)\ , \tag{28.81}$$

and to the same order the motion is $x = A\cos\omega t + (\epsilon A^3/32\omega_0^2)\,(\cos 3\omega t - \cos\omega t)$, free of secular terms.

Rests on Equations (28.70) and (28.80).

Proof. *Derives Theorem 28.72.*

Introduce the stretched time $\tau = \omega t$ with ω unknown, and expand both the solution and the frequency,

$$x = x_0(\tau) + \epsilon x_1(\tau) + \cdots , \qquad \omega = \omega_0 + \epsilon\omega_1 + \cdots ,$$

requiring every x_j to be 2π-periodic in τ — which is the whole of the method: periodicity in τ is imposed, and ω is whatever makes it possible. Since $\mathrm{d}/\mathrm{d}t = \omega\,\mathrm{d}/\mathrm{d}\tau$, Equation (28.70) becomes $\omega^2 x'' + \omega_0^2 x + \epsilon x^3 = 0$ with the prime denoting $\mathrm{d}/\mathrm{d}\tau$. At order ϵ^0, $x_0'' + x_0 = 0$, so $x_0 = A\cos\tau$ after choosing the origin of time. At order ϵ^1,

$$\omega_0^2\,(x_1'' + x_1) = -2\omega_0\omega_1 x_0'' - x_0^3 = 2\omega_0\omega_1 A\cos\tau - A^3\left(\tfrac{3}{4}\cos\tau + \tfrac{1}{4}\cos 3\tau\right) .$$

A term in $\cos\tau$ on the right drives the left-hand operator on resonance and produces exactly the secular term of Proposition 28.71, destroying the periodicity demanded. It is absent if and only if $2\omega_0\omega_1 A = \frac{3}{4}A^3$, that is $\omega_1 = 3A^2/8\omega_0$, which is Equation (28.81). With that choice the remaining equation $x_1'' + x_1 = -\left(A^3/4\omega_0^2\right)\cos 3\tau$ has the bounded periodic solution $x_1 = \left(A^3/32\omega_0^2\right)\cos 3\tau$, to which a multiple of $\cos\tau$ may be added; fixing the amplitude of the fundamental at A makes it $\left(A^3/32\omega_0^2\right)(\cos 3\tau - \cos\tau)$. □

Three things in Theorem 28.72 outlast the example. The frequency shift is quadratic in the amplitude, so an anharmonic oscillator is still isochronous to first order and departs only at second — which is why Phenomenon 28.9 works as well as it does. The response acquires a third harmonic: a nonlinear system driven at one frequency answers at others, which no linear system can do and which is the whole of nonlinear optics (Chapter 61). And the method itself is a renormalization: a parameter of the unperturbed problem is adjusted order by order to absorb what would otherwise be a divergence, which is the same manoeuvre, in a far more elaborate setting, as the mass and charge renormalizations of Chapter 100.

Remark 28.73 (The method's own limits, and where they lead). Theorem 28.72 removes the secular terms order by order and says nothing about whether the resulting series converges. For a single oscillator the answer is benign. For several coupled ones it is not: the analogue of the resonance denominator that produced Equation (28.80) becomes a combination $n_1\omega_1 + \cdots + n_k\omega_k$ that can be made arbitrarily small by choosing the integers n_j, so the corrections are divided by arbitrarily small numbers and the series need not converge at all. Poincaré identified the problem [255]; that the series nevertheless converges for most frequency ratios, and that the corresponding motions survive a small perturbation while the resonant ones do not, is the theorem of Kolmogorov, Arnold and Moser [1247]. Resonance overlap, the destruction of the surviving tori and the onset of chaos are Chapter 32, which is where this chapter hands the anharmonic oscillator on.

Rests on Equation (28.81).

Chapter 29

Rigid Bodies and Rotating Frames

A rigid body is the first mechanical system beyond the point particle that Nature actually supplies: six degrees of freedom, three of them rotational, governed by an inertia tensor rather than by a single mass. This chapter develops rigid-body kinematics and dynamics — the inertia tensor, Euler's equations, tops and gyroscopes — and then turns to motion described from rotating frames, where the centrifugal and Coriolis forces appear and carry the terrestrial evidence of the Earth's rotation: Foucault's pendulum, the eastward deflection of falling bodies, the circulation of the winds, and the Chandler wobble. It builds directly on the dynamics of Chapter 19 and the Lagrangian methods of Chapter 21; the rotation group it works with is treated as algebra in Chapter 4 and as geometry in Chapter 14. Standard treatments are [1585, 2027].

Two conventions are fixed once and used everywhere below. Body axes are always the principal axes of Theorem 29.16, labelled so that I_1, I_2, I_3 are the corresponding moments; and Euler angles are always the z–x–z triple of Notation 29.9. Neither choice is forced by the physics, and a formula quoted from another book will differ from the formulae here if its conventions differ.

29.1 Rigid-body kinematics

29.1.1 Angular velocity and Euler's theorem

Definition 29.1 (Rigid body)**.** A *rigid body* is a system of particles, or a continuous mass distribution, subject to the holonomic constraints

$$|\boldsymbol{r}_a - \boldsymbol{r}_b| = \text{const} \qquad \text{for every pair } a, b\,. \tag{29.1}$$

Rests on Definitions 19.39 and 21.2.

Proposition 29.2 (Six degrees of freedom)**.** *A rigid body containing at least three non-collinear particles has exactly six degrees of freedom: three to locate one of its points and three more to orient it. Its configuration space is* $\mathbb{R}^3 \times \mathrm{SO}(3)$.

Rests on Definitions 21.9 and 29.1.

Proof. *Derives Proposition 29.2.*

Fix three non-collinear particles of the body. Locating the first costs three coordinates. The second is then confined by Equation (29.1) to a sphere about the first, costing two more; the third is confined to a circle about the axis through the first two, costing one more — six in all. Every further particle is then determined, because its distances from three non-collinear points fix it up to a reflection, and a reflection cannot be reached continuously from the identity. The six coordinates split as the position of the chosen point, an element of $\mathbb{R}^3$, and the orientation of the body frame relative to the space frame, which by Definition 14.26 is an element of $\mathrm{SO}(3)$. □

Theorem 29.3 (Euler's rotation theorem)**.** *Every displacement of a rigid body that leaves one point fixed is a rotation through some angle about some axis through that point. That axis is the eigenvector of the displacement matrix belonging to the eigenvalue* $+1$*.*

Rests on Propositions 14.30 and 29.2.

Proof. *Derives Theorem 29.3.*

The displacement preserves all mutual distances and one point, so in Cartesian axes centred on that point it acts as a matrix R with $R^{\mathsf{T}}R = \mathbb{1}$, and it is continuously connected to the identity, so $\det R = +1$: that is, $R \in \mathrm{SO}(3)$ (Definition 14.26). By the Rodrigues formula of Proposition 14.30 the exponential map onto $\mathrm{SO}(3)$ is surjective, so $R = \exp(\theta\, \hat{\boldsymbol{n}} \cdot \boldsymbol{J})$ for some unit $\hat{\boldsymbol{n}}$ and some angle θ; this is by construction the rotation by θ about $\hat{\boldsymbol{n}}$, and $R\hat{\boldsymbol{n}} = \hat{\boldsymbol{n}}$. The general rotation formulae in this form are Euler's [34]. □

Definition 29.4 (Angular velocity)**.** Let the orthonormal body axes be $\hat{\boldsymbol{e}}_i(t) = R(t)\,\hat{\boldsymbol{e}}_i(0)$ with $R(t) \in \mathrm{SO}(3)$. Differentiating $RR^{\mathsf{T}} = \mathbb{1}$ shows that $\dot{R}R^{\mathsf{T}}$ is antisymmetric, hence an element of $\mathfrak{so}(3)$; the *angular velocity* $\boldsymbol{\omega}(t)$ is the vector representing it,

$$\left(\dot{R}R^{\mathsf{T}}\right)_{ij} = -\epsilon_{ijk}\,\omega_k\,, \qquad \text{equivalently} \qquad \dot{R}R^{\mathsf{T}}\boldsymbol{v} = \boldsymbol{\omega} \times \boldsymbol{v} \quad \text{for all } \boldsymbol{v}\,. \tag{29.2}$$

Rests on Definition 14.26, Proposition 14.27, and Lemma 14.62.

The identification of an antisymmetric 3×3 matrix with a vector is the isomorphism $\mathfrak{so}(3) \cong \mathbb{R}^3$ of Proposition 14.27, and it is available in three space dimensions and in no other; that is the technical reason why angular velocity is a vector here and a two-index object in general.

Proposition 29.5 (The velocity field of a rigid body)**.** *If* $\boldsymbol{r}$ *is measured from a point* O *of the body, every material point moves with*

$$\boldsymbol{v} = \boldsymbol{v}_O + \boldsymbol{\omega} \times \boldsymbol{r}\,, \tag{29.3}$$

where $\boldsymbol{v}_O$ *is the velocity of* O *[32].*

Rests on Definition 29.4 and Equation (29.1).

Proof. *Derives Proposition 29.5.*

Write the position of a material point as $\boldsymbol{R}(t) = \boldsymbol{R}_O(t) + R(t)\boldsymbol{r}_0$, with $\boldsymbol{r}_0$ its fixed body coordinates — fixed precisely because of Equation (29.1). Differentiating, $\dot{\boldsymbol{R}} = \boldsymbol{v}_O + \dot{R}\boldsymbol{r}_0 = \boldsymbol{v}_O + \dot{R}R^{\mathsf{T}}(R\boldsymbol{r}_0)$, and by Equation (29.2) the second term is $\boldsymbol{\omega} \times \boldsymbol{r}$ with $\boldsymbol{r} = R\boldsymbol{r}_0$. □

Proposition 29.6 (The angular velocity does not depend on the base point)**.** *If Equation (29.3) holds with respect to* O *and also with respect to a second body point* O'*, the two angular velocities coincide. There is therefore one* $\boldsymbol{\omega}$ *for the body, not one per reference point.*

Rests on Proposition 29.5.

Proof. *Derives Proposition 29.6.*

Let $\boldsymbol{d}$ be the vector from O to O'. Applying Equation (29.3) about each point and subtracting, $(\boldsymbol{\omega} - \boldsymbol{\omega}') \times (\boldsymbol{r} - \boldsymbol{d}) = \boldsymbol{0}$ for every material point. A body with three non-collinear points supplies vectors $\boldsymbol{r} - \boldsymbol{d}$ spanning $\mathbb{R}^3$, and only the zero vector has vanishing cross product with a spanning set, so $\boldsymbol{\omega} = \boldsymbol{\omega}'$. □

Theorem 29.7 (Transport theorem)**.** *Let* $\boldsymbol{Q}(t)$ *be any vector, and let a frame rotate with angular velocity* $\boldsymbol{\omega}$ *relative to an inertial frame. Then*

$$\left(\frac{\mathrm{d}\boldsymbol{Q}}{\mathrm{d}t}\right)_{space} = \left(\frac{\mathrm{d}\boldsymbol{Q}}{\mathrm{d}t}\right)_{body} + \boldsymbol{\omega} \times \boldsymbol{Q}\,, \tag{29.4}$$

where the second derivative is taken holding the rotating basis fixed.

Rests on Definition 29.4 and Proposition 29.5.

Proof. *Derives Theorem 29.7.*

Expand $\boldsymbol{Q} = Q_i \hat{\boldsymbol{e}}_i$ in the rotating basis and differentiate in the inertial frame:

$$\left(\frac{\mathrm{d}\boldsymbol{Q}}{\mathrm{d}t}\right)_{\text{space}} = \dot{Q}_i \hat{\boldsymbol{e}}_i + Q_i \frac{\mathrm{d}\hat{\boldsymbol{e}}_i}{\mathrm{d}t}\,.$$

The first sum is by definition the derivative computed by an observer who regards the basis as fixed. For the second, $\hat{\boldsymbol{e}}_i = R\hat{\boldsymbol{e}}_i(0)$ gives $\mathrm{d}\hat{\boldsymbol{e}}_i/\mathrm{d}t = \dot{R}R^{\mathsf{T}}\hat{\boldsymbol{e}}_i = \boldsymbol{\omega} \times \hat{\boldsymbol{e}}_i$ by Equation (29.2), so the second sum is $\boldsymbol{\omega} \times \boldsymbol{Q}$. □

Theorem 29.7 is the single technical fact behind everything in Sections 29.3 and 29.5: applied to the angular momentum it produces Euler's equations, and applied twice to a position vector it produces the centrifugal and Coriolis terms.

Proposition 29.8 (Chasles: the general displacement is a screw)**.** *Every displacement of a free rigid body can be realised as a rotation about some axis together with a translation* along *that same axis [87].*

Rests on Theorem 29.3 and Proposition 29.5.

Proof. *Derives Proposition 29.8.*

By Theorem 29.3 the displacement is $\boldsymbol{r} \mapsto R\boldsymbol{r} + \boldsymbol{a}$ with R a rotation by θ about a unit vector $\hat{\boldsymbol{n}}$ through the origin. Split $\boldsymbol{a} = a_{\parallel}\hat{\boldsymbol{n}} + \boldsymbol{a}_{\perp}$. Shifting the axis to pass through a point $\boldsymbol{c}$ replaces $\boldsymbol{a}$ by $\boldsymbol{a} + (\mathbb{1} - R)\,\boldsymbol{c}$. Now $\mathbb{1} - R$ annihilates $\hat{\boldsymbol{n}}$ and, for θ not a multiple of 2π, is invertible on the plane orthogonal to $\hat{\boldsymbol{n}}$; choose $\boldsymbol{c}$ in that plane with $(\mathbb{1} - R)\,\boldsymbol{c} = -\boldsymbol{a}_{\perp}$. About the shifted axis the translation is $a_{\parallel}\hat{\boldsymbol{n}}$, parallel to the axis. If θ is a multiple of 2π the displacement is a pure translation, the degenerate screw of infinite pitch. □

29.1.2 Euler angles

Notation 29.9 (The z–x–z Euler angles used in this treatise)*.* Let A be the matrix carrying the components of a vector in the space frame to its components in the body frame. This treatise writes

$$A\,(\varphi, \theta, \psi) = R_3(\psi)\,R_1(\theta)\,R_3(\varphi)\,, \tag{29.5}$$

that is: rotate by φ about the space z axis; then by θ about the new x axis, the *line of nodes*; then by ψ about the new z axis, which is the body axis $\hat{\boldsymbol{e}}_3$. The ranges are $\varphi \in [0, 2\pi)$, $\theta \in [0, \pi]$, $\psi \in [0, 2\pi)$, and the elementary matrices are

$$R_3(\alpha) = \begin{pmatrix} \cos\alpha & \sin\alpha & 0 \\ -\sin\alpha & \cos\alpha & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad R_1(\alpha) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\alpha & \sin\alpha \\ 0 & -\sin\alpha & \cos\alpha \end{pmatrix}.$$

Multiplying out Equation (29.5),

$$A = \begin{pmatrix} \cos\psi\cos\varphi - \cos\theta\sin\varphi\sin\psi & \cos\psi\sin\varphi + \cos\theta\cos\varphi\sin\psi & \sin\psi\sin\theta \\ -\sin\psi\cos\varphi - \cos\theta\sin\varphi\cos\psi & -\sin\psi\sin\varphi + \cos\theta\cos\varphi\cos\psi & \cos\psi\sin\theta \\ \sin\theta\sin\varphi & -\sin\theta\cos\varphi & \cos\theta \end{pmatrix}. \tag{29.6}$$

Rests on Theorem 29.3 and Definition 14.26.

Remark 29.10 (Other conventions, and why the choice must be stated)*.* Twelve orderings of axes are in use, and both the active and the passive reading of the matrices occur. Landau's treatment uses the same z–x–z triple as Equation (29.5) [1585]; aeronautics prefers a z–y–x triple whose angles are yaw, pitch and roll and are *not* the angles here. A formula lifted from another source into this chapter is therefore wrong unless its convention is checked first. Every Euler-angle formula below — Equations (29.7) and (29.35) in particular — is stated in the convention of Notation 29.9 and in no other.

Rests on Notation 29.9.

Proposition 29.11 (Angular velocity in Euler angles)**.** *In the convention of Notation 29.9, the components of* $\boldsymbol{\omega}$ *along the body axes are*

$$\omega_1 = \dot\varphi \sin\theta \sin\psi + \dot\theta \cos\psi \,, \tag{29.7}$$

$$\omega_2 = \dot\varphi \sin\theta \cos\psi - \dot\theta \sin\psi \,, \tag{29.8}$$

$$\omega_3 = \dot\varphi \cos\theta + \dot\psi \,. \tag{29.9}$$

Rests on Notation 29.9 and Definition 29.4.

Proof. *Derives Proposition 29.11.*

The three elementary rotations are performed about the space z axis, about the line of nodes $\hat{\boldsymbol{e}}_N$, and about the body axis $\hat{\boldsymbol{e}}_3$, so the angular velocities add:

$$\boldsymbol{\omega} = \dot\varphi\, \hat{\boldsymbol{z}} + \dot\theta\, \hat{\boldsymbol{e}}_N + \dot\psi\, \hat{\boldsymbol{e}}_3 \,.$$

It remains to resolve each of the three axes along the body frame. The third column of Equation (29.6) gives the body components of $\hat{\boldsymbol{z}}$, namely $(\sin\theta\sin\psi,\ \sin\theta\cos\psi,\ \cos\theta)$. The line of nodes is the x axis of the intermediate frame, so applying only the last rotation $R_3(\psi)$ to $(1,0,0)$ gives $(\cos\psi,\ -\sin\psi,\ 0)$. Finally $\hat{\boldsymbol{e}}_3 = (0,0,1)$ in the body frame. Collecting components yields Equations (29.7) to (29.9). □

Remark 29.12 (The coordinate singularity, and what it is not)*.* Read as a linear map from $\left(\dot\varphi, \dot\theta, \dot\psi\right)$ to $(\omega_1, \omega_2, \omega_3)$, Equations (29.7) to (29.9) have the matrix

$$M = \begin{pmatrix} \sin\theta\sin\psi & \cos\psi & 0 \\ \sin\theta\cos\psi & -\sin\psi & 0 \\ \cos\theta & 0 & 1 \end{pmatrix}, \qquad \det M = -\sin\theta \,.$$

At $\theta = 0$ and $\theta = \pi$ the map is singular: only the sum $\varphi \pm \psi$ is determined, the two rotations having become rotations about the same axis. This is the defect known in instrument engineering as gimbal lock, and it is a property of the *chart*, not of the body: nothing whatever happens to a top as its axis passes through the vertical. No single chart can do better, because SO(3) is a compact three-manifold (Chapter 14) and therefore admits no global coordinate system; a numerical integration that must pass through $\theta = 0$ changes chart, or abandons Euler angles for the group element itself.

Rests on Propositions 14.31 and 29.11.

29.2 The inertia tensor

29.2.1 Definition and principal axes

Definition 29.13 (Inertia tensor, continuum form)**.** For a body of mass density $\rho(\boldsymbol{r})$ occupying a region V, with $\boldsymbol{r}$ measured from a chosen point O, the *inertia tensor* about O is

$$I_{ik} := \int_V \rho(\boldsymbol{r}) \left(r^2 \delta_{ik} - x_i x_k \right) \mathrm{d}^3 r \,, \tag{29.10}$$

which is Equation (19.34) with the sum over particles replaced by an integral over the body. The two are the same quantity for the same reason and are used interchangeably below, but neither expression is a special case of the other as written: a finite set of point masses is not a bounded density, so the discrete form is not obtained by substituting a ρ into Equation (29.10) — it is the same construction with the mass distribution summed rather than integrated. Where a result below holds for only one of the two, the statement says which. Its SI unit is $\mathrm{kg\,m^2}$. It is symmetric, and under a rotation of the axes its components transform as a Cartesian tensor of second rank (Definition 13.5).

Rests on Definitions 7.93, 13.5 and 19.42.

Proposition 29.14 (Angular momentum and kinetic energy)**.** *If the point O is fixed, or is the centre of mass, then*

$$L_i = I_{ik}\,\omega_k\,, \tag{29.11}$$

and the kinetic energy of rotation is the quadratic form

$$T_{rot} = \tfrac{1}{2} I_{ik}\,\omega_i\omega_k = \tfrac{1}{2}\boldsymbol{\omega}\cdot\boldsymbol{L}\,. \tag{29.12}$$

For a general motion the total kinetic energy separates as $T = \tfrac{1}{2}Mv_{cm}^2 + T_{rot}$, with T_{rot} computed about the centre of mass.

Rests on Definitions 19.55 and 29.13 and Proposition 29.5.

Proof. *Derives Proposition 29.14.*

With O fixed, Equation (29.3) gives $\boldsymbol{v} = \boldsymbol{\omega}\times\boldsymbol{r}$, so

$$\boldsymbol{L} = \int_V \rho\,\boldsymbol{r}\times(\boldsymbol{\omega}\times\boldsymbol{r})\,\mathrm{d}^3r = \int_V \rho\left(r^2\boldsymbol{\omega} - (\boldsymbol{r}\cdot\boldsymbol{\omega})\,\boldsymbol{r}\right)\mathrm{d}^3r\,,$$

using the triple-product expansion $\boldsymbol{a}\times(\boldsymbol{b}\times\boldsymbol{c}) = \boldsymbol{b}(\boldsymbol{a}\cdot\boldsymbol{c}) - \boldsymbol{c}(\boldsymbol{a}\cdot\boldsymbol{b})$, which is the contraction $\epsilon_{ijk}\epsilon_{ilm} = \delta_{jl}\delta_{km} - \delta_{jm}\delta_{kl}$ of the Levi-Civita symbol of Lemma 14.62. That contraction is quoted here and not proved: Part II states the invariance of the symbol but carries no labelled form of the identity, so it is used on its own authority. In components the result is exactly Equation (29.10) contracted with ω_k, which is Equation (29.11). For the energy,

$$T = \tfrac{1}{2}\int_V \rho\,|\boldsymbol{\omega}\times\boldsymbol{r}|^2\,\mathrm{d}^3r = \tfrac{1}{2}\int_V \rho\left(\omega^2r^2 - (\boldsymbol{\omega}\cdot\boldsymbol{r})^2\right)\mathrm{d}^3r = \tfrac{1}{2}I_{ik}\omega_i\omega_k\,,$$

by the same identity. The separation of the general motion is the centre-of-mass decomposition of Chapter 19: the cross term carries the factor $\int_V \rho\,\boldsymbol{r}\,\mathrm{d}^3r$, which vanishes when $\boldsymbol{r}$ is measured from the centre of mass. □

Proposition 29.15 (Positivity)**.** *For any unit vector $\hat{\boldsymbol{n}}$,*

$$\hat{\boldsymbol{n}}\cdot I\hat{\boldsymbol{n}} = \int_V \rho\,d^2\,\mathrm{d}^3r \;\geq\; 0\,,$$

where d is the distance of the mass element from the line through O along $\hat{\boldsymbol{n}}$. The form is strictly positive unless the whole mass lies on that line; a body that is not collinear therefore has a positive-definite inertia tensor.

Rests on Definition 29.13.

Proof. *Derives Proposition 29.15.*

Contract Equation (29.10) with $\hat{\boldsymbol{n}}$: $n_in_k\left(r^2\delta_{ik} - x_ix_k\right) = r^2 - (\boldsymbol{r}\cdot\hat{\boldsymbol{n}})^2 = |\boldsymbol{r}|^2\sin^2\alpha = d^2$, with α the angle between $\boldsymbol{r}$ and $\hat{\boldsymbol{n}}$. The integrand is non-negative, and vanishes identically only where ρ is supported on the line $d = 0$. □

Theorem 29.16 (Principal axes)**.** *For every rigid body and every choice of the point O there exists an orthonormal triad $\hat{\boldsymbol{e}}_1, \hat{\boldsymbol{e}}_2, \hat{\boldsymbol{e}}_3$ fixed in the body in which I_{ik} is diagonal,*

$$I = \operatorname{diag}(I_1, I_2, I_3)\,, \qquad I_i \geq 0\,. \tag{29.13}$$

These are the principal axes *and the I_i the* principal moments of inertia *[29]. In such axes $\boldsymbol{L} = (I_1\omega_1, I_2\omega_2, I_3\omega_3)$ and $2T_{rot} = \sum_i I_i\omega_i^2$.*

Rests on Definition 29.13, Theorem 5.75, and Proposition 29.15.

Proof. *Derives Theorem 29.16.*

I_{ik} is a real symmetric matrix, hence self-adjoint with respect to the Euclidean inner product. The spectral theorem (Theorem 5.75) supplies an orthonormal basis of eigenvectors with real eigenvalues, and Corollary 5.27 makes the decomposition orthogonal, so the change of basis is itself a rotation once the triad is ordered to be right-handed. The eigenvalues are the values of the form $\hat{\boldsymbol{n}} \cdot I\hat{\boldsymbol{n}}$ on the eigenvectors, and these are non-negative by Proposition 29.15. The remaining formulae are Equations (29.11) and (29.12) evaluated in the diagonalizing basis. Historically the existence of three orthogonal principal axes is Segner's [29]; the statement here is the modern one, and the mathematics belongs to Chapter 5 rather than to mechanics. □

The eigenvalue problem of Theorem 29.16 is the whole content of the passage from "a body" to "three numbers". Note that $\boldsymbol{L}$ and $\boldsymbol{\omega}$ are parallel only when $\boldsymbol{\omega}$ lies along a principal axis, or when two or three of the I_i coincide; in general the angular momentum of a spinning body does not point along its spin.

Proposition 29.17 (Triangle inequalities)**.** *The principal moments satisfy*

$$I_1 + I_2 \geq I_3\,, \qquad I_2 + I_3 \geq I_1\,, \qquad I_3 + I_1 \geq I_2\,,$$

with equality in the first exactly when the whole mass lies in the $\hat{\boldsymbol{e}}_1\hat{\boldsymbol{e}}_2$ plane.
Rests on Theorem 29.16.

Proof. *Derives Proposition 29.17.*

In principal axes $I_1 = \int \rho\,(y^2+z^2)$, $I_2 = \int \rho\,(z^2+x^2)$ and $I_3 = \int \rho\,(x^2+y^2)$, all integrals over V with measure d^3r. Hence $I_1 + I_2 - I_3 = 2\int_V \rho\, z^2\,\mathrm{d}^3r \geq 0$, which vanishes precisely when ρ is supported on $z = 0$. The other two follow by relabelling. □

Definition 29.18 (Classification of tops)**.** A body is a *spherical top* if $I_1 = I_2 = I_3$, a *symmetric top* if exactly two of the principal moments are equal, and an *asymmetric top* if all three differ. For a symmetric top the two equal moments are written A and the third C; the body is called *prolate* if $C < A$ (a cigar) and *oblate* if $C > A$ (a coin).
Rests on Theorem 29.16.

Definition 29.19 (Inertia ellipsoid)**.** The *inertia ellipsoid* of a body at O is the level surface

$$I_{ik}x_i x_k = 1\,, \tag{29.14}$$

a genuine ellipsoid whenever I is positive definite, with semi-axes $I_i^{-1/2}$ along the principal axes.
Rests on Definition 29.13, Proposition 29.15, and Theorem 29.16.

The ellipsoid has a symmetry axis exactly when the body is a symmetric top, and is a sphere exactly for a spherical top. A cube is a spherical top about its centre, so its inertia ellipsoid is a sphere and every axis through the centre is principal — an example worth keeping in mind, because it shows that the symmetry of the inertia tensor can exceed the symmetry of the body.

29.2.2 Computing moments of inertia

Theorem 29.20 (Parallel-axis theorem)**.** *Let I^{cm}_{ik} be the inertia tensor about the centre of mass and $\boldsymbol{a}$ the vector from a point O to the centre of mass. Then the inertia tensor about O is*

$$I_{ik} = I^{cm}_{ik} + M\left(a^2\delta_{ik} - a_i a_k\right)\,. \tag{29.15}$$

In particular the moment about an axis $\hat{\boldsymbol{n}}$ through O exceeds the moment about the parallel axis through the centre of mass by Md^2, with d the distance between the two axes.
Rests on Definitions 19.47 and 29.13.

Proof. *Derives Theorem 29.20.*

Write $\boldsymbol{r} = \boldsymbol{a} + \boldsymbol{r}'$, with $\boldsymbol{r}'$ measured from the centre of mass, so that $\int_V \rho\, \boldsymbol{r}'\, \mathrm{d}^3 r = \boldsymbol{0}$ by Definition 19.47. Substituting into Equation (29.10),

$$I_{ik} = \int_V \rho \left[\left(a^2 + 2\boldsymbol{a}\cdot\boldsymbol{r}' + r'^2 \right) \delta_{ik} - (a_i + x'_i)\,(a_k + x'_k) \right] \mathrm{d}^3 r \,.$$

Every term linear in $\boldsymbol{r}'$ integrates to zero. What remains is the $\boldsymbol{r}'$-quadratic part, which is I^{cm}_{ik}, plus the $\boldsymbol{a}$-quadratic part times the total mass, which is $M\left(a^2\delta_{ik} - a_i a_k\right)$. Contracting Equation (29.15) with $\hat{\boldsymbol{n}}$ twice gives $Ma^2 - (\boldsymbol{a}\cdot\hat{\boldsymbol{n}})^2 M = Md^2$ for the added term. □

Corollary 29.21 (The centre of mass minimizes the moment)**.** *Among all axes of a given direction, the one through the centre of mass has the smallest moment of inertia.*

Rests on Theorem 29.20.

Proof. *Derives Corollary 29.21.*

The added term Md^2 of Theorem 29.20 is non-negative and vanishes only for $d = 0$. □

This is the mathematical content of Huygens' theory of the compound pendulum and of the centre of oscillation [11]; the experimental use made of it, in Kater's reversible pendulum, is Phenomenon 34.8 and Equation (34.21).

Proposition 29.22 (Perpendicular-axis theorem)**.** *For a plane lamina lying in the xy plane,*

$$I_{zz} = I_{xx} + I_{yy} \,. \tag{29.16}$$

Rests on Definition 29.13 and Proposition 29.17.

Proof. *Derives Proposition 29.22.*

With $z = 0$ throughout the body, Equation (29.10) gives $I_{xx} = \int \rho y^2$, $I_{yy} = \int \rho x^2$ and $I_{zz} = \int \rho\,(x^2 + y^2)$, all over V with measure $\mathrm{d}^3 r$; adding the first two gives the third. It is the equality case of Proposition 29.17. □

The disc entries of Table 29.1 illustrate Proposition 29.22: a disc is a lamina, its two diameters are equivalent, and $MR^2/4 + MR^2/4 = MR^2/2$ is the moment about the symmetry axis, as required.

Example 29.23 (The polar moment of the Earth, and what it reveals)**.** The Earth's moment of inertia about its rotation axis is $C = 8.03 \times 10^{37}\,\mathrm{kg\,m^2}$, against a mass $M = 5.972 \times 10^{24}\,\mathrm{kg}$ and an equatorial radius $a = 6.378 \times 10^{6}\,\mathrm{m}$, so that

$$\frac{C}{Ma^2} = 0.331 \,.$$

Table 29.1 gives 0.4 for a homogeneous sphere. The measured value is seventeen per cent smaller, and it cannot be made smaller by any redistribution that keeps the density uniform: the deficit is a direct measurement, made from the outside, that the Earth's mass is concentrated towards its centre. The same number enters Sections 29.3.4 and 29.4.4, where it fixes the free wobble and the precession rate; the numerical values here are the conventional astronomical ones collected in Table 29.2.

Rests on Definition 29.13 and Table 29.1.

Proposition 29.24 (MacCullagh's formula)**.** *Let a body of mass m, centred on its centre of mass, be viewed from a distant point mass M at position $\boldsymbol{R}$ with R much larger than the size of the body. To quadrupole order the mutual gravitational potential energy is*

$$U = -\frac{GMm}{R} - \frac{GM}{2R^3}\left(I_1 + I_2 + I_3 - 3I_R\right) \,, \tag{29.17}$$

where $I_R = \hat{\boldsymbol{R}}\cdot I\hat{\boldsymbol{R}}$ is the moment of inertia of the body about the line joining the two centres.

Rests on Definition 29.13 and Theorem 9.113.

Table 29.1: Principal moments of inertia of homogeneous bodies of total mass M, about axes through the centre of mass. Each entry follows from Equation (29.10) by a single elementary integral; the last column gives the ratio $I/(MR^2)$ or $I/(M\ell^2)$, which is the dimensionless number that actually distinguishes one shape from another. The values for the rod and the lamina are limits, exact when the neglected dimension is small compared with the one retained.

Body	Axis	I	ratio
Thin rod, length ℓ	perpendicular, through centre	$M\ell^2/12$	0.0833
Thin rod, length ℓ	perpendicular, through one end	$M\ell^2/3$	0.3333
Thin ring, radius R	symmetry axis	MR^2	1
Disc, radius R	symmetry axis	$MR^2/2$	0.5
Disc, radius R	diameter	$MR^2/4$	0.25
Solid cylinder, radius R, length ℓ	transverse, through centre	$M\left(3R^2+\ell^2\right)/12$	—
Solid sphere, radius R	any diameter	$2MR^2/5$	0.4
Spherical shell, radius R	any diameter	$2MR^2/3$	0.6667
Rectangular plate, sides a, b	perpendicular, through centre	$M\left(a^2+b^2\right)/12$	—
Solid ellipsoid, semi-axes a, b, c	the a axis	$M\left(b^2+c^2\right)/5$	—

Proof. *Derives Proposition 29.24.*

Write $U=-GM\int_V \rho(\boldsymbol{r})\,|\boldsymbol{R}-\boldsymbol{r}|^{-1}\,\mathrm{d}^3r$ and expand the kernel in Legendre polynomials by the generating function of Theorem 9.113, with $\cos\gamma=\hat{\boldsymbol{R}}\cdot\hat{\boldsymbol{r}}$:

$$\frac{1}{|\boldsymbol{R}-\boldsymbol{r}|}=\frac{1}{R}\sum_{n\ge 0}\left(\frac{r}{R}\right)^n P_n(\cos\gamma)=\frac{1}{R}+\frac{\boldsymbol{r}\cdot\hat{\boldsymbol{R}}}{R^2}+\frac{3\left(\boldsymbol{r}\cdot\hat{\boldsymbol{R}}\right)^2-r^2}{2R^3}+O\!\left(\frac{r^3}{R^4}\right).$$

The $n=0$ term integrates to m/R. The $n=1$ term vanishes because $\boldsymbol{r}$ is measured from the centre of mass. For $n=2$, note from Equation (29.10) that $I_1+I_2+I_3=\operatorname{tr} I=2\int_V \rho\, r^2\,\mathrm{d}^3r$ and that $I_R=\int_V \rho\left(r^2-\left(\boldsymbol{r}\cdot\hat{\boldsymbol{R}}\right)^2\right)\mathrm{d}^3r$, whence

$$\int_V \rho\left(3\left(\boldsymbol{r}\cdot\hat{\boldsymbol{R}}\right)^2-r^2\right)\mathrm{d}^3r=3\left(\tfrac{1}{2}\operatorname{tr} I-I_R\right)-\tfrac{1}{2}\operatorname{tr} I=\operatorname{tr} I-3I_R\,.$$

Multiplying by $-GM/(2R^3)$ gives Equation (29.17). □

Proposition 29.24 is the bridge from this section to Section 29.4.4: it says that a distant mass feels the orientation of a body only through the combination $\operatorname{tr} I-3I_R$, and therefore exerts on it a torque proportional to the departure of the inertia tensor from a multiple of the identity. A spherical top feels no such torque at all, which is why the precession of the equinoxes measures the Earth's equatorial bulge and nothing else.

29.3 Euler's equations and free rotation

29.3.1 Euler's equations

Theorem 29.25 (Euler's equations)**.** *Referred to the principal axes of a body, and about a point that is either fixed or the centre of mass, the rotational equation of motion* $\mathrm{d}\boldsymbol{L}/\mathrm{d}t=\boldsymbol{\tau}$

reads

$$I_1\dot{\omega}_1 - (I_2 - I_3)\,\omega_2\omega_3 = \tau_1\,, \tag{29.18}$$
$$I_2\dot{\omega}_2 - (I_3 - I_1)\,\omega_3\omega_1 = \tau_2\,, \tag{29.19}$$
$$I_3\dot{\omega}_3 - (I_1 - I_2)\,\omega_1\omega_2 = \tau_3\,, \tag{29.20}$$

where every component is taken along the body axes [32].
Rests on Theorems 29.7 and 29.16 and Postulate 19.22.

Proof. *Derives Theorem 29.25.*

The rotational law of Chapter 19 holds in an inertial frame: $(\mathrm{d}\boldsymbol{L}/\mathrm{d}t)_{\text{space}} = \boldsymbol{\tau}$ (Equation (19.14)). The inertia tensor is constant only in the body frame, so transport the derivative there with Equation (29.4):

$$\left(\frac{\mathrm{d}\boldsymbol{L}}{\mathrm{d}t}\right)_{\text{body}} + \boldsymbol{\omega}\times\boldsymbol{L} = \boldsymbol{\tau}\,. \tag{29.21}$$

From Equations (19.14) and (29.4) (transporting the inertial rotational law into the body frame, where the inertia tensor is constant).

In principal axes $L_i = I_i\omega_i$ with constant I_i (Theorem 29.16), so the first term has components $I_i\dot{\omega}_i$; and $(\boldsymbol{\omega}\times\boldsymbol{L})_1 = \omega_2 L_3 - \omega_3 L_2 = (I_3 - I_2)\,\omega_2\omega_3$, with the other two components obtained by cyclic permutation. Substituting gives Equations (29.18) to (29.20). □

Proposition 29.26 (The two integrals of torque-free motion)**.** *When $\boldsymbol{\tau} = \mathbf{0}$, both the rotational kinetic energy and the magnitude of the angular momentum are conserved:*

$$2T = I_1\omega_1^2 + I_2\omega_2^2 + I_3\omega_3^2\,, \qquad L^2 = I_1^2\omega_1^2 + I_2^2\omega_2^2 + I_3^2\omega_3^2\,, \tag{29.22}$$

both constant. The trajectory in the space of body-frame angular velocities is therefore confined to the intersection of an ellipsoid with a second ellipsoid.
Rests on Theorem 29.25 and Equation (29.12).

Proof. *Derives Proposition 29.26.*

Multiply Equations (29.18) to (29.20) by $\omega_1, \omega_2, \omega_3$ and add: the right-hand side vanishes and the products $(I_2 - I_3)\,\omega_1\omega_2\omega_3$ cancel in pairs, leaving $\mathrm{d}\left(\sum_i I_i\omega_i^2\right)/\mathrm{d}t = 0$. Multiplying instead by $I_1\omega_1, I_2\omega_2, I_3\omega_3$ and adding cancels the same products and leaves $\mathrm{d}\left(\sum_i I_i^2\omega_i^2\right)/\mathrm{d}t = 0$. The second sum is $|\boldsymbol{L}|^2$ by Theorem 29.16. Both statements also follow directly in the inertial frame, where $\boldsymbol{L}$ is constant and $\mathrm{d}T/\mathrm{d}t = \boldsymbol{\omega}\cdot\boldsymbol{\tau}$. □

Remark 29.27 (Euler's equations as a Lie–Poisson system). Equation (29.21) is not a Hamiltonian system on a cotangent bundle: its variables are the three components of $\boldsymbol{L}$, an odd number, and no symplectic form exists on an odd-dimensional space. It is instead a Lie–Poisson system on the dual of $\mathfrak{so}(3)$, with bracket $\{L_i, L_j\} = -\epsilon_{ijk}L_k$ and Hamiltonian $T = \frac{1}{2}\sum_i L_i^2/I_i$; the second integral L^2 of Proposition 29.26 is then not an accident but the Casimir function of that bracket, constant on every trajectory of every Hamiltonian. The structure is developed in Chapter 24 (see Definition 24.40 and Definition 24.37), and it is the reason the torque-free problem is integrable for every body whatever.
Rests on Proposition 29.26 and Definitions 24.37 and 24.40.

29.3.2 The free symmetric top

Proposition 29.28 (Free rotation of a symmetric body)**.** *Let $I_1 = I_2 = A$ and $I_3 = C$, and let $\boldsymbol{\tau} = \mathbf{0}$. Then ω_3 is constant, and:*

1. *Seen from the body, $\boldsymbol{\omega}$ keeps a constant angle with $\hat{\boldsymbol{e}}_3$ and its equatorial part rotates uniformly at*
$$\Omega_{body} = \frac{C - A}{A}\,\omega_3\,. \tag{29.23}$$
2. *Seen from space, $\boldsymbol{\omega}$, $\boldsymbol{L}$ and $\hat{\boldsymbol{e}}_3$ are coplanar at every instant, and both $\boldsymbol{\omega}$ and $\hat{\boldsymbol{e}}_3$ describe cones about the fixed direction $\boldsymbol{L}$ at the rate*
$$\Omega_{space} = \frac{|\boldsymbol{L}|}{A}\,. \tag{29.24}$$

Rests on Theorem 29.25 and Definition 29.18.

Proof. *Derives Proposition 29.28.*

With $I_1 = I_2$ the third of Equation (29.20) reads $C\dot{\omega}_3 = 0$, so ω_3 is constant. The first two become $A\dot{\omega}_1 = (A - C)\,\omega_2\omega_3$ and $A\dot{\omega}_2 = (C - A)\,\omega_3\omega_1$. Setting $\zeta := \omega_1 + \mathrm{i}\omega_2$ combines them into the single equation $\dot{\zeta} = \mathrm{i}\Omega_{\mathrm{body}}\zeta$ with Ω_{body} as in Equation (29.23), whose solution $\zeta = \zeta_0 \mathrm{e}^{\mathrm{i}\Omega_{\mathrm{body}}t}$ has constant modulus: the equatorial part of $\boldsymbol{\omega}$ has fixed length and turns uniformly, which is statement (i).

For (ii), decompose $\boldsymbol{\omega} = \boldsymbol{\omega}_\perp + \omega_3\hat{\boldsymbol{e}}_3$, so that $\boldsymbol{L} = A\boldsymbol{\omega}_\perp + C\omega_3\hat{\boldsymbol{e}}_3$ by Theorem 29.16. Eliminating $\boldsymbol{\omega}_\perp$,
$$\boldsymbol{\omega} = \frac{\boldsymbol{L}}{A} + \left(1 - \frac{C}{A}\right)\omega_3\hat{\boldsymbol{e}}_3\,, \tag{29.25}$$
which exhibits $\boldsymbol{\omega}$ as a combination of $\boldsymbol{L}$ and $\hat{\boldsymbol{e}}_3$ — hence the coplanarity. Since $\hat{\boldsymbol{e}}_3$ is carried by the body, $\mathrm{d}\hat{\boldsymbol{e}}_3/\mathrm{d}t = \boldsymbol{\omega} \times \hat{\boldsymbol{e}}_3$, and substituting Equation (29.25) kills the second term:
$$\frac{\mathrm{d}\hat{\boldsymbol{e}}_3}{\mathrm{d}t} = \frac{\boldsymbol{L}}{A} \times \hat{\boldsymbol{e}}_3\,,$$
which is precisely a rotation of $\hat{\boldsymbol{e}}_3$ about the fixed vector $\boldsymbol{L}$ at the rate $|\boldsymbol{L}|/A$. The angle between $\hat{\boldsymbol{e}}_3$ and $\boldsymbol{L}$ is constant because L_3 and $|\boldsymbol{L}|$ are, so the motion is a cone. □

Both rates matter and they are different. Equation (29.23) is what an observer riding on the body would measure — for the Earth it is the free wobble of Section 29.3.4 — while Equation (29.24) is what an outside observer sees, and for a thrown object it is the visible tumbling. The two cones roll on one another: the *body cone*, traced by $\boldsymbol{\omega}$ about $\hat{\boldsymbol{e}}_3$, rolls without slipping on the *space cone*, traced by $\boldsymbol{\omega}$ about $\boldsymbol{L}$, their common line being the instantaneous axis, whose points are momentarily at rest.

Theorem 29.29 (Poinsot's construction)**.** *In torque-free motion the inertia ellipsoid of the body, carried with it, rolls without slipping on a plane that is fixed in space — the* invariable plane*, perpendicular to $\boldsymbol{L}$ and at the distance $\sqrt{2T}/|\boldsymbol{L}|$ from the fixed point [99].*

Rests on Definition 29.19 and Proposition 29.26.

Proof. *Derives Theorem 29.29.*

Put $\boldsymbol{\rho} := \boldsymbol{\omega}/\sqrt{2T}$. Then $\boldsymbol{\rho} \cdot I\boldsymbol{\rho} = (\boldsymbol{\omega} \cdot I\boldsymbol{\omega})/(2T) = 1$ by Equation (29.12), so $\boldsymbol{\rho}$ lies on the inertia ellipsoid Equation (29.14) at every instant.

The outward normal to the ellipsoid at $\boldsymbol{\rho}$ is the gradient of the quadratic form, $\frac{1}{2}\nabla(\boldsymbol{x} \cdot I\boldsymbol{x}) = I\boldsymbol{\rho} = \boldsymbol{L}/\sqrt{2T}$, which is parallel to $\boldsymbol{L}$ — a direction fixed in space, because the motion is torque-free. The tangent plane at the contact point is therefore perpendicular to $\boldsymbol{L}$ for all time. Its distance from the centre is
$$\boldsymbol{\rho} \cdot \frac{\boldsymbol{L}}{|\boldsymbol{L}|} = \frac{\boldsymbol{\omega} \cdot \boldsymbol{L}}{\sqrt{2T}\,|\boldsymbol{L}|} = \frac{2T}{\sqrt{2T}\,|\boldsymbol{L}|} = \frac{\sqrt{2T}}{|\boldsymbol{L}|}\,,$$
constant by Proposition 29.26. A plane of fixed orientation and fixed distance from a fixed point is a fixed plane.

Finally, the contact point $\boldsymbol{\rho}$ is parallel to $\boldsymbol{\omega}$, so it lies on the instantaneous axis of rotation; by Equation (29.3) its material velocity vanishes. A surface touching a plane at a point of zero velocity rolls without slipping. □

Remark 29.30 (Polhode and herpolhode). The curve traced by the contact point on the ellipsoid is the *polhode*, and the curve it traces on the invariable plane the *herpolhode*. The polhode is closed — it is the intersection of the two ellipsoids of Equation (29.22), rescaled — and it is what makes the whole torque-free motion visible at a glance: for a body whose I_i are all distinct the polhodes encircle the axes of largest and of smallest moment and are separated by two curves crossing at the intermediate axis, which is the geometric form of Phenomenon 29.31 below. The herpolhode need not close, and does not in general, since the two frequencies of the motion are incommensurable.

Rests on Theorem 29.29 and Proposition 29.26.

29.3.3 Stability of rotation about the principal axes

Phenomenon 29.31 (The intermediate-axis instability)**.** A body with three distinct principal moments of inertia, thrown spinning about the axis of largest or of smallest moment, holds that axis steadily; thrown about the intermediate axis it tumbles, flipping end over end at a regular rate however carefully it was launched. The demonstration wants nothing more than a tennis racket, a book held shut, or a mobile telephone, and it works every time — the flipping is not a symptom of an imperfect throw. The same instability decides the fate of tumbling satellites and asteroids: internal dissipation drives a freely rotating body towards spin about the axis of *largest* moment, since that is the state of least kinetic energy at fixed angular momentum [1585, 2027].

Rests on Theorems 29.16 and 29.25.

Derivation. *Derives Phenomenon 29.31.*

Take Euler's torque-free equations in the principal frame (Equation (29.18)),

$$I_1\dot{\omega}_1 = (I_2 - I_3)\,\omega_2\omega_3\,, \qquad \text{and cyclically}\,,$$

and perturb the steady rotation $\boldsymbol{\omega} = (\Omega, 0, 0)$ by writing $\omega_1 = \Omega + \varepsilon_1$, $\omega_2 = \varepsilon_2$ and $\omega_3 = \varepsilon_3$ with the ε_i small. To first order the first equation gives $\dot{\varepsilon}_1 = 0$, and the other two give

$$I_2\dot{\varepsilon}_2 = (I_3 - I_1)\,\Omega\,\varepsilon_3\,, \qquad I_3\dot{\varepsilon}_3 = (I_1 - I_2)\,\Omega\,\varepsilon_2\,.$$

Differentiating the first and substituting the second,

$$\ddot{\varepsilon}_2 = \frac{(I_3 - I_1)\,(I_1 - I_2)}{I_2 I_3}\,\Omega^2\varepsilon_2\,. \tag{29.26}$$

The coefficient on the right is negative — so that ε_2 merely oscillates, and the axis is stable — when I_1 is larger than both of I_2, I_3 or smaller than both; and it is positive — so that ε_2 grows exponentially, and the axis is unstable — exactly when I_1 lies strictly between them. The unstable axis is therefore the intermediate one, and only that one. A body with two equal moments has no intermediate axis and shows no such instability, which is why a symmetric top misbehaves in other ways but never in this one.

The growth rate follows from the same coefficient: writing $\varepsilon_2 \propto \mathrm{e}^{\lambda t}$ about the intermediate axis $I_2 < I_1 < I_3$,

$$\lambda = \Omega\sqrt{\frac{(I_3 - I_1)\,(I_1 - I_2)}{I_2 I_3}}\,, \tag{29.27}$$

which is of the order of the spin rate itself unless two of the moments nearly coincide. That is why the flip is fast, and why it recurs at a regular interval rather than settling: the linearization governs only the departure, and the exact motion returns periodically to the neighbourhood of the intermediate axis, as Remark 29.30 shows geometrically. □

Remark 29.32 (What the linearization is entitled to conclude). The argument just given solves the *linearized* equations and reads off the stability of the full nonlinear system. That step is legitimate here because the linearization is hyperbolic in the unstable case — a real positive exponent Equation (29.27), no zero eigenvalue — but the general theorem licensing it is a statement about systems of ordinary differential equations, not about rigid bodies. Part II's chapter on ordinary differential equations treats the scalar equation and its Wronskian theory but carries neither the constant-coefficient linear *system* $\dot{\boldsymbol{x}} = \mathcal{A}\boldsymbol{x}$ nor Lyapunov's first method; those are owed. In the stable case the conclusion is weaker still and is stated as such: the linearization shows bounded oscillation, and it is Theorem 29.29 and Remark 29.30, which are exact, that show the exact motion stays near the axis.

Rests on Phenomenon 29.31 and Theorem 29.29.

Proposition 29.33 (Dissipation drives a free body to its largest moment)**.** *Among all rotations of a given body with a given angular momentum* $\boldsymbol{L}$*, the rotational kinetic energy*

$$T = \frac{1}{2}\left(\frac{L_1^2}{I_1} + \frac{L_2^2}{I_2} + \frac{L_3^2}{I_3}\right) \tag{29.28}$$

is least when $\boldsymbol{L}$ *lies along the axis of largest moment. A freely rotating body that dissipates energy internally, while conserving* $\boldsymbol{L}$ *because the dissipation is internal, therefore ends in rotation about that axis.*

Rests on Proposition 29.26 and Theorem 29.16.

Proof. *Derives Proposition 29.33.*

Equation (29.28) is Equation (29.12) written in terms of $L_i = I_i\omega_i$. At fixed $L^2 = \sum_i L_i^2$ the right-hand side is a weighted average of the $1/I_i$ with weights L_i^2/L^2 summing to one, so it lies between $L^2/(2I_{\max})$ and $L^2/(2I_{\min})$ and attains the lower bound exactly when all the weight sits on the largest moment. Internal forces exert no external torque (Postulate 19.48), so $\boldsymbol{L}$ is conserved while T decreases; a decreasing quantity bounded below by $L^2/(2I_{\max})$ converges, and the only stationary configurations compatible with the bound are rotations about the axis of largest moment. □

An elongated body set spinning about its long axis — the axis of *smallest* moment — is therefore stable against small perturbations by Phenomenon 29.31 but not against dissipation by Proposition 29.33: it is at a maximum of T at fixed L, and any internal flexing bleeds energy away until it tumbles and then settles into an end-over-end rotation about a transverse axis. This is the fate of a spin-stabilized satellite whose structure is not perfectly rigid, and it is also why small asteroids observed in non-principal-axis rotation are taken to have been disturbed recently. No primary reference is cited here for the satellite history; the mechanical statement is Proposition 29.33 and rests on nothing else.

29.3.4 Free nutation of the Earth: the Chandler wobble

Phenomenon 29.34 (Free nutation of the Earth)**.** The Earth's instantaneous axis of rotation is not fixed within the Earth. The pole traces an irregular, roughly circular path a few metres across on the surface, and that motion contains a free component whose period is near 433 days — some two fifths longer than the 305 days that a *rigid* Earth of the observed dynamical ellipticity would show [2027]. The discrepancy is not an error of measurement. It is the signature of the planet yielding elastically to the centrifugal bulge that its own wobble creates, and the size of the lengthening is therefore a measurement of the rigidity of the Earth's interior, made from the outside.

Rests on Proposition 29.28 and Example 29.23.

Derivation. *Derives Phenomenon 29.34.*

For a rigid symmetric body with equatorial moment A and polar moment C, Euler's torque-free equations (Equation (29.18)) with ω_3 constant read

$$A\dot{\omega}_1 = (A - C)\,\omega_2\omega_3\,, \qquad A\dot{\omega}_2 = (C - A)\,\omega_3\omega_1\,.$$

Setting $\zeta := \omega_1 + \mathrm{i}\omega_2$ combines the two into $\dot{\zeta} = \mathrm{i}\Omega_{\text{free}}\zeta$, so the equatorial part of $\boldsymbol{\omega}$ rotates uniformly within the body at the rate

$$\Omega_{\text{free}} = \frac{C - A}{A}\,\omega_3\,, \tag{29.29}$$

that is, one turn in $A/(C - A)$ rotation periods of the body — which is Equation (29.23) specialized to the Earth. The observed dynamical ellipticity is $H := (C - A)/C = 3.274 \times 10^{-3}$ (Table 29.2), so

$$\frac{A}{C - A} = \frac{1 - H}{H} = 304.5\,,$$

and the rigid prediction is a free wobble of about 305 sidereal days — Euler's number [32], and one that no observation matches. Chandler's analysis of the latitude records gave a free period near 427 days [250], and modern determinations place it near 433 days; the amplitude corresponds to a displacement of the pole of a few metres at the surface.

The elastic correction follows from the same equations once the body is allowed to yield. A wobble tilts the rotation axis to $\boldsymbol{\omega} = \Omega\,(m_1, m_2, 1)$, with $|m|$ of order 5×10^{-7} for a pole displacement of a few metres, and the centrifugal potential energy per unit mass, $\Phi = -\frac{1}{2}\,|\boldsymbol{\omega} \times \boldsymbol{r}|^2$, acquires the perturbation

$$\delta\Phi = \Omega^2 z\,(m_1 x + m_2 y)\,, \tag{29.30}$$

in J/kg: a second-degree harmonic of the same shape as a tide, raised by the wobble itself. The Earth responds to it elastically, and Love's number k_2 is defined as the ratio of the extra gravitational potential the deformation produces at the surface to the potential that provoked it [376]. By Equation (29.17) the orientation-dependent part of the external potential of a body is carried entirely by its inertia tensor, and the part of it belonging to the products of inertia c_{13}, c_{23} is $3G\,(c_{13}xz + c_{23}yz)/r^5$. Equating that at $r = a_\oplus$ to $k_2\,\delta\Phi$ gives

$$c_{13} + \mathrm{i}c_{23} = \kappa\,(m_1 + \mathrm{i}m_2)\,, \qquad \kappa := \frac{k_2\,a_\oplus^5\,\Omega^2}{3G}\,, \tag{29.31}$$

with κ carrying $\mathrm{kg\,m^2}$, as an increment of inertia must.

Now redo the free-wobble calculation with $I = I_0 + c$. Angular momentum is conserved in space, so by Equation (29.4) its body components obey $\dot{\boldsymbol{L}} + \boldsymbol{\omega} \times \boldsymbol{L} = \boldsymbol{0}$, and to first order in m and in c one has $L_1 = \Omega\,(Am_1 + c_{13})$, $L_2 = \Omega\,(Am_2 + c_{23})$ and $L_3 = C\Omega$. Writing $m := m_1 + \mathrm{i}m_2$ and combining the first two components as before,

$$(A + \kappa)\,\dot{m} = \mathrm{i}\Omega\,(C - A - \kappa)\,m\,, \tag{29.32}$$

so the free wobble is still circular, but at the rate

$$\Omega_{\text{Ch}} = \Omega\,\frac{C - A - \kappa}{A + \kappa} \simeq \Omega\,\frac{C - A}{A}\left(1 - \frac{k_2}{k_{\text{s}}}\right), \qquad k_{\text{s}} := \frac{3G\,(C - A)}{a_\oplus^5\,\Omega^2}\,, \tag{29.33}$$

From Equations (29.31) and (29.32) (the elastic increment enters only through the ratio of Love numbers).

the approximation using $\kappa/A \sim 1 \times 10^{-3}$. The dimensionless k_{s} is the Love number a body would have if it yielded until its whole bulge were centrifugal; from Table 29.2, with $C - A = HC = 2.629 \times 10^{35}\,\mathrm{kg\,m^2}$ and $a_\oplus^5 = 1.0556 \times 10^{34}\,\mathrm{m^5}$, it is $k_{\text{s}} = 0.938$.

Equation (29.33) therefore lengthens the period by the factor $(1 - k_2/k_s)^{-1}$, and the observed lengthening from 304.5 to 433 days inverts to

$$k_2 = k_s \left(1 - \frac{304.5}{433}\right) = 0.28\,, \tag{29.34}$$

which is the measurement the phenomenon promised: one number describing how far the whole planet yields, read off a period. It is of the size of, and a little below, the degree-two Love number near 0.30 that Earth-tide observations give—no source is cited here for that comparison value—and the difference is where the fluid outer core, which does not follow the mantle's wobble, and the ocean pole tide enter. Neither is in this calculation. Neither is the damping: the observed wobble decays in a few decades and must therefore be re-excited continually, by some redistribution of mass among the atmosphere, the oceans and the solid Earth. Which of those dominates is a question this treatise does not settle. □

The mechanism was identified by Newcomb within a year of Chandler's announcement [254]: a wobbling Earth deforms under the centrifugal field of its own wobble, and the deformation carries part of the equatorial bulge along with the instantaneous pole, so that the effective $C - A$ opposing the motion is smaller than the static one and the period is correspondingly longer. Equation (29.33) is that argument made quantitative, and it deliberately hides the whole interior in a single number: k_2 is what one gets by refusing to model the planet and asking only how much its external field yields. Computing k_2 from a density and a rigidity profile, rather than reading it off a period, is elastostatics and belongs to Chapter 30. What the observation delivers without any of that is a bulk measurement of the rigidity of the mantle that no laboratory sample can provide.

29.4 The heavy top

29.4.1 The Lagrange top

Definition 29.35 (The Lagrange top)**.** A *Lagrange top* is a symmetric rigid body, $I_1 = I_2 = A$ and $I_3 = C$ about a *fixed point* on its symmetry axis, with its centre of mass a distance ℓ from that point along the same axis, moving under uniform gravity $\boldsymbol{g}$. In the Euler angles of Notation 29.9, with the space z axis vertical, its Lagrangian is

$$\mathcal{L} = \frac{A}{2}\left(\dot\theta^2 + \dot\varphi^2 \sin^2\theta\right) + \frac{C}{2}\left(\dot\psi + \dot\varphi\cos\theta\right)^2 - Mg\ell\cos\theta\,. \tag{29.35}$$

Rests on Proposition 29.11, Definition 21.31, and Theorem 29.16.

The kinetic term is Equation (29.12) in principal axes with $\omega_1^2 + \omega_2^2 = \dot\theta^2 + \dot\varphi^2\sin^2\theta$ and $\omega_3 = \dot\psi + \dot\varphi\cos\theta$, both read off Equations (29.7) to (29.9); the potential is Mgz_{cm} with $z_{\mathrm{cm}} = \ell\cos\theta$. The moments A and C are taken about the fixed point, so A already contains the $M\ell^2$ of Theorem 29.20.

Proposition 29.36 (Three first integrals)**.** *The Lagrange top conserves*

$$p_\psi = C\left(\dot\psi + \dot\varphi\cos\theta\right) = C\omega_3 =: L_3\,, \tag{29.36}$$

$$p_\varphi = A\dot\varphi\sin^2\theta + L_3\cos\theta =: L_z\,, \tag{29.37}$$

$$E = \frac{A}{2}\left(\dot\theta^2 + \dot\varphi^2\sin^2\theta\right) + \frac{L_3^2}{2C} + Mg\ell\cos\theta\,. \tag{29.38}$$

The first two are the components of the angular momentum along the body symmetry axis and along the vertical.

Rests on Equation (29.35) and Theorems 21.36 and 21.43.

Proof. *Derives Proposition 29.36.*

Neither ψ nor φ appears in Equation (29.35): both are cyclic (Definition 21.35), so their conjugate momenta are conserved by Theorem 21.36. Computing them from Equation (29.35) gives Equations (29.36) and (29.37). The Lagrangian has no explicit time dependence, so the energy function of Theorem 21.43 is conserved, and since the kinetic term is quadratic in the velocities it equals $T + V$, which is Equation (29.38). That p_ψ and p_φ are the stated components of $\boldsymbol{L}$ follows because ψ generates rotation about $\hat{\boldsymbol{e}}_3$ and φ rotation about $\hat{\boldsymbol{z}}$. □

Theorem 29.37 (Reduction to one degree of freedom)**.** *Write $u := \cos\theta$ and set*

$$a := \frac{L_3}{A}\,, \qquad b := \frac{L_z}{A}\,, \qquad \alpha := \frac{2}{A}\left(E - \frac{L_3^2}{2C}\right), \qquad \beta := \frac{2Mg\ell}{A}\,.$$

Then the motion of the axis obeys

$$\dot{u}^2 = \left(1 - u^2\right)(\alpha - \beta u) - (b - au)^2 =: f(u)\,, \tag{29.39}$$

a cubic in u with $f(\pm 1) = -(b \mp a)^2 \le 0$ and $f \to +\infty$ as $u \to +\infty$. Except in degenerate cases f has exactly two roots $u_1 \le u_2$ in $[-1, 1]$, and the axis nutates periodically between the corresponding polar angles $\theta_2 \le \theta \le \theta_1$, while

$$\dot{\varphi} = \frac{b - au}{1 - u^2}\,, \qquad \dot{\psi} = \frac{L_3}{C} - \frac{u\,(b - au)}{1 - u^2}\,. \tag{29.40}$$

The solution is reduced to the quadrature $t = \int \mathrm{d}u/\sqrt{f(u)}$.

Rests on Proposition 29.36 and Theorem 7.23.

Proof. *Derives Theorem 29.37.*

Solve Equation (29.37) for $\dot{\varphi}$, obtaining the first of Equation (29.40), and Equation (29.36) for $\dot{\psi}$, obtaining the second. Substituting the first into Equation (29.38) and using $\dot{u} = -\sin\theta\,\dot{\theta}$, so that $\dot{u}^2 = (1 - u^2)\,\dot{\theta}^2$, gives

$$\frac{\dot{u}^2}{1 - u^2} + \frac{(b - au)^2}{1 - u^2} = \alpha - \beta u\,,$$

which rearranges to Equation (29.39). Evaluating f at $u = \pm 1$ kills the first product and leaves $-(b \mp a)^2$, which is negative unless the axis reaches the vertical. Since f is a cubic with positive leading coefficient $\beta > 0$, it tends to $+\infty$ at large u; and physical motion requires $f \ge 0$, which the initial condition supplies at some $u_0 \in (-1, 1)$. The intermediate value theorem (Theorem 7.23) then places a root in $(u_0, 1)$ and another in $(-1, u_0)$, and a cubic has no more than three roots, the third lying above 1 and being unphysical. Between the two roots $\dot{u}^2 > 0$, and the motion runs from one to the other and back, periodically, because Equation (29.39) is autonomous and $\dot{u}$ changes sign only at the roots. □

Phenomenon 29.38 (Nutation of a released top)**.** A rapidly spinning top, held with its axis at an angle to the vertical and then released from rest, does not begin to precess smoothly. Its axis first dips, then rises again to the height it started from, and meanwhile it swings around the vertical; the tip of the axis traces a succession of cusps hanging below the circle of release. The dip and the swing are fast and small compared with the mean progress around the vertical, and the faster the top spins the smaller the dip and the quicker the flutter, until the eye no longer resolves it and the motion looks like the smooth precession of Phenomenon 29.46 [2027].

Rests on Theorem 29.37 and Proposition 29.36.

Derivation. *Derives Phenomenon 29.38.*

Release from rest at θ_0 means $\dot\theta = \dot\varphi = 0$ there, so Equation (29.37) gives $b = au_0$ with $u_0 = \cos\theta_0$, and $f(u_0) = 0$ in Equation (29.39) forces $\alpha = \beta u_0$. Writing $u = u_0 + x$ with x small, $b - au = -ax$ and $\alpha - \beta u = -\beta x$, so

$$\dot x^2 = -\beta\left(1 - u_0^2\right)x - a^2x^2 + O\left(x^3\right). \tag{29.41}$$

Differentiating once, $\ddot x = -a^2x - \frac{1}{2}\beta\sin^2\theta_0$: the variable x performs simple harmonic motion at the angular frequency

$$\omega_{\text{nut}} = a = \frac{C\omega_3}{A}, \tag{29.42}$$

about the displaced centre $x = -\beta\sin^2\theta_0/(2a^2)$, with amplitude equal to that displacement. Since x starts at zero and must be negative for Equation (29.41) to be positive, u decreases and θ increases: the top falls first. Converting the full swing in u to an angle through $\Delta u = \sin\theta_0\Delta\theta$,

$$\Delta\theta = \frac{\beta\sin\theta_0}{a^2} = \frac{2AMg\ell\sin\theta_0}{C^2\omega_3^2}, \tag{29.43}$$

which falls off as the inverse square of the spin.

The precession follows from the first of Equation (29.40): $\dot\varphi = -ax/(1-u^2)$, which vanishes exactly where $x = 0$ — at the top of each nutation swing. There the axis is momentarily at rest in both angles, which is the cusp. Averaging over one nutation period, $\langle -x\rangle$ is the centre offset $\beta\sin^2\theta_0/(2a^2)$, so

$$\langle\dot\varphi\rangle = \frac{a}{\sin^2\theta_0}\cdot\frac{\beta\sin^2\theta_0}{2a^2} = \frac{\beta}{2a} = \frac{Mg\ell}{C\omega_3}, \tag{29.44}$$

which is exactly the fast-top rate Equation (29.55) derived independently below. The two calculations agreeing is the check that the smooth precession of Phenomenon 29.46 is the nutation-averaged motion and not a different phenomenon. □

Proposition 29.39 (Steady precession)**.** *A Lagrange top can precess at constant θ and constant $\dot\varphi = \Omega$ provided*

$$A\Omega^2\cos\theta - C\omega_3\Omega + Mg\ell = 0, \qquad \textit{that is} \qquad \Omega_\pm = \frac{C\omega_3 \pm \sqrt{C^2\omega_3^2 - 4AMg\ell\cos\theta}}{2A\cos\theta}. \tag{29.45}$$

For $\theta < \pi/2$ this requires $C^2\omega_3^2 \geq 4AMg\ell\cos\theta$: below that spin no steady precession at the given inclination exists at all. The slow root reduces to $Mg\ell/(C\omega_3)$ when the spin is large.

Rests on Equation (29.35) and Theorem 16.22.

Proof. *Derives Proposition 29.39.*

The Euler–Lagrange equation (Theorem 16.22) for θ applied to Equation (29.35) is

$$A\ddot\theta = A\dot\varphi^2\sin\theta\cos\theta - C\omega_3\dot\varphi\sin\theta + Mg\ell\sin\theta,$$

using $\omega_3 = \dot\psi + \dot\varphi\cos\theta$ from Equation (29.9). Setting $\ddot\theta = 0$, $\dot\varphi = \Omega$ and $\sin\theta \neq 0$ gives the quadratic in Equation (29.45), whose roots are as stated. Reality of the roots is the discriminant condition. For $C\omega_3 \gg \sqrt{AMg\ell}$, expanding the square root to first order gives $\Omega_- \to Mg\ell/(C\omega_3)$ and $\Omega_+ \to C\omega_3/(A\cos\theta)$. □

Proposition 29.40 (The sleeping top)**.** *A top spinning about the exact vertical, $\theta = 0$, is stable against small disturbances if and only if*

$$C^2\omega_3^2 > 4AMg\ell. \tag{29.46}$$

Above that spin the top "sleeps", standing apparently motionless; below it, the vertical position is unstable and the top falls away. Friction slowly reduces ω_3, so a sleeping top wakes when Equation (29.46) fails, and does so abruptly.

Rests on Theorem 29.37 and Proposition 29.36.

Proof. *Derives Proposition 29.40.*

At $\theta = 0$ the two conserved momenta coincide, $L_z = L_3$, since Equation (29.37) at $\sin\theta = 0$ gives $L_z = L_3 \cos 0$. Eliminating $\dot\varphi$ from Equation (29.38) with Equation (29.40) puts the energy in the one-dimensional form $E' = \tfrac{1}{2}A\dot\theta^2 + V_{\text{eff}}(\theta)$ (Definition 27.25) with

$$V_{\text{eff}}(\theta) = \frac{(L_z - L_3\cos\theta)^2}{2A\sin^2\theta} + Mg\ell\cos\theta\,. \tag{29.47}$$

With $L_z = L_3$ the first term is $(L_3^2/2A)\,(1-\cos\theta)\,/\,(1+\cos\theta)$, which for small θ is $L_3^2\theta^2/(8A)$; and $Mg\ell\cos\theta = Mg\ell - Mg\ell\theta^2/2 + O(\theta^4)$. Hence

$$V_{\text{eff}}(\theta) = Mg\ell + \left(\frac{L_3^2}{8A} - \frac{Mg\ell}{2}\right)\theta^2 + O\!\left(\theta^4\right)\,,$$

so $\theta = 0$ is a minimum — and the motion in θ is bounded near it — exactly when $L_3^2 > 4AMg\ell$, which with $L_3 = C\omega_3$ is Equation (29.46). When the coefficient is negative the effective potential falls away from $\theta = 0$ and no bounded motion near the vertical exists. □

Example 29.41 (A toy gyroscope, in numbers)**.** Take a uniform disc of mass $M = 0.100\,\text{kg}$ and radius $R = 0.0300\,\text{m}$ mounted on a light spindle and pivoted at $\ell = 0.0500\,\text{m}$ from its centre, spinning at 50.0/s, that is $\omega_3 = 314\,\text{rad/s}$. From Table 29.1 and Theorem 29.20,

$$C = \tfrac{1}{2}MR^2 = 4.50\times10^{-5}\,\text{kg m}^2\,, \qquad A = \tfrac{1}{4}MR^2 + M\ell^2 = 2.725\times10^{-4}\,\text{kg m}^2\,,$$

and $Mg\ell = 4.905\times10^{-2}\,\text{N m}$ with $g = 9.81\,\text{m/s}^2$. Then:

- the sleeping criterion Equation (29.46) is met with $C^2\omega_3^2/(4AMg\ell) = 3.74$, so this top would stand upright;
- the fast-top precession rate Equation (29.55) is $Mg\ell/(C\omega_3) = 3.47\,\text{rad/s}$, one turn in 1.81 s;
- at $\theta = 60°$ the exact slow root of Equation (29.45) is 3.59 rad/s, so the fast-top formula is low by 3.5 %, and the fast root is 100 rad/s;
- the nutation frequency Equation (29.42) is $C\omega_3/A = 51.9\,\text{rad/s}$, a period of 0.121 s, and the nutation amplitude Equation (29.43) on release at 60° is 0.116 rad, about 6.6°.

The separation of scales that makes Equation (29.55) useful is visible in the last two entries: the flutter is fifteen times faster than the precession and a few degrees wide, which is exactly what one sees.

Rests on Equations (29.43), (29.45) and (29.55).

Remark 29.42 (The closed form, and the mathematics it needs). The quadrature $t = \int \mathrm{d}u/\sqrt{f(u)}$ of Theorem 29.37 can be carried further. Because f is a cubic, the affine substitution that carries its three roots to 0, 1 and $1/k^2$ puts the integral in Legendre's normal form, so that $u = \cos\theta$ is a Jacobi elliptic function of the time; the nutation period $2\int_{u_1}^{u_2}\mathrm{d}u/\sqrt{f(u)}$ is then a complete elliptic integral of the first kind built on the same roots, and the two degenerate cases in which a pair of roots coalesce return steady precession Equation (29.45) and the sleeping top Equation (29.46).

That is a statement about the integral, and it is recorded here and used nowhere. Elliptic integrals and the Jacobi elliptic functions are not developed anywhere in this treatise—the same absence stops Remark 28.66 at the exact period of the finite-amplitude pendulum—so this chapter asserts nothing whose establishment would need the inversion. The nutation frequency Equation (29.42), the nutation amplitude Equation (29.43), the mean precession Equation (29.44), the steady-precession roots Equation (29.45) and the sleeping-top condition Equation (29.46) were all obtained from Equation (29.39) directly, without ever solving it.

Rests on Theorem 29.37 and Remark 28.66.

29.4.2 Integrable cases and the Kovalevskaya top

The heavy top with a fixed point has three degrees of freedom and always possesses three integrals of motion: the energy, the vertical component L_z of the angular momentum, and the trivial $|\boldsymbol{\gamma}| = 1$, where $\boldsymbol{\gamma}$ denotes the upward vertical resolved along the body axes. Complete integrability requires one more. Exactly three families of bodies supply it for arbitrary initial conditions.

Proposition 29.43 (The three integrable heavy tops)**.** *The heavy top with a fixed point admits a fourth independent integral, for all initial data, in the following three cases and — as Kovalevskaya's analysis of the singularity structure of the solutions established — in no others:*

1. *the* Euler case *[32]: the fixed point is the centre of mass, $\ell = 0$, so the motion is torque-free and the fourth integral is $|\boldsymbol{L}|^2$ of Proposition 29.26;*
2. *the* Lagrange case *[40]: $I_1 = I_2$ with the centre of mass on the symmetry axis, and the fourth integral is $L_3 = C\omega_3$ of Equation (29.36);*
3. *the* Kovalevskaya case *[243]: $I_1 = I_2 = 2I_3$ with the centre of mass in the plane of the two equal moments, and the fourth integral is quartic in the angular velocities.*

Rests on Propositions 29.26 and 29.36.

Proof. *Derives Proposition 29.43.*

Cases (i) and (ii) are read off the results already proved: Proposition 29.26 supplies $|\boldsymbol{L}|^2$ when the torque vanishes, and Proposition 29.36 supplies L_3 when the body is symmetric about the axis carrying the centre of mass. The existence of the fourth integral in case (iii), and the completeness of the list, are Kovalevskaya's and are not reproved here; the fourth integral itself is quoted in Remark 29.44. □

Remark 29.44 (The Kovalevskaya integral). With $I_1 = I_2 = 2I_3$, the centre of mass at distance ℓ from the fixed point along the body 1 axis, and $\boldsymbol{\gamma}$ the upward vertical resolved along the body axes, the conserved quantity Kovalevskaya found is

$$K = \left| (\omega_1 + \mathrm{i}\omega_2)^2 + c_0\,(\gamma_1 + \mathrm{i}\gamma_2) \right|^2 , \qquad c_0 = \frac{Mg\ell}{I_3} , \tag{29.48}$$

whose two factors have the same SI dimension, $1/\mathrm{s}^2$, as they must. The sign of c_0 follows the orientation chosen for the body axes and must be fixed before the expression is used.

Rests on Proposition 29.43.

Proof. *Derives Equation (29.48).*

Write $I_3 =: I$, so that $I_1 = I_2 = 2I$. Keep $\boldsymbol{\gamma}$ the upward vertical, and orient the body 1 axis from the centre of mass towards the fixed point, so that the centre of mass sits at $-\ell\hat{\boldsymbol{e}}_1$ and the gravitational torque about the fixed point is $\boldsymbol{\tau} = (-\ell\hat{\boldsymbol{e}}_1) \times (-Mg\boldsymbol{\gamma}) = Mg\ell\,\hat{\boldsymbol{e}}_1 \times \boldsymbol{\gamma} = Mg\ell\,(0, -\gamma_3, \gamma_2)$. That is the convention of the remark; reversing $\hat{\boldsymbol{e}}_1$ reverses

the torque and with it the sign of c_0, which is the freedom recorded there. Euler's equations Equations (29.18) to (29.20) then read

$$\dot{\omega}_1 = \tfrac{1}{2}\omega_2\omega_3\,, \qquad \dot{\omega}_2 = -\tfrac{1}{2}\omega_3\omega_1 - \tfrac{1}{2}c_0\gamma_3\,, \qquad \dot{\omega}_3 = c_0\gamma_2\,, \tag{29.49}$$

with $c_0 = Mg\ell/I$. The vertical is fixed in space, so Equation (29.4) applied to $\boldsymbol{\gamma}$ gives its body components as

$$\dot{\boldsymbol{\gamma}} = \boldsymbol{\gamma} \times \boldsymbol{\omega}\,. \tag{29.50}$$

Set $\zeta := \omega_1 + \mathrm{i}\omega_2$ and $\eta := \gamma_1 + \mathrm{i}\gamma_2$. Combining the first two components of Equation (29.49), and then of Equation (29.50),

$$\dot{\zeta} = -\tfrac{\mathrm{i}}{2}\omega_3\zeta - \tfrac{\mathrm{i}}{2}c_0\gamma_3\,, \tag{29.51}$$

$$\dot{\eta} = -\mathrm{i}\omega_3\eta + \mathrm{i}\gamma_3\zeta\,. \tag{29.52}$$

Now differentiate $\xi := \zeta^2 + c_0\eta$:

$$\dot{\xi} = 2\zeta\dot{\zeta} + c_0\dot{\eta} = -\mathrm{i}\omega_3\zeta^2 - \mathrm{i}c_0\gamma_3\zeta - \mathrm{i}c_0\omega_3\eta + \mathrm{i}c_0\gamma_3\zeta = -\mathrm{i}\omega_3\,\xi\,. \tag{29.53}$$

From Equations (29.51) and (29.52) (the two terms carrying γ_3 cancel identically).

The coefficient is purely imaginary, so $\mathrm{d}\,|\xi|^2/\mathrm{d}t = \bar{\xi}\dot{\xi} + \xi\bar{\dot{\xi}} = -\mathrm{i}\omega_3\,|\xi|^2 + \mathrm{i}\omega_3\,|\xi|^2 = 0$, and $K = |\xi|^2$ of Equation (29.48) is conserved.

The ratio of the moments is exactly what makes the cancellation happen. Repeat the calculation with $I_1 = I_2 = A$ and $I_3 = C$ arbitrary, the centre of mass still on the body 1 axis. Euler's equations now give $\dot{\zeta} = \mathrm{i}k\,\omega_3\zeta - \mathrm{i}\,(Mg\ell/A)\,\gamma_3$ with $k := (C-A)/A$, while Equation (29.50) is unchanged. For a trial quantity $\xi = \zeta^n + \lambda\eta$,

$$\dot{\xi} = \mathrm{i}nk\,\omega_3\zeta^n - \mathrm{i}n\frac{Mg\ell}{A}\gamma_3\zeta^{n-1} - \mathrm{i}\lambda\omega_3\eta + \mathrm{i}\lambda\gamma_3\zeta\,. \tag{29.54}$$

The two terms in γ_3 cancel for no choice of λ unless $n = 2$, and then only for $\lambda = 2Mg\ell/A$. What survives, $\mathrm{i}\omega_3\,(2k\zeta^2 - \lambda\eta)$, is proportional to $\xi = \zeta^2 + \lambda\eta$ only if $2k = -1$, that is only if $A = 2C$; and then $\lambda = 2Mg\ell/(2C) = Mg\ell/I_3 = c_0$. So the quantity displayed in Equation (29.48) is conserved precisely when $I_1 = I_2 = 2I_3$, which is what singles the Kovalevskaya case out. That no *other* fourth integral exists for other ratios is Kovalevskaya's own theorem [243] and is not proved here. □

Remark 29.45 (What integrability buys, and where it stops). For each of the three cases the four integrals are in involution and the machinery of Chapter 23 applies: the motion is confined to a torus and can be written in action–angle variables (Definition 23.28), so the long-time behaviour is quasi-periodic and predictable indefinitely. A heavy top that is not of one of these three kinds has no such description. Its trajectories are not confined to tori, they are sensitive to initial conditions in the sense of Chapter 32, and no closed-form solution exists — which is the general situation, the three integrable cases being exceptional.

Rests on Proposition 29.43 and Definition 23.28.

29.4.3 Gyroscopes

Phenomenon 29.46 (A fast spinning top does not fall)**.** Set a top spinning rapidly and tilt its axis away from the vertical: it does not topple. Its axis instead sweeps out a cone about the vertical at a slow and steady rate, moving at right angles to the direction in which gravity is pulling it. A spinning bicycle wheel held by one end of its axle behaves the same way, and pushes back sideways against the hand that tries to tilt it. The rate of the sweep is inversely proportional to the spin — the faster the top turns, the slower it precesses and the more nearly it appears simply to stand — and, to the accuracy of the observation, it does not depend on how far the axis is tilted [2027].

Rests on Theorem 29.25 and Equation (19.14).

Derivation. *Derives Phenomenon 29.46.*

Let the top be symmetric, spinning at ω_3 about its own axis $\hat{\boldsymbol{e}}_3$, and supported at a point a distance ℓ from its centre of mass along that axis. In the fast-top limit the angular momentum is dominated by the spin, $\boldsymbol{L} \simeq I_3\omega_3\hat{\boldsymbol{e}}_3$. About the support the weight exerts the torque

$$\boldsymbol{\tau} = \ell\,\hat{\boldsymbol{e}}_3 \times M\boldsymbol{g}\,, \qquad |\boldsymbol{\tau}| = Mg\ell\sin\theta\,,$$

with θ the tilt from the vertical. This torque is perpendicular to $\hat{\boldsymbol{e}}_3$ and hence to $\boldsymbol{L}$, so by $\frac{\mathrm{d}\boldsymbol{L}}{\mathrm{d}t} = \boldsymbol{\tau}$ it can turn $\boldsymbol{L}$ but cannot lengthen or shorten it — which is the whole reason the top turns instead of falling. Writing the motion of the axis as a rotation about the vertical at rate Ω, the tip of $\boldsymbol{L}$ travels on a circle of radius $I_3\omega_3\sin\theta$ at speed $\Omega I_3\omega_3\sin\theta$; equating this to $|\boldsymbol{\tau}|$, the factor $\sin\theta$ cancels and

$$\Omega = \frac{Mg\ell}{I_3\omega_3}\,, \tag{29.55}$$

independent of the tilt and inversely proportional to the spin, as observed. The one approximation made was to neglect the angular momentum of the precession itself beside that of the spin, which is what "fast" means; releasing it produces the superposed nutation of Phenomenon 29.38, and Equation (29.44) shows that averaging that nutation returns Equation (29.55) exactly. □

Foucault gave the instrument its name and exhibited it, in 1852, as a second mechanical proof of the Earth's rotation, complementary to the pendulum of the year before [136]: a pendulum keeps its plane against a rotating frame, and a spinning body keeps its axis. The next proposition is the quantitative form of that claim, and it is the principle of the gyrocompass.

Proposition 29.47 (The gyrocompass)**.** *A symmetric rotor spinning at ω_3, whose axis is constrained to remain horizontal but is free in azimuth, is stable with its spin axis pointing north, and oscillates about that direction at the angular frequency*

$$\omega_{gc} = \sqrt{\frac{C\omega_3\,\Omega\cos\lambda}{A}}\,, \tag{29.56}$$

with Ω the Earth's sidereal angular velocity and λ the latitude. The instrument therefore finds true north without magnetism and without sight of the sky, and it fails at the poles, where $\cos\lambda = 0$ [2027].

Rests on Theorem 29.7 and Equation (29.11).

Proof. *Derives Proposition 29.47.*

Use local axes at latitude λ with x east, y north and z up, in which the Earth's angular velocity is $\boldsymbol{\Omega} = \Omega\,(0, \cos\lambda, \sin\lambda)$. Let α be the azimuth of the spin axis measured from north towards east, so that $\hat{\boldsymbol{e}} = (\sin\alpha, \cos\alpha, 0)$. A rotation carrying north into east is a rotation by $-\alpha$ about $\hat{\boldsymbol{z}}$, so the slew contributes $-A\dot{\alpha}\hat{\boldsymbol{z}}$ to the angular momentum and

$$\boldsymbol{L} = C\omega_3\hat{\boldsymbol{e}} - A\dot{\alpha}\hat{\boldsymbol{z}}\,.$$

Apply Equation (29.4) in the frame rotating with the Earth: $(\mathrm{d}\boldsymbol{L}/\mathrm{d}t)_{\text{Earth}} + \boldsymbol{\Omega}\times\boldsymbol{L} = \boldsymbol{\tau}$. The rotor is balanced, so gravity exerts no torque about the support; the constraint that keeps the axis horizontal acts about a horizontal axis and so has no vertical component. Taking the vertical component of the equation,

$$-A\ddot{\alpha} + (\boldsymbol{\Omega}\times\boldsymbol{L})_z = 0\,, \qquad (\boldsymbol{\Omega}\times\boldsymbol{L})_z = \Omega_x L_y - \Omega_y L_x = -\Omega\cos\lambda\, C\omega_3\sin\alpha\,,$$

whence $A\ddot{\alpha} = -C\omega_3\Omega\cos\lambda\sin\alpha$. This is the pendulum equation with $\alpha = 0$ — the spin axis pointing north — as the stable equilibrium, and linearizing about it gives Equation (29.56). At $\cos\lambda = 0$ the restoring term vanishes identically and no direction is preferred. □

Example 29.48 (Order of magnitude of the gyrocompass period)**.** For a disc rotor, $C/A = 2$. Taking a spin of 100/s, that is $\omega_3 = 628\,\mathrm{rad/s}$, at latitude 45° with $\Omega = 7.292 \times 10^{-5}/\mathrm{s}$, Equation (29.56) gives $\omega_{\mathrm{gc}} = 0.255\,\mathrm{rad/s}$, a period of about 25 s. The result is a genuine consequence of the idealization stated in Proposition 29.47 — an axis held exactly horizontal and free in azimuth — and practical instruments differ from it, being made north-seeking by a pendulous suspension and deliberately damped and detuned; no engineering source is cited here for those refinements.

Rests on Equation (29.56).

29.4.4 Precession of the equinoxes and astronomical nutation

Table 29.2: Values adopted for the calculations of Sections 29.3.4, 29.4.4 and 29.5.3. These are the conventional astronomical and geodetic values; no primary reference is cited for them in this treatise, and each is quoted to the precision actually used below rather than to the precision at which it is known. The gravitational constant itself is CODATA 2018, $G = (6.674\,30 \pm 0.000\,15) \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$ [2392], and enters only through the products GM, which are known far better than G and M separately.

Quantity	Symbol	Value
Earth sidereal angular velocity	Ω	$7.292\,12 \times 10^{-5}/\mathrm{s}$
Earth equatorial radius	$a_\oplus$	$6.3781 \times 10^{6}\,\mathrm{m}$
Earth mass	$M_\oplus$	$5.9722 \times 10^{24}\,\mathrm{kg}$
Earth polar moment of inertia	C	$8.03 \times 10^{37}\,\mathrm{kg\,m^2}$
Earth dynamical ellipticity $(C-A)/C$	H	3.2738×10^{-3}
Obliquity of the ecliptic	ε	23.4393°
Heliocentric gravitational constant	$GM_\odot$	$1.327\,12 \times 10^{20}\,\mathrm{m^3/s^2}$
Lunar gravitational constant	GM_{M}	$4.9028 \times 10^{12}\,\mathrm{m^3/s^2}$
Earth orbital semi-major axis	$a_\odot$	$1.495\,98 \times 10^{11}\,\mathrm{m}$
Lunar orbital semi-major axis	a_{M}	$3.8440 \times 10^{8}\,\mathrm{m}$
Inclination of the lunar orbit to the ecliptic	i	5.145°

Phenomenon 29.49 (Precession of the equinoxes)**.** The Earth's axis of rotation is not fixed among the stars. It describes a cone about the pole of the ecliptic whose half-angle is the obliquity, about 23.4°, carrying the equinoctial points westward along the ecliptic by roughly fifty seconds of arc a year and completing one circuit in about $2.6 \times 10^4\,\mathrm{yr}$. Hipparchus detected the drift in the second century BC by comparing his own star positions with earlier ones, and it is why the pole star changes over historical time and why the zodiacal signs no longer coincide with the constellations that named them. Newton identified the cause: the gravitational torque exerted by the Moon and the Sun upon the Earth's equatorial bulge, so that the planet is a very slow and very large version of Phenomenon 29.46 [14]. The modern value of the drift is 50.29 seconds of arc a year, corresponding to a period of $2.577 \times 10^4\,\mathrm{yr}$.

Rests on Proposition 29.24 and Phenomenon 29.46.

Derivation. *Derives Phenomenon 29.49.*

Treat the Earth as a symmetric top with moments $A = B$ and C and symmetry axis $\hat{\boldsymbol{e}}_3$, and a perturber of mass M on a circular orbit of radius r in a plane with unit normal $\hat{\boldsymbol{n}}$. By Proposition 29.24 the orientation dependence of the potential energy is

$$U_{\mathrm{or}} = \frac{GM\,(C-A)}{2r^3}\left(3\,(\hat{\boldsymbol{e}}_3 \cdot \hat{\boldsymbol{r}})^2 - 1\right), \tag{29.57}$$

since for a symmetric top $\operatorname{tr} I - 3I_r = (C-A)\,(1-3\cos^2\Theta)$ with $\cos\Theta = \hat{\boldsymbol{e}}_3\cdot\hat{\boldsymbol{r}}$. The torque on the Earth is minus the rotational gradient of Equation (29.57),

$$\boldsymbol{\tau} = -\hat{\boldsymbol{e}}_3 \times \frac{\partial U_{\text{or}}}{\partial \hat{\boldsymbol{e}}_3} = -\frac{3GM\,(C-A)}{r^3}\,(\hat{\boldsymbol{e}}_3\cdot\hat{\boldsymbol{r}})\,(\hat{\boldsymbol{e}}_3\times\hat{\boldsymbol{r}})\ . \tag{29.58}$$

Now average over one orbit. Let $\hat{\boldsymbol{e}}_3 = \cos\varepsilon\,\hat{\boldsymbol{n}} + \sin\varepsilon\,\hat{\boldsymbol{u}}$ with $\hat{\boldsymbol{u}}$ in the orbit plane, and $\hat{\boldsymbol{v}} = \hat{\boldsymbol{n}}\times\hat{\boldsymbol{u}}$, and write $\hat{\boldsymbol{r}} = \cos\phi\,\hat{\boldsymbol{u}} + \sin\phi\,\hat{\boldsymbol{v}}$. Then $\hat{\boldsymbol{e}}_3\cdot\hat{\boldsymbol{r}} = \sin\varepsilon\cos\phi$ and

$$\hat{\boldsymbol{e}}_3\times\hat{\boldsymbol{r}} = \cos\varepsilon\cos\phi\,\hat{\boldsymbol{v}} - \cos\varepsilon\sin\phi\,\hat{\boldsymbol{u}} + \sin\varepsilon\sin\phi\,\hat{\boldsymbol{n}}\,.$$

Using $\langle\cos^2\phi\rangle = \tfrac{1}{2}$ and $\langle\cos\phi\sin\phi\rangle = 0$, only the $\hat{\boldsymbol{v}}$ term survives:

$$\langle\boldsymbol{\tau}\rangle = -\frac{3GM\,(C-A)}{2r^3}\sin\varepsilon\cos\varepsilon\ \hat{\boldsymbol{v}}\,. \tag{29.59}$$

Insert this into $\mathrm{d}\boldsymbol{L}/\mathrm{d}t = \langle\boldsymbol{\tau}\rangle$ with $\boldsymbol{L} = C\omega_3\hat{\boldsymbol{e}}_3$, exactly as in Phenomenon 29.46. A precession of $\hat{\boldsymbol{e}}_3$ about $\hat{\boldsymbol{n}}$ at rate Ω_p means $\mathrm{d}\hat{\boldsymbol{e}}_3/\mathrm{d}t = \Omega_p\hat{\boldsymbol{n}}\times\hat{\boldsymbol{e}}_3 = \Omega_p\sin\varepsilon\,\hat{\boldsymbol{v}}$, so the common factor $\sin\varepsilon$ cancels and

$$\Omega_p = -\frac{3}{2}\,\frac{GM}{r^3}\,\frac{C-A}{C}\,\frac{\cos\varepsilon}{\omega_3}\,, \tag{29.60}$$

the sign showing the drift to be retrograde — westward along the ecliptic — as observed.

Now put in the numbers of Table 29.2. For the Sun, $GM_\odot/a_\odot^3 = 3.964\times10^{-14}/\mathrm{s}^2$, and with $H = 3.2738\times10^{-3}$, $\cos\varepsilon = 0.91748$ and $\omega_3 = \Omega$,

$$|\Omega_p|_\odot = 2.449\times10^{-12}/\mathrm{s} = 15.94 \text{ seconds of arc per year}\,.$$

For the Moon, $GM_{\mathrm{M}}/a_{\mathrm{M}}^3 = 8.632\times10^{-14}/\mathrm{s}^2$, larger than the Sun's by the factor 2.177, so the coplanar estimate is 34.71 seconds of arc a year. The lunar orbit is not in the ecliptic but inclined by $i = 5.145^\circ$, and its node regresses in 18.6 yr, which is short compared with the precession; averaging Equation (29.57) a second time over that cone multiplies the orientation-dependent part by $1 - \frac{3}{2}\sin^2 i = 0.98794$, giving 34.29. The two contributions add to

$$15.94 + 34.29 = 50.23 \text{ seconds of arc per year}\,,$$

against the observed 50.29: agreement to one part in a thousand, from the mass and orbit of the Moon, the mass and orbit of the Sun, and one number describing the shape of the Earth. The residual is of the size of the terms deliberately dropped — the orbital eccentricities, the higher multipoles of the Earth's figure, and the periodic terms discarded by the averaging, which are the subject of the nutation. □

Proposition 29.50 (The principal nutation)**.** *The orbital averaging carried out in Phenomenon 29.49 discards a periodic remainder. Averaging the lunar torque over the month but* not *over the* 18.6 yr *regression of the lunar nodes, the Earth's axis oscillates about its mean precessional path with that period, with amplitudes*

$$\Delta\varepsilon = \frac{\Omega_M\sin i}{\Omega_N}\,, \qquad \Delta\psi = \frac{\Omega_M\sin i}{\Omega_N}\,\frac{2\cos 2\varepsilon}{\sin 2\varepsilon}\,, \tag{29.61}$$

in obliquity and in ecliptic longitude respectively. Here Ω_M is the magnitude of the mean lunar precession rate Equation (29.60), Ω_N is the rate at which the lunar nodes regress, and i is the inclination of the lunar orbit to the ecliptic. The two terms are in quadrature: the obliquity follows the cosine of the node angle and the longitude its sine.

Rests on Phenomenon 29.49 and Equations (29.57) and (29.60).

Proof. *Derives Proposition 29.50.*

Return to Equation (29.60) before the second averaging. What that equation describes is a precession of $\hat{\boldsymbol{e}}_3$ about the normal $\hat{\boldsymbol{n}}_{\mathrm{M}}$ of the *lunar* orbit, at a rate proportional to the cosine of the angle ε_{M} between the two:

$$\frac{\mathrm{d}\hat{\boldsymbol{e}}_3}{\mathrm{d}t} = \Lambda \cos\varepsilon_{\mathrm{M}}\,(\hat{\boldsymbol{n}}_{\mathrm{M}} \times \hat{\boldsymbol{e}}_3)\ , \qquad \Lambda = -\frac{3}{2}\,\frac{GM_{\mathrm{M}}}{a_{\mathrm{M}}^3}\,\frac{C-A}{C}\,\frac{1}{\omega_3}\,. \tag{29.62}$$

The lunar orbit normal is not the ecliptic pole $\hat{\boldsymbol{n}}$: it lies on a cone of half-angle i about it and travels once round that cone in 18.6 yr as the nodes regress. In axes with $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$ and $\hat{\boldsymbol{e}}_3 = (\sin\varepsilon, 0, \cos\varepsilon)$,

$$\hat{\boldsymbol{n}}_{\mathrm{M}} = \cos i\,\hat{\boldsymbol{n}} + \sin i\,\hat{\boldsymbol{w}}(t)\,, \qquad \hat{\boldsymbol{w}} = (\cos\phi, \sin\phi, 0)\ , \qquad \phi = -\Omega_{\mathrm{N}} t\,, \tag{29.63}$$

so that $\cos\varepsilon_{\mathrm{M}} = \hat{\boldsymbol{e}}_3 \cdot \hat{\boldsymbol{n}}_{\mathrm{M}} = \cos i\cos\varepsilon + \sin i\sin\varepsilon\cos\phi$. To first order in i, Equation (29.62) splits into a secular part and a periodic one,

$$\frac{\mathrm{d}\hat{\boldsymbol{e}}_3}{\mathrm{d}t} = \Omega_{\mathrm{M}}\,(\hat{\boldsymbol{n}} \times \hat{\boldsymbol{e}}_3) + \Lambda \sin i\,[\sin\varepsilon\cos\phi\,(\hat{\boldsymbol{n}} \times \hat{\boldsymbol{e}}_3) + \cos\varepsilon\,(\hat{\boldsymbol{w}} \times \hat{\boldsymbol{e}}_3)]\ , \tag{29.64}$$

with $\Omega_{\mathrm{M}} := \Lambda\cos\varepsilon$ the mean rate already computed. Both periodic terms matter, and they are different things: the second is the wobble of the axis that the torque precesses the Earth about, the first the modulation of the rate at which it does so.

The response is obtained by integrating the periodic terms directly, because $\Omega_{\mathrm{M}}/\Omega_{\mathrm{N}} \approx 5\times10^{-4}$: the displacement $\boldsymbol{\delta}$ they build up varies at the node rate, so the action of the secular term upon $\boldsymbol{\delta}$ is smaller than $\dot{\boldsymbol{\delta}}$ by that factor and may be dropped. With $\hat{\boldsymbol{n}} \times \hat{\boldsymbol{e}}_3 = (0, \sin\varepsilon, 0)$ and $\hat{\boldsymbol{w}} \times \hat{\boldsymbol{e}}_3 = (\sin\phi\cos\varepsilon, -\cos\phi\cos\varepsilon, -\sin\phi\sin\varepsilon)$, the bracket of Equation (29.64) is

$$\left(\sin\phi\cos^2\varepsilon,\ -\cos\phi\cos 2\varepsilon,\ -\sin\phi\sin\varepsilon\cos\varepsilon\right)\ ,$$

and integrating in time, with $\int \sin\phi\,\mathrm{d}t = \cos\phi/\Omega_{\mathrm{N}}$ and $\int\cos\phi\,\mathrm{d}t = -\sin\phi/\Omega_{\mathrm{N}}$ from $\phi = -\Omega_{\mathrm{N}}t$,

$$\boldsymbol{\delta} = \frac{\Lambda\sin i}{\Omega_{\mathrm{N}}}\left(\cos\phi\cos^2\varepsilon,\ \sin\phi\cos 2\varepsilon,\ -\cos\phi\sin\varepsilon\cos\varepsilon\right)\ . \tag{29.65}$$

From Equations (29.63) and (29.64) (integrating the periodic forcing at the node frequency).

The obliquity is read from the third component: $\cos(\varepsilon + \Delta\varepsilon) = \hat{\boldsymbol{z}} \cdot (\hat{\boldsymbol{e}}_3 + \boldsymbol{\delta}) = \cos\varepsilon + \delta_3$ gives $\Delta\varepsilon = -\delta_3/\sin\varepsilon = (\Omega_{\mathrm{M}}\sin i/\Omega_{\mathrm{N}})\cos\phi$, on using $\Lambda\cos\varepsilon = \Omega_{\mathrm{M}}$. The longitude is read from the second, since displacing ψ moves $\hat{\boldsymbol{e}}_3$ by $\sin\varepsilon\,\Delta\psi$ in the y direction: $\Delta\psi = \delta_2/\sin\varepsilon = (\Omega_{\mathrm{M}}\sin i/\Omega_{\mathrm{N}})\,(2\cos 2\varepsilon/\sin 2\varepsilon)\sin\phi$. The amplitudes are Equation (29.61), quoted as magnitudes: Λ is negative, since the precession it drives is retrograde, and its sign fixes only the phase of each term relative to the node. Note where each amplitude came from: the obliquity term needs only the wobble of the torque axis, while the longitude term needs the rate modulation as well, and dropping that would leave $\cot\varepsilon$ in place of $2\cot 2\varepsilon$ and an answer a quarter too large. □

Put in the numbers. The lunar rate is the coplanar 34.71 seconds of arc a year found above, the node rate is $\Omega_{\mathrm{N}} = 2\pi/18.6\,\mathrm{yr}$, that is 69 677 seconds of arc a year, and $i = 5.145°$ from Table 29.2, so that $\sin i = 0.089\,68$. Hence $\Omega_{\mathrm{M}}\sin i/\Omega_{\mathrm{N}} = 4.47\times10^{-5}$ radians, and with $\varepsilon = 23.4393°$,

$$\Delta\varepsilon = 9.21 \text{ seconds of arc}\,, \qquad \Delta\psi = 17.26 \text{ seconds of arc}\,,$$

against the conventional observed principal terms 9.20 and 17.20; as with Table 29.2, no primary reference is cited here for those two modern values. This is the nodding that Bradley extracted from some twenty years of stellar observations and reported in 1748 [26]. The Sun contributes nothing at this period—its orbit normal *is* the ecliptic pole, so the wobble that drives the effect is absent—and its own nutation terms are semiannual and an order of magnitude smaller; they are not computed here.

29.5 Motion in rotating frames

29.5.1 The transport theorem and the fictitious forces

Theorem 29.51 (Equation of motion in a rotating frame)**.** *Let a frame rotate with angular velocity $\boldsymbol{\omega}(t)$ about a fixed origin of an inertial frame. A particle of mass m at position $\boldsymbol{r}$, with velocity $\boldsymbol{v}$ and acceleration $\boldsymbol{a}$ as measured in the rotating frame, obeys*

$$m\boldsymbol{a} = \boldsymbol{F} - 2m\,\boldsymbol{\omega}\times\boldsymbol{v} - m\,\boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}) - m\,\dot{\boldsymbol{\omega}}\times\boldsymbol{r}\,, \tag{29.66}$$

where $\boldsymbol{F}$ is the true force. The three added terms are the Coriolis *[100],* centrifugal *[11] and* Euler *forces.*

Rests on Theorem 29.7 and Postulate 19.8.

Proof. *Derives Theorem 29.51.*

Apply Equation (29.4) to the position vector: $(\mathrm{d}\boldsymbol{r}/\mathrm{d}t)_{\text{space}} = \boldsymbol{v} + \boldsymbol{\omega}\times\boldsymbol{r}$. Apply it again, to that whole vector:

$$\left(\frac{\mathrm{d}^2\boldsymbol{r}}{\mathrm{d}t^2}\right)_{\text{space}} = \left(\frac{\mathrm{d}}{\mathrm{d}t}\right)_{\text{rot}}(\boldsymbol{v}+\boldsymbol{\omega}\times\boldsymbol{r}) + \boldsymbol{\omega}\times(\boldsymbol{v}+\boldsymbol{\omega}\times\boldsymbol{r})\,.$$

Expanding, the first bracket gives $\boldsymbol{a} + \dot{\boldsymbol{\omega}}\times\boldsymbol{r} + \boldsymbol{\omega}\times\boldsymbol{v}$, so

$$\left(\frac{\mathrm{d}^2\boldsymbol{r}}{\mathrm{d}t^2}\right)_{\text{space}} = \boldsymbol{a} + 2\,\boldsymbol{\omega}\times\boldsymbol{v} + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}) + \dot{\boldsymbol{\omega}}\times\boldsymbol{r}\,.$$

Newton's second law holds in the inertial frame (Postulate 19.8), so $m\,(\mathrm{d}^2\boldsymbol{r}/\mathrm{d}t^2)_{\text{space}} = \boldsymbol{F}$; solving for $m\boldsymbol{a}$ gives Equation (29.66). □

Two features of Equation (29.66) are worth stating plainly. The centrifugal term depends on position but not on velocity, so it can be absorbed into a potential — and is, whenever one speaks of "effective gravity". The Coriolis term depends on velocity but not on position, does no work, since it is perpendicular to $\boldsymbol{v}$, and vanishes for a body at rest in the rotating frame; it cannot therefore be absorbed into any potential, and it is the term that carries the detectable signature of rotation for moving bodies.

Example 29.52 (Sizes of the three terms at the Earth's surface)**.** With $\Omega = 7.292\times10^{-5}/\mathrm{s}$ and $a_\oplus = 6.378\times10^{6}\,\mathrm{m}$:

- centrifugal, at the equator: $\Omega^2 a_\oplus = 3.39\times10^{-2}\,\mathrm{m/s^2}$, about $0.35\,\%$ of g;
- Coriolis, for a body moving at $10\,\mathrm{m/s}$: at most $2\Omega v = 1.46\times10^{-3}\,\mathrm{m/s^2}$, some twenty times smaller;
- Euler: the Earth's rotation rate changes by a few milliseconds of day length per century, giving $\dot\Omega \sim 5\times10^{-22}/\mathrm{s^2}$ and $\dot\Omega a_\oplus \sim 3\times10^{-15}\,\mathrm{m/s^2}$, which is seven orders of magnitude below the sensitivity of the best absolute gravimeter [1906] and is neglected everywhere below.

Rests on Equation (29.66).

29.5.2 Absolute rotation: Newton's bucket and Mach's critique

Phenomenon 29.53 (Rotation is locally detectable, uniform motion is not)**.** A sealed laboratory cannot tell whether it is at rest or moving uniformly, but it can always tell whether it is rotating, and how fast, without consulting anything outside. Water in a spinning bucket climbs the walls and takes a curved surface; a plumb line hangs off the

true vertical; a gyroscope holds a direction the walls do not; a pendulum turns its plane of swing. Newton took the bucket as evidence for absolute space [14]; Mach replied that the water's surface may be answering not to space but to the distant matter of the universe [225]. What is not in dispute is the observation itself: the equivalence of frames that Chapter 18 establishes for uniform translation does not extend to rotation.

Rests on Equation (29.66) *and Postulate 18.16.*

Derivation. *Derives Phenomenon 29.53.*

Work in the frame rotating with the bucket at angular velocity ω about the vertical, in which the water is at rest. The centrifugal term of Equation (29.66) is a gradient and contributes to the effective potential energy per unit mass the amount $-\frac{1}{2}\omega^2 r^2$, so a fluid element at height z and distance r from the axis carries

$$\Phi(r, z) = gz - \tfrac{1}{2}\omega^2 r^2 \,.$$

A free surface in equilibrium must be a surface of constant Φ — otherwise there would be an unbalanced force tangent to it and the fluid would not be at rest — so the surface obeys

$$z = z_0 + \frac{\omega^2 r^2}{2g} \,, \tag{29.67}$$

a paraboloid of revolution whose curvature reports ω^2 directly, from measurements made entirely inside the bucket. Since ω enters quadratically, the reading is blind to the sense of the rotation but never vanishes for $\omega \neq 0$: there is no rotation rate that mimics rest. Contrast the derivation of Chapter 18, where the constancy of the relative velocity made the accelerations — and with them every mechanical observable inside the cabin — identical in the two frames. The difference is that the map to a rotating frame is not constant in time, and its second time derivative does not vanish. □

Remark 29.54 (What the bucket does and does not settle). Equation (29.67) establishes that the water responds to *something*, and that the something is not its motion relative to the bucket, since the water and the bucket end up turning together while the surface stays curved. Newton concluded that the response is to absolute space [14]. Mach's objection is that the experiment has never been performed with the distant matter of the universe removed, so the observation cannot distinguish rotation relative to space from rotation relative to that matter [225]. The objection is not answered by any experiment in this chapter, and it is not answered by mechanics at all; what general relativity has to say about it — that local inertial frames are determined by the metric, which is in turn sourced by matter, but that the determination is not the complete one Mach wanted — belongs to Chapter 43.

Rests on Phenomenon 29.53.

29.5.3 Terrestrial evidence of the Earth's rotation

Phenomenon 29.55 (Effective gravity varies with latitude)**.** The acceleration of free fall measured at the Earth's surface is not the same everywhere. It rises smoothly from about $9.780\,\mathrm{m/s^2}$ at the equator to about $9.832\,\mathrm{m/s^2}$ at the poles, and away from those two places a plumb line does not point at the Earth's centre. The variation is enormous by the standards of the instrument that measures it: an absolute gravimeter is accurate to some $2 \times 10^{-8}\,\mathrm{m/s^2}$ [1906], so the equator-to-pole difference is resolved a million times over. The conventional value $9.806\,65\,\mathrm{m/s^2}$ adopted for the SI is accordingly a convention about which latitude to name, not a measurement of a universal constant [2333].

Rests on Equation (29.66).

Derivation. *Derives Phenomenon 29.55.*

In the frame rotating with the Earth, a body at rest on the surface experiences, besides the gravitational attraction, a centrifugal acceleration $\omega^2\rho$ directed away from the rotation axis, where $\rho = R\cos\lambda$ is the distance from that axis at geographic latitude λ. Its component along the local outward vertical is $\omega^2 R\cos^2\lambda$, and the measured free-fall acceleration is reduced by exactly that amount,

$$g(\lambda) \simeq g_{\mathrm{grav}} - \omega^2 R\cos^2\lambda\,, \tag{29.68}$$

largest in effect at the equator and zero at the poles. With the sidereal rotation rate $\omega = 7.292\times10^{-5}/\mathrm{s}$ and the equatorial radius $R = 6.378\times10^{6}\,\mathrm{m}$,

$$\omega^2 R = 3.39\times10^{-2}\,\mathrm{m/s^2}\,,$$

about two thirds of the observed equator-to-pole difference of $5.2\times10^{-2}\,\mathrm{m/s^2}$. The remaining third is not a defect of the calculation but a second consequence of the same rotation: the Earth is not a sphere, its equatorial radius exceeding the polar by some 21 km, so equatorial ground stands farther from the mass that attracts it. There is also a component of the centrifugal acceleration tangent to the surface, $\omega^2 R\sin\lambda\cos\lambda$, which is what tilts the plumb line; it is largest near 45°, where it amounts to about $1.7\times10^{-2}\,\mathrm{m/s^2}$ and deflects the vertical by roughly a tenth of a degree. □

Phenomenon 29.56 (Falling bodies are deflected eastward)**.** A body released from rest and allowed to fall freely does not land at the point vertically below the release. It lands slightly to the east, by an amount that grows as the three-halves power of the drop height and is largest at the equator. Reich measured it in 1831 in a mineshaft at Freiberg, at latitude about 50.9°: from a drop of 158.5 m, repeated 106 times, the mean eastward displacement was 28.3 mm [92]. The effect is a direct mechanical demonstration of the Earth's rotation, and unlike the pendulum it is over in a few seconds.

Rests on Equation (29.66).

Derivation. *Derives Phenomenon 29.56.*

Use local axes at latitude λ with x east, y north and z up, so that $\boldsymbol{\Omega} = \Omega\,(0, \cos\lambda, \sin\lambda)$. The centrifugal term is absorbed into the effective gravity by Equation (29.68), and the Euler term is negligible (Example 29.52), so Equation (29.66) leaves

$$\ddot{\boldsymbol{r}} = -g\hat{\boldsymbol{z}} - 2\,\boldsymbol{\Omega}\times\dot{\boldsymbol{r}}\,.$$

Solve perturbatively in Ω. At zeroth order $\dot{\boldsymbol{r}} = (0, 0, -gt)$; substituting this into the Coriolis term,

$$-2\,\boldsymbol{\Omega}\times\dot{\boldsymbol{r}} = -2\Omega\,(\cos\lambda\,(-gt) - 0,\ 0,\ 0) = (2\Omega gt\cos\lambda,\ 0,\ 0)\ ,$$

which points due east. Integrating twice from rest,

$$x(t) = \tfrac{1}{3}\Omega g\cos\lambda\, t^3 = \tfrac{1}{3}\Omega\cos\lambda\sqrt{\frac{8h^3}{g}}\,, \tag{29.69}$$

using $h = \tfrac{1}{2}gt^2$ for the drop. There is no first-order deflection in the north–south direction: the Coriolis term acting on a purely vertical velocity has no northward component, and the southward term generated at second order is smaller by a further factor Ωt.

For Reich's shaft, $h = 158.5\,\mathrm{m}$ gives $t = 5.68\,\mathrm{s}$, and with $\lambda = 50.9°$ and $\Omega = 7.292\times10^{-5}/\mathrm{s}$, Equation (29.69) predicts 27.6 mm, against the measured mean of 28.3 mm [92] — agreement to 3 %, which for a measurement of a 28 mm displacement at the bottom of a 160 m shaft in 1831 is remarkable. The prediction contains no adjustable parameter: h and λ are properties of the shaft and Ω is the rotation rate of the Earth. □

Proposition 29.57 (The Eötvös effect)**.** *A body moving horizontally over the Earth's surface has its apparent weight changed by the vertical component of the Coriolis force. For an eastward velocity component v_E at latitude λ the measured gravitational acceleration is reduced by*

$$\Delta g = 2\Omega v_E \cos\lambda\,, \tag{29.70}$$

and increased by the same amount for westward motion. There is no such effect for north–south motion at this order.

Rests on Equation (29.66) *and Phenomenon 29.55.*

Proof. *Derives Proposition 29.57.*

In the local axes of Phenomenon 29.56, with $\dot{\boldsymbol{r}} = (v_E, v_N, 0)$,

$$-2\,\boldsymbol{\Omega}\times\dot{\boldsymbol{r}} = 2\Omega\,(\sin\lambda\, v_N,\ -\sin\lambda\, v_E,\ \cos\lambda\, v_E)\ .$$

The vertical component is $2\Omega v_E\cos\lambda$, upward for $v_E > 0$; a gravimeter, which weighs against the local vertical, therefore reads low by that amount, which is Equation (29.70). The component v_N contributes nothing vertical. □

The effect is not small on the scale of the instrument. A ship steaming east at $5\,\mathrm{m/s}$ near the equator carries $\Delta g = 7.3\times10^{-4}\,\mathrm{m/s^2}$, some four orders of magnitude above the $2\times10^{-8}\,\mathrm{m/s^2}$ accuracy of an absolute gravimeter [1906]; marine and airborne gravity surveys must correct for it before any geological signal can be read, and the correction is named after Eötvös, who identified it in shipborne survey data. No primary reference for that attribution is cited here.

Phenomenon 29.58 (Weather systems circulate, and the sense is set by the hemisphere)**.** Air does not flow straight from high pressure to low. In the northern hemisphere it circulates anticlockwise about a low-pressure centre and clockwise about a high, seen from above; in the southern hemisphere both senses reverse; near the equator the organized circulation fails altogether and no tropical cyclone forms within a few degrees of it. The wind blows very nearly *along* the isobars rather than across them, and its speed can be read off a weather chart from the isobar spacing alone. Hadley explained the steadiness of the trade winds by the Earth's rotation in 1735 [21]; the dynamical term responsible is Coriolis's [100].

Rests on Equation (29.66).

Derivation. *Derives Phenomenon 29.58.*

For horizontal motion only the vertical component of $\boldsymbol{\Omega}$ matters, since the horizontal component produces a vertical Coriolis force that the pressure field balances (this is the same separation used in Proposition 29.57). Define the *Coriolis parameter*

$$f := 2\Omega\sin\lambda\,, \tag{29.71}$$

which at 45° is $1.03\times10^{-4}/\mathrm{s}$ and vanishes on the equator. In the local horizontal plane the equation of motion of a fluid element of density ρ is, from Equation (29.66) with the pressure-gradient force of Chapter 31,

$$\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t} = -\frac{1}{\rho}\nabla_h p - f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}\,.$$

When the flow is steady and slowly varying in space the left-hand side is negligible against either term on the right, and the two balance:

$$f\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -\frac{1}{\rho}\nabla_h p \qquad\Longrightarrow\qquad \boldsymbol{u} = \frac{1}{\rho f}\,\hat{\boldsymbol{z}}\times\nabla_h p\,. \tag{29.72}$$

This is *geostrophic balance*, and it says three things at once. The velocity is perpendicular to the pressure gradient, hence along the isobars. Its sense is fixed by the sign of f, so it

reverses across the equator. And its magnitude is $|\boldsymbol{u}| = |\nabla_h p|\,/(\rho f)$: for a typical gradient of one hectopascal per 100 km, that is $1 \times 10^{-3}\,\mathrm{N/m^3}$, with $\rho = 1.2\,\mathrm{kg/m^3}$ and f at 45°, the wind is 8.1 m/s.

Whether the balance holds is decided by the ratio of the neglected term to the retained one, the *Rossby number* $\mathrm{Ro} = U/(fL)$ for a flow of speed U over a length L. A mid-latitude weather system has $U \sim 10\,\mathrm{m/s}$ and $L \sim 1 \times 10^6\,\mathrm{m}$, so $\mathrm{Ro} \approx 0.10$ and the balance is good. Near the equator $f \to 0$ and Ro diverges, which is why organized cyclonic circulation does not form there. □

Remark 29.59 (The bathtub, and the limits of the argument). The same estimate disposes of the common claim that a draining basin turns one way in the northern hemisphere and the other in the southern. With $U \sim 0.1\,\mathrm{m/s}$ and $L \sim 0.3\,\mathrm{m}$ the Rossby number is $\mathrm{Ro} \approx 3 \times 10^3$: the Coriolis term is three thousand times smaller than the terms neglected in Equation (29.72), and any residual swirl left in the water, or any asymmetry of the basin, dominates it completely. The effect is real and has been made visible in laboratory tanks left still for a day, but it is not what an ordinary basin shows. The lesson is general: a term in Equation (29.66) being non-zero is not the same as its being the term that decides the motion.

Rests on Phenomenon 29.58.

29.5.4 The Foucault pendulum

Theorem 29.60 (Planar central motion in a rotating frame)**.** *Let a particle move in a plane under a central force $\boldsymbol{F} = F(|\boldsymbol{r}|)\,\boldsymbol{r}$, and let the frame rotate uniformly at $\boldsymbol{\Omega} = \Omega\hat{\boldsymbol{z}}$ about the normal to that plane. Writing the position as the complex number $\zeta = x + \mathrm{i}y$, the rotating-frame equation of motion*

$$\ddot{\zeta} = \frac{F}{m}\zeta - 2\mathrm{i}\Omega\dot{\zeta} + \Omega^2\zeta \tag{29.73}$$

is solved exactly *by $\zeta = \mathrm{e}^{-\mathrm{i}\Omega t}\eta$, where η obeys the non-rotating equation $\ddot{\eta} = (F/m)\,\eta$. The motion in the rotating frame is therefore the inertial motion referred to axes turning at $-\Omega$: the Coriolis and centrifugal terms together amount to a rigid rotation of the orbit and to nothing else.*

Rests on Equation (29.66).

Proof. *Derives Theorem 29.60.*

Equation (29.73) is Equation (29.66) written in the plane: for $\boldsymbol{\Omega} = \Omega\hat{\boldsymbol{z}}$ the Coriolis term $-2\boldsymbol{\Omega} \times \boldsymbol{v}$ becomes $-2\mathrm{i}\Omega\dot{\zeta}$ and the centrifugal term $-\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \boldsymbol{r})$ becomes $+\Omega^2\zeta$. Substituting $\zeta = \mathrm{e}^{-\mathrm{i}\Omega t}\eta$,

$$\dot{\zeta} = \mathrm{e}^{-\mathrm{i}\Omega t}\left(\dot{\eta} - \mathrm{i}\Omega\eta\right), \qquad \ddot{\zeta} = \mathrm{e}^{-\mathrm{i}\Omega t}\left(\ddot{\eta} - 2\mathrm{i}\Omega\dot{\eta} - \Omega^2\eta\right).$$

The right-hand side of Equation (29.73) becomes $\mathrm{e}^{-\mathrm{i}\Omega t}\left[(F/m)\,\eta - 2\mathrm{i}\Omega\dot{\eta} - 2\Omega^2\eta + \Omega^2\eta\right]$, and the factor F is unchanged because $|\zeta| = |\eta|$. Cancelling $\mathrm{e}^{-\mathrm{i}\Omega t}$ and subtracting, the terms in $\dot{\eta}$ and the terms in $\Omega^2\eta$ cancel identically on both sides, and $\ddot{\eta} = (F/m)\,\eta$ remains. No approximation in Ω was made. □

The exact cancellation is worth dwelling on: the centrifugal term is not "small enough to neglect" in the Foucault problem, it is *absorbed*, and its whole effect is already contained in the rotation of the axes. Only the first power of Ω survives in the observable rate. The same theorem, applied to an electron in a magnetic field rather than to a mass in a rotating frame, is Larmor's.

Phenomenon 29.61 (The Foucault pendulum)**.** A long pendulum, set swinging carefully in a plane and then left alone, does not keep that plane with respect to the room. The plane turns steadily — clockwise seen from above in the northern hemisphere, anticlockwise in the southern — at a rate proportional to the sine of the latitude: one full turn in about thirty-two hours at the latitude of Paris, in one sidereal day at either pole, and not at all on the equator. Nothing outside the building is consulted and the room may be sealed, so the experiment measures the rotation of the Earth from inside a laboratory. That is what made Foucault's public demonstration of 1851 the version of the argument that convinced people who had not been convinced by astronomy [134]. The measurement, its apparatus and its data are Section 34.5.

Rests on Theorem 29.60 and Equation (29.66)*.*

Derivation. *Derives Phenomenon 29.61.*

Use the local axes of Phenomenon 29.56, in which $\boldsymbol{\Omega} = \Omega\,(0, \cos\lambda, \sin\lambda)$, and let the bob swing with small amplitude about the lowest point of its suspension. Three reductions bring the problem into the form of Theorem 29.60.

First, the centrifugal term of Equation (29.66) is independent of time and is absorbed once and for all into the effective gravity and the local vertical, exactly as in Equation (29.68); the swing is then about that vertical.

Second, split $\boldsymbol{\Omega}$ into its vertical and horizontal parts, $\Omega_z = \Omega\sin\lambda$ and $\Omega_y = \Omega\cos\lambda$. For small oscillations the bob's velocity is horizontal to first order, since the vertical excursion is second order in the amplitude. The Coriolis force built from Ω_y acting on a horizontal velocity is then vertical, and is taken up by the tension in the wire, which is free to adjust; it does not move the bob horizontally. Only Ω_z survives in the horizontal equations, and this is why the experiment reports the component of $\boldsymbol{\Omega}$ along the local vertical rather than the whole of it.

Third, for small amplitude the horizontal restoring force is central and linear, $\boldsymbol{F} = -m\omega_0^2\boldsymbol{r}$ with $\omega_0^2 = g/\ell$ (Equation (28.7)). Theorem 29.60 now applies verbatim with $\Omega \to \Omega_z$: the substitution $\zeta = \mathrm{e}^{-\mathrm{i}\Omega_z t}\eta$ reduces the motion to $\ddot{\eta} = -\omega_0^2\eta$, a plane pendulum whose plane is fixed. Seen from the room, that plane therefore turns at

$$\Omega_{\mathrm{prec}} = -\Omega\sin\lambda\,, \tag{29.74}$$

clockwise from above for $\lambda > 0$, one turn per sidereal day at the pole and none on the equator. Note what does *not* appear: the length, the mass and the amplitude of the pendulum are all absent, so the effect cannot be confused with a property of the particular apparatus. The numerical value at the latitude of Paris, and the data that confirm it, are Equation (34.39) and Section 34.5. □

Remark 29.62 (The same rate read as a holonomy)*.* There is a second reading of Equation (29.74) that uses no forces at all. Over one sidereal day the pendulum is carried once around its circle of latitude, and its swing plane, which no torque about the vertical acts on, is parallel-transported along that circle in the sense of Definition 13.146. Relative to the ground the plane has turned by $2\pi\sin\lambda$, so relative to a direction carried rigidly with the rotating Earth it has failed to return by the angle

$$2\pi - 2\pi\sin\lambda = 2\pi\,(1 - \sin\lambda)\ ,$$

which is numerically the solid angle subtended at the Earth's centre by the spherical cap that the latitude circle bounds, a cap of colatitude $\frac{\pi}{2} - \lambda$ having solid angle $2\pi\,(1 - \sin\lambda)$. The two computations are independent and they agree. That the agreement is a theorem rather than a coincidence — that the holonomy of parallel transport around a closed curve equals the integrated curvature it encloses — is not proved anywhere in this treatise, and nothing above depends on it; the geometric machinery is that of Chapter 13 and Chapter 14.

Read this way the Foucault pendulum is the oldest laboratory measurement of a geometric phase.

Rests on Phenomenon 29.61 and Definition 13.146.

Chapter 30

Continuum Mechanics and Elasticity

Between the finitely many degrees of freedom of Chapter 29 and the fluids of Chapter 31 stands the deformable solid. This chapter replaces the rigid body's six coordinates by continuous fields: the displacement field and its strain tensor, the stress tensor that transmits force through matter, and the linear law — Hooke's — that couples them. From these follow the equations of elastodynamics, the elastic waves that carry earthquakes across the planet, the engineering theories of rods, beams and plates, and the measured elastic constants that anchor every parameter of the theory to experiment. The continuum limit constructed here is also the pattern for every later field theory in the book, from the fluids of the next chapter to the lattice dynamics of Chapter 125 and the Lagrangian fields of Chapter 64. The canonical monograph is Landau and Lifshitz's *Theory of Elasticity* [1778].

The tensor machinery this chapter uses — the transformation law under orthogonal changes of frame, the algebra of Cartesian tensors, the quotient law — is that of Chapter 13, and is not rebuilt here. What is built here is physics: which tensors the solid carries, what the observed relation between them is, and what follows from it.

Notation 30.1 (Strain and displacement share a letter). Following [1778], u_i with one index denotes a component of the displacement *field* and u_{ik} with two denotes a component of the strain *tensor*; they are different objects, related by Equation (30.4). Stress is σ_{ik}, mass density ρ, and repeated Latin indices are summed over the three spatial directions. All indices are Cartesian, so index position carries no meaning (Definition 13.5); the metric is δ_{ik}.

Rests on Definition 13.5.

30.1 The continuum hypothesis

A cubic centimetre of copper holds of order 10^{23} nuclei and as many electrons, and no theory of matter that tracks them individually will ever predict the sag of a bridge. The whole of this chapter rests on replacing that population by a handful of smooth fields. The replacement is not a mathematical convenience but a physical claim with a domain of validity, and the claim can be stated sharply enough to be tested.

Definition 30.2 (Representative volume element; continuum field)**.** Let a be the mean spacing between the constituent particles of a body and L the scale over which the applied loads and the geometry vary. A *representative volume element* at the point $\boldsymbol{x}$ is a region of linear size ℓ centred there with

$$a \ll \ell \ll L\,. \tag{30.1}$$

A *continuum field* is a quantity assigned to $\boldsymbol{x}$ by averaging the corresponding microscopic quantity over the representative volume element: the mass density $\rho(\boldsymbol{x}) = \Delta m/\Delta V$, the velocity $\boldsymbol{v}(\boldsymbol{x}) = \Delta \boldsymbol{p}/\Delta m$, and so on. The *continuum hypothesis* is the assertion that Equation (30.1) can be satisfied, so that the averages are insensitive to ℓ over a wide range and the resulting fields are smooth on the scale L.

Rests on Definition 7.65.

The hypothesis is quantitative because the insensitivity is quantitative. Density fluctuations in a volume holding N particles are of relative size $N^{-1/2}$ (Chapter 55), so the width of the plateau in ℓ is set by how fast N grows.

Example 30.3 (How small a piece of copper is still a continuum)**.** Copper has mass density $8960\,\mathrm{kg/m^3}$ and molar mass $63.55\,\mathrm{g/mol}$, giving a number density $n = 8.49 \times 10^{28}/\mathrm{m^3}$ and a mean spacing $a = n^{-1/3} = 0.227\,\mathrm{nm}$. A cube of side $100\,\mathrm{nm}$ then contains $N = 8.5 \times 10^7$ atoms and its density is defined to a relative precision $N^{-1/2} = 1.1 \times 10^{-4}$. That cube is already 440 atoms across, so it is large in the sense of Equation (30.1); and it is 10^4 times smaller than a millimetre-scale specimen, so it is also small in that sense. Both inequalities in Equation (30.1) hold with four orders of magnitude to spare, which is why elasticity works so well for ordinary solids and why nothing in this chapter needs to know that copper is made of atoms.

Rests on Definition 30.2.

Definition 30.4 (Material and spatial descriptions)**.** Label each material particle by its position $\boldsymbol{X}$ in a chosen reference configuration. The motion is the map $\boldsymbol{x} = \boldsymbol{\chi}(\boldsymbol{X}, t)$, and the *displacement* is

$$\boldsymbol{u}(\boldsymbol{X}, t) = \boldsymbol{\chi}(\boldsymbol{X}, t) - \boldsymbol{X}\,. \tag{30.2}$$

A field written as a function of $(\boldsymbol{X}, t)$ is in the *material* (Lagrangian) description; written as a function of $(\boldsymbol{x}, t)$, in the *spatial* (Eulerian) description. The two are related by the chain rule, so that for any field f

$$\left.\frac{\partial f}{\partial t}\right|_{\boldsymbol{X}} = \left.\frac{\partial f}{\partial t}\right|_{\boldsymbol{x}} + (\boldsymbol{v}\cdot\boldsymbol{\nabla})\, f\,, \tag{30.3}$$

the second form being the *material derivative*.

Rests on Proposition 7.72 and Definition 30.2.

A solid has a preferred reference configuration — the unloaded one, to which it returns — so solid mechanics is naturally Lagrangian. A fluid has none, which is why Chapter 31 is written in the spatial description throughout; Equation (30.3) is the bridge between the two chapters, and the nonlinear term it carries is the origin of the difficulties of that one.

Remark 30.5 (Where the hypothesis fails, and how one can tell)*.* Equation (30.1) is an inequality between measurable lengths, so its failure is measurable too.

- *Rarefied gases.* The relevant microscopic length is the mean free path ℓ_{mfp}, not the particle spacing. Air at room conditions has $\ell_{\mathrm{mfp}} \approx 68\,\mathrm{nm}$, negligible against any laboratory apparatus; but in a high vacuum, or in the upper atmosphere, ℓ_{mfp} grows to metres and the Knudsen number ℓ_{mfp}/L approaches unity. Beyond $\ell_{\mathrm{mfp}}/L \sim 0.1$ the continuum equations of Chapter 31 fail and the kinetic description of Chapter 55 must be used instead.

- *Nanoscale structures.* A wire ten atoms across has no interior: most of its atoms are surface atoms, with a different coordination and a different local stiffness, so no plateau in ℓ exists and the elastic moduli measured on such a specimen depend on its size.

- *Singular regions inside a continuum.* A shock front is a few mean free paths thick and a crack tip has a radius of a few lattice spacings. In both cases Equation (30.1) fails *locally* while holding everywhere else, which is why the continuum theory can keep them as idealised surfaces and points — and also why it predicts infinite stress there (Section 30.7).

What underwrites the hypothesis where it holds is the kinetic theory of Chapter 55: it is the law of large numbers applied to a mechanical system, and the smallness of $N^{-1/2}$ is the whole of the argument.

Rests on Definition 30.2 and Equation (30.1).

30.2 Deformation: the strain tensor

30.2.1 Displacement and linear strain

A displacement field that is the same everywhere translates the body without deforming it, and one that is linear and antisymmetric rotates it. Deformation is therefore carried by the symmetric part of the displacement *gradient*, and this is what the strain tensor isolates. Cauchy introduced both it and the stress tensor of Section 30.3 in the memoir that founded the subject [73].

Definition 30.6 (Linear strain and infinitesimal rotation)**.** For a displacement field $\boldsymbol{u}$ with small gradients, the *strain tensor* and the *rotation tensor* are the symmetric and antisymmetric parts of $\partial_i u_k$:

$$u_{ik} = \tfrac{1}{2}\left(\partial_i u_k + \partial_k u_i\right), \qquad \omega_{ik} = \tfrac{1}{2}\left(\partial_i u_k - \partial_k u_i\right). \tag{30.4}$$

Both are dimensionless. The *dilatation* is the trace $u_{ll} = \boldsymbol{\nabla}\cdot\boldsymbol{u}$, and the traceless remainder

$$d_{ik} = u_{ik} - \tfrac{1}{3}u_{ll}\delta_{ik} \tag{30.5}$$

is the *deviatoric* or shear part.

Rests on Equation (30.2) and Definition 13.91.

Proposition 30.7 (Strain is a Cartesian tensor of rank two)**.** *Under a change of orthonormal frame $x'_i = a_{ik}x_k$ the nine quantities u_{ik} transform as $u'_{ik} = a_{il}a_{km}u_{lm}$, that is, as the components of a rank-two tensor in the sense of Definition 13.5. The same holds for ω_{ik}, d_{ik}, and the trace u_{ll} is a scalar.*

Rests on Definitions 13.5 and 30.6.

Proof. *Derives Proposition 30.7.*

The displacement is a vector, $u'_k = a_{km}u_m$, and for an orthogonal transformation with constant coefficients the differential operator carries a vector index as well, $\partial'_i = a_{il}\partial_l$. The product $\partial_i u_k$ is therefore a rank-two tensor by the product rule of Section 13.2.2, its symmetric and antisymmetric parts are tensors by the addition and index-permutation rules there, and the trace is a rank-zero tensor by the contraction rule. That the trace is a scalar is the statement that $\boldsymbol{\nabla}\cdot\boldsymbol{u}$ does not depend on the frame in which it is computed, which is what makes Proposition 30.8 a statement about the body rather than about the observer. □

This is the reason the subject is written in tensors at all. A material law must relate the deformation to the force without reference to the orientation of the laboratory; a relation between objects with the transformation law of Equation (13.22) has that property automatically, and one between arbitrary arrays of nine numbers does not.

Proposition 30.8 (The trace is the fractional volume change)**.** *To first order in the displacement gradients, a material element of volume* $\mathrm{d}V$ *becomes*

$$\mathrm{d}V' = (1 + u_{ll})\,\mathrm{d}V\,, \tag{30.6}$$

so that u_{ll} *is the fractional change of volume and the deviatoric part* d_{ik} *deforms at constant volume.*

Rests on Definition 30.6 and Equation (30.2).

Proof. *Derives Proposition 30.8.*

The map $\boldsymbol{X} \mapsto \boldsymbol{X} + \boldsymbol{u}(\boldsymbol{X})$ has Jacobian matrix $F_{ik} = \delta_{ik} + \partial_k u_i$, and a volume element is multiplied by $\det F$. For any matrix A, $\det(\mathbb{1} + A) = 1 + \operatorname{tr} A + O(A^2)$, since the terms of the determinant that are not the product of diagonal entries contain at least two off-diagonal factors. Hence $\det F = 1 + \partial_i u_i + O\left((\partial u)^2\right)$, and $\partial_i u_i = u_{ii} = u_{ll}$ because the antisymmetric part of $\partial_i u_k$ has zero trace. The deviatoric part is traceless by construction, so it changes no volumes to this order. □

Proposition 30.9 (Principal strains)**.** *At each point there is an orthonormal frame in which* u_{ik} *is diagonal. Its three diagonal entries* $u^{(1)}, u^{(2)}, u^{(3)}$ *— the* principal strains *— are the fractional extensions along the three corresponding* principal directions*, and* $u_{ll} = u^{(1)} + u^{(2)} + u^{(3)}$.

Rests on Definition 30.6 and Theorem 5.75.

Proof. *Derives Proposition 30.9.*

u_{ik} is a real symmetric array, hence the matrix of a self-adjoint operator on $\mathbb{R}^3$ with the Euclidean inner product; by Theorem 5.75 it has an orthonormal eigenbasis and real eigenvalues. In that basis a material line element along the j-th eigenvector of length $\mathrm{d}l$ becomes, to first order, one of length $\left(1 + u^{(j)}\right)\mathrm{d}l$, since the antisymmetric part contributes a rotation and not a length change. The trace is basis independent by Proposition 30.7. □

Example 30.10 (Simple shear and pure shear are the same strain)**.** Let $\boldsymbol{u} = (\gamma y, 0, 0)$ with $\gamma = 1 \times 10^{-3}$: the displacement gradient has the single entry $\partial_y u_x = \gamma$, so

$$u_{ik} = \begin{pmatrix} 0 & \gamma/2 & 0 \\ \gamma/2 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad \omega_{ik} = \begin{pmatrix} 0 & \gamma/2 & 0 \\ -\gamma/2 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

The principal strains are $\pm\gamma/2$ along the two directions at 45° to the axes, and 0 along z; the trace vanishes, so no volume changes. What distinguishes "simple" shear from "pure" shear is only the accompanying rigid rotation ω_{ik} of magnitude $\gamma/2 = 5 \times 10^{-4}$, and by Proposition 30.7 that rotation cannot enter any material law. A steel bar strained in shear by $\gamma = 1 \times 10^{-3}$ is therefore stressed exactly as one stretched by 5×10^{-4} along one diagonal and compressed by the same amount along the other.

Rests on Proposition 30.9 and Definition 30.6.

30.2.2 Finite strain and compatibility

Definition 30.6 was announced as valid "for small gradients". The exact statement is available and shows precisely what the truncation costs.

Definition 30.11 (Green strain)**.** The *Green (Lagrangian) strain tensor* of the motion Equation (30.2) is

$$E_{ik} = \tfrac{1}{2}\left(\partial_i u_k + \partial_k u_i + \partial_i u_l\, \partial_k u_l\right), \tag{30.7}$$

in which the indices are the material coordinates $\boldsymbol{X}$.

Rests on Equation (30.2) and Definition 30.6.

Proposition 30.12 (The Green strain measures length exactly)**.** *For every material line element* $\mathrm{d}\boldsymbol{X}$*,*

$$\mathrm{d}l'^2 - \mathrm{d}l^2 = 2E_{ik}\,\mathrm{d}X_i\,\mathrm{d}X_k\,, \tag{30.8}$$

with no approximation. Consequently E_{ik} *vanishes identically if and only if the motion is a rigid displacement.*

Rests on Definitions 13.118 and 30.11.

Proof. *Derives Proposition 30.12.*

With $F_{ik} = \partial_k \chi_i = \delta_{ik} + \partial_k u_i$ one has $\mathrm{d}x_i = F_{ik}\mathrm{d}X_k$, so

$$\mathrm{d}l'^2 = \mathrm{d}x_i \mathrm{d}x_i = F_{il}F_{ik}\,\mathrm{d}X_l \mathrm{d}X_k = (\delta_{lk} + \partial_l u_k + \partial_k u_l + \partial_l u_i \partial_k u_i)\,\mathrm{d}X_l \mathrm{d}X_k\,,$$

and subtracting $\mathrm{d}l^2 = \delta_{lk}\mathrm{d}X_l\mathrm{d}X_k$ gives Equation (30.8). If $E_{ik} \equiv 0$ then every material length is preserved, so the motion is an isometry of $\mathbb{R}^3$ and hence (Proposition 13.121) a rotation followed by a translation; the converse is immediate because a rigid motion has $F^{\mathsf{T}}F = \mathbb{1}$. □

Example 30.13 (A rigid rotation forges a strain of $-\theta^2/2$)**.** Rotate a body rigidly about z through θ. Then $\boldsymbol{u} = (R - \mathbb{1})\boldsymbol{X}$ with R the rotation matrix, and the linear strain of Equation (30.4) evaluates to

$$u_{xx} = u_{yy} = \cos\theta - 1 = -\tfrac{1}{2}\theta^2 + O(\theta^4)\,, \qquad u_{xy} = 0\,,$$

while $E_{ik} = 0$ exactly by Proposition 30.12. The linear measure reports a spurious contraction of θ^2 in volume where nothing has been deformed at all. For $\theta = 0.1\,\mathrm{rad}$ — under 6° — that is -5×10^{-3}, four times the elastic strain $\sigma_{\mathrm{y}}/E \approx 1.2 \times 10^{-3}$ at which structural steel yields (Phenomenon 30.73). The linear theory is therefore restricted not by the smallness of the strains but by the smallness of the *rotations*: a thin strip may bend far past $\theta = 0.1$ while every fibre in it stays elastic, and such a problem must be treated with Equation (30.7), or with the special geometrically nonlinear theories of Section 30.6.1.

Rests on Proposition 30.12 and Definition 30.6.

The second question about a strain field is the reverse one. Six functions u_{ik} are prescribed; do they come from any displacement at all? The system Equation (30.4) is six equations for three unknowns, so the answer is no in general, and the obstruction has a name.

Proposition 30.14 (Saint-Venant compatibility is necessary)**.** *If* u_{ik} *is the linear strain of a* C^3 *displacement field, then*

$$\partial_l\partial_k u_{ij} + \partial_i\partial_j u_{kl} - \partial_l\partial_j u_{ik} - \partial_i\partial_k u_{jl} = 0 \tag{30.9}$$

identically. In three dimensions Equation (30.9) has six independent components.

Rests on Definition 30.6 and Proposition 7.73.

Proof. *Derives Proposition 30.14.*

Substitute $u_{ij} = \tfrac{1}{2}(\partial_i u_j + \partial_j u_i)$ into the left-hand side. The first term contributes $\tfrac{1}{2}(\partial_l\partial_k\partial_i u_j + \partial_l\partial_k\partial_j u_i)$ and the other three the analogous expressions; every one of the eight resulting third derivatives appears twice with opposite signs once the partial derivatives are freely commuted, which Proposition 7.73 licenses for a C^3 field. The sum therefore vanishes term by term. The left-hand side is antisymmetric under $i \leftrightarrow l$ and under $j \leftrightarrow k$ and symmetric under the exchange of the pairs, which in three dimensions leaves 3×3 components of which the six symmetric ones are the independent conditions — exactly the index symmetries of a curvature tensor (Proposition 13.154). □

Theorem 30.15 (Compatibility is sufficient on a simply connected body)**.** *Let $\Omega \subset \mathbb{R}^3$ be open, connected and simply connected, and let u_{ik} be a symmetric C^2 field on Ω satisfying Equation (30.9). Then there is a displacement field $\boldsymbol{u}$ on Ω whose linear strain is u_{ik}, unique up to the addition of a rigid displacement $\boldsymbol{a} + \boldsymbol{b} \times \boldsymbol{x}$.*

Rests on Propositions 7.104 and 30.14.

Proof. *Derives Theorem 30.15.*

The construction is Cesàro's: recover first the rotation that the strain does not record, then the displacement. It uses no mathematics beyond Proposition 7.104(3), that a curl-free C^1 field on a simply connected open set is a gradient.

Step 1: the rotation field. Set

$$\Phi_{ijk} := \partial_i u_{jk} - \partial_j u_{ik}\,, \tag{30.10}$$

which is C^1 and antisymmetric in ij. Were u_{ik} already the strain of a displacement, Φ_{ijk} would be $\partial_k \omega_{ij}$ with $\omega_{ij} = \frac{1}{2}(\partial_i u_j - \partial_j u_i)$ the infinitesimal rotation: substituting $u_{jk} = \frac{1}{2}(\partial_j u_k + \partial_k u_j)$ into Equation (30.10) gives $\frac{1}{2}(\partial_i\partial_k u_j - \partial_j\partial_k u_i)$, which is that derivative. Take this as the equation to be solved. For each fixed pair ij the field $k \longmapsto \Phi_{ijk}$ is curl-free exactly when

$$\partial_l \Phi_{ijk} - \partial_k \Phi_{ijl} = \partial_l\partial_i u_{jk} - \partial_l\partial_j u_{ik} - \partial_k\partial_i u_{jl} + \partial_k\partial_j u_{il} \tag{30.11}$$

vanishes, and the right-hand side is the compatibility expression Equation (30.9) with its four indices taken in the order (i,k,l,j) and the sign reversed. It vanishes by hypothesis. By Proposition 7.104(3) on the simply connected Ω there are therefore functions ω_{ij} with $\partial_k \omega_{ij} = \Phi_{ijk}$, each fixed up to a constant. Since $\Phi_{ijk} = -\Phi_{jik}$, the constants may be chosen so that $\omega_{ij} = -\omega_{ji}$, and $\omega_{ii} = 0$.

Step 2: the displacement. For each fixed i consider $k \longmapsto u_{ik} - \omega_{ik}$, which is C^1. Its curl is

$$\begin{aligned} \partial_l\left(u_{ik} - \omega_{ik}\right) - \partial_k\left(u_{il} - \omega_{il}\right) &= \partial_l u_{ik} - \partial_k u_{il} - \Phi_{ikl} + \Phi_{ilk} \\ &= \partial_l u_{ik} - \partial_k u_{il} - (\partial_i u_{kl} - \partial_k u_{il}) \\ &\quad + (\partial_i u_{lk} - \partial_l u_{ik}) = 0\,, \end{aligned} \tag{30.12}$$

every term cancelling in pairs, the last two because $u_{kl} = u_{lk}$. Proposition 7.104(3) again supplies functions u_i with $\partial_k u_i = u_{ik} - \omega_{ik}$. Symmetrising and using the symmetry of u_{ik} with the antisymmetry of ω_{ik},

$$\tfrac{1}{2}\left(\partial_k u_i + \partial_i u_k\right) = \tfrac{1}{2}\left[(u_{ik} - \omega_{ik}) + (u_{ki} - \omega_{ki})\right] = u_{ik}\,, \tag{30.13}$$

so $\boldsymbol{u}$ has the prescribed strain.

Step 3: uniqueness. Let $\boldsymbol{v}$ have zero strain, $\partial_i v_k + \partial_k v_i = 0$. The identity of step 1, applied with $u_{ik} = 0$, gives $\partial_k w_{ij} = \Phi_{ijk} = 0$ for $w_{ij} = \frac{1}{2}(\partial_i v_j - \partial_j v_i)$, so w is a constant antisymmetric array on the connected Ω. The symmetric part of $\partial_j v_k$ vanishes by hypothesis, so $\partial_j v_k = w_{jk}$ is constant and $v_k = a_k + w_{jk}x_j$ with a_k constant; writing the antisymmetric w_{jk} as $\varepsilon_{jkm}b_m$ and using the cyclic symmetry of ε puts this in the form $\boldsymbol{v} = \boldsymbol{a} + \boldsymbol{b} \times \boldsymbol{x}$. Conversely every such field has zero strain. Two displacements with the same strain differ by one of them, which is the stated uniqueness. □

Remark 30.16 (Incompatibility is curvature). The index symmetries found in the proof of Proposition 30.14 are not a coincidence. The deformed body carries the metric $g_{ik} = \delta_{ik} + 2E_{ik}$ by Equation (30.8), and to first order in E the left-hand side of Equation (30.9) is -2 times the linearised Riemann tensor of that metric (Theorem 13.152). Compatibility says that the deformed body is still a piece of flat Euclidean space — that it can be laid down in $\mathbb{R}^3$ without tearing or overlapping. An incompatible strain field is one that cannot: it

describes a body with built-in stresses that no external load produces and no unloading removes. Crystal dislocations are the physical realisation, and their density is precisely the incompatibility Equation (30.9); the microscopic account belongs to Chapter 125.

Rests on Equation (30.9) and Theorem 13.152.

30.3 Stress: the Cauchy tensor

30.3.1 Traction and the existence of the stress tensor

Definition 30.17 (Traction)**.** Cut the body along a surface through the point $\boldsymbol{x}$ with unit normal $\boldsymbol{n}$. The material on the side into which $\boldsymbol{n}$ points exerts on the material on the other side a force $\Delta\boldsymbol{F}$ across an element of area ΔA of the cut. The *traction* is

$$\boldsymbol{t}(\boldsymbol{x},\boldsymbol{n}) = \lim_{\Delta A\to 0} \frac{\Delta \boldsymbol{F}}{\Delta A}\,, \tag{30.14}$$

an SI force per unit area, measured in $\mathrm{N/m^2} = \mathrm{Pa}$. It depends on the orientation of the cut as well as on the point.

Rests on Definitions 7.94 and 30.2.

That the traction depends on $\boldsymbol{n}$ at all is what distinguishes a solid from an ideal fluid, in which the traction is $-p\boldsymbol{n}$ for every $\boldsymbol{n}$. The content of Cauchy's theorem is that the dependence is as simple as it could possibly be.

Theorem 30.18 (Cauchy: the stress tensor exists)**.** *There is a field $\sigma_{ik}(\boldsymbol{x})$, a Cartesian tensor of rank two, such that for every unit vector $\boldsymbol{n}$*

$$t_i(\boldsymbol{x},\boldsymbol{n}) = \sigma_{ik}(\boldsymbol{x})\, n_k\,. \tag{30.15}$$

Its column σ_{ik} at fixed k is the traction across the coordinate plane with normal $\hat{\boldsymbol{e}}_k$.

Rests on Definitions 13.5 and 30.17.

Proof. *Derives Theorem 30.18.*

First, $\boldsymbol{t}(\boldsymbol{x},-\boldsymbol{n}) = -\boldsymbol{t}(\boldsymbol{x},\boldsymbol{n})$. Apply Newton's second law to a flat pillbox of face area A and thickness h straddling the cut: the mass and hence the inertia and the body force are $O(hA)$, while the two faces contribute $[\boldsymbol{t}(\boldsymbol{n}) + \boldsymbol{t}(-\boldsymbol{n})]\,A$ and the rim $O\left(hA^{1/2}\right)$. Dividing by A and letting $h \to 0$ leaves the stated relation.

Now take a tetrahedron with three faces in the coordinate planes, meeting at $\boldsymbol{x}$, and a fourth face of area A with outward unit normal $\boldsymbol{n}$ at perpendicular distance h from $\boldsymbol{x}$. The coordinate faces have areas An_k and outward normals $-\hat{\boldsymbol{e}}_k$, and the volume is $hA/3$. Newton's second law for the tetrahedron reads

$$\frac{\rho h A}{3}\,(\boldsymbol{a}-\boldsymbol{b}) = \boldsymbol{t}(\boldsymbol{n})\,A - \sum_k \boldsymbol{t}(\hat{\boldsymbol{e}}_k)\,An_k\,,$$

where $\boldsymbol{b}$ is the body force per unit mass and the mean values of the continuous fields over the faces have been used. Divide by A and let $h \to 0$: the left side vanishes, and

$$t_i(\boldsymbol{n}) = \sum_k t_i(\hat{\boldsymbol{e}}_k)\, n_k =: \sigma_{ik} n_k\,.$$

This is Equation (30.15). The nine numbers σ_{ik} so defined are a tensor by the quotient law of Section 13.2.2: t_i and n_k are vectors and $\boldsymbol{n}$ is arbitrary, so the array contracting one into the other must transform as a rank-two tensor. Note that no constitutive assumption of any kind has been made — the argument is pure balance of momentum, and Equation (30.15) therefore holds for fluids, plastic solids and viscoelastic media as well. □

Proposition 30.19 (The stress tensor is symmetric)**.** *In the absence of distributed body couples, $\sigma_{ik} = \sigma_{ki}$.*

Rests on Theorem 30.18 and Definition 30.17.

Proof. *Derives Proposition 30.19.*

Apply the balance of angular momentum about its own centre to a cube of side ℓ centred at $\boldsymbol{x}$. The torque about the z axis from the tractions on the four vertical faces is, to leading order, $(\sigma_{yx} - \sigma_{xy})\,\ell^3$; the torque from the body force is $O(\ell^4)$, because $\int (\boldsymbol{r} \times \boldsymbol{f}) \mathrm{d}V$ over a region of size ℓ centred on the reference point carries one factor of ℓ from $\boldsymbol{r}$ and three from $\mathrm{d}V$; and the moment of inertia is $\rho \ell^5/6$. Hence the angular acceleration is

$$\dot{\Omega}_z = \frac{6\,(\sigma_{yx} - \sigma_{xy})}{\rho \ell^2} + O\!\left(\ell^{-1}\right) ,$$

which diverges as $\ell \to 0$ unless $\sigma_{yx} = \sigma_{xy}$. The same argument on the other two axes completes the proof. The hypothesis is essential and is not vacuous: a medium carrying an intrinsic torque per unit volume — a magnetised body in a field (Chapter 129), a liquid crystal — adds a term of order ℓ^3 to the numerator and does support an antisymmetric part. □

Definition 30.20 (Pressure and deviatoric stress)**.** The *pressure* and the *deviatoric stress* are

$$p = -\tfrac{1}{3}\sigma_{ll} , \qquad s_{ik} = \sigma_{ik} + p\,\delta_{ik} , \tag{30.16}$$

so that $\sigma_{ik} = -p\,\delta_{ik} + s_{ik}$ with $s_{ll} = 0$. By Proposition 30.19 and Theorem 5.75 there is an orthonormal frame in which σ_{ik} is diagonal; its entries $\sigma_1 \geq \sigma_2 \geq \sigma_3$ are the *principal stresses*, and $p = -\left(\sigma_1 + \sigma_2 + \sigma_3\right)/3$.

Rests on Proposition 30.19 and Theorem 5.75.

The split is not cosmetic. Phenomenon 30.28 will show that p and s_{ik} are controlled by two independent material constants; Proposition 30.74 will show that plastic failure is governed by s_{ik} alone. A steel specimen at the bottom of the ocean, with $p = 110\,\mathrm{MPa}$ and $s_{ik} = 0$, is compressed by about 6.6×10^{-4} in volume and is in no danger whatever; the same material at $\sigma_1 - \sigma_3 = 500\,\mathrm{MPa}$ has already yielded.

30.3.2 Momentum balance

Theorem 30.21 (Cauchy's equation of motion)**.** *For a continuum of density ρ carrying a body force f_i per unit volume,*

$$\rho\,\partial_t^2 u_i = \partial_k \sigma_{ik} + f_i , \tag{30.17}$$

in the material description and for small displacements. Statics is the case $\partial_t^2 u_i = 0$, giving the equilibrium equations $\partial_k \sigma_{ik} + f_i = 0$.

Rests on Theorems 7.101 and 30.18.

Proof. *Derives Theorem 30.21.*

Let V be any fixed material region with boundary S. Newton's second law for the material in V balances the rate of change of its momentum against the surface tractions and the body force:

$$\int_V \rho\,\partial_t^2 u_i \,\mathrm{d}V = \oint_S t_i \,\mathrm{d}S + \int_V f_i \,\mathrm{d}V = \oint_S \sigma_{ik} n_k \,\mathrm{d}S + \int_V f_i \,\mathrm{d}V ,$$

using Equation (30.15). By the divergence theorem (Theorem 7.101) applied to each of the three vector fields $k \mapsto \sigma_{ik}$,

$$\int_V \left(\rho\,\partial_t^2 u_i - \partial_k \sigma_{ik} - f_i\right) \mathrm{d}V = 0 .$$

The region V was arbitrary and the integrand is continuous, so it vanishes pointwise — the argument of the fundamental lemma Lemma 16.18, applied here with arbitrary subregions rather than arbitrary test functions. □

Definition 30.22 (Boundary conditions of elastostatics)**.** The boundary $\partial\Omega$ is partitioned into a part $\partial\Omega_{\mathrm{u}}$ where the displacement is prescribed, $u_i = \bar{u}_i$, and a part $\partial\Omega_{\mathrm{t}}$ where the traction is prescribed, $\sigma_{ik}n_k = \bar{t}_i$. A free surface is the case $\bar{t}_i = 0$. A *kinematically admissible* field is any C^1 field agreeing with $\bar{u}_i$ on $\partial\Omega_{\mathrm{u}}$.

Rests on Theorem 30.21 and Definition 10.24.

Proposition 30.23 (Virtual work; the weak form)**.** *Let σ_{ik} satisfy equilibrium and the traction condition of Definition 30.22. Then for every field w_i vanishing on $\partial\Omega_{\mathrm{u}}$,*

$$\int_\Omega \sigma_{ik}\, w_{ik}\,\mathrm{d}V = \int_\Omega f_i w_i\,\mathrm{d}V + \int_{\partial\Omega_{\mathrm{t}}} \bar{t}_i w_i\,\mathrm{d}S\,, \tag{30.18}$$

with $w_{ik} = \tfrac{1}{2}(\partial_i w_k + \partial_k w_i)$; and conversely, a stress field satisfying Equation (30.18) for all such w_i is in equilibrium.

Rests on Theorem 30.21 and Definition 30.22.

Proof. *Derives Proposition 30.23.*

Because σ_{ik} is symmetric, $\sigma_{ik}\partial_k w_i = \sigma_{ik}w_{ik}$. Integrate the identity $\partial_k(\sigma_{ik}w_i) = (\partial_k\sigma_{ik})\,w_i + \sigma_{ik}\partial_k w_i$ over Ω and apply Theorem 7.101:

$$\oint_{\partial\Omega} \sigma_{ik}n_k w_i\,\mathrm{d}S = \int_\Omega (\partial_k\sigma_{ik})\,w_i\,\mathrm{d}V + \int_\Omega \sigma_{ik}w_{ik}\,\mathrm{d}V\,.$$

On $\partial\Omega_{\mathrm{u}}$ the field w_i vanishes and on $\partial\Omega_{\mathrm{t}}$ the traction is $\bar{t}_i$; substituting $\partial_k\sigma_{ik} = -f_i$ rearranges the display into Equation (30.18). For the converse, run the computation backwards: Equation (30.18) becomes $\int_\Omega (\partial_k\sigma_{ik} + f_i)\,w_i\mathrm{d}V = \int_{\partial\Omega_{\mathrm{t}}} (\bar{t}_i - \sigma_{ik}n_k)\,w_i\mathrm{d}S$ for all admissible w_i, and choosing w_i supported in the interior and then near the traction boundary kills the two brackets in turn by Lemma 16.18. □

Equation (30.18) is the principle of virtual work of Chapter 27 written for a continuum, and it is the form in which elasticity is actually solved: it asks only one derivative of the displacement instead of two, which is what makes the finite-element method and the Sobolev theory of Definition 10.85 and Theorem 10.88 applicable.

30.4 Linear elasticity: Hooke's law and the moduli

30.4.1 Hooke's law

Hooke published the law in 1676 as the anagram *ceiiinosssttuv* and unscrambled it two years later as *ut tensio, sic vis* — as the extension, so the force [13]. What he had was a statement about springs and wires; the tensorial statement below is what it becomes when the body is described by Definition 30.6 and Theorem 30.18.

Definition 30.24 (The elasticity tensor)**.** The *elastic energy density* $F(u_{ik})$ is the reversible work done per unit volume in bringing the body from its unstrained state to the strain u_{ik}, and the stress is

$$\sigma_{ik} = \frac{\partial F}{\partial u_{ik}}\,. \tag{30.19}$$

The *elasticity tensor* is $C_{iklm} = \partial^2 F/\partial u_{ik}\partial u_{lm}$ evaluated at $u_{ik} = 0$, a rank-four Cartesian tensor with the SI dimension of pressure, Pa.

Rests on Definition 30.6 and Theorem 30.18.

Proposition 30.25 (Twenty-one constants)**.** *C_{iklm} obeys the* minor *symmetries $C_{iklm} = C_{kilm} = C_{ikml}$, which follow from the symmetry of u_{ik} and of σ_{ik}, and the* major *symmetry $C_{iklm} = C_{lmik}$, which follows from the existence of the energy F. A general anisotropic solid therefore has* 21 *independent elastic constants.*

Rests on Definition 30.24 and Proposition 7.73.

Proof. *Derives Proposition 30.25.*

Only the part of C_{iklm} symmetric in (ik) and in (lm) can contribute to $C_{iklm}u_{ik}u_{lm}$, since u_{ik} is symmetric; this is the minor symmetry, and it reduces each index pair to the 6 values $\{11, 22, 33, 23, 13, 12\}$. The major symmetry is $\partial^2 F/\partial u_{ik}\partial u_{lm} = \partial^2 F/\partial u_{lm}\partial u_{ik}$, which is Proposition 7.73 for the smooth function F; without an energy function there would be no reason for it. The array is therefore a symmetric 6×6 matrix, with $6 \times 7/2 = 21$ independent entries. □

Lemma 30.26 (Isotropic Cartesian tensors of rank four)**.** *Every rank-four Cartesian tensor invariant under all of* SO(3) *is a linear combination*

$$T_{iklm} = a\,\delta_{ik}\delta_{lm} + b\,\delta_{il}\delta_{km} + c\,\delta_{im}\delta_{kl} \tag{30.20}$$

of the three products of Kronecker deltas, with a, b, c scalars.

Rests on Theorem 5.128 and Definition 13.5.

Full derivation: Appendix A.56 (p. 3100).

Derives Lemma 30.26.

The classification of the isotropic Cartesian tensors of ranks two, three and four is invariant theory for the rotation group — general mathematics rather than elasticity — and it is proved in Part II, for ranks one to four together, as Theorem 5.128; the ranks are settled in one theorem because they share the same machinery, not because the higher needs the lower. The rank-four case is restated here in the notation of this chapter because it is the one step that turns Proposition 30.25's twenty-one constants into two; the appendix section additionally carries the cubic case, which Part II does not treat.

Remark 30.27 (Two results this chapter borrows from Part II). Two pieces of general mathematics are used below and proved nowhere in this chapter, so they are named here rather than passed over. Both were written into Part II in August 2026 after this chapter reported them missing, and the entries stand as a record of what this chapter rests on. *First*, the classification just stated: the isotropic Cartesian tensors of rank two, three and four are spanned by δ_{ik}, by ε_{ikl} and by the three products Equation (30.20) respectively. It is invariant theory for SO(3), and it is Theorem 5.128, with Section 13.2.2 recording what it does for the tensor algebra. *Second*, the Helmholtz decomposition — that a vector field on a suitable domain splits into a gradient and a curl — which is Theorem 7.105. This chapter does *not* use it: the potential representation of Proposition 30.48 is introduced as an ansatz and verified, which proves that the Rayleigh wave exists and is all that proposition claims. The decomposition would be needed only to prove that *every* plane-strain motion is of that form, a completeness statement made nowhere in this chapter.

Rests on Theorems 5.128 and 7.105.

Phenomenon 30.28 (Hooke's law)**.** For sufficiently small deformations the response of a solid is linear and reversible: the elongation of a loaded spring or bar is proportional to the load and is recovered in full when the load is removed — "ut tensio, sic vis" [13]. In continuum terms the stress is a linear function of the strain, and for an isotropic body it depends on the strain through two material constants alone,

$$\sigma_{ik} = \lambda\,u_{ll}\,\delta_{ik} + 2\mu\,u_{ik} \tag{30.21}$$

[138, 1778]. In structural metals the linear regime extends to strains of order 10^{-3} and ends at the yield point of Phenomenon 30.73.

Rests on Definition 30.24 and Lemma 30.26.

Derivation. *Derives Phenomenon 30.28.*

The undeformed state is an equilibrium and carries no stress, so the expansion of the energy density about $u_{ik} = 0$ has neither a constant nor a linear term:

$$F = \tfrac{1}{2}\, C_{iklm}\, u_{ik} u_{lm} + O(u^3)\,, \tag{30.22}$$

with the constant coefficients of Definition 30.24. By Equation (30.19) the stress is then linear in the strain up to the cubic remainder, $\sigma_{ik} = C_{iklm} u_{lm}$. That is Hooke's law, and its observed domain of validity is precisely the range of strains over which the remainder is negligible — which is why the law is a small-strain statement and not a property of any particular material.

If the body is isotropic, C_{iklm} is invariant under every rotation of the frame, so by Lemma 30.26 it has the form Equation (30.20). The minor symmetries of Proposition 30.25 force $b = c$, since exchanging i and k in Equation (30.20) exchanges the coefficients of $\delta_{il}\delta_{km}$ and $\delta_{im}\delta_{kl}$. Writing $a = \lambda$ and $b = c = \mu$ and contracting with u_{lm} gives $\sigma_{ik} = \lambda u_{ll}\delta_{ik} + 2\mu u_{ik}$, which is Equation (30.21). That two constants suffice for an isotropic solid is a consequence of symmetry, not a further approximation [1778]. □

Remark 30.29 (The Lamé constants and the energy). λ and μ are the *Lamé constants* [138], both measured in Pa. Substituting Equation (30.21) into Equation (30.19) and integrating gives the energy density, which in terms of the split Equation (30.5) reads

$$F = \tfrac{1}{2}\lambda\,(u_{ll})^2 + \mu\, u_{ik} u_{ik} = \tfrac{1}{2} K\,(u_{ll})^2 + \mu\, d_{ik} d_{ik}\,, \qquad K = \lambda + \tfrac{2}{3}\mu\,. \tag{30.23}$$

The second form is the useful one: it separates the energy of a pure volume change from that of a pure shape change, and shows that the two are stored independently. μ is the *shear modulus* and K the *bulk modulus*.

Rests on Equations (30.5) and (30.21).

Proposition 30.30 (Stability bounds)**.** *The unstrained state is a strict minimum of the elastic energy if and only if*

$$\mu > 0 \qquad \text{and} \qquad K = \lambda + \tfrac{2}{3}\mu > 0\,. \tag{30.24}$$

Rests on Equation (30.23) and Theorem 5.112.

Proof. *Derives Proposition 30.30.*

The second form of Equation (30.23) is a sum of two squares in variables that are independent — the trace u_{ll} and the five components of the traceless d_{ik} — so the quadratic form is positive definite exactly when both coefficients are positive, which is Theorem 5.112 read on a form already in normal shape. Each condition is realised by an admissible strain: a pure dilatation $u_{ik} = \epsilon\delta_{ik}$ has $F = \frac{9}{2} K\epsilon^2$ and no shear, and a pure shear as in Example 30.10 has $F = \mu\gamma^2/2$ and no dilatation. A body violating either bound would gain energy by deforming and would not be found in the unstrained state at all. □

30.4.2 The elastic moduli and their measurement

The two constants of Equation (30.21) may be traded for any other independent pair, and the laboratory has good reasons to prefer other pairs: λ corresponds to no experiment anyone performs, whereas the modulus that a tensile machine measures does.

Definition 30.31 (The engineering moduli)**.** For an isotropic solid define

- the *bulk modulus* K by $p = -K\, u_{ll}$ under hydrostatic loading;
- the *shear modulus* μ by $s_{ik} = 2\mu\, d_{ik}$;

- *Young's modulus* E [53] by $\sigma = E\,u_{\parallel}$ under uniaxial stress;
- *Poisson's ratio* ν [86] by $\nu = -u_{\perp}/u_{\parallel}$ under uniaxial stress;
- the *P-wave modulus* $M = \lambda + 2\mu$, the stiffness under uniaxial *strain*.

All but ν are pressures, measured in Pa; ν is dimensionless.
Rests on Equation (30.21) *and Definition 30.20.*

Phenomenon 30.32 (Poisson contraction)**.** A bar stretched along its axis contracts in the two transverse directions. Under uniaxial stress the ratio of transverse contraction to longitudinal extension is a material constant, Poisson's ratio ν [86], and the axial strain is itself proportional to the applied stress, the constant of proportionality being Young's modulus E [53]. The measured value of ν for every ordinary solid lies inside the stability window

$$-1 < \nu < \tfrac{1}{2}\,, \tag{30.25}$$

clustering near $\nu \approx 0.3$ for structural metals and approaching the upper, incompressible end for materials whose shear modulus is small against their bulk modulus [1455].
Rests on Phenomenon 30.28 and Proposition 30.30.

Derivation. *Derives Phenomenon 30.32.*

Take the bar along z and impose the uniaxial stress $\sigma_{zz} = \sigma$ with all other stress components zero. By isotropy the strain is diagonal, with $u_{xx} = u_{yy} \equiv u_{\perp}$ and $u_{zz} \equiv u_{\parallel}$. The transverse components of Equation (30.21) read $0 = \lambda(2u_{\perp} + u_{\parallel}) + 2\mu u_{\perp}$, so

$$\nu \equiv -\frac{u_{\perp}}{u_{\parallel}} = \frac{\lambda}{2(\lambda+\mu)}\,, \tag{30.26}$$

which is positive whenever $\lambda > 0$: the transverse strain has the sign opposite to the axial one, as observed. Substituting back into the axial component gives $\sigma = \mu(3\lambda + 2\mu)u_{\parallel}/(\lambda+\mu)$, so that $E = \mu(3\lambda+2\mu)/(\lambda+\mu)$ — the modulus is not an independent constant but a combination of the two in Equation (30.21). For the bounds, use Proposition 30.30: $\mu > 0$ and $K = \lambda + \frac{2}{3}\mu > 0$. Writing $x = \mu/K$, so that x ranges over $(0, \infty)$, Equation (30.26) becomes

$$\nu = \frac{3 - 2x}{2(3+x)}\,, \tag{30.27}$$

a strictly decreasing function of x with limits $\frac{1}{2}$ as $x \to 0$ and -1 as $x \to \infty$. Its range is therefore the open interval of Equation (30.25). A solid far harder to compress than to shear sits at the top of that interval: it is effectively incompressible and contracts transversely by half of what it extends. □

Proposition 30.33 (Conversion among the moduli)**.** *Any two of* $(\lambda, \mu, K, E, \nu, M)$ *determine the rest. In particular*

$$\mu = \frac{E}{2(1+\nu)}\,, \qquad K = \frac{E}{3(1-2\nu)}\,, \qquad \lambda = \frac{2\mu\nu}{1-2\nu}\,, \tag{30.28}$$

$$E = \frac{9K\mu}{3K+\mu}\,, \qquad \nu = \frac{3K-2\mu}{2(3K+\mu)}\,, \qquad M = K + \tfrac{4}{3}\mu\,. \tag{30.29}$$

Rests on Phenomenon 30.32 and Definition 30.31.

Proof. *Derives Proposition 30.33.*

The derivation of Phenomenon 30.32 gave $\nu = \lambda/\left[2(\lambda+\mu)\right]$ and $E = \mu(3\lambda+2\mu)/(\lambda+\mu)$. Solving the first for λ gives $\lambda(1-2\nu) = 2\mu\nu$, the third relation of Equation (30.28); substituting it into the second gives $E = \mu\left[3\cdot 2\mu\nu/(1-2\nu) + 2\mu\right] / \left[2\mu\nu/(1-2\nu) + \mu\right] = 2\mu(1+\nu)$, the first. Then $K = \lambda + \frac{2}{3}\mu = 2\mu\nu/(1-2\nu) + \frac{2}{3}\mu = \frac{2}{3}\mu(1+\nu)/(1-2\nu) =$

$E/[3(1-2\nu)]$, the second. Eliminating ν between the first two of Equation (30.28) gives $3K(1-2\nu) = 2\mu(1+\nu)$, hence $\nu = (3K-2\mu)/[2(3K+\mu)]$ and, back-substituting, $E = 2\mu(1+\nu) = 9K\mu/(3K+\mu)$. Finally $M = \lambda + 2\mu = \left(K - \tfrac{2}{3}\mu\right) + 2\mu = K + \tfrac{4}{3}\mu$. □

One further consequence of the quadratic energy is needed before the measured values, because it is what turns an assumed deformation into a rigorous *bound* on a modulus.

Proposition 30.34 (Minimum of the potential energy)**.** *Among all kinematically admissible displacement fields, the equilibrium field — and only it, up to a rigid displacement compatible with the constraints — minimises*

$$\Pi[\boldsymbol{v}] = \int_\Omega F\left(v_{ik}\right) \mathrm{d}V - \int_\Omega f_i v_i \,\mathrm{d}V - \int_{\partial\Omega_\mathrm{t}} \bar{t}_i v_i \,\mathrm{d}S\,. \tag{30.30}$$

Rests on Propositions 30.23 and 30.30.

Proof. *Derives Proposition 30.34.*

Let $\boldsymbol{u}$ be the equilibrium field and $\boldsymbol{v} = \boldsymbol{u} + \boldsymbol{w}$ any admissible competitor, so that $\boldsymbol{w}$ vanishes on $\partial\Omega_\mathrm{u}$. Because F is the quadratic form Equation (30.22), $F(u_{ik}+w_{ik}) = F(u_{ik}) + \sigma_{ik}w_{ik} + F(w_{ik})$ exactly, the cross term being $C_{iklm}u_{lm}w_{ik} = \sigma_{ik}w_{ik}$ by the major symmetry of Proposition 30.25. Hence

$$\Pi[\boldsymbol{v}] - \Pi[\boldsymbol{u}] = \int_\Omega \sigma_{ik}w_{ik}\,\mathrm{d}V - \int_\Omega f_i w_i \,\mathrm{d}V - \int_{\partial\Omega_\mathrm{t}} \bar{t}_i w_i \,\mathrm{d}S + \int_\Omega F(w_{ik})\,\mathrm{d}V\,.$$

The first three terms cancel by Proposition 30.23, and the last is non-negative by Proposition 30.30, vanishing only if $w_{ik} \equiv 0$, i.e. only if $\boldsymbol{w}$ is a rigid displacement (Proposition 30.12). This is the Dirichlet principle of Proposition 10.91 for the elastic operator, and the same convexity underwrites the direct method Theorem 16.70. □

Table 30.1: Measured room-temperature elastic constants of five cubic single crystals, in the Voigt notation of Definition 30.37, from the compilation of Simmons and Wang [1455]. The spread between independent determinations of these quantities is typically 1 %, which is the uncertainty to attach to every entry. $A = 2C_{44}/(C_{11}-C_{12})$ is the anisotropy factor, equal to 1 for an isotropic solid; the last column tests the Cauchy relation $C_{12} = C_{44}$ of Proposition 30.38, which holds only for the ionic crystal.

Crystal	C_{11} (GPa)	C_{12} (GPa)	C_{44} (GPa)	A	C_{12}/C_{44}
Aluminium	106.8	60.4	28.3	1.22	2.13
Copper	168.4	121.4	75.4	3.21	1.61
Iron	231.4	134.7	116.4	2.41	1.16
Sodium chloride	49.1	12.8	12.8	0.71	1.00
Diamond	1076	125	577	1.21	0.22

Example 30.35 (From single crystals to the isotropic aggregate)**.** A polycrystal is a mass of randomly oriented anisotropic grains and is isotropic on the average, so it must be described by two constants built from the three of Table 30.1. For a cubic crystal the bulk modulus is exact and orientation independent, $K = (C_{11}+2C_{12})/3$. The shear modulus is not, and is bracketed by two estimates: assuming a uniform *strain* throughout the aggregate gives the Voigt value $\mu_\mathrm{V} = (C_{11}-C_{12}+3C_{44})/5$, and assuming a uniform *stress* gives the Reuss value $\mu_\mathrm{R} = 5(C_{11}-C_{12})C_{44}/[4C_{44}+3(C_{11}-C_{12})]$. A uniform strain is a kinematically admissible field but not the equilibrium one, so by Proposition 30.34 it stores more energy

Table 30.2: Isotropic (polycrystalline aggregate) moduli computed from Table 30.1 by the averaging of Example 30.35, with ν and E then following from Equation (30.29). The propagated uncertainty is about 1 % on K, μ and E and about 0.01 on ν, inherited from the single-crystal data; the residual disagreement with handbook values for the corresponding polycrystals is of the same size.

Material	K (GPa)	μ (GPa)	E (GPa)	ν
Aluminium	75.9	26.1	70.4	0.345
Copper	137.1	47.3	127.3	0.345
Iron	166.9	81.8	210.9	0.289
Sodium chloride	24.9	14.7	36.8	0.253
Diamond	442	534	1142	0.069

than the true field does at the same overall deformation: the aggregate looks stiffer than it is, and μ_{V} is a rigorous upper bound. μ_{R} is the corresponding uniform-stress estimate; it falls below μ_{V} for every entry of Table 30.1, and the dual variational principle — minimum complementary energy at fixed stress, which this chapter states without proving — is what makes that ordering general. Their arithmetic mean is a convention, not a theorem, and it is what Table 30.2 reports.

For iron the arithmetic is $K = (231.4 + 269.4)/3 = 166.9\,\mathrm{GPa}$, $\mu_{\mathrm{V}} = (96.7 + 349.2)/5 = 89.2\,\mathrm{GPa}$, $\mu_{\mathrm{R}} = 5(96.7)(116.4)/(465.6 + 290.1) = 74.5\,\mathrm{GPa}$, mean $81.8\,\mathrm{GPa}$; then Equation (30.29) gives $E = 211\,\mathrm{GPa}$ and $\nu = 0.289$. Those are the values quoted for structural steel in every engineering handbook, obtained here from three ultrasonic measurements on a single crystal of pure iron and one averaging assumption. The width of the Voigt–Reuss bracket, 18 % of the mean, is a direct measure of the anisotropy $A = 2.41$; for aluminium, with $A = 1.22$, the same bracket is under 1 % wide, and the Hill convention costs nothing there.

Rests on Propositions 30.33 and 30.34.

Remark 30.36 (How the moduli are actually measured). Three routes, of increasing precision, all traceable to the SI metre, second and kilogram (Chapter 2).

- *Static loading.* Hang a known force on a bar of known cross-section and measure the extension. A steel bar at $\sigma = 200\,\mathrm{MPa}$ — a working stress — stretches by $u_{\parallel} = \sigma/E = 9.5 \times 10^{-4}$, about one part in a thousand, so a metre of bar lengthens by 0.95 mm. That is easy to see and hard to measure to better than 1 %, and the method is further limited by grip effects and by creep.

- *Resonance.* Excite a bar or plate and count its natural frequencies; the moduli follow from the eigenvalue relations of Propositions 30.57 and 30.66. Counting is the one laboratory operation done without error, so this is immediately two orders of magnitude better.

- *Ultrasonic pulse-echo.* Time a pulse across a specimen of measured thickness and obtain v_{P} and v_{S} directly; then by Equation (30.35)

$$\mu = \rho\, v_{\mathrm{S}}^2\,, \qquad \lambda = \rho\left(v_{\mathrm{P}}^2 - 2v_{\mathrm{S}}^2\right). \tag{30.31}$$

  This needs one length, two times and a density, is insensitive to the specimen's shape, and works on a crystal small enough that no static test could grip it — which is why the tabulated single-crystal constants of Table 30.1 are almost all ultrasonic.

Rests on Equation (30.35) and Proposition 30.33.

30.4.3 Anisotropic elasticity

Definition 30.37 (Voigt notation)**.** Map each symmetric index pair to a single index by $11 \mapsto 1$, $22 \mapsto 2$, $33 \mapsto 3$, $23 \mapsto 4$, $13 \mapsto 5$, $12 \mapsto 6$, and write $C_{\alpha\beta}$ for the resulting symmetric 6×6 matrix of Proposition 30.25 [364]. The stress components map directly, σ_α; the strain components carry a factor two on the shear entries, $u_4 = 2u_{23}$, $u_5 = 2u_{13}$, $u_6 = 2u_{12}$, so that $\sigma_\alpha = C_{\alpha\beta} u_\beta$ and $F = \tfrac{1}{2} C_{\alpha\beta} u_\alpha u_\beta$ both hold with no stray factors.

Rests on Proposition 30.25 and Definition 30.24.

Crystal symmetry cuts the 21 constants down. Each symmetry operation of the crystal class must leave $C_{\alpha\beta}$ invariant, and the resulting linear conditions leave 13 constants for the monoclinic classes, 9 for the orthorhombic, 6 or 7 for the tetragonal and trigonal, 5 for the hexagonal, 3 for the cubic — C_{11}, C_{12} and C_{44}, the constants tabulated in Table 30.1 — and 2 for the isotropic limit, where in addition $C_{11} = \lambda + 2\mu$, $C_{12} = \lambda$ and $C_{44} = \mu$, so that $A = 2C_{44}/(C_{11} - C_{12}) = 1$ [364]. The measured A is thus a direct readout of how far a crystal is from isotropy, and Table 30.1 shows it ranging from 0.71 for sodium chloride to 3.21 for copper: a copper single crystal is more than three times stiffer in shear on one set of planes than on another, which is why a textured copper sheet is not an isotropic body.

Proposition 30.38 (The Cauchy relations)**.** *Suppose the atoms of a crystal sit at centres of symmetry of the lattice and interact through central pair potentials $\varphi(r)$, and that the crystal is under no external stress. Then C_{iklm} is symmetric under* every *permutation of its four indices, so that six further relations hold and only* 15 *constants remain. For a cubic crystal the single relation is*

$$C_{12} = C_{44}\,. \tag{30.32}$$

Rests on Definition 30.24 and Proposition 30.25.

Proof. *Derives Proposition 30.38.*

Write $\eta_b = u_{ik} n_i n_k$ for the bond of length r_b and direction $\hat{\boldsymbol{n}}$. By Equation (30.8) the strained length is $r_b' = r_b\,(1 + 2\eta_b)^{1/2} = r_b \left(1 + \eta_b - \tfrac{1}{2}\eta_b^2 + \cdots\right)$. Because every atom sits at a centre of symmetry the bonds come in antiparallel pairs, so no internal relaxation of the sublattices is induced by a homogeneous strain and the energy per unit volume is simply $\sum_b \varphi(r_b')$ over the bonds of one cell divided by its volume. Expanding,

$$\varphi(r_b') = \varphi(r_b) + \varphi'(r_b)\, r_b\, \eta_b + \tfrac{1}{2}\left[\varphi''(r_b) - \frac{\varphi'(r_b)}{r_b}\right] r_b^2\, \eta_b^2 + O(\eta^3)\,.$$

The coefficient of the term linear in u_{ik} is the residual stress, which vanishes by the zero-stress hypothesis. The quadratic term gives

$$C_{iklm} = \sum_b w_b\, n_i n_k n_l n_m\,, \qquad w_b = \frac{1}{V}\left[\varphi''(r_b) - \frac{\varphi'(r_b)}{r_b}\right] r_b^2\,,$$

since $\eta_b^2 = u_{ik} u_{lm} n_i n_k n_l n_m$; the weights w_b depend on the bond length alone, and their exact normalisation — how the bond sum is counted — does not matter for what follows. Every summand is a product of four components of one and the same unit vector, hence invariant under any permutation of $iklm$; so is C_{iklm}. In particular $C_{1122} = C_{1212}$, which in the notation of Definition 30.37 reads $C_{12} = C_{66}$, and $C_{66} = C_{44}$ for a cubic crystal: that is Equation (30.32). The other five relations are the remaining independent identifications among the 21 constants. □

Remark 30.39 (The rari-constant controversy, decided by measurement). Proposition 30.38 was the ground of a nineteenth-century dispute. Navier and Poisson built elasticity on central forces between molecules and so predicted 15 constants, and 1 for an isotropic body

— with $\lambda = \mu$ and therefore $\nu = \frac{1}{4}$ exactly [80, 86]. Green and Lamé built it on the energy alone and predicted 21 and 2 [138]. The question is empirical, and Table 30.1 settles it: the last column should be 1.00 for every crystal if the Cauchy relations held, and it is 1.00 only for sodium chloride, running to 2.13 for aluminium and 0.22 for diamond. Voigt's systematic measurements across the crystal classes are what closed the matter in favour of the multi-constant theory [364]. The physical reading is now clear: an ionic crystal is held together by very nearly central forces between closed shells, so it nearly obeys the relations; a metal is held together by a delocalised electron gas and diamond by directional covalent bonds, and neither is a sum of central pair potentials. That is a statement about the electronic structure, and it is settled in Chapter 126; the elastic constants of Table 30.1 are among the sharpest classical constraints on it, and they reappear as the long-wavelength limit of the lattice dynamics of Chapter 125.

Rests on Proposition 30.38 and Definition 30.37.

30.5 Elastodynamics and elastic waves

30.5.1 The Navier–Cauchy equations

Theorem 30.40 (Navier–Cauchy equations)**.** *A homogeneous isotropic linearly elastic body obeys*

$$\rho\,\partial_t^2 \boldsymbol{u} = (\lambda+\mu)\,\boldsymbol{\nabla}\,(\boldsymbol{\nabla}\cdot\boldsymbol{u}) + \mu\,\nabla^2\boldsymbol{u} + \boldsymbol{f}\,. \tag{30.33}$$

Rests on Theorem 30.21 and Equation (30.21).

Proof. *Derives Theorem 30.40.*

Substitute Equation (30.21), with $u_{ik} = \frac{1}{2}(\partial_i u_k + \partial_k u_i)$, into Cauchy's equation Equation (30.17). Since λ and μ are constants,

$$\partial_k \sigma_{ik} = \lambda\,\partial_i(\boldsymbol{\nabla}\cdot\boldsymbol{u}) + \mu\,\partial_k(\partial_i u_k + \partial_k u_i) = (\lambda+\mu)\,\partial_i(\boldsymbol{\nabla}\cdot\boldsymbol{u}) + \mu\,\nabla^2 u_i\,,$$

where $\partial_k\partial_i u_k = \partial_i\partial_k u_k = \partial_i(\boldsymbol{\nabla}\cdot\boldsymbol{u})$ by Proposition 7.73. This is Equation (30.33). Navier reached the same equation from a molecular model in which the constants were not independent [80]; Cauchy reached it from the stress tensor, in which they are [73], and Remark 30.39 says which of the two the measurements support. □

Proposition 30.41 (Energy balance and its flux)**.** *Define the energy density and the energy flux*

$$e = \tfrac{1}{2}\rho\,\dot{u}_i\dot{u}_i + F\,(u_{ik})\;, \qquad q_k = -\sigma_{ik}\dot{u}_i\,. \tag{30.34}$$

Then $\partial_t e + \partial_k q_k = f_i\dot{u}_i$: elastic energy is locally conserved, and it is transported at the rate at which the internal tractions do work.

Rests on Theorem 30.40 and Equation (30.23).

Proof. *Derives Proposition 30.41.*

Differentiate: $\partial_t e = \rho\dot{u}_i\ddot{u}_i + \sigma_{ik}\dot{u}_{ik}$, using Equation (30.19) for the second term. Because σ_{ik} is symmetric, $\sigma_{ik}\dot{u}_{ik} = \sigma_{ik}\partial_k\dot{u}_i$. Substituting $\rho\ddot{u}_i = \partial_k\sigma_{ik} + f_i$ from Equation (30.17),

$$\partial_t e = \dot{u}_i\partial_k\sigma_{ik} + \sigma_{ik}\partial_k\dot{u}_i + f_i\dot{u}_i = \partial_k(\sigma_{ik}\dot{u}_i) + f_i\dot{u}_i\,,$$

which is the stated balance with q_k as defined. □

Theorem 30.42 (Uniqueness in elastodynamics)**.** *The initial-boundary-value problem for Equation (30.33) — with $\boldsymbol{u}$ and $\dot{\boldsymbol{u}}$ given at $t = 0$, and with either the displacement or the traction prescribed at every point of $\partial\Omega$ at every time — has at most one solution, up to a time-independent rigid displacement when no displacement is prescribed anywhere.*

Rests on Propositions 30.30 and 30.41.

Proof. *Derives Theorem 30.42.*

Let $\boldsymbol{w}$ be the difference of two solutions. It solves Equation (30.33) with $\boldsymbol{f} = 0$, with zero initial data, and with $\boldsymbol{w} = 0$ or $\sigma_{ik}[\boldsymbol{w}]n_k = 0$ at each boundary point. By Proposition 30.41 its total energy $\mathcal{E}(t) = \int_\Omega e \, \mathrm{d}V$ satisfies

$$\frac{\mathrm{d}\mathcal{E}}{\mathrm{d}t} = -\oint_{\partial\Omega} q_k n_k \, \mathrm{d}S = \oint_{\partial\Omega} \sigma_{ik} n_k \, \dot{w}_i \, \mathrm{d}S = 0 \,,$$

by Theorem 7.101, since on each part of the boundary one factor of the integrand vanishes — the traction where the traction is prescribed, the velocity where the displacement is. Hence $\mathcal{E}(t) = \mathcal{E}(0) = 0$ for all t. But $\mathcal{E}$ is an integral of a sum of two non-negative terms, the second positive definite by Proposition 30.30, so $\dot{\boldsymbol{w}} \equiv 0$ and $w_{ik} \equiv 0$; by Proposition 30.12 $\boldsymbol{w}$ is a rigid displacement, constant in time, and it vanishes if the displacement is prescribed anywhere. This is what makes the problem well posed in the sense of Definition 10.24, and the same energy identity gives the continuous dependence on the data. □

30.5.2 P and S waves

Phenomenon 30.43 (Two bulk wave speeds)**.** An isotropic elastic solid transmits exactly two kinds of bulk wave: a longitudinal, compressional wave (the P phase of seismology) and a transverse, shear wave (the S phase), travelling at the distinct speeds

$$v_\mathrm{P} = \sqrt{\frac{\lambda + 2\mu}{\rho}} \,, \qquad v_\mathrm{S} = \sqrt{\frac{\mu}{\rho}} \,, \tag{30.35}$$

with $v_\mathrm{P} > v_\mathrm{S}$ in every material [86]. The P arrival therefore always precedes the S arrival on a seismogram, and their separation measures the distance to the source [293]. A fluid, which cannot support a static shear, has $\mu = 0$ and carries no transverse branch at all.

Rests on Theorem 30.40 and Proposition 30.30.

Derivation. *Derives Phenomenon 30.43.*

Look for plane-wave solutions of the source-free Equation (30.33), $\boldsymbol{u} = \boldsymbol{A} \exp\left[\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega t)\right]$, with $\boldsymbol{A}$ a constant polarization vector. Each spatial derivative brings down $\mathrm{i}k_j$ and each time derivative $-\mathrm{i}\omega$, so $\boldsymbol{\nabla}(\boldsymbol{\nabla}\cdot\boldsymbol{u}) \mapsto -(\boldsymbol{k}\cdot\boldsymbol{A})\,\boldsymbol{k}$ and $\nabla^2\boldsymbol{u} \mapsto -k^2\boldsymbol{A}$, giving

$$\rho\,\omega^2 A_i = \Gamma_{il} A_l \,, \qquad \Gamma_{il} = (\lambda + \mu)\, k_i k_l + \mu k^2 \delta_{il} \,. \tag{30.36}$$

A plane wave exists exactly when $\boldsymbol{A}$ is an eigenvector of the *acoustic tensor* Γ_{il}, with $\rho\omega^2$ the eigenvalue. Γ is real and symmetric, so Theorem 5.75 supplies an orthonormal eigenbasis, and it can be read off: $\hat{\boldsymbol{k}}$ is an eigenvector with eigenvalue $(\lambda+\mu)k^2 + \mu k^2 = (\lambda + 2\mu)k^2$, and every vector orthogonal to $\boldsymbol{k}$ is an eigenvector with eigenvalue μk^2. Those three exhaust $\mathbb{R}^3$, so there are no other polarizations. Hence

$$\omega^2 = \frac{\lambda + 2\mu}{\rho}\, k^2 \quad \text{for } \boldsymbol{A} \parallel \boldsymbol{k} \,, \qquad \omega^2 = \frac{\mu}{\rho}\, k^2 \quad \text{for } \boldsymbol{A} \perp \boldsymbol{k} \,,$$

which are the two speeds Equation (30.35). Both branches are non-dispersive: ω is proportional to k, so a pulse travels undistorted, which is what makes an arrival time a meaningful observable at all.

The physical labels follow from the polarizations. The longitudinal branch has $\boldsymbol{\nabla}\times\boldsymbol{u} = 0$ and carries the dilatation $\boldsymbol{\nabla}\cdot\boldsymbol{u}$; the transverse branch has $\boldsymbol{\nabla}\cdot\boldsymbol{u} = 0$ and carries the rotation, deforming without changing any volume. Finally

$$v_\mathrm{P}^2 - v_\mathrm{S}^2 = \frac{\lambda + \mu}{\rho} = \frac{K + \frac{1}{3}\mu}{\rho} > 0$$

by Proposition 30.30: the ordering of the two speeds is not an accident of the materials that happen to exist but follows from the existence of a stable unstrained state. Setting $\mu = 0$ annihilates the transverse branch and leaves $v_{\mathrm{P}} = \sqrt{K/\rho}$, the sound speed of Chapter 31. □

Proposition 30.44 (The speed ratio is fixed by Poisson's ratio)**.**

$$\frac{v_{\mathrm{P}}}{v_{\mathrm{S}}} = \sqrt{\frac{2(1-\nu)}{1-2\nu}}\,, \tag{30.37}$$

a strictly increasing function of ν on Equation (30.25) with range $\left(2/\sqrt{3}, \infty\right)$. No elastic solid whatever has $v_{\mathrm{P}}/v_{\mathrm{S}} \le 2/\sqrt{3} = 1.1547$, and a measurement of the ratio determines ν without any knowledge of the density.

Rests on Equation (30.35) and Proposition 30.33.

Proof. *Derives Proposition 30.44.*

From Equation (30.35), $v_{\mathrm{P}}^2/v_{\mathrm{S}}^2 = (\lambda + 2\mu)/\mu = \lambda/\mu + 2$, and $\lambda/\mu = 2\nu/(1-2\nu)$ by Equation (30.28); adding gives $(2\nu + 2 - 4\nu)/(1-2\nu) = 2(1-\nu)/(1-2\nu)$, which is Equation (30.37). Differentiating the square, $\mathrm{d}\left[2(1-\nu)/(1-2\nu)\right]/\mathrm{d}\nu = 2/(1-2\nu)^2 > 0$, so it increases; its values at the endpoints $\nu = -1$ and $\nu \to \frac{1}{2}$ are $4/3$ and $+\infty$. The density cancels between the two speeds, which is the practical point: an ultrasonic apparatus that measures only times and one length returns ν directly. □

Example 30.45 (Elastic waves in steel, and the distance to a source)**.** Take the aggregate iron of Table 30.2, $E = 211\,\mathrm{GPa}$, $\nu = 0.289$, with $\rho = 7850\,\mathrm{kg/m^3}$. Then $\mu = E/\left[2(1+\nu)\right] = 81.8\,\mathrm{GPa}$ and $M = \lambda + 2\mu = K + \frac{4}{3}\mu = 276\,\mathrm{GPa}$, so

$$v_{\mathrm{P}} = \sqrt{\frac{2.76 \times 10^{11}\,\mathrm{Pa}}{7850\,\mathrm{kg/m^3}}} = 5.93 \times 10^3\,\mathrm{m/s}\,, \qquad v_{\mathrm{S}} = 3.23 \times 10^3\,\mathrm{m/s}\,,$$

in a ratio 1.84, which Equation (30.37) returns from $\nu = 0.289$ alone. These are the handbook speeds for steel, and the agreement is a closed loop: three ultrasonic constants of a single crystal in Table 30.1, averaged in Example 30.35, reproduce the ultrasonic speeds of the polycrystal.

The separation of the two arrivals then gives the distance. A source at range d sends its P and S phases along the same path, so

$$\Delta t = d\left(\frac{1}{v_{\mathrm{S}}} - \frac{1}{v_{\mathrm{P}}}\right)\,, \tag{30.38}$$

and for the steel above $\Delta t/d = 1.41 \times 10^{-4}\,\mathrm{s/m}$: a delay of one millisecond places the source 7.1 m away. The same arithmetic on a planetary scale, with the phases identified on a seismogram written thousands of kilometres from the epicentre, is Oldham's method and the foundation of seismology [293].

Rests on Proposition 30.44 and Equation (30.35).

Remark 30.46 (Why the plane-wave route, and not the potentials). The derivation of Phenomenon 30.43 was carried out on plane waves, where the completeness of the two polarizations is the spectral theorem for the 3×3 matrix Γ_{il} and nothing more. The usual textbook route instead splits an *arbitrary* displacement field as $\boldsymbol{u} = \boldsymbol{\nabla}\phi + \boldsymbol{\nabla} \times \boldsymbol{\psi}$ with $\boldsymbol{\nabla} \cdot \boldsymbol{\psi} = 0$ and shows that ϕ and $\boldsymbol{\psi}$ separately obey wave equations with the speeds Equation (30.35). That route needs the Helmholtz decomposition theorem — existence and uniqueness of the split, with the conditions at infinity that make it unique — which is general vector analysis and is Theorem 7.105, proved in Appendix A.45. Either route is therefore available. The plane-wave argument is kept because it is self-contained and

because it is what the seismological data are read against; the same theorem is what the potentials of Proposition 30.48 would need if that proposition claimed completeness, which it does not — see Remark 30.27.

Rests on Phenomenon 30.43 and Theorems 7.105 and 30.40.

30.5.3 Surface waves and the seismological evidence

Phenomenon 30.47 (The three seismic phases)**.** A seismogram written far from an earthquake shows three groups of arrivals in a fixed order: a first, small compressional motion, a second and larger shear motion, and last of all a long, slowly decaying train of large-amplitude waves whose period varies through the train [293]. The third group is confined to the neighbourhood of the free surface, travels more slowly than either bulk wave of Phenomenon 30.43, and decays with depth over a distance of the order of a wavelength; its two polarizations are the vertically polarized Rayleigh wave, which exists on a homogeneous half-space [232], and the horizontally polarized Love wave, which requires a surface layer of lower shear speed over a faster substrate [376].

Rests on Phenomenon 30.43 and Proposition 30.49.

Derivation. *Derives Phenomenon 30.47.*

The order of the first two groups is Equation (30.38) with $v_{\mathrm{P}} > v_{\mathrm{S}}$, established in Phenomenon 30.43. That the third group comes last is Proposition 30.49 and Proposition 30.50: both surface branches travel below v_{S}, the Rayleigh wave at $0.919\,v_{\mathrm{S}}$ for a Poisson solid and the Love wave between the two shear speeds of the layered structure. That the third group is the *largest* at great range, though the source radiates mostly body waves, is geometric. A body wave from a point source spreads over a hemisphere of area $2\pi r^2$, so its energy flux falls as r^{-2} and its amplitude as r^{-1}; a surface wave is confined to a skin of fixed thickness of order one wavelength and spreads over a cylinder of area $2\pi r \times \text{const}$, so its flux falls as r^{-1} and its amplitude only as $r^{-1/2}$. At $r = 1000\,\mathrm{km}$ from a source of characteristic size $10\,\mathrm{km}$ the surface wave is therefore favoured by a factor $(r/r_0)^{1/2} = 10$ in amplitude over the body waves, which is why it dominates a distant record.

That the train is long and its period varies through it — the observed *dispersion* — is Proposition 30.50: the Love speed depends on $\omega H/\beta$, so different periods arrive at different times and a single impulsive source is drawn out into a train ordered in period. A homogeneous half-space would give a Rayleigh wave with no dispersion at all (Proposition 30.48 contains no length), so the observed dispersion is itself the evidence that the Earth is layered. Finally, the confinement to the surface: both branches are built from solutions decaying as e^{-qz} with q of order k, so the motion is negligible below a depth of about one wavelength — $35\,\mathrm{km}$ for a $10\,\mathrm{s}$ Love wave travelling at $3.5\,\mathrm{km/s}$. □

Proposition 30.48 (Rayleigh's secular equation)**.** *On the traction-free surface of a homogeneous isotropic half-space there is a wave whose displacement is confined to a plane containing the propagation direction and the normal, decays exponentially with depth, and travels at a speed $c = \xi v_{\mathrm{S}}$ where ξ solves*

$$\left(2-\xi^2\right)^2 = 4\sqrt{1-\xi^2}\,\sqrt{1-\gamma\xi^2}\,, \qquad \gamma = \frac{v_{\mathrm{S}}^2}{v_{\mathrm{P}}^2} = \frac{1-2\nu}{2-2\nu}\,, \tag{30.39}$$

with $0 < \xi < 1$ [232]. The equation contains no length, so the wave is non-dispersive.

Rests on Theorem 30.40 and Definition 30.22.

Proof. *Derives Proposition 30.48.*

Let z measure depth from the free surface, so that the solid occupies $z > 0$, let the propagation be along x, and seek a motion with $u_y = 0$ and no dependence on y. Build it from two potentials,

$$u_x = \partial_x\phi + \partial_z\psi\,, \qquad u_z = \partial_z\phi - \partial_x\psi\,. \tag{30.40}$$

This is an ansatz, not a decomposition theorem, and it is all the proposition needs: it asserts that such a wave *exists*, so it is enough to exhibit one. Since $\boldsymbol{\nabla}\cdot\boldsymbol{u}=\nabla^2\phi$, substituting Equation (30.40) into the source-free Equation (30.33) and collecting gives

$$\partial_x\left[\rho\partial_t^2\phi-(\lambda+2\mu)\nabla^2\phi\right]+\partial_z\left[\rho\partial_t^2\psi-\mu\nabla^2\psi\right]=0$$

for the x component and the same two brackets differentiated by ∂_z and $-\partial_x$ for the z component, so it suffices that each bracket vanish: ϕ obeys the wave equation at v_{P} and ψ at v_{S}, the two speeds Equation (30.35).

Take the surface wave

$$\phi=A\,\mathrm{e}^{-pz}\,\mathrm{e}^{\mathrm{i}(kx-\omega t)}\,,\qquad \psi=B\,\mathrm{e}^{-qz}\,\mathrm{e}^{\mathrm{i}(kx-\omega t)}\,, \tag{30.41}$$

with $k>0$. The two wave equations fix $p^2=k^2-\omega^2/v_{\mathrm{P}}^2$ and $q^2=k^2-\omega^2/v_{\mathrm{S}}^2$, so writing $c=\omega/k=\xi v_{\mathrm{S}}$,

$$p=k\sqrt{1-\gamma\xi^2}\,,\qquad q=k\sqrt{1-\xi^2}\,, \tag{30.42}$$

both real and positive — so that the motion decays with depth over a distance of order $1/k$ — precisely when $0<\xi<1$, since $\gamma<1$ by $v_{\mathrm{S}}<v_{\mathrm{P}}$ (Phenomenon 30.43).

The free surface $z=0$ carries no traction (Definition 30.22), which for this motion is the two conditions $\sigma_{zz}=\sigma_{xz}=0$. From Equation (30.21),

$$\sigma_{zz}=\lambda\nabla^2\phi+2\mu\left(\partial_z^2\phi-\partial_x\partial_z\psi\right)\,, \tag{30.43}$$

$$\sigma_{xz}=\mu\left[2\partial_x\partial_z\phi+\left(\partial_z^2-\partial_x^2\right)\psi\right]\,. \tag{30.44}$$

Insert Equation (30.41). In the first, the coefficient of A is $\lambda\left(p^2-k^2\right)+2\mu p^2=(\lambda+2\mu)p^2-\lambda k^2=2\mu k^2-\rho\omega^2=\mu k^2\left(2-\xi^2\right)$, using $\rho\omega^2=\mu k^2\xi^2$; in the second, the coefficient of B is $\mu\left(q^2+k^2\right)=\mu k^2\left(2-\xi^2\right)$, the same combination. The cross terms are $2\mathrm{i}\mu kq$ in the first and $-2\mathrm{i}\mu kp$ in the second. Dividing throughout by μ, the two conditions at $z=0$ are therefore

$$k^2\left(2-\xi^2\right)A+2\mathrm{i}kq\,B=0\,,\qquad -2\mathrm{i}kp\,A+k^2\left(2-\xi^2\right)B=0\,, \tag{30.45}$$

a homogeneous pair with a non-trivial solution only if its determinant $k^4\left(2-\xi^2\right)^2-4k^2pq$ vanishes. Dividing by k^4 and substituting Equation (30.42) gives Equation (30.39).

It remains to know that an admissible root exists. Put $t=\xi^2$ and $f(t)=(2-t)^2-4\sqrt{(1-t)\,(1-\gamma t)}$. Then $f(0)=0$ and $f'(0)=-4+2\,(1+\gamma)=2\,(\gamma-1)<0$, so f is negative just to the right of the origin, while $f(1)=1>0$; by the intermediate value theorem (Theorem 7.23) f has a root in $(0,1)$, and $\xi=\sqrt{t}$ is the Rayleigh ratio. Finally, no length enters Equation (30.39): ξ depends on γ alone, so $c=\xi v_{\mathrm{S}}$ is independent of k and the wave does not disperse. The depth of penetration, by contrast, is $1/p$ and $1/q$, both of order the wavelength. □

Proposition 30.49 (The Rayleigh speed of a Poisson solid)**.** *For $\nu=\frac{1}{4}$ — the case $\lambda=\mu$, $\gamma=1/3$ — Equation (30.39) has exactly one admissible root, and*

$$\xi^2=2-\frac{2}{\sqrt{3}}\,,\qquad \xi=0.919\,40\,,\qquad c_{\mathrm{R}}=0.9194\,v_{\mathrm{S}}\,. \tag{30.46}$$

Rests on Proposition 30.48.

Proof. *Derives Proposition 30.49.*

Put $t=\xi^2$ and $\gamma=1/3$ and square Equation (30.39):

$$(2-t)^4=16\,(1-t)\left(1-\tfrac{1}{3}t\right)\,.$$

Expanding, $(2-t)^4 = t^4 - 8t^3 + 24t^2 - 32t + 16$ and the right side is $16 - \frac{64}{3}t + \frac{16}{3}t^2$, so the difference is $t^4 - 8t^3 + \frac{56}{3}t^2 - \frac{32}{3}t = \frac{t}{3}\,(3t^3 - 24t^2 + 56t - 32)$. The root $t = 0$ is the trivial static solution. The cubic has $t = 4$ as a root by inspection, and dividing out leaves $3t^2 - 12t + 8 = 0$ with roots $t = 2 \pm 2/\sqrt{3}$. Admissibility requires $0 < t < 1$, since both radicals in Equation (30.39) must be real for the depth dependence to decay: this excludes $t = 4$ and $t = 2 + 2/\sqrt{3} = 3.1547$ and leaves $t = 2 - 2/\sqrt{3} = 0.845\,299$. Squaring can create roots, so verify in the unsquared equation: $(2-t)^2 = 1.333\,33$ and $4\sqrt{1-t}\sqrt{1-t/3} = 4(0.393\,320)(0.847\,487) = 1.333\,33$, so it is genuine. Hence $\xi = \sqrt{0.845\,299} = 0.919\,40$. The Rayleigh wave is thus slower than the S wave by 8 %, which is what puts it last on the seismogram of Phenomenon 30.47, and its speed is a fixed multiple of v_{S} with no free length — so on a homogeneous half-space it does not disperse. □

Proposition 30.50 (Love waves need a slow surface layer)**.** *Let a layer of thickness H, density ρ_1 and shear modulus μ_1 rest on a half-space with ρ_2, μ_2, and write $\beta_j = \sqrt{\mu_j/\rho_j}$. Horizontally polarized surface waves of angular frequency ω and speed $c = \omega/k$ exist if and only if $\beta_1 < c < \beta_2$ and*

$$\tan\left(kH\sqrt{\frac{c^2}{\beta_1^2} - 1}\right) = \frac{\mu_2\sqrt{1 - c^2/\beta_2^2}}{\mu_1\sqrt{c^2/\beta_1^2 - 1}}\,. \tag{30.47}$$

In particular no such wave exists unless $\beta_1 < \beta_2$, and the speed depends on ω: the Love wave is dispersive [376].

Rests on Theorem 30.40 and Definition 30.22.

Proof. *Derives Proposition 30.50.*

Let z measure depth from the free surface, and look for a motion purely along y, $\boldsymbol{u} = (0, v, 0)$ with $v = f(z)\exp[\mathrm{i}(kx - \omega t)]$. Such a field has $\boldsymbol{\nabla}\cdot\boldsymbol{u} = 0$, so Equation (30.33) reduces in each homogeneous medium to $\rho\,\partial_t^2 v = \mu\nabla^2 v$, and hence to

$$f'' + \left(\frac{\omega^2}{\beta^2} - k^2\right) f = 0\,.$$

In the layer take $c > \beta_1$, so $s^2 = \omega^2/\beta_1^2 - k^2 > 0$ and $f = A\cos sz + B\sin sz$. The free surface carries the traction $\sigma_{yz} = \mu_1\partial_z v$, which must vanish at $z = 0$: hence $B = 0$ and $f = A\cos sz$. In the half-space take $c < \beta_2$, so $q^2 = k^2 - \omega^2/\beta_2^2 > 0$ and the only solution bounded at depth is $f = C\mathrm{e}^{-q(z-H)}$. Continuity of the displacement and of the traction $\mu\partial_z v$ across $z = H$ gives

$$A\cos sH = C\,, \qquad -\mu_1 As\sin sH = -\mu_2 qC\,,$$

and dividing the second by the first, $\mu_1 s\tan sH = \mu_2 q$, which is Equation (30.47) once s and q are written out. If $\beta_1 \geq \beta_2$ the two requirements $c > \beta_1$ and $c < \beta_2$ are incompatible and no solution exists — a homogeneous half-space, in particular, carries no Love wave, which is why Love had to introduce the layer [376]. Finally k and ω enter Equation (30.47) separately and not only through c, so c depends on frequency; as $\omega \to \infty$ the wave concentrates in the layer and $c \to \beta_1$, while near the cut-off of each higher branch $c \to \beta_2$. □

30.6 Rods, beams and plates

A rod, a beam, a plate and a shell are not new physics: they are Equation (30.33) on a domain with one or two small dimensions, reduced by exploiting that smallness. The reduction replaces a three-dimensional problem by a one- or two-dimensional one and turns the elastic energy into a functional of a single function, after which the machinery of Chapter 16 does the rest.

30.6.1 The elastica and Euler buckling

Proposition 30.51 (Moment and curvature)**.** *Let a slender rod of cross-section S lie along x and bend in the xz plane with small deflection $w(x)$. If plane cross-sections remain plane and normal to the deformed axis, and if the only non-negligible stress is the axial one, then the fibre at height z carries the strain and stress*

$$u_{xx} = -z\,w''(x)\,, \qquad \sigma_{xx} = -Ez\,w''(x)\,, \tag{30.48}$$

and the internal bending moment about the neutral axis is

$$M = EI\,w''(x)\,, \qquad I = \int_S z^2\,\mathrm{d}S\,, \tag{30.49}$$

with I the second moment of area, of SI dimension m^4*.*
Rests on Equation (30.21) *and Definition 30.31.*

Proof. *Derives Proposition 30.51.*

Under the kinematic hypothesis, a cross-section at x rotates through the angle $w'(x)$, so the axial displacement of the fibre at height z is $u_x = -z\,w'(x)$ and its axial strain is $u_{xx} = \partial_x u_x = -z\,w''$. The lateral faces of the rod are free, so $\sigma_{yy} = \sigma_{zz} = 0$ and the state is uniaxial *stress* — whence $\sigma_{xx} = E\,u_{xx}$ by Definition 30.31, with E and not M appearing. The moment of these stresses about the axis $z = 0$ is $-\int_S \sigma_{xx} z\,\mathrm{d}S = Ew'' \int_S z^2 \mathrm{d}S = EIw''$. The axis $z = 0$ is fixed by requiring zero net axial force, $\int_S \sigma_{xx}\mathrm{d}S = 0$, i.e. $\int_S z\,\mathrm{d}S = 0$: the neutral axis passes through the centroid. □

Phenomenon 30.52 (Euler buckling)**.** A slender straight column under a slowly increased axial compression remains straight, shortening elastically, until at a definite critical load it bows sideways; the deflection appears suddenly and the column carries no more load. The critical load does not depend on the strength of the material but on its stiffness, and falls as the inverse square of the length: for a column of length L, Young's modulus E and area moment of inertia I, pinned at both ends,

$$P_{\mathrm{crit}} = \frac{\pi^2 EI}{L^2}\,. \tag{30.50}$$

Doubling the length of a column therefore quarters the load it can bear [23].
Rests on Proposition 30.51 and Theorem 16.22.

Derivation. *Derives Phenomenon 30.52.*

Let the column occupy $0 \le x \le L$ under the axial compression P and let $y(x)$ be a small lateral deflection, with the ends pinned so that $y(0) = y(L) = 0$ and no moment is transmitted there. By Proposition 30.51 the bending moment at x is $EI\,y''(x)$, and the moment of the applied load about the same section is $-P\,y(x)$; equilibrium of the deflected shape therefore requires

$$EI\,y'' + P\,y = 0\,, \qquad y(0) = y(L) = 0\,. \tag{30.51}$$

This is an eigenvalue problem. Writing $k^2 = P/(EI)$, the general solution is $y = A\sin kx + B\cos kx$; the condition at $x = 0$ forces $B = 0$, and the condition at $x = L$ then requires either $A = 0$ — the straight column, available at every load — or $\sin kL = 0$, i.e. $kL = n\pi$ with n a positive integer. A deflected equilibrium therefore exists only at the discrete loads $P_n = n^2\pi^2 EI/L^2$, and the smallest of them, $n = 1$, is Equation (30.50). Below it the straight column is the only equilibrium; at it a one-parameter family of bent shapes appears, which is what is seen as the sudden onset of buckling. Note that the material enters only through E and the cross-section only through I: the yield stress of Phenomenon 30.73 plays no part, so a slender column fails long before its material does. □

Example 30.53 (A steel rod buckles at a twentieth of its crushing load)**.** Take a circular steel rod of diameter 10 mm and length 1 m, pinned at both ends, with $E = 210\,\mathrm{GPa}$. Its area moment is $I = \pi d^4/64 = 4.91 \times 10^{-10}\,\mathrm{m}^4$ and its area $S = 7.85 \times 10^{-5}\,\mathrm{m}^2$, so Equation (30.50) gives

$$P_{\mathrm{crit}} = \frac{\pi^2 \left(2.10 \times 10^{11}\,\mathrm{Pa}\right)\left(4.91 \times 10^{-10}\,\mathrm{m}^4\right)}{\left(1\,\mathrm{m}\right)^2} = 1.02\,\mathrm{kN}\,,$$

an axial stress of only 13.0 MPa. Crushing the same rod would need $\sigma_{\mathrm{y}} S = 19.6\,\mathrm{kN}$ at a yield stress of 250 MPa: buckling arrives at a nineteenth of that. The dimensionless control parameter is the slenderness L/r with $r = \sqrt{I/S} = d/4 = 2.5\,\mathrm{mm}$ the radius of gyration, here $L/r = 400$, and Equation (30.50) in those terms is $\sigma_{\mathrm{crit}} = \pi^2 E/(L/r)^2$. Yield and buckling change places at $L/r = \pi\sqrt{E/\sigma_{\mathrm{y}}} = 91$: a rod stubbier than that is crushed, a slenderer one buckles. This is the single most consequential formula in structural engineering, and it was the first instability ever computed.

Rests on Phenomenon 30.52 and Equation (30.50)*.*

Remark 30.54 (Other end conditions, and what buckling is variationally)*.* Clamping the ends changes only the length of the half-wave that must fit: Equation (30.50) holds with L replaced by an effective length $L_{\mathrm{eff}} = \kappa L$, with $\kappa = 1$ pinned at both ends, $\kappa = 2$ for a cantilever fixed at one end and free at the other, $\kappa = \frac{1}{2}$ clamped at both, and $\kappa = 0.699$ clamped at one and pinned at the other. The load capacity therefore varies by a factor 16 between the extremes at fixed L.

Read variationally, buckling is the loss of positive-definiteness of a second variation. The energy of the compressed column is

$$\Pi[y] = \int_0^L \left[\tfrac{1}{2} EI\,(y'')^2 - \tfrac{1}{2} P\,(y')^2\right] \mathrm{d}x\,,$$

the second term being the work done by P as the bent column shortens. This is exactly the accessory functional of Proposition 16.50, and Equation (30.51) is its Jacobi equation (Definition 16.53); $P = P_{\mathrm{crit}}$ is the load at which $x = L$ first becomes conjugate to $x = 0$, and Theorem 16.55 is the statement that the straight column ceases to be a minimum there. The two subjects — the sufficiency theory of the calculus of variations and the stability of structures — are the same theory.

Rests on Phenomenon 30.52 and Theorem 16.55.

Remark 30.55 (Beyond the critical load: the elastica)*.* Equation (30.51) is the small-deflection limit. Euler solved the exact problem in the appendix on elastic curves of the *Methodus inveniendi* [23]: parametrising the rod by arc length s and letting $\theta(s)$ be the angle of the tangent, the exact statement that the curvature is proportional to the moment is

$$EI\,\frac{\mathrm{d}^2\theta}{\mathrm{d}s^2} + P\sin\theta = 0\,, \tag{30.52}$$

which is the pendulum equation of Chapter 28 with s in place of time. Its solutions are elliptic functions, and the amplitude of the buckled shape grows as $\theta_{\max} \propto (P/P_{\mathrm{crit}} - 1)^{1/2}$ just above threshold — a supercritical pitchfork bifurcation (Chapter 32). The linear theory predicts the threshold exactly and the amplitude not at all, which is the generic situation for a bifurcation and is why Equation (30.50) is safe to design with and useless for predicting how far a buckled column bends.

Rests on Phenomenon 30.52 and Equation (30.7)*.*

30.6.2 Euler–Bernoulli beam theory

Theorem 30.56 (The beam equation)**.** *A slender rod of bending stiffness EI, mass per unit length ρS, carrying a transverse load $q(x)$ per unit length, has transverse deflection $w(x,t)$ obeying*

$$\rho S\,\partial_t^2 w + \partial_x^2\left(EI\,\partial_x^2 w\right) = q\,. \tag{30.53}$$

At a free end the natural *boundary conditions $EIw'' = 0$ and $(EIw'')' = 0$ hold — vanishing moment and vanishing shear force.*

Rests on Proposition 30.51 and Theorem 16.38.

Proof. *Derives Theorem 30.56.*

By Equation (30.48) the elastic energy density is $\tfrac{1}{2}E\,(zw'')^2$; integrating over the cross-section gives $\tfrac{1}{2}EI\,(w'')^2$ per unit length, so the action of the rod is $\iint \mathcal{L}\,\mathrm{d}x\,\mathrm{d}t$ with Lagrangian density

$$\mathcal{L} = \tfrac{1}{2}\rho S\,(\partial_t w)^2 - \tfrac{1}{2}EI\left(\partial_x^2 w\right)^2 + qw\,.$$

The density depends on a second derivative, so the stationarity condition is the Euler–Poisson equation Theorem 16.38,

$$\frac{\partial \mathcal{L}}{\partial w} - \partial_x\frac{\partial \mathcal{L}}{\partial(\partial_x w)} + \partial_x^2\frac{\partial \mathcal{L}}{\partial(\partial_x^2 w)} - \partial_t\frac{\partial \mathcal{L}}{\partial(\partial_t w)} = 0\,,$$

which evaluates to $q - \partial_x^2\,(EIw'') - \rho S\partial_t^2 w = 0$, i.e. Equation (30.53). The boundary terms produced by the integration by parts are $[EIw''\,\delta w']_0^L$ and $-\left[(EIw'')'\,\delta w\right]_0^L$; where the end is free, δw and $\delta w'$ are unconstrained and each bracket must vanish separately, which is Theorem 16.31. Where the end is clamped, δw and $\delta w'$ vanish and the conditions are $w = w' = 0$ instead — two conditions at each end in every case, as a fourth-order equation requires. □

Proposition 30.57 (Bending waves are dispersive)**.** *Free waves on a uniform beam obey*

$$\omega = k^2\sqrt{\frac{EI}{\rho S}}\,, \tag{30.54}$$

so the phase velocity ω/k grows without bound with k and the group velocity is twice the phase velocity. The natural frequencies of a beam of length L are $\omega_n = (\beta_n L)^2\sqrt{EI/(\rho S L^4)}$ with $\beta_n L$ fixed by the end conditions; for a cantilever the roots of $\cos\beta L\cosh\beta L + 1 = 0$ give $\beta_1 L = 1.8751$.

Rests on Theorem 30.56 and Definition 9.2.

Proof. *Derives Proposition 30.57.*

Substitute $w = \exp[\mathrm{i}\,(kx - \omega t)]$ into the source-free Equation (30.53) with EI constant: $-\rho S\omega^2 + EIk^4 = 0$, which is Equation (30.54). Then $v_{\mathrm{ph}} = \omega/k = k\sqrt{EI/\rho S}$ and $v_{\mathrm{g}} = \mathrm{d}\omega/\mathrm{d}k = 2k\sqrt{EI/\rho S} = 2v_{\mathrm{ph}}$. For a finite beam, separating $w = W(x)\mathrm{e}^{-\mathrm{i}\omega t}$ gives $W'''' = \beta^4 W$ with $\beta^4 = \rho S\omega^2/(EI)$, whose general solution is a combination of $\sin\beta x, \cos\beta x, \sinh\beta x, \cosh\beta x$; imposing $W = W' = 0$ at the clamped end and $W'' = W''' = 0$ at the free one gives a 4×4 homogeneous system whose determinant reduces to $\cos\beta L\cosh\beta L + 1 = 0$, and its smallest positive root is $\beta_1 L = 1.8751$. □

Example 30.58 (A steel ruler)**.** Clamp a steel strip 20 mm wide and 2 mm thick with 300 mm projecting. Then $I = bh^3/12 = 1.33\times 10^{-11}\,\mathrm{m}^4$, $EI = 2.80\,\mathrm{N\,m^2}$ and $\rho S = 0.314\,\mathrm{kg/m}$, so

$$f_1 = \frac{(1.8751)^2}{2\pi}\sqrt{\frac{2.80\,\mathrm{N\,m^2}}{(0.314\,\mathrm{kg/m})\,(0.3\,\mathrm{m})^4}} = 18.6\,\mathrm{Hz}\,,$$

which is what a twanged ruler does. Note the scaling that Proposition 30.57 encodes: $f_1 \propto h/L^2$ at fixed material, since $\sqrt{EI/\rho S} \propto h$ for a rectangle. Halving the overhang quadruples the pitch — two octaves — and this is the measurement route to E of Remark 30.36, since f_1 can be counted to 1×10^{-4} while an extension of a millimetre cannot.

Rests on Proposition 30.57 and Theorem 30.56.

Remark 30.59 (Where Euler–Bernoulli fails). Equation (30.54) is unphysical at large k: the phase velocity grows without limit and eventually exceeds v_{P}, which no disturbance in an elastic solid can do. The reason is that the theory neglects the shear deformation of the cross-section and its rotary inertia, and both matter once the wavelength approaches the depth h. Comparing Equation (30.54) with the shear speed for a rectangular section, $\sqrt{EI/\rho S} = h\sqrt{E/\rho}/\sqrt{12}$, the two agree when $kh = \sqrt{12\mu/E} = \sqrt{6/(1+\nu)} \approx 2.2$: the theory degrades once the wavelength falls below about three times the beam depth. Timoshenko's correction restores both neglected effects and gives a dispersion relation with two branches, both with bounded phase velocity [482]. This is the general pattern of a reduced theory: the reduction assumes a separation of scales, and it fails exactly where the separation does — as in Equation (30.1), one level up.

Rests on Proposition 30.57 and Equation (30.35).

30.6.3 Torsion

Phenomenon 30.60 (Coulomb's law of torsion)**.** A thin metal wire clamped at one end and twisted at the other exerts a restoring torque proportional to the angle of twist, and independent of the angle's history provided the twist is small. Coulomb measured the constant of proportionality and found it proportional to the fourth power of the diameter and inversely proportional to the length,

$$\tau = -\kappa\,\Phi\,, \qquad \kappa = \frac{\pi \mu\, d^4}{32\, L}\,, \tag{30.55}$$

with κ measured in $\mathrm{N\,m/rad}$ [36]. A body of moment of inertia I_0 suspended on such a fibre oscillates with period $T = 2\pi\sqrt{I_0/\kappa}$, which is how κ is measured and how the fibre becomes an instrument.

Rests on Equation (30.21) and Definition 30.31.

Derivation. Derives Phenomenon 30.60.

Take a circular cylinder of radius $a = d/2$ along z and twist it uniformly, so that the section at height z rotates through $\theta' z$ with $\theta' = \Phi/L$ the twist per unit length. In cylindrical coordinates the displacement is $u_\phi = \theta' z r$, $u_r = u_z = 0$, whose only non-vanishing strain component is $u_{\phi z} = \tfrac{1}{2}\theta' r$; the deformation is a pure shear, so no volume changes and only μ can enter. By Equation (30.21) the stress is $\sigma_{\phi z} = 2\mu u_{\phi z} = \mu\theta' r$, and the torque transmitted across a section is

$$\tau = \int_S \sigma_{\phi z}\, r\, \mathrm{d}S = \mu\theta' \int_S r^2 \mathrm{d}S = \mu\theta' J\,, \qquad J = \frac{\pi a^4}{2} = \frac{\pi d^4}{32}\,. \tag{30.56}$$

Setting $\theta' = \Phi/L$ gives Equation (30.55). The d^4 is the content of Coulomb's measurement: a factor d^2 because the sheared area grows so, and a second factor d^2 because the lever arm and the strain each grow with r. The restoring torque is linear in Φ because Hooke's law is linear in the strain, so the torsional pendulum is harmonic and its period is amplitude independent, giving $T = 2\pi\sqrt{I_0/\kappa}$ from Chapter 28. □

Example 30.61 (A torsion fibre as a force sensor)**.** A fused-silica fibre of diameter $50\,\mu\mathrm{m}$ and length $1\,\mathrm{m}$, with shear modulus $\mu = 31\,\mathrm{GPa}$, has

$$\kappa = \frac{\pi\,(3.1\times10^{10}\,\mathrm{Pa})\,(5.0\times10^{-5}\,\mathrm{m})^4}{32\,(1\,\mathrm{m})} = 1.90\times10^{-8}\,\mathrm{N\,m/rad}\,.$$

A bar carrying $I_0 = 1.0 \times 10^{-4}\,\mathrm{kg\,m^2}$ then swings with period $T = 2\pi\sqrt{I_0/\kappa} = 456\,\mathrm{s}$, about 7.6 min. Because κ is read from that period and from a moment of inertia — a mass and a length — the instrument measures torque on an absolute scale, and a deflection of 1 mrad, easily resolved optically, corresponds to $1.9 \times 10^{-11}\,\mathrm{N\,m}$. That sensitivity, and nothing more exotic, is what makes the Cavendish measurement of Chapter 33 possible, and the same fibre reappears in every torsion-balance test of the equivalence principle.

Rests on Phenomenon 30.60 and Equation (30.55).

Remark 30.62 (Saint-Venant's theory: non-circular sections warp). Equation (30.56) used the circular symmetry twice: to assert that plane sections stay plane and to evaluate $\int r^2 \mathrm{d}S$. Neither survives for a general cross-section. Saint-Venant's solution adds an axial displacement $u_z = \theta' \psi(x, y)$ — the *warping function* — and equilibrium then requires $\nabla^2 \psi = 0$ inside the section with a Neumann condition on its boundary, an ordinary potential problem of Section 10.4.3 [144]. The torsional rigidity that results is always *less* than μJ: the circle is the only section that does not warp, and it is the stiffest section of given area in torsion. For an ellipse of semi-axes a and b the exact rigidity is $\mu\pi a^3 b^3/(a^2 + b^2)$, which is $4a^2b^2/(a^2 + b^2)^2$ times μJ — 64 % for a 2 : 1 ellipse, and falling to zero for a slit. Using μJ for a non-circular shaft therefore overestimates its stiffness, sometimes grossly, which is why open thin-walled sections are avoided wherever torsion is carried.

Rests on Phenomenon 30.60 and Equation (30.55).

30.6.4 Plates and shells

Definition 30.63 (Flexural rigidity)**.** For a plate of thickness h made of an isotropic material, the *flexural rigidity* is

$$D = \frac{E h^3}{12\,(1 - \nu^2)}\,, \tag{30.57}$$

with SI dimension N m. The factor $(1 - \nu^2)^{-1}$ distinguishes a plate from a beam: a plate bent in one direction is prevented by its own width from contracting transversely, so the relevant stiffness is the plane-strain modulus $E/(1 - \nu^2)$ and not E.

Rests on Propositions 30.33 and 30.51.

Theorem 30.64 (The Kirchhoff plate equation)**.** *Under the hypotheses that the plate is thin, that normals to the mid-surface remain normal, and that the transverse normal stress is negligible, the transverse deflection $w(x, y, t)$ of a plate of uniform thickness obeys*

$$\rho h\, \partial_t^2 w + D\, \nabla^4 w = q\,, \tag{30.58}$$

with $\nabla^4 = \nabla^2 \nabla^2$ the biharmonic operator and q the transverse load per unit area. At a free edge the two boundary conditions are Kirchhoff's: the bending moment vanishes, and the transverse shear combined with the gradient of the twisting moment vanishes [130].

Rests on Definition 30.63 and Theorem 16.38.

Full derivation: Appendix A.57 (p. 3105).

Derives Theorem 30.64.

The reduction has three stages, all carried out there. The Kirchhoff kinematics — $u_x = -z\,\partial_x w$, $u_z = w$, and the plane-stress condition $\sigma_{zz} = 0$ in place of plane strain — turns the isotropic energy density into a quadratic in the curvatures of the mid-surface, and integrating it across the thickness produces the flexural rigidity Equation (30.57) together with a term proportional to the Gaussian curvature of the deflected surface, which is a pure boundary term whenever the edge is clamped. Varying the resulting functional gives Equation (30.58) by the Euler–Poisson equation Theorem 16.38. The third stage is Kirchhoff's: the variation leaves three boundary quantities at a free edge, one more than a fourth-order equation can carry, and the twisting moment is integrated by parts along the

edge so that its gradient joins the transverse shear, leaving two conditions and a concentrated corner force.

Phenomenon 30.65 (Chladni figures)**.** Sand strewn on a flat plate driven at one of its resonances is swept off the moving regions and collects along sharp curves — the nodal lines of the excited mode. The pattern is not continuous in the driving frequency: it is unchanged through a resonance and jumps to a wholly different figure at the next, so that a given plate and clamping reproduce the same discrete set of frequencies and the same set of figures every time [39]. The mode frequencies of geometrically similar plates of the same material scale in proportion to the thickness and inversely as the square of the lateral dimension [70, 130].

Rests on Theorem 30.64 and Proposition 30.66.

Derivation. Derives Phenomenon 30.65.

Free harmonic motion of the plate is $w = W(x,y)\mathrm{e}^{-\mathrm{i}\omega t}$ in Equation (30.58) with $q = 0$, so W satisfies $D\nabla^4 W = \rho h\omega^2 W$ with the plate's own boundary conditions. That is a self-adjoint eigenvalue problem of the kind of Definition 9.54: its spectrum is a discrete increasing sequence $\omega_1 < \omega_2 < \cdots$, so a resonance can only occur at one of countably many frequencies and the mode shape is locked to the frequency. That is the observed discontinuity: sweeping the driving frequency, nothing changes until the next ω_n is reached, and then the whole figure is replaced by the next eigenfunction.

The sand marks the nodal set $\{W = 0\}$ because a grain leaves the surface whenever the plate's peak downward acceleration exceeds g: with local amplitude A the condition is $\omega^2 A > g$, so at $f = 500\,\mathrm{Hz}$ any region moving by more than $A = g/\omega^2 = 1.0\,\mu\mathrm{m}$ throws its grains clear. They land elsewhere, are thrown again, and random-walk until they reach a region where A falls below the threshold — the neighbourhood of a node. The figure is therefore a picture of $\{W = 0\}$ broadened by the threshold, which is why the curves are sharp: near a nodal line W grows linearly, so the width of the deposit is the threshold amplitude divided by the slope of W, and both are small.

The scaling is Proposition 30.66. Nothing in this argument is peculiar to a plate; the same three statements — discrete spectrum, nodal set, threshold — describe every visualisation of a standing wave in Chapter 35. □

Proposition 30.66 (Chladni scaling)**.** *For geometrically similar plates of the same material, thickness h, lateral dimension a and fixed boundary conditions, the natural frequencies are*

$$\omega_n = \sqrt{\Lambda_n}\,\frac{h}{a^2}\sqrt{\frac{E}{12\rho\,(1-\nu^2)}}\,, \tag{30.59}$$

with Λ_n a pure number depending on the shape and the boundary conditions but on nothing else.

Rests on Theorem 30.64 and Definition 30.63.

Proof. Derives Proposition 30.66.

Write $\boldsymbol{x} = a\boldsymbol{\zeta}$ with $\boldsymbol{\zeta}$ ranging over the fixed reference shape. Then $\nabla^4 = a^{-4}\nabla_\zeta^4$, and the eigenvalue problem $D\nabla^4 W = \rho h\omega^2 W$ becomes $\nabla_\zeta^4 W = \Lambda W$ with $\Lambda = \rho h\omega^2 a^4/D$. The reduced problem involves only the reference shape and the boundary conditions, so its eigenvalues Λ_n are pure numbers. Solving for ω,

$$\omega_n^2 = \Lambda_n \frac{D}{\rho h a^4} = \Lambda_n \frac{E h^2}{12\rho\,(1-\nu^2)\,a^4}\,,$$

using Equation (30.57), and taking the square root gives Equation (30.59): proportional to h, inversely proportional to a^2, exactly as observed in Phenomenon 30.65. The same relation read backwards is a measurement of $E/\left[\rho(1-\nu^2)\right]$ from a frequency, a thickness and a diameter. □

Remark 30.67 (Germain, Kirchhoff, and the edge conditions). Chladni's figures were an open challenge for a generation. Germain won the Academy prize with an essay containing the fourth-order equation Equation (30.58) [70]; her edge conditions were not correct, and neither were Poisson's, who imposed three conditions on a free edge where a fourth-order equation admits only two. Kirchhoff resolved the conflict by deriving the conditions from the variation of the energy rather than from a force balance — the natural boundary conditions of Theorem 16.31 — which combine the transverse shear and the twisting moment into a single *effective* shear [130]. The episode is a clean instance of the general point: for a variational problem, the boundary conditions are not free to be chosen, they are part of the answer.

Rests on Theorems 16.31 and 30.64.

Remark 30.68 (Shells carry load in a different way). Give the mid-surface curvature $1/R$ and the reduction changes character. A transverse load on a flat plate can only be resisted by bending, with stiffness proportional to h^3 through Equation (30.57); on a curved shell it is resisted also by stretching of the mid-surface, with stiffness proportional to h. The ratio of the two is of order $(R/h)^2$, which for an eggshell — $R \approx 20\,\mathrm{mm}$, $h \approx 0.35\,\mathrm{mm}$ — is about 3000. That is why an egg is hard to crush end-on and trivial to break on a rim, and why every efficient structure that spans a distance is curved. The price is that a shell resists load by membrane stress and can therefore lose it catastrophically by buckling, at a load far below the Euler estimate of Equation (30.50) and notoriously sensitive to imperfections.

Rests on Definition 30.63 and Phenomenon 30.52.

30.7 Static problems and contact

Remark 30.69 (Saint-Venant's principle, and its exact status). Every reduced theory of Section 30.6 replaced a real end loading — a clamp, a pin, a hydraulic ram — by a resultant force and moment, and the replacement is licensed by what is called Saint-Venant's principle: two loadings of the same small region with the same resultant force and moment produce stress fields differing appreciably only within a distance of the order of the diameter of that region [144]. The physical content is that a self-equilibrated load — zero resultant, zero moment — produces a field that decays exponentially, and the decay length is set by the only length in the problem, the size of the loaded region.

It is called a principle and not a theorem for good reason. It is provable for a cylinder of compact cross-section, where the decay rates are the eigenvalues of an explicit auxiliary problem, and it *fails* for thin-walled and for strongly anisotropic structures, where a self-equilibrated end load can propagate for many diameters. The honest statement is that it is a very good rule for stocky isotropic bodies, that it is what makes the whole engineering theory of structures possible, and that a designer using it on a thin-walled box section is relying on something known to be false there.

Rests on Proposition 30.23 and Theorem 30.21.

Phenomenon 30.70 (Hertzian contact)**.** Two elastic bodies pressed together touch over a finite area, not at a point, and the force required grows faster than linearly with the approach of their centres. For two spheres of radii R_1, R_2 the measured relation between the normal force F and the mutual approach δ is

$$F = \tfrac{4}{3} E^* R^{1/2} \delta^{3/2}\,, \qquad \frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2}\,, \qquad \frac{1}{E^*} = \frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2}\,, \tag{30.60}$$

with contact radius $a = \sqrt{R\delta}$ and peak pressure $p_0 = 3F/(2\pi a^2)$ [218]. The contact is therefore *stiffening*: doubling the approach requires nearly three times the force.

Rests on Proposition 30.23 and Definition 30.31.

Derivation. *Derives Phenomenon 30.70.*

The exponent follows from three geometric and dimensional statements and needs no solution of the elastic problem. Let a be the radius of the contact circle. First, the geometry of two nearly touching spheres gives $\delta = a^2/R$ to leading order in a/R, since the gap between the undeformed surfaces at distance a from the axis is $a^2/2R_1 + a^2/2R_2 = a^2/2R$ and the two surfaces must meet there. Second, the only strain scale in the contact region is the indentation divided by its own size, $\delta/a = a/R$, because a is the only length over which the displacement varies. Third, the stress is then E^* times that strain and acts over an area πa^2, so

$$F \sim E^* \frac{a}{R}\, a^2 = E^* \frac{a^3}{R} = E^* \frac{(R\delta)^{3/2}}{R} = E^* R^{1/2} \delta^{3/2} ,$$

which is Equation (30.60) up to the pure number $4/3$. The exponent $3/2$ is exact and is purely geometric: it says that a Hertzian contact stiffens because the contact area grows with the load, not because any material stiffens. The combination E^* is the plane-strain modulus $E/(1-\nu^2)$ of Definition 30.63, appearing because the material just under a broad contact patch is laterally confined, and the two bodies act as compliances in series — hence the sum of reciprocals. The coefficient $4/3$ and the pressure distribution $p(r) = p_0\sqrt{1 - r^2/a^2}$ require the full elastic solution for a half-space [218]. □

Full derivation: Appendix A.58 (p. 3112).

Derives Phenomenon 30.70.

What is left to the appendix is the part the scaling argument cannot reach: the numerical coefficient $4/3$ and the pressure profile $p(r) = p_0\sqrt{1 - r^2/a^2}$. It is obtained from Boussinesq's solution for a half-space loaded by a prescribed normal pressure over a circle — the surface displacement is a potential-theory integral of the pressure, of the kind of Section 10.4.3 — together with the two contact conditions: inside the circle the two deformed surfaces coincide, which for spheres means the surface displacement must vary as $\delta - r^2/2R$; outside it they separate and the pressure vanishes. The elliptic profile is the unique pressure whose Boussinesq displacement is quadratic in r inside the circle, and integrating it over the contact area gives $F = \frac{2}{3} p_0 \pi a^2$, which with $a = \sqrt{R\delta}$ is Equation (30.60).

Example 30.71 (Contact stresses are enormous)**.** Press two steel balls of radius 10 mm together with 1 N. With $E = 210\,\mathrm{GPa}$ and $\nu = 0.29$, $E^* = 115\,\mathrm{GPa}$ and $R = 5\,\mathrm{mm}$, so Equation (30.60) gives a contact radius $a = [3FR/(4E^*)]^{1/3} = 32\,\mu\mathrm{m}$, an approach $\delta = a^2/R = 0.20\,\mu\mathrm{m}$ and a peak pressure

$$p_0 = \frac{3F}{2\pi a^2} = \frac{3\,(1\,\mathrm{N})}{2\pi\,(3.2\times10^{-5}\,\mathrm{m})^2} = 4.7\times10^8\,\mathrm{Pa} = 470\,\mathrm{MPa}\,.$$

One newton — the weight of an apple — generates half a gigapascal, nearly twice the yield stress of mild steel. The mean contact strain $a/R = 6.4\times10^{-3}$ is nevertheless small, so linear elasticity is self-consistent as a description of the *strain*; what is not small is the stress, because E is large. This is why ball bearings are made of hardened steel with $\sigma_\mathrm{y} \approx 2\,\mathrm{GPa}$ rather than of the structural steel of Example 30.53, and why every rolling contact eventually fails by subsurface fatigue rather than by wear.

Rests on Phenomenon 30.70 and Equation (30.60).

Remark 30.72 (Stress concentration). A uniform tension σ in a large plate is tripled at the edge of a small circular hole: the peak stress is 3σ, independent of the hole's size [1778]. For an elliptical hole of semi-axes a across the tension and b along it, with tip radius of curvature $\varrho = b^2/a$, the peak is

$$\sigma_\mathrm{max} = \sigma\left(1 + \frac{2a}{b}\right) = \sigma\left(1 + 2\sqrt{\frac{a}{\varrho}}\right) , \tag{30.61}$$

which diverges as the ellipse degenerates into a crack, $\varrho \to 0$. Two consequences run through the rest of engineering. First, holes and notches must be given generous radii; a sharp re-entrant corner is a mathematical singularity and a practical crack starter. Second, and more seriously, Equation (30.61) says that linear elasticity predicts *infinite* stress at a crack tip for any applied load whatever, so it cannot by itself say when a cracked body breaks. Resolving that is the content of Proposition 30.76, and the resolution is to abandon the stress criterion for an energy one.

Rests on Equation (30.21) and Theorem 30.18.

30.8 The limits of elasticity

Everything above rests on Equation (30.22): that the energy is quadratic and the stress therefore linear. Four distinct things end that regime, and it is worth being explicit that they are different failures with different signatures.

Phenomenon 30.73 (Yield and brittle fracture)**.** Elasticity has a boundary, and it is reached in two different ways. A ductile metal loaded beyond a critical stress ceases to recover its shape and flows: the flow sets in when the maximum shear stress in the body reaches a material constant, and superposing a hydrostatic pressure — however large — does not by itself produce it [161]. A brittle solid does not flow but breaks, and its measured strength is one to two orders of magnitude below the stress at which the interatomic bonds would part; the strength is set by the largest pre-existing flaw and falls as the inverse square root of its length, so that fine fibres of the same glass are far stronger than bulk specimens [475].

Rests on Propositions 30.74 and 30.76.

Derivation. *Derives Phenomenon 30.73.*

The two halves are Proposition 30.74 and Proposition 30.76 respectively. What the pair says together is that "strength" is not one material property but two, governed by different parts of the stress tensor: ductile flow by the deviatoric part s_{ik} of Equation (30.16), which is why it is insensitive to pressure, and brittle fracture by the elastic energy available to be released, which is why it is sensitive to the flaw population and hence to the specimen's history rather than to its composition alone. That is also why the same material can do both: a steel that flows at room temperature cleaves below its transition temperature, where the shear stress needed for flow rises above the stress needed to run a crack. □

Proposition 30.74 (The maximum shear stress, and its indifference to pressure)**.** *The largest shear traction over all planes through a point is*

$$\tau_{\max} = \tfrac{1}{2}\,(\sigma_1 - \sigma_3)\ , \tag{30.62}$$

attained on the two planes bisecting the extreme principal directions, and it is unchanged by the addition of any hydrostatic stress $\sigma_{ik} \mapsto \sigma_{ik} - p_0\delta_{ik}$. A yield criterion of the form $\tau_{\max} = k$ is therefore independent of pressure [161].

Rests on Definition 30.20 and Theorem 30.18.

Proof. *Derives Proposition 30.74.*

Work in the principal frame of Definition 30.20, so $\sigma = \operatorname{diag}(\sigma_1, \sigma_2, \sigma_3)$ with $\sigma_1 \ge \sigma_2 \ge \sigma_3$. For a unit normal $\boldsymbol{n}$ the traction is $t_i = \sigma_i n_i$ (no sum), its normal component is $\bar\sigma = \sum_i \sigma_i m_i$ with $m_i = n_i^2$, and the shear component has magnitude

$$\tau^2 = |\boldsymbol{t}|^2 - \bar\sigma^2 = \sum_i \sigma_i^2 m_i - \Big(\sum_i \sigma_i m_i\Big)^2 , \qquad m_i \ge 0\,,\ \sum_i m_i = 1\,.$$

Since $\sigma_3 \le \sigma_i \le \sigma_1$ we have $(\sigma_i - \sigma_3)(\sigma_1 - \sigma_i) \ge 0$ for each i; averaging with the weights m_i gives $\sum_i \sigma_i^2 m_i \le (\sigma_1 + \sigma_3)\,\bar\sigma - \sigma_1\sigma_3$. Hence

$$\tau^2 \le (\sigma_1 + \sigma_3)\,\bar\sigma - \sigma_1\sigma_3 - \bar\sigma^2 = (\bar\sigma - \sigma_3)(\sigma_1 - \bar\sigma) \le \left[\frac{\sigma_1 - \sigma_3}{2}\right]^2 ,$$

the last step being the inequality between the geometric and arithmetic means of two non-negative numbers whose sum is $\sigma_1 - \sigma_3$. Both inequalities are equalities when $m = \left(\tfrac12, 0, \tfrac12\right)$, i.e. for $\boldsymbol{n}$ at 45° between the first and third principal directions, giving Equation (30.62). Adding $-p_0\delta_{ik}$ shifts every principal stress by the same $-p_0$ and leaves every difference, hence $\tau_{\max}$, unchanged. □

Remark 30.75 (Two criteria, one uncited). Equation (30.62) is not the only pressure-independent function of the deviator. The alternative in general engineering use replaces it by the second invariant $\sqrt{\tfrac32 s_{ik}s_{ik}}$, which is smooth where Equation (30.62) has corners and fits ductile metals somewhat better; the two differ by at most 15 % for any stress state. This treatise cites no primary source for that criterion, because none was located in the accessible literature during the preparation of this chapter, and the claim is recorded here as uncited rather than attached to a reference that does not support it. Tresca's criterion, by contrast, rests on his own extrusion measurements [161].

Rests on Proposition 30.74 and Definition 30.20.

Proposition 30.76 (Griffith's criterion)**.** *A plate under remote tension σ containing a through-crack of length $2c$ releases elastic energy $\pi\sigma^2c^2/E$ per unit thickness and creates surface energy $4\gamma c$, with γ the surface energy per unit area. The total energy has a maximum at*

$$\sigma_{\mathrm f} = \sqrt{\frac{2E\gamma}{\pi c}}\,, \tag{30.63}$$

so a crack shorter than $2E\gamma/(\pi\sigma^2)$ is stable and a longer one runs away. Strength therefore falls as $c^{-1/2}$ and is a property of the flaw population, not of the bonds [475].

Rests on Remark 30.72 and Equation (30.23).

Proof. *Derives Proposition 30.76.*

Let $U(c)$ be the total energy of the plate at fixed remote displacement, measured from the uncracked state. Introducing the crack relaxes the material near it and releases stored elastic energy; the elastic solution for an elliptical hole degenerating to a crack, which Griffith took over for this purpose, gives that release as $\pi\sigma^2c^2/E$ per unit thickness [475]. Creating the two new faces costs γ per unit area, and the two faces of a crack of length $2c$ have total area $4c$ per unit thickness. Hence

$$U(c) = -\frac{\pi\sigma^2c^2}{E} + 4\gamma c\,, \qquad \frac{\mathrm dU}{\mathrm dc} = -\frac{2\pi\sigma^2 c}{E} + 4\gamma\,.$$

The derivative vanishes at $c^* = 2E\gamma/(\pi\sigma^2)$ and $\mathrm d^2U/\mathrm dc^2 = -2\pi\sigma^2/E < 0$, so c^* is a *maximum* of the energy — an unstable equilibrium. A crack shorter than c^* can only grow by climbing the energy barrier and does not; one longer than c^* releases more energy than it costs at every subsequent length and accelerates without limit. Solving $c = c^*$ for σ gives Equation (30.63). The criterion is an energy balance and not a stress criterion, which is exactly what was needed: Remark 30.72 showed that the stress at a crack tip is infinite for any load, so no stress criterion could ever have distinguished a safe crack from a dangerous one. □

Example 30.77 (Why glass is weak, and thin glass is not)**.** Take a silicate glass with $E = 70\,\mathrm{GPa}$ and a surface energy $\gamma = 0.5\,\mathrm{J/m^2}$, and a surface flaw of half-length $c = 2\,\mu\mathrm{m}$ — a scratch invisible to the eye. Then Equation (30.63) gives

$$\sigma_{\mathrm{f}} = \sqrt{\frac{2\,(7.0\times10^{10}\,\mathrm{Pa})\,(0.5\,\mathrm{J/m^2})}{\pi\,(2.0\times10^{-6}\,\mathrm{m})}} = 1.06\times10^{8}\,\mathrm{Pa} = 106\,\mathrm{MPa}\,,$$

which is squarely inside the range that bulk glass actually shows. The stress the bonds themselves could support is of order $\sqrt{E\gamma/a_0}$ with $a_0 = 0.3\,\mathrm{nm}$ an interatomic spacing, about 11 GPa — a hundredfold higher, and that hundredfold is the whole of the discrepancy the phenomenon reports. Reduce the flaw to $c = 20\,\mathrm{nm}$, which is what drawing and fire-polishing a fine fibre does, and Equation (30.63) predicts 1.1 GPa; this is why Griffith found the strength of his glass fibres rising steeply as their diameter fell, and it is why an optical fibre with a pristine surface outperforms structural steel in tension [475]. Nothing about the glass changed between the two numbers — only the largest scratch on it.

Rests on Proposition 30.76 and Equation (30.63).

Remark 30.78 (Anharmonicity: what the quadratic energy also suppresses)*.* The cubic remainder discarded in Equation (30.22) is not only a correction to Hooke's law; it is the entire origin of two effects that a perfectly harmonic solid does not have. A harmonic solid does not expand when heated — the mean position of every atom sits at the minimum of a symmetric well regardless of the amplitude — and it has infinite thermal conductivity, because its normal modes never scatter off one another. Real solids do both, with a coefficient of linear expansion of order $1\times10^{-5}\,1/\mathrm{K}$ for metals, and the microscopic account is the anharmonic lattice dynamics of Chapter 125. The macroscopic bookkeeping is that the elastic moduli measured adiabatically and isothermally differ, by a term proportional to the square of the expansion coefficient; for metals at room temperature that is a fraction of a percent, which is at the level of the uncertainties in Table 30.1.

Rests on Phenomenon 30.28 and Definition 30.24.

Definition 30.79 (Maxwell viscoelasticity)**.** A *Maxwell material* in shear responds to a deviatoric stress s_{ik} with a deviatoric strain rate

$$\dot{d}_{ik} = \frac{\dot{s}_{ik}}{2\mu} + \frac{s_{ik}}{2\eta}\,, \tag{30.64}$$

the two terms being an elastic and a viscous contribution in series, with η the shear viscosity in Pa s. Its *relaxation time* is

$$t_{\mathrm{r}} = \frac{\eta}{\mu}\,. \tag{30.65}$$

Rests on Equation (30.21) and Definition 30.20.

Proposition 30.80 (A Maxwell material is a solid or a fluid depending on how long you watch)**.** *Under a step of stress applied at $t = 0$ and held, Equation (30.64) gives $d_{ik}(t) = (s_{ik}/2\mu)\,(1 + t/t_{\mathrm{r}})$: the response is elastic for $t \ll t_{\mathrm{r}}$ and viscous for $t \gg t_{\mathrm{r}}$. Under a step of strain held fixed, the stress decays as $s_{ik}(t) = s_{ik}(0)\mathrm{e}^{-t/t_{\mathrm{r}}}$.*

Rests on Definition 30.79.

Proof. *Derives Proposition 30.80.*

For a constant s_{ik} the first term of Equation (30.64) vanishes after the step and integration gives $d_{ik}(t) = d_{ik}(0) + s_{ik}t/(2\eta)$ with the instantaneous elastic response $d_{ik}(0) = s_{ik}/(2\mu)$; factoring out $s_{ik}/2\mu$ and using Equation (30.65) gives the stated form. For constant d_{ik} the left side vanishes and Equation (30.64) becomes $\dot{s}_{ik} = -\,(\mu/\eta)\,s_{ik}$, whose solution is the stated exponential. □

The ratio t_r to the time of observation decides which chapter a material belongs in. Window glass at room temperature has t_r of order 10^{20} years and is a solid by any test that will ever be applied to it; the Earth's mantle has $\eta \approx 1 \times 10^{21}\,\mathrm{Pa\,s}$ and $\mu \approx 1 \times 10^{11}\,\mathrm{Pa}$, so $t_r \approx 10^{10}$ seconds — a few hundred years. It therefore transmits the seismic waves of Phenomenon 30.43 as an elastic solid on a timescale of minutes and convects as a fluid on a timescale of millions of years, and both descriptions are correct at their own frequency. That is the sense in which Chapter 31 is not a different subject but the same one at a different value of ωt_r; the Cauchy momentum equation Equation (30.17) is common to both, and only the constitutive law relating σ_{ik} to the motion changes — from Equation (30.21), linear in the strain, to a law linear in the strain *rate*.

Chapter 31

Fluid Dynamics

A fluid is the continuum of Chapter 30 with one constitutive change that carries an entire subject: it cannot support a shear stress at rest. From that single statement follow the Euler and Navier–Stokes equations, ideal and viscous flow, Bernoulli's theorem, the conservation laws of vorticity, and the turbulence phenomenology that a century and a half of effort has organized but not derived. The chapter is built, like the rest of this part, on the measured record: the viscosities, drag laws and pipe-flow data that test every equation stated here, from Poiseuille's capillaries [105] to Reynolds's dye experiments [226] and the tidal-channel spectra that confirmed Kolmogorov's scaling [1227].

It closes the mechanics of continuous media begun in Chapter 30 and opens three doors: sound and shock waves connect to Chapter 28; the loss of stability and the transition to turbulence are the laboratory of Chapter 32; and electrically conducting fluids return as the magnetohydrodynamics of Chapter 66. The molecular origin of viscosity belongs to Chapter 55. The canonical monograph is [1340], and the measurements that discipline the whole chapter are collected in Chapter 36.

The reader should keep one asymmetry in view from the start. Everything in Sections 31.1 to 31.6.2 is derived: given the constitutive relation and the boundary conditions, the results follow. Everything in Section 31.9 is not: it is organized measurement, dimensional analysis and hypotheses that have been tested but not proved, resting moreover on equations whose well-posedness is an open problem (Section 31.4.5). The chapter marks the boundary between the two wherever it is crossed.

31.1 Kinematics of flow

31.1.1 The continuum hypothesis and the two descriptions

Definition 31.1 (Fluid)**.** A *fluid* is a continuous medium (Section 30.1) whose stress tensor in equilibrium is purely isotropic,

$$\sigma_{ij}^{(\mathrm{rest})} = -p\,\delta_{ij}\,, \tag{31.1}$$

with p the *pressure*, measured in Pa. Equivalently: a fluid at rest exerts no tangential traction on any internal surface, so a shear stress of any magnitude, however small, sets it in motion and keeps it moving.

Rests on Theorem 30.18.

The sign is a convention with content: a fluid at rest pushes on every surface along the inward normal, and $p > 0$ for every fluid treated in this chapter. Solids differ precisely in admitting a static deviatoric part, which is what Chapter 30 is about.

Definition 31.2 (Knudsen number)**.** For a flow of characteristic length L in a gas whose molecular mean free path is λ, the *Knudsen number* is the dimensionless ratio

$$\mathrm{Kn} = \frac{\lambda}{L}\,. \tag{31.2}$$

The field description of this chapter is legitimate when $\mathrm{Kn} \ll 1$.

Rests on Definition 31.1.

Remark 31.3 (When the continuum picture is allowed)*.* The mean free path in air at room temperature and atmospheric pressure is of order $7 \times 10^{-8}\,\mathrm{m}$ (Chapter 55), so $\mathrm{Kn} < 10^{-3}$ for any apparatus larger than a tenth of a millimetre and the continuum description is very safe indeed. It fails, and visibly, in three places this chapter does not treat: rarefied gases, where λ is comparable with the apparatus; the interior of a shock, whose thickness is a few mean free paths (Section 31.10.2); and the last nanometres against a wall, which is where the no-slip condition of Section 31.4.2 is ultimately decided (Section 36.2).

Rests on Definition 31.2.

Granted the hypothesis, there are two ways to label what is moving, and both go back to Euler's memoir [30]. The *material* or Lagrangian description follows an identified fluid particle, labelled by its position $\boldsymbol{X}$ at some reference time and carried to $\boldsymbol{x}(\boldsymbol{X}, t)$; the *spatial* or Eulerian description abandons the particles and records instead the fields $\boldsymbol{v}(\boldsymbol{x}, t)$, $\rho(\boldsymbol{x}, t)$, $p(\boldsymbol{x}, t)$ at fixed points of space. The Eulerian fields are what an instrument in the flow measures, and they are what the equations of this chapter are written for; the material description survives in one construction, the derivative that follows a particle.

Definition 31.4 (Material derivative)**.** The *material derivative* of a field $f(\boldsymbol{x}, t)$ is its rate of change along the motion of a fluid particle,

$$\frac{Df}{Dt} := \frac{\partial f}{\partial t} + (\boldsymbol{v}\cdot\boldsymbol{\nabla})\, f\,. \tag{31.3}$$

Rests on Proposition 7.72 and Equation (7.85).

Derivation. *Derives Definition 31.4.*

Let $\boldsymbol{x}(t)$ be the path of a particle, so that $\mathrm{d}\boldsymbol{x}/\mathrm{d}t = \boldsymbol{v}(\boldsymbol{x}(t), t)$. The chain rule in several variables (Proposition 7.72) gives

$$\frac{\mathrm{d}}{\mathrm{d}t} f(\boldsymbol{x}(t), t) = \frac{\partial f}{\partial t} + \frac{\mathrm{d}x_i}{\mathrm{d}t}\frac{\partial f}{\partial x_i} = \frac{\partial f}{\partial t} + v_i\, \partial_i f\,,$$

which is Equation (31.3). The two terms are physically distinct and it is worth naming them: $\partial_t f$ is the change an instrument at a fixed point records, and $(\boldsymbol{v}\cdot\boldsymbol{\nabla})f$ is the change a particle experiences merely by being carried into a region where f is different. A steady flow, $\partial_t f = 0$ everywhere, can therefore accelerate a particle violently — which is what happens in the Venturi throat of Section 31.3.2, and the reason the acceleration in the equations below is not $\partial_t \boldsymbol{v}$. □

Remark 31.5 (Vector identities this chapter uses, and where they belong)*.* Three identities of the nabla calculus are used repeatedly below:

$$(\boldsymbol{v}\cdot\boldsymbol{\nabla})\,\boldsymbol{v} = \boldsymbol{\nabla}\left(\tfrac{1}{2}v^2\right) - \boldsymbol{v}\times(\boldsymbol{\nabla}\times\boldsymbol{v})\,, \tag{31.4}$$

$$\boldsymbol{\nabla}\times(\boldsymbol{a}\times\boldsymbol{b}) = (\boldsymbol{b}\cdot\boldsymbol{\nabla})\,\boldsymbol{a} - (\boldsymbol{a}\cdot\boldsymbol{\nabla})\,\boldsymbol{b} + \boldsymbol{a}\,(\boldsymbol{\nabla}\cdot\boldsymbol{b}) - \boldsymbol{b}\,(\boldsymbol{\nabla}\cdot\boldsymbol{a})\,, \tag{31.5}$$

$$\boldsymbol{\nabla}\times(\boldsymbol{\nabla}\times\boldsymbol{a}) = \boldsymbol{\nabla}\,(\boldsymbol{\nabla}\cdot\boldsymbol{a}) - \nabla^2\boldsymbol{a}\,, \qquad \boldsymbol{\nabla}\cdot(\boldsymbol{\nabla}\times\boldsymbol{a}) = 0\,. \tag{31.6}$$

Each is an exercise in the permutation identity $\epsilon_{ijk}\epsilon_{klm} = \delta_{il}\delta_{jm} - \delta_{im}\delta_{jl}$ together with the equality of mixed partial derivatives. They are stated here rather than proved because they

are general mathematics, not physics: Chapter 7 defines the nabla operator (Equations (7.85) and (7.87)), proves the integral theorems and proves $\boldsymbol{\nabla} \times \boldsymbol{\nabla} f = \mathbf{0}$ (Equation (7.128)), but does not yet carry the product and second-order identities. They belong in that chapter and are recorded here as a debt against it, not as a result of fluid mechanics.

Rests on Equations (7.87) and (7.128).

Definition 31.6 (Streamline, pathline, streakline)**.** At a fixed instant t, a *streamline* is a curve everywhere tangent to $\boldsymbol{v}(\cdot, t)$, i.e. a solution of $\mathrm{d}\boldsymbol{x}/\mathrm{d}s = \boldsymbol{v}(\boldsymbol{x}, t)$ with t held fixed. A *pathline* is the trajectory of one fluid particle, the solution of $\mathrm{d}\boldsymbol{x}/\mathrm{d}t = \boldsymbol{v}(\boldsymbol{x}, t)$ with t running. A *streakline* is the locus at time t of all particles that have passed through a fixed point — the visible line of dye or smoke in an experiment.

Rests on Definition 31.4.

Proposition 31.7 (The three coincide in steady flow)**.** *If $\partial_t \boldsymbol{v} = \mathbf{0}$ everywhere, the streamlines, pathlines and streaklines of the flow are the same family of curves. If the flow is unsteady they need not be, and in general are not.*

Rests on Definition 31.6.

Proof. *Derives Proposition 31.7.*

When $\boldsymbol{v}$ does not depend on t, the two ordinary differential equations of Definition 31.6 are the same autonomous system, and by uniqueness of its solutions (Theorem 9.8) the curve through a given point is the same in both cases. Every particle passing through a fixed point therefore follows the identical curve, so the streakline is that curve too. In unsteady flow the streamline pattern changes while a particle is traversing it and the three families separate: this is why a smoke photograph of an unsteady flow is not a picture of its instantaneous streamlines, and why the dye filament of Section 36.3 is read as a streakline. □

Definition 31.8 (Rate of strain and vorticity)**.** The velocity-gradient tensor $\partial_j v_i$ splits into its symmetric and antisymmetric parts,

$$e_{ij} := \tfrac{1}{2}\left(\partial_i v_j + \partial_j v_i\right), \qquad \boldsymbol{\omega} := \boldsymbol{\nabla} \times \boldsymbol{v}, \tag{31.7}$$

e_{ij} being the *rate-of-strain tensor*, in 1/s, and $\boldsymbol{\omega}$ the *vorticity*, also in 1/s.

Rests on Equation (7.87) and Definition 13.91.

Proposition 31.9 (Cauchy–Stokes decomposition)**.** *The velocity of the fluid at a point $\boldsymbol{x} + \delta\boldsymbol{x}$ near a point $\boldsymbol{x}$ is, to first order in $\delta\boldsymbol{x}$,*

$$\delta v_i = e_{ij}\,\delta x_j + \tfrac{1}{2}\left(\boldsymbol{\omega} \times \delta\boldsymbol{x}\right)_i . \tag{31.8}$$

A fluid element therefore moves as the superposition of a translation, a rigid rotation at angular velocity $\boldsymbol{\omega}/2$, and a pure straining motion with no rotation.

Rests on Definition 31.8.

Proof. *Derives Proposition 31.9.*

Taylor's theorem gives $\delta v_i = (\partial_j v_i)\,\delta x_j$ to first order. Split the gradient into symmetric and antisymmetric parts, $\partial_j v_i = e_{ij} + \Omega_{ij}$ with $\Omega_{ij} = \frac{1}{2}\left(\partial_j v_i - \partial_i v_j\right)$. Now

$$-\tfrac{1}{2}\epsilon_{ijk}\omega_k = -\tfrac{1}{2}\epsilon_{ijk}\epsilon_{klm}\partial_l v_m = -\tfrac{1}{2}\left(\partial_i v_j - \partial_j v_i\right) = \Omega_{ij},$$

so that $\Omega_{ij}\delta x_j = -\frac{1}{2}\epsilon_{ijk}\omega_k \delta x_j = \frac{1}{2}\epsilon_{ikj}\omega_k \delta x_j = \frac{1}{2}\left(\boldsymbol{\omega} \times \delta\boldsymbol{x}\right)_i$, which is Equation (31.8). The factor of one half is the whole content of the statement that vorticity is *twice* the local angular velocity, and it is a standing source of confusion: a fluid in rigid rotation at angular velocity $\boldsymbol{\Omega}$ (Chapter 29) has $\boldsymbol{\omega} = 2\boldsymbol{\Omega}$, not $\boldsymbol{\Omega}$. □

Remark 31.10 (Vorticity is local rotation, not curvature of the path). Two examples fix the distinction, and both are realized in the laboratory. A fluid in rigid rotation, $\boldsymbol{v} = \boldsymbol{\Omega} \times \boldsymbol{x}$, has $\boldsymbol{\omega} = 2\boldsymbol{\Omega}$ everywhere although each particle moves on a circle. The *free vortex* $\boldsymbol{v} = (\Gamma/2\pi r)\,\hat{\boldsymbol{\varphi}}$ has $\boldsymbol{\omega} = \boldsymbol{0}$ everywhere except on the axis, although every particle also moves on a circle: a small paddle carried round by that flow does not turn, because the outer side of it moves more slowly than the inner. Circular streamlines are neither necessary nor sufficient for vorticity.

Rests on Proposition 31.9.

31.1.2 The continuity equation

Lemma 31.11 (Transport theorem for a material volume). *Let $V(t)$ be a volume that moves with the fluid, so that it always consists of the same particles, and let $f(\boldsymbol{x}, t)$ be continuously differentiable. Then*

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{V(t)} f \,\mathrm{d}V = \int_{V(t)} \left[\frac{\partial f}{\partial t} + \boldsymbol{\nabla}\cdot(f\boldsymbol{v})\right] \mathrm{d}V = \int_{V(t)} \left[\frac{Df}{Dt} + f\,\boldsymbol{\nabla}\cdot\boldsymbol{v}\right] \mathrm{d}V\,. \tag{31.9}$$

Rests on Theorem 7.101 and Definition 31.4.

Proof. *Derives Lemma 31.11.*

In a time $\mathrm{d}t$ the boundary element $\mathrm{d}S$ with outward unit normal $\boldsymbol{n}$ sweeps the volume $(\boldsymbol{v}\cdot\boldsymbol{n})\,\mathrm{d}S\,\mathrm{d}t$, so the integral changes for two reasons and only two: the integrand changes at fixed points, and the domain moves. Hence

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{V(t)} f \,\mathrm{d}V = \int_{V} \frac{\partial f}{\partial t}\,\mathrm{d}V + \oint_{\partial V} f\,(\boldsymbol{v}\cdot\boldsymbol{n})\,\mathrm{d}S\,,$$

and the divergence theorem (Theorem 7.101) turns the surface term into $\int_V \boldsymbol{\nabla}\cdot(f\boldsymbol{v})\,\mathrm{d}V$. Expanding $\boldsymbol{\nabla}\cdot(f\boldsymbol{v}) = \boldsymbol{v}\cdot\boldsymbol{\nabla}f + f\,\boldsymbol{\nabla}\cdot\boldsymbol{v}$ and using Equation (31.3) gives the second form. The first term of the first form requires differentiating an integral with respect to a parameter under a fixed domain, which is elementary here because f is C^1 and V is bounded. □

Theorem 31.12 (Conservation of mass). *For any fluid motion,*

$$\frac{\partial\rho}{\partial t} + \boldsymbol{\nabla}\cdot(\rho\boldsymbol{v}) = 0\,, \qquad \textit{equivalently} \qquad \frac{D\rho}{Dt} + \rho\,\boldsymbol{\nabla}\cdot\boldsymbol{v} = 0\,. \tag{31.10}$$

Rests on Lemma 31.11.

Proof. *Derives Theorem 31.12.*

The mass of a material volume is constant, since the volume contains the same particles at all times and mass is neither created nor destroyed. Setting $f = \rho$ in Equation (31.9) and equating the result to zero,

$$\int_{V(t)} \left[\frac{\partial\rho}{\partial t} + \boldsymbol{\nabla}\cdot(\rho\boldsymbol{v})\right] \mathrm{d}V = 0$$

for *every* material volume. A continuous function whose integral vanishes over every subvolume vanishes identically — if it were positive at a point it would be positive on a ball about that point, by continuity, and the integral over that ball would not vanish — which is Equation (31.10). The second form follows from the first by Equation (31.3). First written as a field equation by Euler [30]. □

Corollary 31.13 (Incompressible flow). *The density of every fluid particle is constant, $D\rho/Dt = 0$, if and only if the velocity field is solenoidal,*

$$\boldsymbol{\nabla}\cdot\boldsymbol{v} = 0\,. \tag{31.11}$$

Rests on Theorem 31.12.

Proof. *Derives Corollary 31.13.*

Immediate from the second form of Equation (31.10), since $\rho > 0$. Note what the statement does *not* say: it does not say the density is uniform. Salt water stratified by depth satisfies Equation (31.11) exactly while ρ varies from place to place, and that is precisely the configuration of the Rayleigh–Taylor and Kelvin–Helmholtz problems of Section 31.8.1. □

Remark 31.14 (When incompressibility is legitimate). Equation (31.11) is an approximation to Equation (31.10), and its validity is a statement about three comparisons, not one. Write c for the sound speed of Section 31.10.1, U and L for the speed and size of the flow, and T for the time over which it changes. Then the fractional density change is of order $\mathrm{Ma}^2 = U^2/c^2$ from the Bernoulli pressure variation, of order L^2/c^2T^2 from unsteadiness, and of order gL/c^2 from the hydrostatic pressure variation. All three must be small. The first is the familiar one and is the reason the flow of water and of air below about 100 m/s may be treated as incompressible: with $c \approx 343\,\mathrm{m/s}$ in air [1340], that is $\mathrm{Ma}^2 \approx 0.085$, so the density varies by under a tenth. The third is why the atmosphere as a whole is not incompressible even when the wind is slow: with L the scale height of Example 31.19, gL/c^2 is of order unity.

Rests on Corollary 31.13.

Example 31.15 (The stream function of a plane flow)**.** Let the flow be independent of one Cartesian coordinate z and have no z component — an idealization of flow past a long cylinder or a wing of large span, and the setting of Section 31.7.1. Then Equation (31.11) reads $\partial_x v_x + \partial_y v_y = 0$, which is satisfied identically by

$$v_x = \frac{\partial \psi}{\partial y}\,, \qquad v_y = -\frac{\partial \psi}{\partial x}\,, \tag{31.12}$$

for a *stream function* $\psi(x, y, t)$ in m^2/s. Since $\boldsymbol{v} \cdot \boldsymbol{\nabla}\psi = 0$, the level curves of ψ are the streamlines, and the difference of ψ between two of them is the volume flux per unit span flowing between them. The existence of ψ on a simply connected domain is the two-dimensional face of Proposition 7.104 applied to the field $(-v_y, v_x)$, whose curl is $-\boldsymbol{\nabla} \cdot \boldsymbol{v} = 0$.

Rests on Corollary 31.13 and Proposition 7.104.

31.2 Hydrostatics

Proposition 31.16 (Hydrostatic balance)**.** *In a fluid at rest in a body-force field $\boldsymbol{g}$ per unit mass,*

$$\boldsymbol{\nabla} p = \rho \boldsymbol{g}\,. \tag{31.13}$$

In a uniform gravitational field $\boldsymbol{g} = -g\hat{\boldsymbol{z}}$ this makes p a function of height alone, $\mathrm{d}p/\mathrm{d}z = -\rho g$, and requires ρ to be a function of height alone as well.

Rests on Definition 31.1 and Theorem 30.21.

Proof. *Derives Proposition 31.16.*

By Definition 31.1 the traction on any internal surface of a fluid at rest is $-p\boldsymbol{n}$. The force on a volume V is therefore $-\oint_{\partial V} p\boldsymbol{n}\,\mathrm{d}S = -\int_V \boldsymbol{\nabla} p\,\mathrm{d}V$ by the divergence theorem (Theorem 7.101), and the body force is $\int_V \rho\boldsymbol{g}\,\mathrm{d}V$. Equilibrium requires the sum to vanish for every V, hence Equation (31.13) pointwise. Taking the curl of Equation (31.13) with $\boldsymbol{g} = -g\hat{\boldsymbol{z}}$ constant gives $\boldsymbol{\nabla}\rho \times \boldsymbol{g} = \boldsymbol{0}$, so $\boldsymbol{\nabla}\rho$ is vertical: a fluid at rest in gravity is necessarily stratified horizontally, which is why a tilted density interface cannot be at rest. □

Phenomenon 31.17 (Pascal's principle)**.** A pressure applied to a confined liquid is transmitted undiminished to every part of the liquid and to the walls of its container [7]. In

consequence a small force applied to a piston of area A_1 balances a large force on a piston of area A_2 in the same closed vessel at the same height,

$$\frac{F_2}{F_1} = \frac{A_2}{A_1}\,, \tag{31.14}$$

which is the hydraulic press. The work done is the same at both pistons, the smaller one moving farther in the ratio A_2/A_1.

Derivation. *Derives Phenomenon 31.17.*

Let the applied pressure change the boundary value from p to $p + \Delta p$ with the fluid remaining at rest and its density unchanged. Both states satisfy Equation (31.13) with the same right-hand side, so the difference field satisfies $\boldsymbol{\nabla}(\Delta p) = \mathbf{0}$ and Δp is the same constant throughout a connected body of liquid — which is Pascal's statement. The force on a piston of area A is then $F = \Delta p\, A$ at each piston, giving Equation (31.14). Conservation of volume for an incompressible liquid, $A_1 d_1 = A_2 d_2$ for the displacements d_i, gives $F_1 d_1 = F_2 d_2$: the press multiplies force and divides distance, and creates no energy. The idealization is the constancy of ρ; a real liquid transmits the change at the sound speed of Section 31.10.1, not instantaneously. □

Phenomenon 31.18 (Archimedes' principle)**.** A body wholly or partly immersed in a fluid at rest is acted on by an upward force equal to the weight of the fluid it displaces,

$$\boldsymbol{F}_\mathrm{b} = -\rho_\mathrm{f} V \boldsymbol{g}\,, \tag{31.15}$$

where V is the immersed volume and ρ_f the density of the fluid; the line of action passes through the centre of mass of the displaced fluid, and neither the magnitude nor the point of application depends on what the body is made of. A body free to move therefore floats at the depth at which the displaced weight equals its own [274].

Rests on Proposition 31.16.

Derivation. *Derives Phenomenon 31.18.*

A fluid at rest carries no shear stress, so the traction on any internal surface is the normal pressure alone and the balance of forces on a fluid element reads $\boldsymbol{\nabla} p = \rho_\mathrm{f} \boldsymbol{g}$. The force exerted on the immersed body is the integral of that pressure over its wetted surface S, directed inwards along the outward normal $\boldsymbol{n}$:

$$\boldsymbol{F}_\mathrm{b} = -\oint_S p\,\boldsymbol{n}\,\mathrm{d}S = -\int_V \boldsymbol{\nabla} p\,\mathrm{d}V = -\int_V \rho_\mathrm{f}\boldsymbol{g}\,\mathrm{d}V = -\rho_\mathrm{f} V \boldsymbol{g}\,,$$

the second step by the divergence theorem (Theorem 7.101). The manoeuvre deserves a word: the pressure field is defined only outside the body, and what the divergence theorem is applied to is its hydrostatic continuation into V. That is legitimate because the surface integral depends only on the boundary values, which are unchanged if the body is replaced by the same volume of fluid — and that replacement is in equilibrium, which is Archimedes' own argument. Taking moments the same way places the resultant at the centroid of V, the centre of buoyancy. Since $\boldsymbol{F}_\mathrm{b}$ involves the body only through V, two bodies of equal volume are buoyed equally however they differ in material, and a body of mean density ρ_b floats with the fraction $\rho_\mathrm{b}/\rho_\mathrm{f}$ of its volume submerged. □

Example 31.19 (The barometric distribution)**.** For an isothermal ideal gas of molar mass M at temperature T, $\rho = Mp/RT$, and Equation (31.13) integrates to

$$p(z) = p(0)\exp\left(-\frac{z}{H}\right), \qquad H = \frac{RT}{Mg}\,. \tag{31.16}$$

For air, $M = 2.896 \times 10^{-2}\,\mathrm{kg/mol}$ and $T = 288\,\mathrm{K}$ with $g = 9.806\,65\,\mathrm{m/s^2}$ (Appendix B) give a scale height $H = 8.4\,\mathrm{km}$, which is the right order for the observed decay of atmospheric pressure with altitude. The isothermal assumption is the weak point — the real troposphere has a lapse rate — and the molecular reading of Equation (31.16), as the Boltzmann distribution in the gravitational potential, belongs to Chapter 55.

Rests on Proposition 31.16.

Phenomenon 31.20 (Capillary rise)**.** A liquid that wets the wall of a narrow vertical tube dipped into it climbs above the outer free surface, to a height inversely proportional to the radius of the tube,

$$h = \frac{2\gamma \cos\theta}{\rho g r}\,, \tag{31.17}$$

where γ is the surface tension of the liquid–air interface, in N/m, and θ the contact angle at the wall. For clean water against glass, $\gamma \approx 7.3 \times 10^{-2}\,\mathrm{N/m}$ at room temperature [1340] and $\theta \approx 0$, so a tube of radius 0.1 mm raises the water by about 0.15 m. A liquid that does not wet the wall, such as mercury against glass, is depressed instead, the same formula with $\cos\theta < 0$.

Derivation. Derives Phenomenon 31.20.

A curved interface supports a pressure difference, the Young–Laplace relation [50],

$$\Delta p = \gamma \left(\frac{1}{R_1} + \frac{1}{R_2} \right)\,, \tag{31.18}$$

the pressure being higher on the concave side; R_1 and R_2 are the principal radii of curvature of the surface (Section 13.3.3). In a tube of radius r wetted at contact angle θ the meniscus is a spherical cap of radius $R = r/\cos\theta$, so both principal radii equal R and the pressure immediately below the meniscus is lower than the atmospheric pressure above it by $2\gamma\cos\theta/r$. Hydrostatic balance (Equation (31.13)) along the liquid from that point down to the level of the flat outer surface, where the pressure is atmospheric, requires the meniscus to stand a height h above it with $\rho g h = 2\gamma\cos\theta/r$, which is Equation (31.17). Two checks are worth making. The rise is not a force exerted by the tube on the liquid — it is the pressure deficit under a curved surface — so it does not depend on the thickness or material of the wall except through θ. And the $1/r$ dependence is the measured signature: a set of tubes of different bores gives a straight line through the origin when h is plotted against $1/r$, from whose slope γ is obtained, which is the classical capillary measurement of surface tension. □

31.3 Ideal flow: the Euler equations

31.3.1 The Euler equations

Definition 31.21 (Ideal fluid)**.** An *ideal* fluid is one whose stress tensor is isotropic *in motion as well as at rest*, $\sigma_{ij} = -p\delta_{ij}$ everywhere and at all times. Equivalently, its viscosity is taken to be exactly zero.

Rests on Definition 31.1.

Theorem 31.22 (Euler's equations of motion)**.** *The motion of an ideal fluid in a body-force field $\boldsymbol{g}$ per unit mass satisfies*

$$\rho \frac{D\boldsymbol{v}}{Dt} = \rho \left[\frac{\partial \boldsymbol{v}}{\partial t} + (\boldsymbol{v}\cdot\boldsymbol{\nabla})\,\boldsymbol{v} \right] = -\boldsymbol{\nabla} p + \rho \boldsymbol{g}\,, \tag{31.19}$$

which together with Equation (31.10) and an equation of state closes the system [30].

Rests on Definition 31.21, Lemma 31.11, and Theorem 30.21.

Proof. *Derives Theorem 31.22.*

Apply Lemma 31.11 to the momentum of a material volume, $f = \rho v_i$, and use Equation (31.10):

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{V(t)} \rho v_i \,\mathrm{d}V = \int_V \left[\frac{D(\rho v_i)}{Dt} + \rho v_i\, \boldsymbol{\nabla}\cdot\boldsymbol{v}\right]\mathrm{d}V = \int_V \rho\,\frac{Dv_i}{Dt}\,\mathrm{d}V\,,$$

the cross terms cancelling by Equation (31.10) exactly. The rate of change of momentum equals the applied force, which for an ideal fluid is the pressure traction plus the body force, $-\oint_{\partial V} p n_i \,\mathrm{d}S + \int_V \rho g_i \,\mathrm{d}V = \int_V (-\partial_i p + \rho g_i)\,\mathrm{d}V$ by Theorem 7.101. Equating the two for every material volume, and arguing from continuity as in Theorem 31.12, gives Equation (31.19). The result is Cauchy's momentum equation (Section 30.3.2) with the constitutive relation of Definition 31.21 inserted, so nothing new about mechanics has been assumed: the whole content of Equation (31.19) is Definition 31.21. □

Remark 31.23 (Boundary conditions, and what the ideal model omits). Equation (31.19) is first order in space in the velocity, so it admits only one scalar boundary condition on a solid wall: non-penetration, $\boldsymbol{v}\cdot\boldsymbol{n} = 0$ on the wall, with the tangential velocity left free to slip. The Navier–Stokes equations of Section 31.4.2 are second order and demand one more — no slip, $\boldsymbol{v} = \boldsymbol{0}$ — and that extra condition cannot be imposed on Equation (31.19). The whole difficulty of the inviscid limit lives in that mismatch: the small parameter multiplies the highest derivative, so the limit is singular and a thin layer must appear in which the discarded term is restored. That layer is Prandtl's (Section 31.7.2), and until it was identified the ideal theory returned the flatly false answer of Section 31.3.3.

Rests on Theorem 31.22.

31.3.2 Bernoulli's theorem

Theorem 31.24 (Bernoulli). *Let the flow be steady, let the body force be conservative, $\boldsymbol{g} = -\boldsymbol{\nabla}\Phi$, and let the fluid be ideal and barotropic, $\rho = \rho(p)$, so that a pressure function $P(p) = \int^p \mathrm{d}p'/\rho(p')$ exists. Then the* Bernoulli head

$$B := P + \tfrac{1}{2}v^2 + \Phi \tag{31.20}$$

is constant along each streamline. If the flow is in addition irrotational, $\boldsymbol{\omega} = \boldsymbol{0}$, then B takes the same value on every streamline. If the flow is unsteady and irrotational with $\boldsymbol{v} = \boldsymbol{\nabla}\phi$, the corresponding statement is that

$$\frac{\partial\phi}{\partial t} + P + \tfrac{1}{2}v^2 + \Phi = F(t) \tag{31.21}$$

holds throughout the fluid, with F a function of time alone.

Rests on Theorem 31.22 and Equation (31.4).

Proof. *Derives Theorem 31.24.*

Divide Equation (31.19) by ρ and use Equation (31.4) on the advective term together with $\boldsymbol{\nabla}p/\rho = \boldsymbol{\nabla}P$, valid exactly when $\rho = \rho(p)$:

$$\frac{\partial\boldsymbol{v}}{\partial t} + \boldsymbol{\nabla}\left(P + \tfrac{1}{2}v^2 + \Phi\right) = \boldsymbol{v}\times\boldsymbol{\omega}\,. \tag{31.22}$$

For steady flow the first term vanishes and $\boldsymbol{\nabla}B = \boldsymbol{v}\times\boldsymbol{\omega}$. Contract with $\boldsymbol{v}$: the right-hand side is orthogonal to $\boldsymbol{v}$, so $\boldsymbol{v}\cdot\boldsymbol{\nabla}B = 0$, and B is constant along the integral curves of $\boldsymbol{v}$ — the streamlines (Definition 31.6). If moreover $\boldsymbol{\omega} = \boldsymbol{0}$ then $\boldsymbol{\nabla}B = \boldsymbol{0}$ outright and B is one constant for the whole (connected) fluid. Finally, if $\boldsymbol{v} = \boldsymbol{\nabla}\phi$ then $\partial_t\boldsymbol{v} = \boldsymbol{\nabla}\partial_t\phi$ and $\boldsymbol{v}\times\boldsymbol{\omega} = \boldsymbol{0}$, so Equation (31.22) says that the gradient of the left-hand side of Equation (31.21) vanishes,

which is the claim. Note which hypothesis does which work: barotropy is what makes $\boldsymbol{\nabla} p/\rho$ a gradient, steadiness is what removes $\partial_t \boldsymbol{v}$, and irrotationality is what upgrades "along a streamline" to "everywhere". Dropping any one of them leaves a weaker but still usable statement, and dropping viscosity is what restricts every application to regions outside boundary layers and wakes. □

Phenomenon 31.25 (Pressure falls where the flow speeds up)**.** In the steady flow of a liquid of small viscosity the static pressure is lower where the fluid moves faster. Along a streamline the combination

$$p + \tfrac{1}{2}\rho v^2 + \rho g z = \text{const} \tag{31.23}$$

is observed to be constant [22, 30]. Two instruments measure the statement directly: a Pitot tube, whose mouth faces upstream and brings the flow to rest, reads a pressure exceeding the ambient static pressure by $\tfrac{1}{2}\rho v^2$, and is on that basis the standard airspeed and flow meter [20]; and a Venturi contraction shows a pressure drop at its throat fixed by the ratio of throat to inlet area, from which the volume flux follows [42].

Rests on Theorem 31.24.

Derivation. *Derives Phenomenon 31.25.*

For steady flow of a fluid of constant density in a uniform gravitational field the Euler equation reads $\rho(\boldsymbol{v}\cdot\boldsymbol{\nabla})\boldsymbol{v} = -\boldsymbol{\nabla} p - \rho g \boldsymbol{\nabla} z$. Use the identity Equation (31.4) and divide by ρ:

$$\boldsymbol{\nabla}\left(\frac{p}{\rho} + \frac{v^2}{2} + g z\right) = \boldsymbol{v} \times (\boldsymbol{\nabla} \times \boldsymbol{v})\,.$$

Project onto the local flow direction. The right-hand side is orthogonal to $\boldsymbol{v}$ and its projection vanishes identically, so the directional derivative of the bracket along a streamline is zero and the bracket is constant on each streamline — which is Equation (31.23), the constant-density case of Equation (31.20). Two riders follow at once. If the flow is in addition irrotational, $\boldsymbol{\nabla}\times\boldsymbol{v} = 0$ everywhere and the constant is the same on every streamline. And at a stagnation point, where $v = 0$ at the same height, the pressure exceeds the free-stream value by exactly $\tfrac{1}{2}\rho v^2$: that difference is what a Pitot tube reads [20]. The derivation used the inviscid equation, so the relation holds only where viscous stresses are negligible along the streamline followed — outside boundary layers and away from wakes. □

Example 31.26 (The Venturi meter)**.** A pipe of cross-section A_1 contracts smoothly to a throat of section A_2 and expands again. Mass conservation for an incompressible liquid gives $v_1 A_1 = v_2 A_2$, and Equation (31.23) along the axis at constant height gives $p_1 - p_2 = \tfrac{1}{2}\rho\,(v_2^2 - v_1^2)$. Eliminating the velocities,

$$Q = v_1 A_1 = A_2 \sqrt{\frac{2\,(p_1 - p_2)}{\rho\left[1 - (A_2/A_1)^2\right]}}\,, \tag{31.24}$$

so a differential pressure reading and two areas give the volume flux with no calibration constant whatever [42]. In practice a discharge coefficient near unity is applied, and its departure from unity measures exactly what the derivation left out: the boundary layer on the wall of the contraction. The efflux problem, in which the same theorem is applied between a free surface and a jet, is Phenomenon 36.1; there the ideal theory gets the speed exactly right and the discharge wrong, for the reason set out in Section 36.1.

Rests on Phenomenon 31.25.

Remark 31.27 (What the 1738 source contains). The relation Equation (31.23) is universally called Bernoulli's, and the *Hydrodynamica* [22] is the right source for the physical content — efflux from vessels, the exchange between what he calls the ascending force and the motion

of the liquid. It does not contain the formula in the modern local form, which is a *vis viva* argument for a stream tube rather than a statement about a velocity field, and the field form together with the equations it follows from is Euler's [30]. The distinction is recorded because a reader who checks the 1738 source against Equation (31.23) will not find it there, and should know that this is a fact about the history and not an error in the citation.

Rests on Phenomenon 31.25.

31.3.3 Potential flow and the d'Alembert paradox

Proposition 31.28 (Potential flow reduces to Laplace's equation)**.** *Let an incompressible flow be irrotational on a simply connected region. Then there is a velocity potential ϕ with $\boldsymbol{v} = \boldsymbol{\nabla}\phi$, and it is harmonic (Definition 10.66),*

$$\nabla^2 \phi = 0 \,, \tag{31.25}$$

with the boundary condition $\partial\phi/\partial n = \boldsymbol{U}\cdot\boldsymbol{n}$ on a solid surface moving at velocity $\boldsymbol{U}$. The velocity field is therefore determined by the geometry and the boundary motion alone; the pressure follows afterwards from Equation (31.21), and the density never enters the kinematics.

Rests on Corollary 31.13, Proposition 7.104, and Equation (10.24).

Proof. *Derives Proposition 31.28.*

Irrotationality is $\boldsymbol{\nabla}\times\boldsymbol{v} = \boldsymbol{0}$; on a simply connected region Proposition 7.104 then supplies a potential ϕ with $\boldsymbol{v} = \boldsymbol{\nabla}\phi$. Substituting into Equation (31.11) gives $\boldsymbol{\nabla}\cdot\boldsymbol{\nabla}\phi = \nabla^2\phi = 0$, which is Equation (31.25), an elliptic equation with the full apparatus of Section 10.4.3 available: uniqueness up to a constant for the Neumann problem, the maximum principle (Theorem 10.77) applied to each velocity component, and separation of variables in the coordinate systems of Theorem 10.34. Ellipticity has a physical reading worth stating: the potential at each point depends on the boundary data everywhere, instantaneously, so an incompressible ideal fluid transmits the influence of a moving boundary with infinite speed. That is a property of the incompressible idealization, not of nature, and it is repaired by the finite sound speed of Section 31.10.1. □

Example 31.29 (Flow past a sphere)**.** For a sphere of radius a held in a stream of speed U along $\hat{\boldsymbol{z}}$, the harmonic function satisfying $\partial_r\phi = 0$ at $r = a$ and $\boldsymbol{v} \longrightarrow U\hat{\boldsymbol{z}}$ at infinity is

$$\phi = U\cos\theta\left(r + \frac{a^3}{2r^2}\right) , \tag{31.26}$$

whence, using Equation (7.92),

$$v_r = U\cos\theta\left(1 - \frac{a^3}{r^3}\right) , \qquad v_\theta = -U\sin\theta\left(1 + \frac{a^3}{2r^3}\right) . \tag{31.27}$$

On the surface $v_r = 0$ as required and the speed is $q = \tfrac{3}{2}U\sin\theta$: the fluid at the equator of the sphere moves half again as fast as the free stream, and comes to rest at the two poles. Equation (31.23) then gives the surface pressure

$$p(\theta) = p_\infty + \tfrac{1}{2}\rho U^2\left(1 - \tfrac{9}{4}\sin^2\theta\right) . \tag{31.28}$$

Rests on Proposition 31.28.

Phenomenon 31.30 (Steady ideal flow exerts no drag)**.** A body held in the steady potential flow of an ideal incompressible fluid experiences zero force along the stream [27]. The conclusion is in flat contradiction with every observation of a real fluid, however small

its viscosity is made, and it is not repaired by taking the viscosity smaller: the measured drag coefficient of a sphere tends to a constant of order unity as the Reynolds number grows (Phenomenon 31.55), not to zero. This is the sharpest failure of a limit in classical physics, and its resolution — that the limit of vanishing viscosity is not uniform near a wall — is Phenomenon 36.12.

Derivation. *Derives Phenomenon 31.30.*

Take the sphere of Example 31.29. The drag is the component of the pressure resultant along the stream,

$$F_z = -\oint_S p\, n_z \,\mathrm{d}S = -\int_0^{\pi} p(\theta)\cos\theta \, 2\pi a^2 \sin\theta \,\mathrm{d}\theta \,,$$

and by Equation (31.28) the integrand is a combination of $\cos\theta\sin\theta$ and $\cos\theta\sin^3\theta$, both odd about $\theta = \pi/2$ and both integrating to zero over $(0,\pi)$. Hence $F_z = 0$ exactly. The mechanism is visible in Equation (31.28): the pressure distribution is symmetric fore and aft, so the high pressure at the rear stagnation point pushes the sphere forward exactly as hard as the high pressure at the front pushes it back. The general statement, for a body of arbitrary shape in three dimensions, follows from the same fore-and-aft structure of the far field and is left to the appendix. □

Full derivation: Appendix A.59 (p. 3118).
Derives Phenomenon 31.30.

Remark 31.31 (Two escapes, and only two). The theorem has exactly two loopholes, and both are realized. The first is circulation: if the fluid region is not simply connected — around a body of large span, in the plane transverse to it — the potential need not be single valued, the flow may carry a circulation, and a transverse force appears. That is the lift of Section 31.7.1, and it is still *drag* free, so the paradox survives it. The second is that the flow may fail to be steady or to remain attached, which is what happens in nature and is Section 31.7.2. Lamb's treatise [701] is the classical repository of the potential solutions, and its value is undiminished by the fact that its central prediction about drag is wrong: the outer flow it computes is what the streak photographs of Section 36.5 actually show.
Rests on Phenomenon 31.30.

31.4 Viscous flow: the Navier–Stokes equations

31.4.1 Viscosity

Definition 31.32 (Newtonian fluid; dynamic and kinematic viscosity)**.** A fluid is *Newtonian* if the deviatoric part of its stress tensor is a linear, isotropic, instantaneous function of the rate of strain e_{ij} of Equation (31.7). For the simple shearing motion $\boldsymbol{v} = v(y)\hat{\boldsymbol{x}}$ this reduces to Newton's own statement [14]

$$\sigma_{xy} = \mu \,\frac{\mathrm{d}v}{\mathrm{d}y} \,, \tag{31.29}$$

defining the *dynamic viscosity* μ, whose SI unit is the pascal second, $\mathrm{Pa\,s} = \mathrm{kg/(m\,s)}$. The *kinematic viscosity* is $\nu := \mu/\rho$, in $\mathrm{m^2/s}$.
Rests on Definitions 31.1 and 31.8.

Remark 31.33 (Reading the two viscosities). μ is the constant of the constitutive relation and is what a viscometer measures; ν is the diffusivity of momentum, and it is ν that appears in the equations of motion once they are divided by ρ. The distinction is not pedantry: air is about fifty times less viscous than water in μ and about fifteen times *more* viscous in ν, so momentum diffuses faster in air, and the boundary layer of Section 31.7.2 on a given body

at a given speed is thicker in air than in water. Table 31.1 gives the values used throughout this chapter.

Rests on Definition 31.32.

Table 31.1: Density, dynamic and kinematic viscosity of the two fluids used in the worked numbers of this chapter, at 20 °C and, for air, at a pressure of 101 325 Pa. Values rounded to three significant figures from the tabulation in [1340]; all three quantities vary appreciably with temperature, the viscosity of water by a few percent per kelvin, which is why the capillary measurements of Section 36.2 were made in a controlled bath.

Fluid	ρ (kg/m^3)	μ (Pa s)	ν (m^2/s)
Water	998	1.00×10^{-3}	1.00×10^{-6}
Air	1.20	1.81×10^{-5}	1.51×10^{-5}

Phenomenon 31.34 (The viscosity of a gas does not depend on its density)**.** The dynamic viscosity of a gas is, over a wide range of pressures, independent of the density of the gas: pumping half the air out of a vessel does not halve the damping of a body oscillating inside it. The result was predicted from a molecular model and then measured by Maxwell in a torsional oscillation apparatus [167], and it is counter-intuitive enough that it served as the decisive early test of the kinetic theory — a continuum theory of viscosity has nothing to say about it either way. The independence fails at low enough pressure, where the mean free path becomes comparable with the apparatus and Definition 31.2 is no longer small.

Derivation. Derives Phenomenon 31.34.

The derivation is molecular and belongs to Chapter 55, where it is carried out; the one-line reason is that momentum is carried across a shear layer by molecules crossing it, at a rate proportional to the number density n, each carrying the momentum difference accumulated over one mean free path $\lambda \propto 1/n$, so that $\mu \sim n\lambda \times$ (molecular momentum) is independent of n. What belongs *here* is the consequence: the continuum theory of this chapter takes μ as an empirical coefficient and can neither predict this behaviour nor be embarrassed by it. That is the honest division of labour between Chapter 31 and Chapter 55, and it is why the value of μ appears in Table 31.1 as a measurement. □

Remark 31.35 (Non-Newtonian fluids are out of scope). Many real materials — polymer solutions, suspensions, molten plastics, blood in the smallest vessels — have a deviatoric stress that depends nonlinearly on e_{ij}, or on its history, or both. They are not covered by Definition 31.32 and nothing in this chapter applies to them. Air, water, mercury, glycerol and the light oils are Newtonian to high accuracy over the range of shear rates considered here, which is what makes the agreement reported in Section 36.2 a test of the equations rather than of a fitting form.

Rests on Definition 31.32.

31.4.2 The Navier–Stokes equations

Theorem 31.36 (The Newtonian constitutive relation)**.** *The most general stress tensor that is (i) linear in the velocity gradient, (ii) isotropic, (iii) symmetric, and (iv) reduces to $-p\delta_{ij}$ when the fluid is in rigid-body motion, is*

$$\sigma_{ij} = -p\,\delta_{ij} + 2\mu\left(e_{ij} - \tfrac{1}{3}e_{kk}\delta_{ij}\right) + \zeta\, e_{kk}\,\delta_{ij}\,, \tag{31.30}$$

with exactly two independent coefficients: the shear viscosity μ of Definition 31.32 and the bulk viscosity *ζ, both in* Pa s.

Rests on Definition 31.32 and Proposition 31.9.

Proof. *Derives Theorem 31.36.*

By (i), $\sigma_{ij} + p\delta_{ij} = A_{ijkl}\partial_k v_l$ for a constant fourth-rank tensor A. By (ii) that tensor is isotropic, and every isotropic fourth-rank tensor in three dimensions is a combination of the three available products of Kronecker deltas,

$$A_{ijkl} = \lambda\,\delta_{ij}\delta_{kl} + \mu_1\,\delta_{ik}\delta_{jl} + \mu_2\,\delta_{il}\delta_{jk}\,,$$

a representation this chapter takes from the algebra of Cartesian tensors (Section 13.2.2). Symmetry of σ in (i,j) forces $\mu_1 = \mu_2 =: \mu$, and then

$$\sigma_{ij} + p\delta_{ij} = \lambda\,(\boldsymbol{\nabla}\cdot\boldsymbol{v})\,\delta_{ij} + \mu\,(\partial_i v_j + \partial_j v_i) = \lambda\,e_{kk}\,\delta_{ij} + 2\mu\,e_{ij}\,,$$

which involves only the symmetric part e_{ij} — so requirement (iv) is automatically met, since the antisymmetric part of the velocity gradient, which by Proposition 31.9 is the rigid rotation, has dropped out. Writing $e_{ij} = \left(e_{ij} - \frac{1}{3}e_{kk}\delta_{ij}\right) + \frac{1}{3}e_{kk}\delta_{ij}$ and collecting the isotropic pieces gives Equation (31.30) with $\zeta = \lambda + \frac{2}{3}\mu$. The split is the useful one because the first viscous term is trace free and responds only to shape change, while ζ responds only to volume change and therefore cannot be measured in any incompressible flow. □

Theorem 31.37 (The Navier–Stokes equations)**.** *For a Newtonian fluid,*

$$\rho\frac{D\boldsymbol{v}}{Dt} = -\boldsymbol{\nabla}p + \mu\nabla^2\boldsymbol{v} + \left(\zeta + \tfrac{1}{3}\mu\right)\boldsymbol{\nabla}\,(\boldsymbol{\nabla}\cdot\boldsymbol{v}) + \rho\boldsymbol{g}\,, \tag{31.31}$$

and when the flow is incompressible and μ uniform this reduces to

$$\frac{\partial\boldsymbol{v}}{\partial t} + (\boldsymbol{v}\cdot\boldsymbol{\nabla})\,\boldsymbol{v} = -\frac{1}{\rho}\boldsymbol{\nabla}p + \nu\nabla^2\boldsymbol{v} + \boldsymbol{g}\,, \qquad \boldsymbol{\nabla}\cdot\boldsymbol{v} = 0\,. \tag{31.32}$$

The boundary condition at a solid surface is no slip*: the fluid velocity equals the velocity of the surface, both normal and tangential components.*

Rests on Theorems 31.22 and 31.36.

Proof. *Derives Theorem 31.37.*

Cauchy's momentum equation (Section 30.3.2), derived exactly as in Theorem 31.22 but keeping the full traction, is $\rho\,Dv_i/Dt = \partial_j\sigma_{ij} + \rho g_i$. Insert Equation (31.30) with μ and ζ constant:

$$\partial_j\sigma_{ij} = -\partial_i p + \mu\left(\nabla^2 v_i + \partial_i\partial_j v_j\right) - \tfrac{2}{3}\mu\,\partial_i\,(\partial_j v_j) + \zeta\,\partial_i\,(\partial_j v_j)\,,$$

which collects to Equation (31.31). Under Equation (31.11) every term carrying $\boldsymbol{\nabla}\cdot\boldsymbol{v}$ vanishes and division by ρ gives Equation (31.32). The bulk viscosity has disappeared, which is why it plays no part anywhere in this chapter except in the attenuation of sound.

The equations are second order in space, so they carry one more boundary condition than Equation (31.19) (Remark 31.23). That the extra condition is *no slip* rather than some finite slip is not a theorem: it is a physical hypothesis, and the one Navier's own derivation from a molecular model [75] left open. It was settled by measurement, and the measurement is Poiseuille's — Section 36.2 turns the accuracy of Equation (31.35) into a bound on the slip length of a few tens of nanometres. □

Remark 31.38 (Whose equations, and the Stokes hypothesis). The customary name compresses a sequence. Navier reached Equation (31.32) in 1822 from a molecular model with one coefficient [75]; Cauchy and Poisson rederived it on other grounds; Saint-Venant published the equations in essentially their final continuum form in 1843 [110], two years before Stokes, whose memoir [117] gave the constitutive argument reproduced in Theorem 31.36 and argued the no-slip condition. The label "Navier–Stokes" is therefore a convention rather than a

priority claim, and Saint-Venant's omission from it is the clearest instance in this chapter of a name recording custom rather than history.

Stokes further proposed $\zeta = 0$, which is exact for a monatomic dilute gas and is a good approximation for many others, but is not a consequence of anything in Theorem 31.36. Nothing in this chapter depends on it.

Rests on Theorem 31.37.

31.4.3 Exact solutions: Couette and Poiseuille flow

The nonlinear term of Equation (31.32) is what makes the system intractable, so the solutions that are known in closed form are almost exactly the flows in which it vanishes identically. In a unidirectional flow $\boldsymbol{v} = v(y)\hat{\boldsymbol{x}}$ or $v(r)\hat{\boldsymbol{z}}$ the advective term $(\boldsymbol{v}\cdot\boldsymbol{\nabla})\boldsymbol{v}$ is zero because v does not vary along the direction in which it points. The solutions below are therefore *exact* solutions of the full equations, not approximations, and that is what makes their comparison with measurement a clean test.

Proposition 31.39 (Plane Couette flow)**.** *Between two parallel plates a distance h apart, one at rest and one moving in its own plane at speed U, with no applied pressure gradient, the steady solution of Equation (31.32) is*

$$v(y) = U\,\frac{y}{h}\,, \tag{31.33}$$

and the tangential stress transmitted to each plate is uniform and equal to $\mu U/h$.

Rests on Theorem 31.37.

Proof. *Derives Proposition 31.39.*

With $\boldsymbol{v} = v(y)\hat{\boldsymbol{x}}$ the advective term vanishes, the flow is divergence free, and the steady x component of Equation (31.32) without a pressure gradient reduces to $\mu\,\mathrm{d}^2v/\mathrm{d}y^2 = 0$. Hence v is linear in y; no slip at both plates fixes $v(0) = 0$ and $v(h) = U$, giving Equation (31.33). The stress follows from Equation (31.29). Two features are worth recording: the profile is independent of μ, so a Couette measurement determines μ from the *force* and not from the shape of the profile, and the velocity gradient is uniform, so this is the one flow in which the constitutive relation Equation (31.29) is tested at a single, controlled shear rate. Couette's rotating-cylinder viscometer [246] is the practical realization, with the small gap between the cylinders playing the part of h. □

Proposition 31.40 (Circular Couette flow)**.** *Between coaxial cylinders of radii $R_1 < R_2$ rotating at angular velocities Ω_1 and Ω_2, the steady azimuthal solution is*

$$v_\varphi(r) = Ar + \frac{B}{r}\,, \qquad A = \frac{\Omega_2 R_2^2 - \Omega_1 R_1^2}{R_2^2 - R_1^2}\,, \qquad B = \frac{(\Omega_1 - \Omega_2)\,R_1^2 R_2^2}{R_2^2 - R_1^2}\,, \tag{31.34}$$

and the viscous torque per unit length transmitted between the cylinders is $G = 4\pi\mu B$, independent of r.

Rests on Theorem 31.37 and Proposition 31.39.

Proof. *Derives Proposition 31.40.*

Seek $\boldsymbol{v} = v_\varphi(r)\hat{\boldsymbol{\varphi}}$. The flow is divergence free, and the advective term contributes only the centripetal $-v_\varphi^2/r$ in the radial direction, which is balanced by the radial pressure gradient and does not enter the azimuthal equation. That equation is

$$\frac{\mathrm{d}}{\mathrm{d}r}\left[\frac{1}{r}\frac{\mathrm{d}\,(r v_\varphi)}{\mathrm{d}r}\right] = 0\,,$$

whose general solution is $v_\varphi = Ar + B/r$; the two no-slip conditions $v_\varphi(R_i) = \Omega_i R_i$ give the constants in Equation (31.34). The term Ar is rigid rotation and carries no shear; the shear

stress is $\sigma_{r\varphi} = \mu r\,\mathrm{d}\left(v_\varphi/r\right)/\mathrm{d}r = -2\mu B/r^2$, so the torque per unit length on a cylindrical surface of radius r is $2\pi r^2 \times 2\mu B/r^2 = 4\pi\mu B$, the same at every radius — as it must be, since no torque accumulates in a steady state. This is the working equation of the Couette viscometer [246]. The solution loses stability when the inner cylinder rotates fast enough, in the way computed and measured by Taylor [505] and described in Section 31.8.2. □

Phenomenon 31.41 (The fourth-power law of pipe flow)**.** Steady laminar flow of a viscous liquid along a straight circular tube delivers a volume flux proportional to the applied pressure difference and to the *fourth* power of the tube radius,

$$Q = \frac{\pi R^4}{8\mu}\,\frac{\Delta p}{L}\,, \tag{31.35}$$

inversely proportional to the length of the tube and to the viscosity of the liquid. Halving the radius at fixed pressure drop therefore divides the delivery by sixteen. The law was established by measurement — independently by Hagen in brass tubes [104] and by Poiseuille in fine glass capillaries [105] — before it was derived, and it is accurate enough to serve as a viscometric standard.

Rests on Theorem 31.37.

Derivation. *Derives Phenomenon 31.41.*

Seek a steady, axisymmetric, unidirectional solution $\boldsymbol{v} = v(r)\,\hat{\boldsymbol{z}}$ of the incompressible Navier–Stokes equations in a tube of radius R. Such a field is divergence-free automatically, and its inertial term vanishes identically: $(\boldsymbol{v}\cdot\boldsymbol{\nabla})\boldsymbol{v} = v\,\partial_z(v\,\hat{\boldsymbol{z}}) = 0$, so the nonlinearity plays no part and the solution below is exact rather than approximate. What remains, using the cylindrical Laplacian Equation (7.91), is the axial component

$$0 = -\frac{\mathrm{d}p}{\mathrm{d}z} + \frac{\mu}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left(r\,\frac{\mathrm{d}v}{\mathrm{d}r}\right),$$

in which the first term is independent of r and the second independent of z, so both are the same constant: $\mathrm{d}p/\mathrm{d}z = -\Delta p/L$. Integrating once and discarding the $\ln r$ solution as singular on the axis, then integrating again and imposing the no-slip condition $v(R) = 0$ at the wall,

$$v(r) = \frac{\Delta p}{4\mu L}\left(R^2 - r^2\right), \tag{31.36}$$

the parabolic profile. The flux is

$$Q = \int_0^R v(r)\,2\pi r\,\mathrm{d}r = \frac{\pi\Delta p}{2\mu L}\int_0^R \left(R^2 r - r^3\right)\mathrm{d}r = \frac{\pi R^4}{8\mu}\,\frac{\Delta p}{L}\,,$$

which is Equation (31.35). The fourth power is the signature: two of its powers come from the cross-sectional area and two from the mean speed, which itself grows as R^2 because the wall is the only brake on the flow. The agreement of the measured flux with Equation (31.35), with no fitted constant beyond the viscosity, is the quantitative laboratory test of the no-slip condition: a wall at which the liquid retained a finite tangential speed would deliver a larger flux than this, by the factor computed in Equation (36.8). □

Remark 31.42 (The entry length). Equation (31.36) is the flow far from the inlet. A fluid entering the tube with a flat profile carries the wall's influence inwards by viscous diffusion, over a transverse distance that grows as $\sqrt{\nu t}$ with $t = z/\bar{v}$ the time since entry (Section 31.7.2). The parabolic profile is established when that distance reaches the axis, $\sqrt{\nu z/\bar{v}} \sim R$, i.e. at

$$\frac{L_\mathrm{e}}{D} \sim \mathrm{Re}\,, \qquad \mathrm{Re} = \frac{\rho\bar{v}D}{\mu}\,, \tag{31.37}$$

so the entry length grows in proportion to both the diameter and the Reynolds number. The estimate gives the scaling and not the coefficient, which is measured to be of order 10^{-1}; a tube short enough that L is comparable with L_e delivers less than Equation (31.35), which is the first of the two failures reported in Section 36.2.

Rests on Phenomenon 31.41.

31.4.4 Stokes flow

Definition 31.43 (Creeping flow)**.** When $\mathrm{Re} \ll 1$ the inertial terms of Equation (31.32) are negligible against the viscous term and the equations linearize to the *Stokes equations*

$$\mathbf{0} = -\boldsymbol{\nabla} p + \mu \nabla^2 \boldsymbol{v}\,, \qquad \boldsymbol{\nabla} \cdot \boldsymbol{v} = 0\,, \tag{31.38}$$

in which time appears only through the boundary conditions.

Rests on Theorem 31.37 and Equation (31.42).

Proposition 31.44 (Kinematic reversibility)**.** *If $(\boldsymbol{v}, p)$ solves Equation (31.38) with boundary velocity $\boldsymbol{U}$, then $(-\boldsymbol{v}, -p)$ solves it with boundary velocity $-\boldsymbol{U}$. Reversing the motion of the boundaries therefore reverses the motion of every fluid particle exactly, and a body that repeats a sequence of shapes in reverse order returns the fluid to its initial configuration.*

Rests on Definition 31.43.

Proof. *Derives Proposition 31.44.*

Equation (31.38) is linear and homogeneous in $(\boldsymbol{v}, p)$, so multiplying a solution by -1 gives a solution, and the boundary data are multiplied by -1 with it; uniqueness of the Stokes problem then identifies it as *the* solution. Nothing of the sort holds for Equation (31.32), whose advective term is quadratic and changes sign under $\boldsymbol{v} \longmapsto -\boldsymbol{v}$ in a way the other terms do not. The consequence is observable and is the reason a swimming micro-organism cannot propel itself by any reciprocal stroke: a sequence of shapes retraced in reverse produces no net displacement whatever, however fast it is performed, because the speed cancels out of Equation (31.38) entirely. □

Phenomenon 31.45 (Stokes drag on a sphere)**.** A sphere of radius a moving slowly at speed U through a fluid of viscosity μ experiences a resisting force

$$F = 6\pi \mu a U\,, \tag{31.39}$$

proportional to the first power of the speed and to the first power of the radius, and independent of the density of the fluid [135]. It is the law by which a falling sphere measures a viscosity, by which particles settle out of suspension, and by which the charged oil droplets of Millikan's measurement of the elementary charge were sized [407].

Derivation. *Derives Phenomenon 31.45.*

What can be settled in a few lines is the *form* of Equation (31.39), and it is worth separating that from the numerical factor because the form is what carries the physics. Equation (31.38) is linear in $\boldsymbol{v}$ and the boundary data are linear in U, so the solution, and with it the traction integrated over the sphere, is exactly proportional to U: the drag is linear in the speed, not quadratic, and this is a theorem rather than a small-amplitude approximation. The quantities available are then μ, a and U, whose dimensions $\mathsf{M}\mathsf{L}^{-1}\mathsf{T}^{-1}$, L and $\mathsf{L}\mathsf{T}^{-1}$ admit exactly one combination with the dimensions of force (Theorem D.2), namely $\mu a U$; note that ρ cannot appear, because it has been removed from the equations along with the inertial terms. Hence $F = C\mu a U$ with C a pure number. Solving Equation (31.38) in full for the sphere and integrating the traction gives $C = 6\pi$ [135]; that calculation is longer than a page and is carried out in the appendix. □

Full derivation: Appendix A.60 (p. 3121).

Derives Phenomenon 31.45.

Example 31.46 (Terminal velocity, and Millikan's droplets)**.** A sphere of density ρ_s falling under gravity in a fluid of density ρ_f reaches the speed at which Equation (31.39) balances its weight less the buoyancy of Equation (31.15):

$$U_t = \frac{2a^2\,(\rho_s - \rho_f)\,g}{9\mu}\,. \tag{31.40}$$

For an oil droplet of radius 1 µm and density 900 kg/m^3 in air (Table 31.1) this is $U_t \approx 1.1 \times 10^{-4}$ m/s, about a tenth of a millimetre per second, and the Reynolds number of the motion is then $\rho_f U_t a/\mu \approx 7 \times 10^{-6}$ — amply inside the regime of Definition 31.43, which is what justifies using Equation (31.39) to convert an observed fall speed into a droplet radius [407]. The quadratic dependence on a is what makes sedimentation a size separation: doubling the radius quadruples the settling speed.

Rests on Phenomena 31.18 and 31.45.

Remark 31.47 (The Oseen correction, and why the obvious expansion fails)*.* Equation (31.39) is the leading term of an expansion in Re, and the next term is not obtained by simply iterating Equation (31.38) with the neglected inertia treated as a small forcing. The reason is that the neglect is not uniformly valid: the Stokes velocity disturbance decays only as a/r, so the neglected inertial term $\rho\,(\boldsymbol{v}\cdot\boldsymbol{\nabla})\,\boldsymbol{v}$ falls off more slowly than the retained viscous term $\mu\nabla^2\boldsymbol{v}$, and beyond a distance of order a/Re the ordering is reversed. The naive second approximation then cannot be made to satisfy the condition at infinity at all — Whitehead's paradox. Oseen's repair is to keep the advection by the uniform stream in the far field from the start, giving

$$C_D = \frac{24}{\mathrm{Re}}\left(1 + \frac{3}{16}\mathrm{Re} + \cdots\right), \qquad \mathrm{Re} = \frac{2\rho a U}{\mu}\,, \tag{31.41}$$

with C_D as in Phenomenon 31.55. The structure — an inner region where viscosity dominates and an outer region where it does not, matched to each other — is the same one that resolves the opposite limit in Section 31.7.2, and it is the general method pointed to in Chapter 82.

Rests on Phenomenon 31.45.

31.4.5 Existence and smoothness: an open problem

Remark 31.48 (What is actually proved)*.* Everything in this chapter is a statement about solutions of Equation (31.32), and it is not known that those solutions exist. The position, stated exactly, is this. Leray proved in 1934 that from smooth initial data of finite energy the three-dimensional incompressible equations possess a global *weak* solution — one satisfying the equations in an integrated sense against test functions, and obeying an energy inequality [745]. It is not known whether that solution is unique, and it is not known whether it remains smooth: a weak solution is permitted, as far as anything proved goes, to develop a singularity in finite time at which the velocity gradient blows up. Conversely, a strong solution is known to exist and be unique for a finite time from smooth data, and to persist for all time if the data are small enough; what is missing is the passage between the two regimes. The Clay Millennium problem asks for a proof of global regularity or a counterexample [2094], and neither exists.

Two consequences are owed to the reader. The first is that the turbulence statements of Section 31.9 rest on equations whose well-posedness is open, which is a situation without parallel elsewhere in this treatise — and the empirical adequacy of those equations, which is not in doubt, is no substitute. The second is that the question is not idle: a singularity would be a genuine physical event in the model, at which the continuum hypothesis of Definition 31.2 would have to be abandoned, so the answer matters for what the equations are taken to describe and not only for mathematics. The problem is catalogued with the others in Chapter 133.

Rests on Theorem 31.37.

31.5 Dynamical similarity

31.5.1 The Reynolds number

Phenomenon 31.49 (Dynamical similarity)**.** Two incompressible flows past geometrically similar bodies are observed to be similar to each other — same streamline pattern, same dimensionless force coefficients, same transition points — whenever they agree in the single dimensionless combination

$$\mathrm{Re} = \frac{\rho v L}{\mu}\,, \tag{31.42}$$

whatever the separate values of size, speed, density and viscosity. Drag measurements taken on bodies of very different size and in different fluids collapse onto one curve when plotted against Re [226, 384], and it is this observed collapse, not any argument of principle, that licenses wind-tunnel and towing-tank practice.

Rests on Theorem 31.37.

Derivation. *Derives Phenomenon 31.49.*

Let L and U be the size of the body and the free-stream speed, and measure lengths, velocities, times and pressures in the units L, U, L/U and ρU^2, writing the resulting dimensionless variables with primes. The incompressible Navier–Stokes system

$$\partial_t \boldsymbol{v} + (\boldsymbol{v}\cdot\boldsymbol{\nabla})\boldsymbol{v} = -\frac{1}{\rho}\boldsymbol{\nabla} p + \frac{\mu}{\rho}\nabla^2\boldsymbol{v}\,, \qquad \boldsymbol{\nabla}\cdot\boldsymbol{v} = 0$$

becomes, after dividing throughout by U^2/L,

$$\partial_{t'}\boldsymbol{v}' + (\boldsymbol{v}'\cdot\boldsymbol{\nabla}')\boldsymbol{v}' = -\boldsymbol{\nabla}' p' + \frac{1}{\mathrm{Re}}\nabla'^2\boldsymbol{v}'\,, \qquad \boldsymbol{\nabla}'\cdot\boldsymbol{v}' = 0\,, \tag{31.43}$$

From Equations (31.32) and (31.42) (measuring lengths in L, speeds in U, times in L/U and pressures in ρU^2, then dividing throughout by U^2/L).

with Re as in Equation (31.42) the only parameter left. Geometric similarity of the bodies makes the dimensionless boundary conditions identical as well. Two flows agreeing in Re therefore solve the same dimensionless problem, and if that problem has a unique solution their primed fields coincide; every dimensionless quantity built from them — the drag coefficient, the pressure coefficient, the Strouhal number of any shedding — is a function of Re alone. The same count follows from the Π theorem (Theorem D.2): five dimensional quantities ρ, U, L, μ and the force, in three independent dimensions, leave $5-3=2$ dimensionless groups, one of which may be taken as the drag coefficient and the other as Re [413].

The uniqueness clause is load-bearing and is exactly where the argument stops: two flows at the same Re solve the same problem, but if that problem admits more than one solution — as pipe flow above $\mathrm{Re}\approx 2000$ manifestly does — similarity says nothing about which one is realized. □

Remark 31.50 (Reading the Reynolds number). Equation (31.42) is the ratio of the inertial term $\rho U^2/L$ to the viscous term $\mu U/L^2$ in Equation (31.32), and equivalently the ratio of the time L^2/ν for momentum to diffuse across the flow to the time L/U for it to be carried across. The range spanned in nature is enormous, and it is why one subject contains such different-looking regimes: a swimming bacterium works at $\mathrm{Re}\sim 10^{-5}$, where Proposition 31.44 governs everything; a raindrop falls at $\mathrm{Re}\sim 10^{3}$; a thrown cricket ball flies at $\mathrm{Re}\sim 10^{5}$, close enough to the crisis of Phenomenon 31.55 that its surface finish changes its flight; and an airliner's wing works at $\mathrm{Re}\sim 10^{7}$. No single approximation covers that span, which is the organizing fact of the chapter.

Rests on Phenomenon 31.49.

Definition 31.51 (The other similarity groups)**.** The same nondimensionalization applied to the further terms of the equations of motion produces one dimensionless group per physical effect retained. Those used in this chapter are

$$\mathrm{Fr} = \frac{U}{\sqrt{gL}} \qquad \text{inertia to gravity,} \tag{31.44}$$

$$\mathrm{Ma} = \frac{U}{c} \qquad \text{flow speed to sound speed,} \tag{31.45}$$

$$\mathrm{St} = \frac{fL}{U} \qquad \text{shedding frequency to flow rate,} \tag{31.46}$$

$$\mathrm{We} = \frac{\rho U^2 L}{\gamma} \qquad \text{inertia to surface tension,} \tag{31.47}$$

$$\mathrm{Ra} = \frac{g\alpha\,\Delta T\,d^3}{\nu\kappa} \qquad \text{buoyancy to diffusion,} \tag{31.48}$$

in which c is the sound speed of Equation (31.75), f a shedding or oscillation frequency, γ the surface tension of Equation (31.18), and, for the last, α the thermal expansion coefficient, κ the thermal diffusivity, d the depth of the layer and ΔT the temperature difference imposed across it. All are pure numbers, so that each carries the same value in every system of units (Appendix D).

Rests on Phenomenon 31.49 and Theorem D.2.

Remark 31.52 (Similarity is only as good as the control of the data). Matching Re between a model and a full-scale body is frequently impossible — a model at one tenth scale would need ten times the speed in the same fluid, which changes Ma — and the practical art consists in deciding which group must be matched and which may be violated. Worse, and more instructive: the interior equations do not see the disturbance level of the incoming stream, which is a further dimensionless datum of the experiment. Two flows at the same Re in tunnels of different quality are *not* the same flow, which is the observation Reynolds himself made when patient settling of his tank moved the transition threshold upward without limit [226].

Rests on Phenomenon 31.49.

Phenomenon 31.53 (Transition to turbulence in a pipe)**.** Below a Reynolds number of the order of 2000 the flow of water along a straight pipe is laminar: a filament of dye released on the axis travels the length of the tube as an unbroken coloured thread. Above it the thread breaks up at some point down the tube and mixes across the whole section, and the pressure drop needed to drive a given flux ceases to follow the linear law of Equation (31.35), rising instead roughly as the square of the flux [226]. The threshold is not sharp: with a smooth inlet and a quiet supply the laminar thread survives to much higher Re, so the observed transition depends on the amplitude of the disturbances present and not on Re alone [226, 2169].

Rests on Phenomena 31.41 and 31.49.

Derivation. *Derives Phenomenon 31.53.*

Three statements are contained in the phenomenon and they have three quite different standings. Separating them is the substance of this derivation, because two of the three follow and the third does not.

That the criterion, if there is one, is a condition on a pure number. A straight circular pipe fixes the geometry completely, so by Phenomenon 31.49 the dimensionless problem Equation (31.43) carries the single parameter $\mathrm{Re} = \rho\bar{v}D/\mu$ and nothing else. Any criterion separating the two observed states is therefore a condition on Re alone, and not on the diameter, the speed, the density or the viscosity separately. That is a prediction and it is the one Reynolds tested: he varied the diameter and, by warming the water, the viscosity,

and located the change of state at one value of the combination rather than at one value of any factor in it [226]. What the same argument declines to supply is the number. The uniqueness clause in the proof of Phenomenon 31.49 is exactly what fails here — above the threshold the dimensionless problem possesses two attracting states, and similarity says nothing whatever about which of them is realized.

That the threshold is not the onset of a linear instability. The laminar profile Equation (31.36) is parabolic, so its curvature keeps one sign across the whole section and it possesses no inflexion point. For the plane analogue Theorem 31.77 then forbids inviscid instability outright, and for the circular pipe the computed viscous spectrum is damped at every Reynolds number [2169]: the laminar solution does not lose stability at $\mathrm{Re} \approx 2000$, or anywhere else. Whatever the transition is, it is not a bifurcation of the laminar state, and no linearization about that state can produce the observed threshold. This is the exact complement of Phenomenon 31.78, where the same programme delivers a threshold and a length scale with no adjustable parameter.

That the resistance rises as the square of the flux. The momentum balance on the column of fluid between two sections a distance L apart is exact and assumes no model of the motion: the pressure force on the two faces is carried entirely by the shear on the wall, so

$$\tau_{\mathrm{w}} = \frac{D}{4}\,\frac{\Delta p}{L}\,. \tag{31.49}$$

Below the threshold Equation (31.35) gives $\Delta p/L = 32\mu\bar{v}/D^2$ and hence $\tau_{\mathrm{w}} = 8\mu\bar{v}/D$, linear in the speed because the transverse transport of streamwise momentum is molecular. Above it that transport is carried instead by the Reynolds stress $-\rho\left\langle v_i' v_j' \right\rangle$ of Equation (31.70), in which the viscosity does not appear at all. Grant that the wall stress becomes independent of μ and the quantities left are ρ, $\bar{v}$ and D, from which Theorem D.2 admits exactly one form, $\tau_{\mathrm{w}} = \frac{1}{2} f \rho \bar{v}^2$ with f a pure number; then Equation (31.49) and $Q = \pi D^2 \bar{v}/4$ give

$$\frac{\Delta p}{L} = \frac{2 f \rho \bar{v}^2}{D} = \frac{32 f \rho}{\pi^2 D^5}\, Q^2\,. \tag{31.50}$$

The exponent moves from one to two because the mechanism of transverse momentum transport moves from molecular to inertial, and that is all this argument establishes. It is not exact, and the discrepancy is measurable: f is not quite constant but falls slowly as Re grows in a smooth pipe, so the observed exponent over Reynolds's own range is close to 1.72 rather than 2 [226], and approaches 2 only when the wall is rough enough for the roughness height to replace the viscous scale.

What is not derived is the threshold itself, and Remark 31.54 states what stands in its place. □

Remark 31.54 (This one is not a gap in the writing). The missing third of the derivation above is not a derivation that exists and has not been transcribed. No derivation of the pipe threshold from Equation (31.32) is known. Since the laminar state never loses stability, the turbulent state cannot be reached from it by an infinitesimal disturbance, and the transition is subcritical: it requires a disturbance of finite amplitude, so that the observed threshold is a property of the disturbance environment as much as of the equations. What replaces a stability calculation is a statistical criterion over the localized turbulent patches, or *puffs*, that the flow supports below the threshold. Each puff has a finite probability per unit time of decaying and a finite probability of splitting in two, both measured; the turbulence is sustained indefinitely exactly when splitting outruns decay, and that crossing occurs at $\mathrm{Re} = 2040 \pm 10$ [2169]. That is a sharp and reproducible number, but it is a measured lifetime balance and not a consequence of Equation (31.32) that anyone has derived. The honest statement is that the pipe has two available states and that no theory predicts the

boundary between them; Section 36.3 sets out the measurements a future theory must reproduce.

Rests on Phenomenon 31.53.

31.5.2 Drag laws

Phenomenon 31.55 (Drag, and the failure of ideal flow)**.** Every body moved steadily through a real fluid experiences a force opposing its motion, and the power needed to keep it moving is the product of that force with its speed. Steady potential flow of an inviscid fluid past a finite body predicts exactly zero — Phenomenon 31.30 — so the observation falsifies the inviscid model no matter how small the viscosity of the fluid is made, which is the sharpest failure of a limit in classical physics. The measured drag coefficient of a sphere, $C_{\mathrm{D}} = F/(\frac{1}{2}\rho v^2 \pi a^2)$, falls in inverse proportion to Re in the creeping-flow regime [135], flattens to a plateau of order unity over several decades of Re, and then drops abruptly by a factor of several near $\mathrm{Re} \approx 3 \times 10^5$ — the drag crisis, at which a rougher sphere is measurably *less* resistant than a smooth one [384].

Rests on Phenomena 31.30 and 31.45.

Derivation. *Derives Phenomenon 31.55.*

Three separate statements are contained in the phenomenon, and they have very different standing.

That the ideal model gives zero is Phenomenon 31.30, proved above for the sphere. That the real drag is not zero, and does not tend to zero as $\mu \longrightarrow 0$, follows from the boundary-layer scaling of Section 31.7.2: the viscous stress at the wall is of order $\mu U/\delta$ with $\delta \sim L\,\mathrm{Re}^{-1/2}$, so it falls only as $\mathrm{Re}^{-1/2}$ while the area over which it acts is fixed, and the separated wake contributes a pressure defect that does not fall at all. The limit of vanishing viscosity is not uniform, which is why setting $\mu = 0$ in the equation gives the wrong answer for any μ however small.

That the drag is measurable from the wake alone is the quantitative statement, and it follows from momentum conservation. Take a control volume bounded by a large cylinder around the body, with plane faces far upstream and far downstream where the pressure has returned to p_∞. The flux of x momentum into the volume through the upstream face is $\rho U^2 A$; out through the downstream face it is $\rho \int u^2 \,\mathrm{d}A$; mass conservation requires the deficit $\int (U-u)\,\mathrm{d}A$ to leave through the side, carrying x momentum $\rho U \int (U-u)\,\mathrm{d}A$ with it. The net force on the body is the imbalance,

$$F = \rho \int u\,(U-u)\,\mathrm{d}A\,, \tag{31.51}$$

From Equations (31.10) and (31.19) (balancing the flux of streamwise momentum through a large control surface, the mass deficit leaving through its sides carrying momentum ρU per unit volume).

the integral running over the wake, where alone $u \neq U$. Two things follow: the drag is exactly the momentum deficit the body leaves behind, so a body with no wake has no drag — which is Phenomenon 31.30 again, read backwards — and the drag can be measured by traversing a Pitot tube across the wake, without touching the body at all.

What is *not* derived here is the size of the wake, which requires the boundary layer to be followed to its separation point, and with it both the value of the plateau coefficient and the location and depth of the drag crisis. □

Remark 31.56 (What of the drag curve is owed, and where it is paid). Two of the three things left open above are settled later in this chapter and one is not, and the difference is worth marking here rather than leaving the reader to discover it. The criterion for the wake to exist at all — that the boundary layer can separate only where the external pressure rises along the flow — is derived, from the layer equations at the wall, in Proposition 31.73; the

delay of separation by a layer that has itself become turbulent, and with it the drag crisis and the dimpled golf ball, follow from the same criterion and are given there.

What is not derived, here or there, is any of the numbers. Locating the separation point requires integrating the boundary-layer equations along the surface under the external pressure distribution, and for a bluff body that distribution is itself set by the wake whose size is being sought, so the problem is not closed by the boundary-layer approximation at all. The plateau value $C_{\mathrm{D}} \approx 0.4$ to 0.5 and the Reynolds number $\mathrm{Re} \approx 3 \times 10^5$ at which the crisis occurs are therefore measured quantities [384], reported in Remark 31.57 and in Chapter 36 as measurements, and the chapter claims no derivation of either.

Rests on Phenomenon 31.55 and Proposition 31.73.

Remark 31.57 (The measured curve as the chapter's running test). The drag coefficient of a sphere as a function of Re is one curve spanning nine decades, and each approximation in this chapter is answerable to one stretch of it. Below $\mathrm{Re} \approx 1$ it is $C_{\mathrm{D}} = 24/\mathrm{Re}$, which is Equation (31.39) rewritten, with the Oseen correction Equation (31.41) extending the agreement upward. Through the intermediate decades it flattens to a plateau of order 0.4 to 0.5, which is the momentum-flux estimate $F \sim \rho U^2 a^2$ of Equation (31.51) with a wake comparable to the body. Near $\mathrm{Re} \approx 3 \times 10^5$ it falls abruptly by a factor of several, which is Phenomenon 36.12 operating; that is Eiffel's discovery [384], and the reason a golf ball is dimpled. No part of the curve is derived from first principles across its whole range, and the chapter says so rather than presenting the pieces as a theory.

Rests on Phenomenon 31.55.

31.6 Vorticity

31.6.1 Vortex lines and Helmholtz's theorems

Theorem 31.58 (The vorticity transport equation)**.** *For a fluid of uniform density obeying Equation* (31.32) *with a conservative body force,*

$$\frac{D\boldsymbol{\omega}}{Dt} = (\boldsymbol{\omega} \cdot \boldsymbol{\nabla})\,\boldsymbol{v} + \nu \nabla^2 \boldsymbol{\omega}\,. \tag{31.52}$$

If the density is not uniform the right-hand side acquires the baroclinic *term* $(\boldsymbol{\nabla}\rho \times \boldsymbol{\nabla}p)/\rho^2$*, which vanishes if and only if surfaces of constant density and constant pressure coincide.*

Rests on Theorem 31.37 and Equation (31.5).

Proof. *Derives Theorem 31.58.*

Write Equation (31.32) using Equation (31.4) and $\boldsymbol{g} = -\boldsymbol{\nabla}\Phi$:

$$\frac{\partial \boldsymbol{v}}{\partial t} - \boldsymbol{v} \times \boldsymbol{\omega} = -\boldsymbol{\nabla}\left(\frac{p}{\rho} + \frac{v^2}{2} + \Phi\right) + \nu \nabla^2 \boldsymbol{v}\,.$$

Take the curl. Every gradient dies by Equation (7.128), so the pressure and the body force disappear entirely — the first thing to notice about vorticity is that pressure cannot create it. Expanding $\boldsymbol{\nabla} \times (\boldsymbol{v} \times \boldsymbol{\omega})$ by Equation (31.5) and using $\boldsymbol{\nabla} \cdot \boldsymbol{\omega} = 0$ (a curl is solenoidal, Equation (31.6)) together with $\boldsymbol{\nabla} \cdot \boldsymbol{v} = 0$,

$$\boldsymbol{\nabla} \times (\boldsymbol{v} \times \boldsymbol{\omega}) = (\boldsymbol{\omega} \cdot \boldsymbol{\nabla})\,\boldsymbol{v} - (\boldsymbol{v} \cdot \boldsymbol{\nabla})\,\boldsymbol{\omega}\,,$$

which rearranges to Equation (31.52). For non-uniform density the pressure term is $-\boldsymbol{\nabla} \times (\boldsymbol{\nabla}p/\rho) = -\boldsymbol{\nabla}(1/\rho) \times \boldsymbol{\nabla}p = (\boldsymbol{\nabla}\rho \times \boldsymbol{\nabla}p)/\rho^2$, as stated.

The two terms on the right of Equation (31.52) are the whole dynamics of the subject. The first, $(\boldsymbol{\omega} \cdot \boldsymbol{\nabla})\,\boldsymbol{v}$, is *vortex stretching*: a vortex line lying along a direction in which the fluid is being stretched has its vorticity amplified in proportion, because angular momentum

is conserved while the moment of inertia falls. It is absent in any flow independent of one Cartesian direction, which is why such flows cannot produce the cascade of Section 31.9.2 and why turbulence is an intrinsically three-dimensional phenomenon. The second, $\nu\nabla^2\boldsymbol{\omega}$, diffuses vorticity, with ν as the diffusivity — which is the reading of the kinematic viscosity promised in Remark 31.33. □

Theorem 31.59 (Helmholtz's vortex theorems)**.** *Define the* strength *of a vortex tube as the flux of vorticity across any cross-section of it, equivalently by Theorem 7.100 the circulation around any circuit girdling it once. Then:*

1. *the strength is the same at every cross-section, so a vortex tube cannot end within the fluid but must close on itself or terminate on a boundary;*
2. *in an ideal barotropic fluid with conservative body forces, vortex lines are material lines — they move with the fluid; and*
3. *the strength of a vortex tube is then constant in time.*

The first is kinematic and holds in every flow whatever; the second and third require the hypotheses stated [150].

Rests on Theorems 31.58 and 31.64.

Proof. *Derives Theorem 31.59.*

(1) $\boldsymbol{\nabla}\cdot\boldsymbol{\omega} = 0$ identically by Equation (31.6). Apply the divergence theorem (Theorem 7.101) to the piece of tube between two cross-sections: the side wall is made of vortex lines and carries no flux, so the two end fluxes are equal. If a tube ended in the interior its strength would have to fall to zero there, contradicting that equality.

(2) and (3) follow from Kelvin's theorem (Theorem 31.64), which is proved below independently. Take a material circuit lying in the surface of a vortex tube and not girdling it; the circulation around it is zero at the initial instant, hence zero for all time, so the circuit continues to lie in a surface of vortex lines — the tube surface is a material surface, and since this holds for every tube of every thickness the vortex lines themselves are material. Take next a material circuit girdling the tube once: its circulation is the strength, and Kelvin's theorem says the strength does not change. The three statements are Helmholtz's [150], and they are the reason a vortex ring is a persistent object: it cannot end, it cannot be cut, and its strength cannot decay, until viscosity is restored. □

Example 31.60 (Vortex rings)**.** A puff of fluid ejected from a circular orifice rolls up into a ring of vorticity that then propels itself along its own axis — an arrangement satisfying Theorem 31.59 exactly, since the vortex line closes on itself. The ring's self-induced speed follows from the velocity that the ring's own vorticity induces at its core, and grows as the ring becomes thinner at fixed strength; two coaxial rings pass repeatedly through one another, each contracting and accelerating as it passes through the other and then widening and slowing, a motion which is a direct visual demonstration that the vorticity is being carried by the fluid rather than diffusing through it. The persistence of smoke rings over many diameters is the measured content of Theorem 31.59, and their eventual decay is the measured content of the viscous term in Equation (31.52).

Rests on Theorem 31.59.

Phenomenon 31.61 (The vortex street and its tone)**.** A circular cylinder held across a stream sheds vorticity alternately from its two sides, forming two staggered rows of vortices that travel downstream — the Kármán vortex street. The shedding is periodic, and over the wide range $300 \lesssim \mathrm{Re} \lesssim 2\times10^5$ its frequency f satisfies

$$\mathrm{St} = \frac{f d}{U} \approx 0.2\,, \tag{31.53}$$

nearly independent of Re, where d is the diameter and U the stream speed. Strouhal established the proportionality $f \propto U/d$ by measuring the musical tone emitted by wires in a wind — the Aeolian tone — and obtained a coefficient near 0.185 for fine wires [203]; the value quoted in Equation (31.53) is the modern one for a circular cylinder [1340]. Von Kármán showed that of all the staggered double rows only one spacing is not immediately destroyed by its own induced motion, namely that with the ratio of row separation to streamwise spacing

$$\frac{h}{a} = \frac{1}{\pi}\cosh^{-1}\sqrt{2} \approx 0.281\,, \tag{31.54}$$

which is close to what the photographs show [375].

Rests on Theorem 31.58.

Full derivation: Appendix A.61 (p. 3125).

Derives Phenomenon 31.61.

Remark 31.62 (What the spacing calculation settles, and what it does not). The appendix settles Equation (31.54) and nothing further, and both halves of that sentence matter. It is a theorem about point vortices in an unbounded ideal fluid: the row is idealized as two staggered infinite sequences of line vortices, the cylinder that made them does not appear in the calculation, and what is found is *neutral* stability at one ratio rather than stability, the configuration being unstable at higher order and the observed spacing drifting slowly downstream. That it nonetheless reproduces the photographed ratio to within a few percent is the interesting fact [375].

Equation (31.53) is of a different kind altogether. No derivation from Equation (31.32) predicts the value one fifth. What Phenomenon 31.49 does establish is that the shedding frequency of a given shape can only enter through the dimensionless combination fd/U, and that this must be a function of Re alone; the frequency therefore scales as U/d, which is Strouhal's observation and is why a wire's tone rises with the wind [203]. That the function is nearly flat over three decades of Re, and that its value there is close to 0.2, are measured facts about the coupling between the two boundary layers and the near wake [1340]. They are reported in this chapter as measurements and are not derived in it.

Rests on Phenomena 31.49 and 31.61.

31.6.2 Kelvin's circulation theorem

Definition 31.63 (Circulation)**.** The *circulation* around a closed circuit C is

$$\Gamma := \oint_C \boldsymbol{v}\cdot \mathrm{d}\boldsymbol{x}\,, \tag{31.55}$$

in m^2/s. By Stokes' theorem (Theorem 7.100) it equals the flux of vorticity through any surface spanning C, provided such a surface lies wholly in the fluid.

Rests on Definition 31.8 and Theorem 7.100.

Theorem 31.64 (Kelvin's circulation theorem)**.** *In an ideal barotropic fluid subject to conservative body forces, the circulation around any circuit that moves with the fluid is constant in time,*

$$\frac{D\Gamma}{Dt} = 0\,. \tag{31.56}$$

Rests on Theorem 31.22 and Definition 31.63.

Proof. *Derives Theorem 31.64.*

Let $C(t)$ be a material circuit and parametrize it by a label s carried with the fluid, so that differentiating under the integral sign is legitimate:

$$\frac{D}{Dt}\oint_{C(t)} \boldsymbol{v}\cdot \mathrm{d}\boldsymbol{x} = \oint_C \frac{D\boldsymbol{v}}{Dt}\cdot \mathrm{d}\boldsymbol{x} + \oint_C \boldsymbol{v}\cdot \frac{D\,(\mathrm{d}\boldsymbol{x})}{Dt}\,.$$

The second integral is elementary: a material line element is stretched by the velocity difference across it, so $D(\mathrm{d}\boldsymbol{x})/Dt = \mathrm{d}\boldsymbol{v}$, and $\oint \boldsymbol{v}\cdot\mathrm{d}\boldsymbol{v} = \oint \mathrm{d}\left(\tfrac{1}{2}v^2\right) = 0$ because the circuit is closed. In the first integral substitute Equation (31.19) divided by ρ: with $\rho = \rho(p)$ the pressure term is $-\boldsymbol{\nabla}P$ and with conservative forces the body force is $-\boldsymbol{\nabla}\Phi$, so the integrand is an exact differential and its integral around a closed circuit vanishes by Equation (7.127). Hence Equation (31.56) [176]. □

Corollary 31.65 (Lagrange: an irrotational flow stays irrotational)**.** *If an ideal barotropic fluid under conservative forces is irrotational at one instant throughout a region, it is irrotational in the material image of that region at every later instant.*

Rests on Theorems 31.59 and 31.64.

Proof. *Derives Corollary 31.65.*

By Theorem 7.100 the circulation around every reducible circuit in the region is zero initially, hence by Theorem 31.64 zero at all times, hence the vorticity flux through every small surface vanishes and $\boldsymbol{\omega} = \mathbf{0}$. This is what justifies the potential-flow model of Section 31.3.3 for a body set in motion from rest in still fluid — and, read the other way, it is exactly the difficulty of the lift problem, since it forbids the circulation of Section 31.7.1 from ever appearing. The escape is that the theorem is about a *material* region, and the circuit that would have to be used around an aerofoil sweeps through the boundary layer and the wake, where the hypotheses fail. □

Remark 31.66 (Only three things make circulation)*.* Reading the hypotheses of Theorem 31.64 backwards gives the complete list of ways vorticity can be generated in a fluid initially free of it: viscosity, which enters as the diffusive term of Equation (31.52) and acts overwhelmingly at solid boundaries, where the no-slip condition of Theorem 31.37 is a vorticity source; baroclinicity, when $\boldsymbol{\nabla}\rho$ and $\boldsymbol{\nabla}p$ are not parallel, which is what drives the Rayleigh–Taylor instability of Section 31.8.1 and every buoyancy-driven flow; and non-conservative body forces, which in this chapter do not occur but which in the conducting fluids of Chapter 66 are the Lorentz force. There is no fourth mechanism, and that is a strong statement: every vortex in the atmosphere and the ocean was made at a boundary or by buoyancy.

Rests on Theorem 31.64.

31.7 Lift and the boundary layer

31.7.1 The Kutta–Joukowski theorem

Take the flow to be independent of one Cartesian coordinate, the span, and to have no velocity component along it — the idealization of a wing of large aspect ratio, and the setting in which the complex methods of Chapter 8 apply. Write $z = x + \mathrm{i}y$ for the position in the transverse plane and $w(z) = \phi + \mathrm{i}\psi$ for the complex potential built from the velocity potential of Proposition 31.28 and the stream function of Example 31.15; the Cauchy–Riemann equations (Theorem 8.6) are exactly Equation (31.12) together with $\boldsymbol{v} = \boldsymbol{\nabla}\phi$, so w is holomorphic wherever the flow is irrotational, and

$$\frac{\mathrm{d}w}{\mathrm{d}z} = v_x - \mathrm{i}v_y\,. \tag{31.57}$$

Lemma 31.67 (Blasius' force formula)**.** *Let a body of contour C be held in a steady plane potential flow of a fluid of uniform density ρ, with C traversed once counterclockwise. The force per unit span exerted on it by the fluid pressure is*

$$X - \mathrm{i}Y = \frac{\mathrm{i}\rho}{2}\oint_C \left(\frac{\mathrm{d}w}{\mathrm{d}z}\right)^2 \mathrm{d}z\,. \tag{31.58}$$

Rests on Theorems 8.6 and 31.24.

Proof. *Derives Lemma 31.67.*

For a counterclockwise contour the outward normal is $(\mathrm{d}y, -\mathrm{d}x)\,/\,|\mathrm{d}z|$, so the pressure force on an element is $\mathrm{d}X = -p\,\mathrm{d}y$ and $\mathrm{d}Y = p\,\mathrm{d}x$, whence

$$X - \mathrm{i}Y = -\oint_C p\,(\mathrm{d}y + \mathrm{i}\,\mathrm{d}x) = -\mathrm{i}\oint_C p\,(\mathrm{d}x - \mathrm{i}\,\mathrm{d}y) = -\mathrm{i}\oint_C p\,\overline{\mathrm{d}z}\,.$$

By Equation (31.23) at constant height, $p = B - \tfrac{1}{2}\rho q^2$ with $q^2 = (\mathrm{d}w/\mathrm{d}z)\,\overline{(\mathrm{d}w/\mathrm{d}z)}$; the constant B contributes $-\mathrm{i}B\oint \overline{\mathrm{d}z} = 0$ around a closed contour. Hence

$$X - \mathrm{i}Y = \frac{\mathrm{i}\rho}{2}\oint_C \frac{\mathrm{d}w}{\mathrm{d}z}\,\overline{\left(\frac{\mathrm{d}w}{\mathrm{d}z}\right)}\,\overline{\mathrm{d}z} = \frac{\mathrm{i}\rho}{2}\oint_C \frac{\mathrm{d}w}{\mathrm{d}z}\,\overline{\mathrm{d}w}\,.$$

The body surface is a streamline, so ψ is constant along C and $\mathrm{d}w = \mathrm{d}\phi$ is real there: $\overline{\mathrm{d}w} = \mathrm{d}w = (\mathrm{d}w/\mathrm{d}z)\,\mathrm{d}z$. Substituting gives Equation (31.58). The integrand is holomorphic everywhere in the fluid, so by the deformation theorem (Corollary 8.15) the contour may be pushed out to any circuit enclosing the body — which is what makes the formula usable, since the far field is known even when the body's shape is not. □

Theorem 31.68 (Kutta–Joukowski)**.** *A body held in a steady plane potential flow of speed U along the x axis, around which the circulation is Γ measured counterclockwise, experiences no force along the stream and a transverse force per unit span*

$$Y = -\rho U\Gamma\,, \tag{31.59}$$

that is, a force of magnitude $\rho U\,|\Gamma|$ directed towards the side on which the fluid moves faster [307, 362].

Rests on Lemma 31.67 and Theorem 8.24.

Proof. *Derives Theorem 31.68.*

Far from the body the complex velocity is holomorphic in an annulus and has a Laurent expansion (Theorem 8.21); the constant term is the free stream and the $1/z$ coefficient is fixed by the circulation, since $\oint (\mathrm{d}w/\mathrm{d}z)\,\mathrm{d}z = \Gamma + \mathrm{i}Q$ with Q the volume flux out of the contour, zero for a solid body. Hence

$$\frac{\mathrm{d}w}{\mathrm{d}z} = U - \frac{\mathrm{i}\Gamma}{2\pi z} + \frac{a_2}{z^2} + \cdots\,, \qquad \left(\frac{\mathrm{d}w}{\mathrm{d}z}\right)^2 = U^2 - \frac{\mathrm{i}U\Gamma}{\pi z} + O\!\left(\frac{1}{z^2}\right).$$

Only the $1/z$ term survives the contour integral, by the residue theorem (Theorem 8.24): $\oint (\mathrm{d}w/\mathrm{d}z)^2\,\mathrm{d}z = 2\pi\mathrm{i}\times(-\mathrm{i}U\Gamma/\pi) = 2U\Gamma$. Substituting in Equation (31.58),

$$X - \mathrm{i}Y = \frac{\mathrm{i}\rho}{2}\cdot 2U\Gamma = \mathrm{i}\rho U\Gamma \quad\Longrightarrow\quad X = 0\,, \qquad Y = -\rho U\Gamma\,,$$

which is Equation (31.59). The sign is worth checking physically rather than trusting: a counterclockwise circulation added to a rightward stream speeds the flow up underneath the body and slows it on top, so by Phenomenon 31.25 the pressure is lower underneath and the force is downward — which is what $Y = -\rho U\Gamma < 0$ says for $\Gamma > 0$. That $X = 0$ is Phenomenon 31.30 once more: circulation buys lift and not one newton of drag. □

Remark 31.69 (The Kutta condition, and where the circulation comes from). Theorem 31.68 determines the lift given Γ and says nothing about what Γ is; the potential problem of Proposition 31.28 has a one-parameter family of solutions, one for each circulation, all of them irrotational and all satisfying non-penetration. The physical selection is the *Kutta condition*: of that family, the realized flow is the one for which the velocity at a sharp trailing edge is finite, every other member requiring the fluid to turn the corner at infinite speed. That fixes Γ, and for a thin aerofoil the value it fixes is the content of Proposition 31.70

below — Kutta's computation [307], with the general circulation theorem due to Joukowski, first published in Russian in 1906 [362].

The Kutta condition is an extra physical hypothesis, and its justification is viscous: the boundary layer of Section 31.7.2 cannot negotiate the infinite adverse gradient at the edge and leaves the surface there. Its consistency with Corollary 31.65 is secured by the *starting vortex*: when a wing is set in motion the circulation around a large material circuit enclosing both wing and starting point remains zero, and a vortex of circulation $-\Gamma$ is shed and left behind. It is photographable, and the photographs are the direct evidence that the bound circulation is real.

Rests on Theorem 31.68 and Corollary 31.65.

Proposition 31.70 (The lift-curve slope of a thin aerofoil)**.** *Let a thin, uncambered profile of chord c with a sharp trailing edge be held at a small angle of attack α in a plane potential stream of speed U. Of the one-parameter family of irrotational flows past it, the Kutta condition selects*

$$\Gamma = -\pi c U \alpha\,, \qquad C_{\mathrm{L}} := \frac{Y}{\frac{1}{2}\rho U^2 c} = 2\pi\alpha\,, \tag{31.60}$$

the lift per unit span rising by 2π per radian of incidence, with no dependence whatever on the thickness or on the detailed shape of the section. Thickness, camber and finite span all modify the result, and camber alone shifts the zero-lift angle without altering the slope.

Rests on Theorem 31.68 and Proposition 31.28.

Full derivation: Appendix A.62 (p. 3131).

Derives Proposition 31.70.

31.7.2 The Prandtl boundary layer

Theorem 31.71 (Boundary-layer thickness)**.** *In steady flow of speed U past a body of streamwise extent L at $\mathrm{Re} \gg 1$, viscous effects are confined to a layer against the surface whose thickness satisfies*

$$\frac{\delta}{L} \sim \mathrm{Re}^{-1/2}\,, \tag{31.61}$$

outside which the flow is described by Equation (31.19). The wall shear stress is then of order $\mu U/\delta \sim \rho U^2 \mathrm{Re}^{-1/2}$, which tends to zero with the viscosity, but the dissipation and the drag do not, because the region in which they occur sharpens at the compensating rate [315].

Rests on Theorem 31.37 and Phenomenon 31.30.

Proof. *Derives Theorem 31.71.*

Within the layer the streamwise velocity rises from zero at the wall to U over the transverse distance δ, so transverse gradients exceed streamwise ones by the factor $L/\delta \gg 1$ and the dominant viscous term in Equation (31.32) is $\nu\,\partial_y^2 u \sim \nu U/\delta^2$. The streamwise inertia is $u\,\partial_x u \sim U^2/L$. A layer in which viscosity acts at all is one where these balance, $\nu U/\delta^2 \sim U^2/L$, giving Equation (31.61). The same statement read as a diffusion problem is more transparent: momentum diffuses away from the wall a distance $\sqrt{\nu t}$ in time t, and the time available is the transit time L/U, so $\delta \sim \sqrt{\nu L/U}$, which is Equation (31.61) again — and is the estimate used for the entry length in Remark 31.42.

The scaling settles Phenomenon 31.30 as a matter of principle. The layer disappears as $\mu \longrightarrow 0$, which is why the outer potential solution describes the observed streamlines ever better; but the velocity gradient across it grows as $U/\delta \sim \mathrm{Re}^{1/2}$, so the surface stress falls only as $\mathrm{Re}^{-1/2}$ over a fixed area, and the separated wake it permits contributes a pressure drag that does not fall at all. A limit of that kind cannot be taken by setting the small parameter to zero in the equation, which is exactly what d'Alembert's argument does. Prandtl's water channel made the layer visible and, by removing it through a suction slit, showed that the whole flow around the body is controlled by it (Section 36.5). □

Remark 31.72 (The Blasius solution and its numbers). For the one case that solves completely — a flat plate aligned with a uniform stream, so that the external pressure gradient vanishes — the boundary-layer equations admit a similarity solution in the variable $\eta = y\sqrt{U/\nu x}$, reducing to a single third-order ordinary differential equation [341]. Its numerical solution gives the thickness at which the velocity reaches 99 % of the free stream as $\delta_{99} \approx 5.0\, x\, \mathrm{Re}_x^{-1/2}$, a local friction coefficient $0.664\, \mathrm{Re}_x^{-1/2}$, and a friction drag coefficient $1.328\, \mathrm{Re}_L^{-1/2}$ for one side of a plate of length L. Concretely: a plate 1 m long in water at 1 m/s has $\mathrm{Re}_L = 10^6$ and a layer about 5 mm thick at the trailing edge, half a percent of the plate. The derivation of the similarity reduction is set out in Section 36.5, where the same numbers are used to interpret the streak photographs.

Rests on Theorem 31.71.

Proposition 31.73 (Separation requires an adverse pressure gradient). *In a steady two-dimensional boundary layer the wall curvature of the velocity profile is fixed by the external pressure gradient,*

$$\mu \left(\frac{\partial^2 u}{\partial y^2} \right)_{y=0} = \frac{\mathrm{d}p}{\mathrm{d}x} \,. \tag{31.62}$$

A profile with reversed flow at the wall, and hence a separation point where $(\partial u/\partial y)_{y=0} = 0$, can therefore occur only where $\mathrm{d}p/\mathrm{d}x > 0$ — where the external pressure rises along the flow.

Rests on Theorem 31.71.

Proof. *Derives Proposition 31.73.*

Evaluate the streamwise momentum equation of the layer, $\rho\,(u\partial_x u + v\partial_y u) = -\mathrm{d}p/\mathrm{d}x + \mu\partial_y^2 u$, at the wall, where no slip makes $u = v = 0$: the entire left-hand side vanishes and Equation (31.62) remains. If $\mathrm{d}p/\mathrm{d}x < 0$ the profile is concave towards the wall throughout and $\partial_y u$ cannot vanish inside the layer, so the flow cannot reverse; if $\mathrm{d}p/\mathrm{d}x > 0$ the profile has an inflexion and reversal becomes possible. The criterion is necessary and not sufficient — how far into a rising pressure the layer can go before separating depends on its history — but its necessity already explains the observations of Section 36.5: separation occurs on the rear of a bluff body and in a diverging channel, both of them regions of rising pressure, and never on the accelerating forward face.

The drag crisis follows from the same criterion applied to a layer that has itself become turbulent. A turbulent layer carries fast-moving fluid closer to the wall, so it withstands more adverse pressure before reversing, separates further back, leaves a narrower wake and by Equation (31.51) a smaller drag. That is why roughening a sphere can reduce its resistance [384], and it is Prandtl's explanation of Eiffel's measurement. □

31.8 Instability and transition

31.8.1 Shear and buoyancy instabilities

Theorem 31.74 (The interface dispersion relation). *Let two ideal, incompressible, immiscible fluids be in horizontal layers: fluid 1 of density ρ_1, uniform velocity $U_1\hat{\boldsymbol{x}}$ and depth h_1 above a flat interface at $y = 0$; fluid 2 of density ρ_2, velocity $U_2\hat{\boldsymbol{x}}$ and depth h_2 below it; gravity $-g\hat{\boldsymbol{y}}$; interfacial tension γ; rigid boundaries at $y = h_1$ and $y = -h_2$. Then a small disturbance of the interface proportional to $\exp[\mathrm{i}\,(kx - \omega t)]$, $k > 0$, requires*

$$\rho_1 \coth(kh_1)\,(\omega - kU_1)^2 + \rho_2 \coth(kh_2)\,(\omega - kU_2)^2 = k\left[(\rho_2 - \rho_1)\,g + \gamma k^2\right] . \tag{31.63}$$

The interface is unstable at wavenumber k precisely when this quadratic has a root with $\mathrm{Im}\,\omega > 0$.

Rests on Proposition 31.28 and Theorem 31.24.

Proof. *Derives Theorem 31.74.*

Each layer is irrotational in the undisturbed state and remains so by Corollary 31.65, so write $\boldsymbol{v}_j = U_j \hat{\boldsymbol{x}} + \boldsymbol{\nabla}\phi_j$ with ϕ_j harmonic (Proposition 31.28) and small. Separable harmonic solutions periodic in x with wavenumber k and satisfying $\partial_y \phi = 0$ on the rigid boundaries are

$$\phi_1 = A \cosh\left[k\,(y - h_1)\right] E\,, \qquad \phi_2 = B \cosh\left[k\,(y + h_2)\right] E\,, \qquad E = \mathrm{e}^{\mathrm{i}(kx - \omega t)}\,,$$

and let the interface be $y = \eta = HE$. Write $s_j := \mathrm{i}\,(kU_j - \omega)$, so that $(\partial_t + U_j \partial_x)$ acting on anything proportional to E multiplies it by s_j.

Kinematic condition. A particle on the interface stays on it, so to first order $(\partial_t + U_j \partial_x)\,\eta = \partial_y \phi_j$ at $y = 0$ for each fluid. This gives $s_1 H = -Ak \sinh(kh_1)$ and $s_2 H = Bk \sinh(kh_2)$, whence

$$\phi_1(0) = -\frac{s_1 H}{k} \coth(kh_1)\,, \qquad \phi_2(0) = \frac{s_2 H}{k} \coth(kh_2)\,.$$

Dynamic condition. The unsteady Bernoulli relation Equation (31.21) in each layer, linearized about the uniform stream, gives the pressure at the interface as $p_j = -\rho_j\,(\partial_t + U_j \partial_x)\,\phi_j - \rho_j g \eta + \text{const}$, the constants being equal because the undisturbed interface is in equilibrium. The Young–Laplace relation Equation (31.18) for a surface of small slope reads $p_2 - p_1 = -\gamma\,\partial_x^2 \eta = \gamma k^2 \eta$. Substituting,

$$-\rho_2 s_2 \phi_2(0) + \rho_1 s_1 \phi_1(0) + (\rho_1 - \rho_2)\, gH = \gamma k^2 H\,,$$

and inserting the two expressions for $\phi_j(0)$ together with $s_j^2 = -\,(kU_j - \omega)^2$ gives Equation (31.63) after multiplying through by $-k/H$. The disturbance grows exponentially when ω has a positive imaginary part, and since the two roots of a real quadratic are complex conjugates, instability at a given k is equivalent to the discriminant being negative. □

Corollary 31.75 (Rayleigh–Taylor instability)**.** *For two deep layers at rest, $U_1 = U_2 = 0$ and $kh_j \gg 1$, Equation (31.63) gives*

$$\omega^2 = \frac{k\left[(\rho_2 - \rho_1)\, g + \gamma k^2\right]}{\rho_1 + \rho_2}\,. \tag{31.64}$$

A heavy fluid resting on a light one, $\rho_1 > \rho_2$, is therefore unstable at every wavenumber below the cut-off

$$k_{\mathrm{c}} = \sqrt{\frac{(\rho_1 - \rho_2)\, g}{\gamma}}\,, \qquad \lambda_{\mathrm{c}} = 2\pi \sqrt{\frac{\gamma}{(\rho_1 - \rho_2)\, g}}\,, \tag{31.65}$$

with growth rate $\sqrt{\mathcal{A} g k}$ at long wavelengths, where $\mathcal{A} = (\rho_1 - \rho_2)\,/\,(\rho_1 + \rho_2)$ is the Atwood number [221].

Rests on Theorem 31.74.

Proof. *Derives Corollary 31.75.*

Set $U_j = 0$ and $\coth(kh_j) \longrightarrow 1$ in Equation (31.63) and solve for ω^2, giving Equation (31.64). With $\rho_1 > \rho_2$ the bracket is negative for $k < k_{\mathrm{c}}$, so $\omega^2 < 0$, ω is purely imaginary, and one root grows. Neglecting γ gives $|\omega| = \sqrt{\mathcal{A} g k}$. The cut-off is the physically important part: surface tension stabilizes short wavelengths, so a water surface held above air is stable in a tube narrower than λ_{c}, which for water is a few centimetres — the reason a glass of water inverted over a fine mesh does not empty. □

Corollary 31.76 (Kelvin–Helmholtz instability)**.** *For two deep layers in relative motion, the discriminant of Equation (31.63) is negative — and the interface unstable — precisely when*

$$\rho_1 \rho_2\,(U_1 - U_2)^2 > (\rho_1 + \rho_2)\left[(\rho_2 - \rho_1)\,\frac{g}{k} + \gamma k\right]. \tag{31.66}$$

In particular a vortex sheet in a fluid of uniform density with neither gravity nor surface tension is unstable at every *wavelength, with growth rate* $k\,|U_1 - U_2|\,/2$ *[172, 182].*

Rests on Theorem 31.74.

Proof. *Derives Corollary 31.76.*

Write Equation (31.63) with coth $\longrightarrow 1$ as a quadratic in the phase speed $c = \omega/k$: $(\rho_1 + \rho_2)\,c^2 - 2\,(\rho_1 U_1 + \rho_2 U_2)\,c + \rho_1 U_1^2 + \rho_2 U_2^2 - \gamma k - (\rho_2 - \rho_1)\,g/k = 0$. Its discriminant, divided by four, is

$$(\rho_1 U_1 + \rho_2 U_2)^2 - (\rho_1 + \rho_2)\left(\rho_1 U_1^2 + \rho_2 U_2^2\right) + (\rho_1 + \rho_2)\left[\gamma k + (\rho_2 - \rho_1)\,\frac{g}{k}\right],$$

and the first two terms combine to $-\rho_1\rho_2\,(U_1 - U_2)^2$ identically. The discriminant is negative exactly under Equation (31.66). Setting $\rho_1 = \rho_2 = \rho$ and $g = \gamma = 0$ leaves $c = \frac{1}{2}\,(U_1 + U_2) \pm \frac{\mathrm{i}}{2}\,|U_1 - U_2|$, unstable at every k with growth rate $k\,|U_1 - U_2|\,/2$, which grows without bound as $k \longrightarrow \infty$ — the vortex sheet is an idealization whose short-wave behaviour is regularized in a real fluid by the finite thickness of the shear layer and by viscosity.

Two consequences of Equation (31.66) are worth recording because both are observed. Stable stratification does not confer immunity: with the denser fluid below, the right-hand side is positive but has a minimum over k, so a large enough velocity difference destabilizes some band of wavelengths — which is how billow clouds form on a temperature inversion, and how wind raises waves on water. And with g and γ present the instability sets in first at a definite wavelength, so the billows appear with a selected spacing rather than at all scales at once. □

Theorem 31.77 (Rayleigh's inflexion-point criterion)**.** *Let an ideal fluid flow in a channel with velocity profile* $U(y)$ *parallel to the walls, and consider disturbances proportional to* $\exp\left[\mathrm{i}k\,(x - ct)\right]$ *with transverse amplitude* $\varphi(y)$ *vanishing at both walls. If the flow is unstable* — $\operatorname{Im} c \neq 0$ — *then* $U''(y)$ *must vanish somewhere strictly inside the channel: a necessary condition for instability of an inviscid parallel shear flow is that its velocity profile possess an inflexion point [210].*

Rests on Theorems 31.22 and 31.58.

Proof. *Derives Theorem 31.77.*

Linearizing Equation (31.19) about the parallel flow and eliminating the pressure gives Rayleigh's equation,

$$(U - c)\left(\varphi'' - k^2\varphi\right) - U''\varphi = 0\,, \qquad \varphi\,(y_1) = \varphi\,(y_2) = 0\,. \tag{31.67}$$

Suppose $\operatorname{Im} c \neq 0$. Then $U - c$ never vanishes and the equation may be divided by it. Multiply by the complex conjugate φ^* and integrate across the channel, integrating the first term by parts and using the boundary conditions:

$$-\int_{y_1}^{y_2}\left(|\varphi'|^2 + k^2\,|\varphi|^2\right)\mathrm{d}y - \int_{y_1}^{y_2}\frac{U''\,|\varphi|^2}{U - c}\,\mathrm{d}y = 0\,.$$

The first integral is real. Taking the imaginary part of the second, with $c = c_\mathrm{r} + \mathrm{i}c_\mathrm{i}$ and $1/(U - c) = (U - c_\mathrm{r} + \mathrm{i}c_\mathrm{i})\,/\,|U - c|^2$, leaves

$$c_\mathrm{i}\int_{y_1}^{y_2}\frac{U''\,|\varphi|^2}{|U - c|^2}\,\mathrm{d}y = 0\,.$$

Since $c_\mathrm{i} \neq 0$ by hypothesis and the remaining weight $|\varphi|^2\,/\,|U - c|^2$ is non-negative and not identically zero, U'' must change sign, hence vanish, somewhere in the interval.

The criterion is necessary and not sufficient, and it is worth seeing what it does and does not settle. A free shear layer or a jet has an inflexion point and is violently unstable, which is Corollary 31.76 in a smoothed form. The parabolic pipe and channel profiles of Equation (31.36) have none, so they are stable in the inviscid theory — and they are observed to break down anyway (Phenomenon 31.53), which is the first hint that the pipe transition is not a linear instability at all. □

31.8.2 Rayleigh–Bénard convection and Taylor–Couette flow

Phenomenon 31.78 (Convective onset at a computed threshold)**.** A horizontal fluid layer of depth d heated from below transports heat by conduction alone, at rest, until the imposed temperature difference exceeds a threshold; above it a steady cellular circulation appears whose horizontal periodicity is a fixed multiple of d, independent of the lateral size of the vessel [288]. The control parameter is the Rayleigh number Equation (31.48), and for a layer between stress-free perfectly conducting boundaries Rayleigh's linearized calculation [438] gives

$$\mathrm{Ra}_\mathrm{c} = \frac{27\pi^4}{4} \approx 657.5\,, \qquad \lambda_\mathrm{c} = 2\sqrt{2}\,d \approx 2.83\,d\,, \tag{31.68}$$

with no adjustable parameter whatever; for two rigid boundaries, the commoner laboratory case, the same calculation gives $\mathrm{Ra}_\mathrm{c} \approx 1708$ [1199]. Both threshold and scale are observed.

Rests on Definition 31.51 and Theorem 31.37.

Derivation. *Derives Phenomenon 31.78.*

The reduction of the linearized Boussinesq system to the marginal relation $\mathrm{Ra}(a) = (\pi^2 + a^2)^3 / a^2$ between Rayleigh number and dimensionless horizontal wavenumber, and the minimization of that curve which yields Equation (31.68), are carried out in Section 36.4, where they are set beside the measurement. The point to be taken here is the contrast with Phenomenon 31.53: the same programme — linearize about the base state, seek normal modes, find the parameter value at which the growth rate first reaches zero — delivers a threshold and a length scale in this problem and delivers nothing in the pipe. The failure there is therefore a property of that particular flow, not of the method, and Theorem 31.77 says why: the parabolic profile has no inflexion point, so its instability, if it is one, cannot be of the kind linear theory finds. □

Remark 31.79 (Bénard's own cells, and Taylor's cylinders). Two qualifications belong with Phenomenon 31.78. The first is that Bénard's thin layers had a free upper surface, where the temperature dependence of the surface tension drives a competing instability with its own threshold; the cells he photographed are now attributed largely to that mechanism rather than to buoyancy, so the name is attached to the wrong experiment and the buoyancy instability is properly tested between two plates (Section 36.4). The second is that the calculation predicts only the onset — not the hexagonal plan form, not the amplitude, and nothing about the sequence of further instabilities that follows as the heating is raised, which is the experimental material of Chapter 32.

The analogous problem for the circular Couette flow of Equation (31.34) is Taylor's, and it deserves its priority: rotating the inner cylinder fast enough destabilizes the flow into a stack of toroidal vortices at a critical value of a Taylor number built from the gap, the angular velocity and ν, and Taylor's 1923 comparison of the computed threshold with his measurements was the first quantitative agreement between a hydrodynamic stability calculation and an experiment [505]. The underlying criterion — that the flow is unstable when the angular momentum $r v_\varphi$ decreases outward — is Rayleigh's, and is proved as Proposition 31.80 below; it is stated with its viscous corrections in [1199], and it is not in the convection paper [438] cited above, which is a different problem.

Rests on Phenomenon 31.78 and Proposition 31.40.

Proposition 31.80 (Rayleigh's circulation criterion)**.** *Let an ideal fluid rotate steadily about an axis with azimuthal velocity $v_\varphi(r)$, and write $L(r) := r v_\varphi(r)$ for its angular momentum per unit mass. The motion is unstable to axisymmetric disturbances if the* Rayleigh discriminant

$$\Phi(r) := \frac{1}{r^3}\frac{\mathrm{d}L^2}{\mathrm{d}r} \tag{31.69}$$

is negative anywhere, that is wherever the magnitude of the angular momentum decreases outward. For the circular Couette solution Equation (31.34), $L = Ar^2 + B$ and $\Phi = 4Av_\varphi/r$; so a fluid driven by the inner cylinder with the outer one held at rest, for which $A < 0$ while $v_\varphi > 0$ everywhere except at the outer wall, is unstable at every rotation rate however small.
Rests on Proposition 31.40 and Theorem 31.22.

Proof. *Derives Proposition 31.80.*

Take two thin coaxial rings of equal volume, and hence in an incompressible fluid of equal mass m, at radii $r_1 < r_2$, carrying angular momenta per unit mass L_1 and L_2. Interchange them and leave the rest of the fluid undisturbed. In an ideal axisymmetric motion nothing exerts a torque about the axis on a ring — viscous stresses are absent by hypothesis and the pressure force on a ring is directed through the axis — so each ring carries its own L to its new radius. The two rings have equal volume, so the ambient pressure field does no net work on the pair. The kinetic energy of the azimuthal motion of a ring is $\frac{1}{2}mv_\varphi^2 = \frac{1}{2}mL^2/r^2$, so the interchange costs

$$\Delta E = \frac{m}{2}\left(\frac{L_1^2}{r_2^2} + \frac{L_2^2}{r_1^2} - \frac{L_1^2}{r_1^2} - \frac{L_2^2}{r_2^2}\right) = \frac{m}{2}\left(L_2^2 - L_1^2\right)\left(\frac{1}{r_1^2} - \frac{1}{r_2^2}\right).$$

The second bracket is positive because $r_1 < r_2$. So the interchange must be paid for from outside exactly when L^2 increases outward, and it releases kinetic energy — and will therefore proceed of itself, which is instability — exactly when L^2 decreases outward. Applied to neighbouring radii this is the sign of $\mathrm{d}L^2/\mathrm{d}r$, and dividing by the positive r^3 to make a quantity with the dimensions of the square of a frequency gives Equation (31.69).

For Equation (31.34), $L = r\,(Ar + B/r) = Ar^2 + B$, so $\mathrm{d}L^2/\mathrm{d}r = 2L \cdot 2Ar = 4Ar^2 v_\varphi$ and $\Phi = 4Av_\varphi/r$. With the outer cylinder at rest, $A = -\Omega_1 R_1^2/\left(R_2^2 - R_1^2\right) < 0$ while v_φ falls from $\Omega_1 R_1$ to zero across the gap, so $\Phi < 0$ throughout the interior of the gap and the inviscid flow is unstable for any $\Omega_1 > 0$. Rotating the outer cylinder instead, with the inner one at rest, gives $A > 0$ and $\Phi > 0$: that flow is stable to axisymmetric disturbances at every speed. That asymmetry between driving from inside and driving from outside is what the experiment shows, and it is why Couette's viscometer turns the outer cylinder and measures the torque on the inner one [246]. □

Remark 31.81 (Where the threshold comes from, and what it costs). Proposition 31.80 predicts instability at every rotation rate; the experiment shows a definite threshold, the laminar solution surviving until the inner cylinder is turned fast enough and only then breaking into the stack of toroidal vortices Taylor photographed [505]. The difference is viscosity, which the criterion discards and which both damps the disturbance and diffuses the angular momentum gradient that drives it. Restoring it turns the question into an eigenvalue problem: linearize Equation (31.32) about Equation (31.34) for axisymmetric disturbances proportional to $\mathrm{e}^{\mathrm{i}kz+st}$ and find the rotation rate at which the largest s first reaches zero. In the narrow-gap limit $d := R_2 - R_1 \ll R_1$ the resulting sixth-order system has the same form as the linearized Boussinesq system behind Phenomenon 31.78, with a Taylor number built from d, the angular velocity and ν standing in for the Rayleigh number; its critical value and the axial wavelength of the first vortices — about twice the gap width, so that each vortex is square in section — are computed and tabulated in [1199]. Taylor obtained both and measured both, and the agreement was the first quantitative

confirmation of a hydrodynamic stability calculation [505]. Two things should be carried away. The threshold is a property of the viscous eigenvalue problem and not of the inviscid criterion, which is why no rearrangement of Equation (31.69) will produce it. And it is a computed number rather than a closed formula, which is why this chapter quotes it from the monograph instead of deriving it.

Rests on Proposition 31.80 and Phenomenon 31.78.

31.9 Turbulence

This section is different in kind from those before it, and the difference is stated at the outset rather than left to be inferred. What follows is not a theory of turbulence. It is an averaging procedure that reorganizes Equation (31.32) without closing it, a picture of energy transfer that is suggestive rather than deductive, and a similarity hypothesis that is assumed and then tested. All of it rests on equations whose well-posedness is open (Remark 31.48). The measured regularities are real and are reported; the derivations are labelled by exactly what they assume.

31.9.1 The Reynolds decomposition and the closure problem

Theorem 31.82 (The Reynolds-averaged equations)**.** *Split each field into a mean and a fluctuation, $\boldsymbol{v} = \boldsymbol{V} + \boldsymbol{v}'$ and $p = P + p'$, with $\langle \boldsymbol{v}' \rangle = \boldsymbol{0}$ and the averaging operation linear and commuting with differentiation. Then the mean flow of an incompressible Newtonian fluid obeys*

$$\rho\left(\frac{\partial V_i}{\partial t} + V_j \partial_j V_i\right) = -\partial_i P + \partial_j\left(2\mu E_{ij} - \rho\left\langle v_i' v_j' \right\rangle\right) + \rho g_i\,, \qquad \partial_i V_i = 0\,, \tag{31.70}$$

with E_{ij} the rate of strain of the mean field. The extra term $-\rho\left\langle v_i' v_j' \right\rangle$, the Reynolds stress*, is a new unknown [268].*

Rests on Theorem 31.37.

Proof. *Derives Theorem 31.82.*

Average Equation (31.32) written in conservation form, $\rho\partial_t v_i + \rho\partial_j\left(v_i v_j\right) = -\partial_i p + \mu\nabla^2 v_i + \rho g_i$, which is equivalent to it by Equation (31.11). Every term is linear in the fields except the advective one, and for that

$$\langle v_i v_j \rangle = \left\langle \left(V_i + v_i'\right)\left(V_j + v_j'\right)\right\rangle = V_i V_j + \left\langle v_i' v_j' \right\rangle\,,$$

the cross terms vanishing because $\langle v' \rangle = 0$ and V is already an average. Moving the correlation to the right-hand side and using the averaged continuity equation gives Equation (31.70). Nothing has been approximated: Equation (31.70) is exact. □

Remark 31.83 (The closure problem, stated exactly). Equation (31.70) is four equations for four mean unknowns $(\boldsymbol{V}, P)$ *plus* the six independent components of $\left\langle v_i' v_j' \right\rangle$: ten unknowns, four equations. Deriving an evolution equation for the Reynolds stress from Equation (31.32) is straightforward and produces terms in $\left\langle v_i' v_j' v_k' \right\rangle$; an equation for those produces quadruple correlations, and so on without end. The hierarchy never closes, at any order, and the reason is structural: the nonlinearity of Equation (31.32) is quadratic, so averaging always leaves one more moment than it determines. This is not a temporary gap in knowledge that a cleverer manipulation will fill.

Every practical calculation of a turbulent flow therefore closes the hierarchy by hypothesis. The oldest such hypothesis writes $-\rho\left\langle v_i' v_j' \right\rangle = 2\rho\nu_{\mathrm{T}} E_{ij}$ in imitation of Equation (31.30), defining an *eddy viscosity* ν_{T}. The imitation is formal only. A molecular viscosity is a

property of the fluid, measured once and valid in every flow, because the mean free path is small against the gradients (Definition 31.2); an eddy viscosity is a property of the *flow*, differs from point to point, and is defined by eddies whose size is comparable to the gradients they are supposed to smooth out — the very condition under which the analogy fails. Eddy viscosities and their descendants are engineering correlations fitted to data. They are useful, they are not mechanics, and this treatise does not present them as derived.

Rests on Theorem 31.82.

31.9.2 The energy cascade and Kolmogorov's 1941 theory

Richardson's picture organizes what the closure problem leaves unstructured [494]: energy is fed in at the scale of the geometry that stirs the flow, passed by the nonlinear term to successively smaller eddies with negligible loss, and dissipated by viscosity only at the smallest scales. The picture is consistent with Equation (31.32) — the vortex-stretching term of Equation (31.52) is the mechanism, and its absence in flows independent of one direction is why those flows cascade the other way — but it is not derived from it.

Phenomenon 31.84 (The five-thirds spectrum)**.** In turbulence at high Reynolds number the energy spectrum measured over the intermediate range of scales — small against the geometry that stirs the flow, large against the scale at which viscosity acts — is a power law of exponent $-5/3$,

$$E(k) = C\,\varepsilon^{2/3} k^{-5/3}\,, \tag{31.71}$$

in which ε is the mean rate of energy dissipation per unit mass, in W/kg, and C is a constant of order unity that does not depend on the flow producing the turbulence. The form was predicted from similarity hypotheses [857, 861] and confirmed over a wide range of wavenumbers by the measurements of Grant, Stewart and Moilliet in a tidal channel [1227], whose Reynolds number no laboratory could then reach.

Rests on Theorems 31.58 and D.2.

Derivation. *Derives Phenomenon 31.84.*

The derivation is dimensional, and rests on two hypotheses that are themselves not derived from the Navier–Stokes equations but assumed and then tested: that at scales far below the stirring scale the statistics are locally isotropic and independent of how the turbulence was made, and that in the intermediate range they are independent of the viscosity as well, depending only on the rate ε at which energy is passed down the scales [857]. Granted these, $E(k)$ can depend only on ε and k. In the base dimensions of length L and time T, the spectrum is an energy per unit mass per unit wavenumber and so carries $[\,E\,] = \mathsf{L}^3\mathsf{T}^{-2}$, while ε is an energy per unit mass per unit time, $[\,\varepsilon\,] = \mathsf{L}^2\mathsf{T}^{-3}$, and $[\,k\,] = \mathsf{L}^{-1}$. Setting $E = C\varepsilon^a k^b$ and matching both dimensions,

$$\mathsf{L}^3\mathsf{T}^{-2} = \left(\mathsf{L}^2\mathsf{T}^{-3}\right)^a \left(\mathsf{L}^{-1}\right)^b \implies -3a = -2\,, \quad 2a - b = 3\,,$$

so $a = 2/3$ and $b = -5/3$, which is Equation (31.71); the exponents are fixed uniquely by Theorem D.2 and the only freedom left is the dimensionless C. The same argument locates the lower end of the range: the only length that can be built from ε and the kinematic viscosity ν is $\eta = (\nu^3/\varepsilon)^{1/4}$, below which the second hypothesis must fail because viscosity is precisely what acts there. What the argument does *not* give is any justification of the hypotheses, and measurement has since found small but systematic departures from $-5/3$ at high order — the intermittency corrections — so Equation (31.71) is a leading approximation confirmed to within those, not an identity [1227]. □

Proposition 31.85 (The Kolmogorov scales)**.** *The only combinations of ε and ν with the dimensions of length, velocity and time are*

$$\eta = \left(\frac{\nu^3}{\varepsilon}\right)^{1/4}, \qquad u_\eta = (\nu\varepsilon)^{1/4}, \qquad \tau_\eta = \left(\frac{\nu}{\varepsilon}\right)^{1/2}, \tag{31.72}$$

and the Reynolds number formed from them is exactly unity, which is what identifies η as the scale at which the cascade stops. If the energy is supplied at scale L with velocity U and $\varepsilon \sim U^3/L$, then

$$\frac{L}{\eta} \sim \mathrm{Re}^{3/4}, \qquad \frac{\textit{degrees of freedom}}{\textit{unit volume}} \sim \left(\frac{L}{\eta}\right)^3 \sim \mathrm{Re}^{9/4}. \tag{31.73}$$

Rests on Phenomenon 31.84 and Theorem D.2.

Proof. *Derives Proposition 31.85.*

The dimensions are $[\,\nu\,] = \mathsf{L}^2\mathsf{T}^{-1}$ and $[\,\varepsilon\,] = \mathsf{L}^2\mathsf{T}^{-3}$, and eliminating T between them gives Equation (31.72) uniquely (Theorem D.2). Then $u_\eta\eta/\nu = (\nu\varepsilon)^{1/4}\,(\nu^3/\varepsilon)^{1/4}\,/\nu = 1$. With $\varepsilon \sim U^3/L$ — the statement that the energy U^2 is passed down in the eddy turnover time L/U, which is the cascade hypothesis and not a theorem — $L/\eta = L\,(\varepsilon/\nu^3)^{1/4} \sim (UL/\nu)^{3/4}$, and the number of independent degrees of freedom needed to represent the field is the number of boxes of side η in the volume.

The last estimate is the practical face of the closure problem. At $\mathrm{Re} = 10^6$, a modest laboratory value, Equation (31.73) demands of order 10^{13} degrees of freedom per stirring volume for a computation resolving every scale. For concreteness, in the atmospheric surface layer $\varepsilon \approx 1 \times 10^{-2}\,\mathrm{W/kg}$ and, with air from Table 31.1, Equation (31.72) gives $\eta \approx 0.8\,\mathrm{mm}$ — so the smallest structures in a kilometre-deep flow are under a millimetre across, a scale separation of six decades. □

Remark 31.86 (The one exact result, and the split attribution)*.* The dimensional argument above assumes and does not prove. There is exactly one nontrivial statement about turbulence that *is* derived from Equation (31.32): for homogeneous isotropic turbulence in a statistically steady state, the third moment of the longitudinal velocity increment across a separation r in the inertial range obeys

$$\left\langle \left(\delta u_\parallel\right)^3 \right\rangle = -\tfrac{4}{5}\,\varepsilon\, r\,, \tag{31.74}$$

with no adjustable constant [857]. It follows from the Karman–Howarth relation, itself an exact consequence of the equations under the stated symmetry assumptions, in the limit of vanishing viscosity. Its negative sign is the direction of the cascade made quantitative — energy flows from large scales to small — and it is the one place where the phenomenology touches the equations.

Two attributions should be read correctly. The similarity hypotheses and Equation (31.74) are Kolmogorov's [857]; the spectral form Equation (31.71) in wavenumber is Obukhov's [861], published the same year, and both are customarily filed together under the label "K41". And the constant C in Equation (31.71) is not predicted by any of this: it is measured, close to 1.5 in the three-dimensional normalization used here, and a reader comparing that figure with the literature must first check which of several spectral conventions is in force, since the one-dimensional constant is smaller by a factor of order three.

Rests on Phenomenon 31.84.

Full derivation: Appendix A.63 (p. 3135).

Derives Equation (31.74).

Remark 31.87 (What a theory of turbulence would have to do). Set against the rest of this chapter the position is unusual and should not be softened. The equations are believed correct and are confirmed wherever they can be solved; they are not known to possess smooth solutions; the transition to the turbulent state is not predicted (Phenomenon 31.53); the averaged equations do not close (Remark 31.83); and the statistical description that organizes the measurements is an assumption that measurement has confirmed to leading order and falsified in its details, the intermittency corrections being real. Chapter 36 sets out the specific measured regularities that any future theory will be asked to reproduce before it is asked to predict anything new.

Rests on Remarks 31.48 and 31.83.

31.10 Compressible flow

31.10.1 Sound

Phenomenon 31.88 (Sound travels at the adiabatic speed)**.** Small pressure disturbances propagate through a gas without change of form and without dispersion, at a speed that depends on the state of the gas but not on the amplitude or the frequency of the disturbance. The measured speed in air exceeds by about one part in six the value $\sqrt{p/\rho}$ that Newton obtained by treating the compressions as isothermal [14], and agrees instead with the adiabatic compressibility [59]:

$$c = \sqrt{\left(\frac{\partial p}{\partial \rho}\right)_s} = \sqrt{\frac{\gamma p}{\rho}}\,, \tag{31.75}$$

γ being the ratio of the specific heats, close to $7/5$ for a diatomic gas. The ratio of the two predictions is $\sqrt{\gamma}$, about 1.18 — which is the discrepancy observed.

Rests on Theorems 31.12 and 31.22.

Derivation. *Derives Phenomenon 31.88.*

Write $\rho = \rho_0 + \rho'$, $p = p_0 + p'$ with the primed quantities and the velocity small, and keep first-order terms in the continuity and Euler equations of a fluid at rest:

$$\partial_t \rho' + \rho_0 \,\boldsymbol{\nabla}\cdot\boldsymbol{v} = 0\,, \qquad \rho_0\,\partial_t \boldsymbol{v} = -\boldsymbol{\nabla} p'\,.$$

Take ∂_t of the first and the divergence of the second and subtract: $\partial_t^2 \rho' = \nabla^2 p'$. If the disturbance follows some definite thermodynamic path, $p' = (\mathrm{d}p/\mathrm{d}\rho)\rho'$ along it, and the result is the wave equation $\partial_t^2 \rho' = c^2 \nabla^2 \rho'$ with $c^2 = \mathrm{d}p/\mathrm{d}\rho$ — non-dispersive, as observed, because c carries no reference to the wavelength.

Which path? Newton took the compressions to be isothermal, giving $p \propto \rho$ and $c^2 = p/\rho$ [14]. The justification fails on comparison of two times: heat must diffuse between a compression and the adjacent rarefaction, half a wavelength away, within half a period, and for air at audible frequencies the thermal diffusion length in that time is smaller than the wavelength by orders of magnitude. The compressions are therefore adiabatic, not isothermal. For an ideal gas the adiabat is $p \propto \rho^\gamma$, whence $(\partial p/\partial \rho)_s = \gamma p/\rho$ and Equation (31.75) [59]. Numerically, for air at 20 °C treated as an ideal gas with specific gas constant $287\,\mathrm{J/(kg\,K)}$ and $\gamma = 7/5$, Equation (31.75) gives $c = 343\,\mathrm{m/s}$ against Newton's $290\,\mathrm{m/s}$, and the measured value [1340] is the former. The two answers differ by the factor $\sqrt{\gamma} = \sqrt{7/5} \approx 1.18$ for a diatomic gas, and the measured speed in air selects the adiabatic one. The episode is a clean instance of the pattern this treatise follows throughout: a derivation whose logic is sound fails numerically, and the failure localizes the one assumption — here the thermodynamic path — that has to be replaced. □

Remark 31.89 (The Mach number and the regimes it separates). Equation (31.75) supplies the speed against which Equation (31.45) compares the flow, and the comparison partitions the subject. For $\mathrm{Ma} \ll 1$ the density is effectively constant (Remark 31.14) and the rest of this chapter applies. For $\mathrm{Ma} < 1$ but not small, the flow is compressible but disturbances still travel upstream, so the fluid ahead of a body is forewarned of its approach. For $\mathrm{Ma} > 1$ they cannot: no signal outruns the body, the region it influences is confined to a cone behind it, and the transition between influenced and uninfluenced fluid is the discontinuity of Section 31.10.2. The wave machinery underlying all of this is that of Chapter 28.

Rests on Phenomenon 31.88 and Definition 31.51.

31.10.2 Shock waves

Remark 31.90 (Why a compression wave must steepen). The linearization of Phenomenon 31.88 discards precisely the term responsible for the phenomenon of this subsection. In a one-dimensional simple wave the disturbance at each point travels at $u + c$ rather than at c, and both contributions rise with the local compression: the fluid there is moving forward, and its higher density raises its sound speed. The crest of a compression therefore overtakes the trough ahead of it. Following the characteristics (Proposition 10.15), which for this system are the curves $\mathrm{d}x/\mathrm{d}t = u \pm c$, they cross after a finite time, at which point the smooth solution would become multivalued — an impossibility. What actually forms is a surface across which the fields jump, of thickness a few molecular mean free paths, so thin that the continuum description of Definition 31.2 fails inside it and must be replaced by matching conditions across it.

Rests on Phenomenon 31.88 and Proposition 10.15.

Theorem 31.91 (Rankine–Hugoniot jump conditions)**.** *Let a plane discontinuity be at rest and let the fluid cross it with normal velocity u_1 ahead and u_2 behind. Then conservation of mass, momentum and energy require*

$$\rho_1 u_1 = \rho_2 u_2\,, \qquad p_1 + \rho_1 u_1^2 = p_2 + \rho_2 u_2^2\,, \qquad h_1 + \tfrac{1}{2}u_1^2 = h_2 + \tfrac{1}{2}u_2^2\,, \tag{31.76}$$

with h the specific enthalpy [178, 242]. These three relations, with the equation of state, determine the state behind the shock from the state ahead of it and the shock speed, with no reference whatever to the mechanism operating inside the discontinuity.

Rests on Theorems 31.12 and 31.22.

Proof. *Derives Theorem 31.91.*

Work in the frame in which the discontinuity is stationary and the flow is steady and one-dimensional. Each of mass, momentum and energy obeys a conservation law of the form $\partial_t q + \partial_x F = 0$, which in the steady state reduces to $\mathrm{d}F/\mathrm{d}x = 0$: the flux is the same on both sides however violently q varies between them. Integrating each across a pillbox straddling the surface and shrinking its thickness to zero, only the flux difference survives, and the three fluxes are ρu, $p + \rho u^2$ and $\rho u\left(h + \tfrac{1}{2}u^2\right)$ — the last dividing through by the mass flux, which is common to both sides by the first relation. That gives Equation (31.76). The viscous and conducting terms of Equation (31.31) contribute nothing to the integrated balance because they are gradients of quantities that are equal on the two sides, where the flow is uniform; that is why the result is independent of μ, ζ and the thermal conductivity, although those are exactly what determine the shock's internal structure and thickness. □

Remark 31.92 (Entropy selects the physical branch). Equation (31.76) is symmetric under interchange of the two sides and therefore admits, formally, both compression and rarefaction discontinuities. Only one of them occurs. Computing the entropy from the jump conditions shows that $s_2 > s_1$ for a compression and $s_2 < s_1$ for a rarefaction, so the second law excludes the latter: shocks compress, and a rarefaction spreads out smoothly instead of

steepening — consistently with Remark 31.90, in which it is the compressive part of the wave whose characteristics converge. For a strong shock in a polytropic gas the density ratio saturates at $\rho_2/\rho_1 \longrightarrow (\gamma+1)/(\gamma-1)$, which is 6 for $\gamma = 7/5$: however hard a gas is hit, a single normal shock cannot compress it by more than a factor of six, while the temperature behind it grows without bound.

Rests on Theorem 31.91.

Phenomenon 31.93 (The Mach cone)**.** A body moving through a gas faster than the sound speed is followed by a conical shock surface whose half-angle μ satisfies

$$\sin\mu = \frac{1}{\mathrm{Ma}} = \frac{c}{U}\,, \tag{31.77}$$

so that measuring the angle measures the speed. Mach and Salcher photographed the cone around a supersonic projectile by spark-illuminated schlieren imaging, the first direct observation of a shock in flight [235].

Rests on Remark 31.89 and Theorem 31.91.

Derivation. *Derives Phenomenon 31.93.*

Each point of the trajectory emits a disturbance that spreads as a sphere of radius ct about the point of emission, while the body advances Ut. For $U > c$ the spheres are contained within the envelope that touches all of them, a cone whose apex is the body and whose half-angle satisfies $\sin\mu = ct/Ut$, which is Equation (31.77). For $U < c$ no envelope exists and the disturbance eventually fills the whole space, which is Remark 31.89 restated geometrically. The cone is the locus at which the fluid first learns of the body, so it is where the state jumps, and Theorem 31.91 applies to the component of the velocity normal to it. For a body of finite thickness the attached cone becomes a detached bow shock at speeds close to the sound speed, which is what the photographs of [235] also show. □

31.11 Surface waves and solitary waves

Theorem 31.94 (Gravity–capillary waves on a free surface)**.** *Small-amplitude waves on the free surface of a layer of ideal incompressible liquid of depth h, density ρ and surface tension γ, over a flat rigid bottom, satisfy*

$$\omega^2 = \left(gk + \frac{\gamma k^3}{\rho}\right)\tanh(kh)\,. \tag{31.78}$$

Rests on Theorem 31.74.

Proof. *Derives Theorem 31.94.*

This is Equation (31.63) with the upper fluid removed, $\rho_1 = 0$ and $U_1 = U_2 = 0$, the lower fluid identified as the liquid, $\rho_2 = \rho$ and $h_2 = h$: $\rho\coth(kh)\,\omega^2 = k\,(\rho g + \gamma k^2)$, which rearranges to Equation (31.78). Setting $\gamma = 0$ recovers the classical gravity-wave relation of [701]. The hypotheses inherited from Theorem 31.74 are worth restating because each is visible in the failures of the formula: ideal fluid, so no attenuation is predicted although real waves damp; irrotational motion, so no mean drift; and small amplitude, so no steepening or breaking. □

Phenomenon 31.95 (The observed dispersion of water waves)**.** Waves on deep water are dispersive: long waves travel faster than short ones, so a disturbance spreads into a train with the longest waves at the front, and the energy of the train travels at half the speed of its crests. In shallow water the dispersion disappears and all long waves travel at $\sqrt{gh}$, which is why a tsunami keeps its shape across an ocean. Between the two regimes, surface

tension takes over at short wavelengths and the phase speed passes through a minimum: for a clean water surface

$$c_{\min} = \left(\frac{4g\gamma}{\rho}\right)^{1/4} \approx 0.23\,\mathrm{m/s}\,, \qquad \lambda_{\min} = 2\pi\sqrt{\frac{\gamma}{\rho g}} \approx 1.7\,\mathrm{cm}\,, \tag{31.79}$$

below which the ripples are governed by capillarity and above which by gravity. A steadily moving disturbance slower than $c_{\min}$ therefore generates no waves at all, which is why a slowly drawn wire leaves a still surface.

Rests on Theorem 31.94.

Derivation. *Derives Phenomenon 31.95.*

From Equation (31.78) the phase speed is $c = \omega/k = \sqrt{(g/k + \gamma k/\rho)\tanh(kh)}$. For $kh \gg 1$, $\tanh \longrightarrow 1$; with γ negligible, $c = \sqrt{g/k}$, which decreases with k — long waves are faster — and the group velocity is

$$c_{\mathrm{g}} = \frac{\mathrm{d}\omega}{\mathrm{d}k} = \frac{\mathrm{d}}{\mathrm{d}k}\sqrt{gk} = \tfrac{1}{2}\sqrt{\frac{g}{k}} = \tfrac{1}{2}c\,.$$

For $kh \ll 1$, $\tanh(kh) \approx kh$ and $\omega^2 \approx gh\,k^2$, so $c = c_{\mathrm{g}} = \sqrt{gh}$ independent of k: no dispersion, and the shallow-water speed. For the minimum, the deep-water phase speed $c^2 = g/k + \gamma k/\rho$ is a sum of a decreasing and an increasing term, minimized where their derivatives cancel, $-g/k^2 + \gamma/\rho = 0$, i.e. at $k_{\min} = \sqrt{\rho g/\gamma}$, giving $c^2_{\min} = 2\sqrt{g\gamma/\rho}$ and hence Equation (31.79). With $\gamma = 7.3 \times 10^{-2}\,\mathrm{N/m}$ and $\rho = 998\,\mathrm{kg/m^3}$ these evaluate to $0.23\,\mathrm{m/s}$ and $1.7\,\mathrm{cm}$, both directly observable on a still pond. The factor of one half between energy and crest speed is likewise observable: a group of deep-water waves advances with individual crests appearing at its rear, travelling through it and vanishing at its front. The same factor fixes the half-angle of a ship's wake at $\arcsin(1/3) \approx 19.5°$, independent of the speed of the ship, which is the most easily checked prediction in this section. □

Phenomenon 31.96 (The solitary wave)**.** A single elevation of the free surface of a shallow channel can travel a great distance without change of form and without a train of following waves, at a speed exceeding $\sqrt{gh}$ by an amount fixed by its height. Russell observed such a wave on the Union Canal in 1834, followed it on horseback for over a mile, and reproduced it in a wave tank, where he measured

$$c^2 = g\,(h + a) \tag{31.80}$$

for a wave of amplitude a on water of depth h [116]. The observation was disputed for half a century because linear theory (Theorem 31.94) forbids it: every disturbance should disperse. It is reconciled by the Korteweg–de Vries equation, in which the weak nonlinearity that steepens the wave exactly balances the weak dispersion that spreads it [265].

Rests on Theorem 31.94.

Derivation. *Derives Phenomenon 31.96.*

Long waves of small but finite amplitude on shallow water obey, to leading order in both small parameters a/h and $(h/\ell)^2$ with ℓ the length of the disturbance, the Korteweg–de Vries equation [265]

$$\frac{\partial \eta}{\partial t} + c_0\left(1 + \frac{3\eta}{2h}\right)\frac{\partial \eta}{\partial x} + \frac{c_0 h^2}{6}\,\frac{\partial^3 \eta}{\partial x^3} = 0\,, \qquad c_0 = \sqrt{gh}\,, \tag{31.81}$$

whose two non-trivial terms are exactly the two effects named above: the amplitude-dependent speed $c_0\,(1 + 3\eta/2h)$, which steepens the front, and the third derivative, which is the first correction to $\omega = c_0 k$ obtained by expanding $\tanh(kh)$ in Equation (31.78). Seek a

solution travelling without change of form, $\eta = \eta(x - ct)$. Substituting and integrating twice, with η and its derivatives vanishing at infinity, gives a first-order equation whose solution is

$$\eta = a\,\operatorname{sech}^2\!\left(\frac{x - ct}{\ell}\right), \qquad c = c_0\left(1 + \frac{a}{2h}\right), \qquad \ell^2 = \frac{4h^3}{3a}. \tag{31.82}$$

Two of the three relations are testable and both were tested by Russell. The speed agrees with Equation (31.80) to first order, since $\sqrt{g\,(h+a)} = c_0\sqrt{1 + a/h} \approx c_0\,(1 + a/2h)$, and the expansion is consistent only for $a \ll h$, which is Russell's regime. And the width is *inversely* related to the amplitude, $\ell \propto a^{-1/2}$: a taller solitary wave is narrower and faster, which is the counter-intuitive prediction, and it is what the wave-tank measurements show. The derivation of Equation (31.81) itself from the free-surface equations is longer than a page and is left to the appendix; the modern reading of Equation (31.82) as a soliton, with the collision properties that follow, belongs to Chapter 32. □

Full derivation: Appendix A.64 (p. 3142).
Derives Equation (31.81).

Chapter 32

Nonlinear Dynamics and Chaos

Determinism does not imply predictability. The equations of this part are ordinary differential equations whose solutions exist and are unique, and yet—for the generic nonlinear system—two states closer than any measurement can distinguish separate exponentially fast, so that the deterministic flow forgets its initial condition on a finite horizon. This chapter develops the geometry of phase-space flows, fixed points and their bifurcations, limit cycles, and the Lyapunov exponents that quantify sensitivity; it then follows deterministic chaos from Poincaré's three-body analysis to its experimental record, from convecting fluids and driven pendula to Chua-type circuits. The standard modern text is [1888].

The chapter is the counterpoint to the integrable mechanics of Chapter 23: there the invariant tori organize phase space, and here the KAM theorem states exactly how much of that order survives perturbation, in the symplectic language of Chapter 24. On the dissipative side it supplies what Chapter 31 needs for the transition to turbulence. Chaos is classical determinism at its most honest, and its measured record—period-doubling constants, Lyapunov exponents, fractal dimensions—is as quantitative as any spectroscopy in this book.

Remark 32.1 (What is proved here and what is quoted). Nonlinear dynamics is a branch of mathematics before it is a branch of physics, and this chapter is careful about the difference. Everything that is a computation about a particular system—the amplitude of the van der Pol cycle, the contraction rate of the Lorenz flow, the parameter at which the logistic two-cycle loses stability, the locations of the Kirkwood gaps—is derived here in full. Four general theorems are *quoted*: Poincaré–Bendixson (Theorem 32.30), Hartman–Grobman (Theorem 32.15), the multiplicative ergodic theorem (Theorem 32.74) and KAM (Theorem 32.51). Each is mathematics that belongs in Chapter 9 or in a measure-theoretic chapter that Part II does not yet contain, and each carries a flagged remark saying so where it is used. Three further results—the Hopf bifurcation theorem (Theorem 32.25), the conjugacy of the horseshoe to a shift (Theorem 32.42) and Poincaré's non-integrability theorem (Theorem 32.47)—are likewise quoted, and each says so in its own title. Two further quotations are narrower and are marked where they occur: the existence of the fixed point of the doubling operator, from which Feigenbaum's constants come (Remark 32.88), and the Newhouse–Ruelle–Takens classification of what replaces a destroyed torus (Remark 32.94). Everything quoted is quoted with its primary source where this bibliography has one, and where it does not the attribution is made in words and said to be uncited. Nothing in this chapter's own derivations rests on an unstated result.

Remark 32.2 (Units, and the honest reading of a dimensionless model). The dynamical systems of this subject are almost always written down in dimensionless form—the Lorenz equations, the logistic map, the standard map—and the temptation is to treat the resulting numbers as if they were physical. They are not, and this chapter never quotes one as if it were. Every model below is introduced first in SI variables and then reduced by an *explicit*

scaling, stated in full, so that each dimensionless parameter can be read back as a ratio of measured quantities: the Lorenz σ is the Prandtl number ν/κ of the fluid, its r is the Rayleigh number in units of its critical value, the standard map's K is $K'T^2/I$ built from a kick energy, a kick period and a moment of inertia. Measured quantities—Lyapunov times, cell temperatures, dimensions of attractors reconstructed from data—carry SI units and uncertainties throughout.

32.1 Flows in phase space

32.1.1 Dynamical systems, flows and maps

The object of study is a first-order autonomous system of ordinary differential equations. Any higher-order system is brought to this form by taking the derivatives as further coordinates, and any explicitly time-dependent system by taking the time itself as a further coordinate, so nothing is lost by the restriction.

Definition 32.3 (Dynamical system, phase space, flow)**.** A *continuous dynamical system* on a phase space $U \subseteq \mathbb{R}^n$ is an autonomous first-order system

$$\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}), \qquad \boldsymbol{x} \in U \subseteq \mathbb{R}^n, \tag{32.1}$$

with $\boldsymbol{f}$ continuously differentiable. If $\boldsymbol{x}$ carries the SI units of its physical coordinates, $\boldsymbol{f}$ carries those units divided by s. The *flow* is the map $\varphi_t(\boldsymbol{x}_0) = \boldsymbol{x}(t)$ carrying an initial state to the state t later. A *discrete* dynamical system is an iterated map $\boldsymbol{x}_{n+1} = \boldsymbol{P}(\boldsymbol{x}_n)$; the two are connected by Definition 32.38 below.

Rests on Definitions 9.1 and 13.82.

Proposition 32.4 (The flow is a one-parameter group)**.** *Wherever solutions of Equation* (32.1) *exist for all the times involved,*

$$\varphi_0 = \mathrm{id}, \qquad \varphi_t \circ \varphi_s = \varphi_{t+s}, \qquad \varphi_t^{-1} = \varphi_{-t}. \tag{32.2}$$

Rests on Definition 32.3 and Theorem 9.8.

Proof. *Derives Proposition 32.4.*

Fix $\boldsymbol{x}_0$ and set $\boldsymbol{y}(t) = \varphi_t(\varphi_s(\boldsymbol{x}_0))$ and $\boldsymbol{z}(t) = \varphi_{t+s}(\boldsymbol{x}_0)$. Both solve Equation (32.1)—the second because the system is autonomous, so a time-translated solution is again a solution—and both take the value $\varphi_s(\boldsymbol{x}_0)$ at $t = 0$. Since $\boldsymbol{f}$ is continuously differentiable it is locally Lipschitz (Definition 9.4), so by Picard–Lindelöf (Theorem 9.8) the initial value problem has exactly one solution and $\boldsymbol{y} = \boldsymbol{z}$. The remaining two statements are the cases $s = 0$ and $s = -t$. □

Corollary 32.5 (Trajectories do not cross)**.** *Two distinct trajectories of Equation* (32.1) *never meet, and a single trajectory never crosses itself: a trajectory that returns to a point it has already visited is a closed orbit, traversed periodically forever.*

Rests on Proposition 32.4 and Theorem 9.8.

Proof. *Derives Corollary 32.5.*

If two trajectories shared a point $\boldsymbol{p}$ at times t_1 and t_2, then by Proposition 32.4 each is the flow of $\boldsymbol{p}$ time-translated, hence they are the same trajectory. If one trajectory has $\boldsymbol{x}(t_0+T) = \boldsymbol{x}(t_0)$ with $T > 0$, then φ_T fixes $\boldsymbol{x}(t_0)$ and, by the group property, $\varphi_{t+T} = \varphi_t \circ \varphi_T$ agrees with φ_t on that point for every t: the solution is T-periodic. □

This is why phase portraits in the plane are so rigid, and it is the first hint of the dimension counting that runs through the whole chapter: a bounded, non-self-intersecting curve in a plane has very few places to go.

Theorem 32.6 (Evolution of phase volume)**.** *Let $V(t)$ be the volume of the image $\varphi_t(V_0)$ of a region V_0 of phase space carried along by the flow Equation (32.1). Then*

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \int_{V(t)} \boldsymbol{\nabla}\cdot\boldsymbol{f}\,\mathrm{d}^n x\,. \tag{32.3}$$

Rests on Definition 32.3 and Theorem 7.101.

Proof. *Derives Theorem 32.6.*

In a time $\mathrm{d}t$ a surface element $\mathrm{d}\boldsymbol{S}$ of the boundary is swept through the displacement $\boldsymbol{f}\,\mathrm{d}t$, so it contributes $\boldsymbol{f}\cdot\mathrm{d}\boldsymbol{S}\,\mathrm{d}t$ to the enclosed volume. Summing over the boundary,

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \oint_{\partial V} \boldsymbol{f}\cdot\mathrm{d}\boldsymbol{S}\,,$$

and the divergence theorem (Theorem 7.101) converts the surface integral into Equation (32.3). □

Definition 32.7 (Conservative and dissipative flows)**.** A flow is *volume-preserving*, or *conservative*, where $\boldsymbol{\nabla}\cdot\boldsymbol{f} = 0$, and *dissipative* where $\boldsymbol{\nabla}\cdot\boldsymbol{f} < 0$ throughout the region of interest.

Rests on Theorem 32.6.

Hamiltonian flows are conservative: that is exactly Liouville's theorem (Theorem 24.21), $\operatorname{div} X_{\mathcal{H}} = 0$, and it is what makes the Hamiltonian chaos of Section 32.4 qualitatively different from the dissipative chaos of Section 32.5. A Hamiltonian system can have no attractor at all, because an attractor would be a set of smaller volume than its basin.

Definition 32.8 (Attractor and basin)**.** A compact set A invariant under the flow is an *attractor* if it has a neighbourhood B every point of which is carried into A—$\varphi_t(\boldsymbol{x}) \to A$ as $t \to \infty$ for all $\boldsymbol{x} \in B$—and if A contains a dense orbit, so that it cannot be split into two smaller attractors. The largest such B is the *basin of attraction* of A.

Rests on Definitions 6.9 and 32.3.

Remark 32.9 (The dimension count that locates chaos). Three facts together fix where chaos can live. A one-dimensional flow $\dot{x} = f(x)$ is monotone between its fixed points, so every bounded solution converges to one of them. A two-dimensional flow is confined by Poincaré–Bendixson (Theorem 32.30) to fixed points and closed orbits. Only from three dimensions on can a bounded trajectory avoid both without crossing itself, which by Corollary 32.5 it must. For *maps* the count is one lower, because a map's orbit is a sequence of points and has nothing to cross: a one-dimensional map can already be chaotic, which is what makes the logistic map of Section 32.6.1 the cheapest laboratory in the subject.

The programme itself—study the geometry of the family of solutions rather than hunt for a formula for one of them—is Poincaré's, set out in the memoir on curves defined by a differential equation [216] and carried into celestial mechanics in [247, 255].

32.1.2 Fixed points and Lyapunov stability

Definition 32.10 (Fixed point)**.** A *fixed point* (equilibrium, critical point) of Equation (32.1) is a point $\boldsymbol{x}^*$ with $\boldsymbol{f}(\boldsymbol{x}^*) = \boldsymbol{0}$. It is a trajectory in its own right: $\varphi_t(\boldsymbol{x}^*) = \boldsymbol{x}^*$ for all t.

Rests on Definition 32.3.

Definition 32.11 (Lyapunov stability)**.** A fixed point $\boldsymbol{x}^*$ is *stable in the sense of Lyapunov* if for every $\varepsilon > 0$ there is a $\delta > 0$ such that $|\boldsymbol{x}_0 - \boldsymbol{x}^*| < \delta$ implies $|\varphi_t(\boldsymbol{x}_0) - \boldsymbol{x}^*| < \varepsilon$ for all $t \geq 0$; it is *asymptotically stable* if in addition $\varphi_t(\boldsymbol{x}_0) \to \boldsymbol{x}^*$; and *unstable* otherwise [253].

Rests on Definition 32.10.

The two conditions are independent and both are needed. A point can be stable without being asymptotically stable—the centre of a frictionless oscillator, whose neighbours orbit it forever without approaching—and, less obviously, a point can attract every nearby trajectory while failing to be stable, if the approach takes the trajectory far away first.

Definition 32.12 (Linearization)**.** Write $\boldsymbol{x} = \boldsymbol{x}^* + \delta\boldsymbol{x}$. Taylor's theorem (Theorem 7.38) applied to each component of $\boldsymbol{f}$ gives

$$\dot{\delta\boldsymbol{x}} = A\,\delta\boldsymbol{x} + \mathcal{O}(|\delta\boldsymbol{x}|^2)\,, \qquad A_{ij} = \left.\frac{\partial f_i}{\partial x_j}\right|_{\boldsymbol{x}^*}, \tag{32.4}$$

in which A is the *Jacobian matrix* of $\boldsymbol{f}$ at $\boldsymbol{x}^*$, with SI units of 1/s. The fixed point is *hyperbolic* if no eigenvalue of A has zero real part.

Rests on Definition 32.10 and Theorem 7.38.

Theorem 32.13 (Linear stability)**.** *Let A be diagonalizable with eigenvalues $\lambda_1, \dots, \lambda_n$. If $\Re\lambda_i < 0$ for every i, then $\boldsymbol{x}^*$ is asymptotically stable. If $\Re\lambda_i > 0$ for some i, then $\boldsymbol{x}^*$ is unstable.*

Rests on Definition 32.12 and Theorem 5.73.

Proof. *Derives Theorem 32.13.*

Consider first the linear system $\dot{\boldsymbol{y}} = A\boldsymbol{y}$ alone. Let $\{\boldsymbol{v}_i\}$ be a basis of eigenvectors (Definition 5.65), which exists by hypothesis (Theorem 5.73), and expand $\boldsymbol{y}_0 = \sum_i c_i \boldsymbol{v}_i$. Then

$$\boldsymbol{y}(t) = \sum_i c_i\, \mathrm{e}^{\lambda_i t}\, \boldsymbol{v}_i \tag{32.5}$$

satisfies the system—differentiate term by term and use $A\boldsymbol{v}_i = \lambda_i \boldsymbol{v}_i$—and takes the value $\boldsymbol{y}_0$ at $t = 0$; by Theorem 9.8 it is the only solution. Its norm is bounded by $C \max_i \mathrm{e}^{(\Re\lambda_i)t}\,|\boldsymbol{y}_0|$ with C the condition number of the eigenbasis, so every solution decays to zero when all $\Re\lambda_i < 0$, and the component along an eigenvector with $\Re\lambda_i > 0$ grows without bound.

The passage from the linear system to Equation (32.4) uses that the neglected terms are $\mathcal{O}(|\delta\boldsymbol{x}|^2)$: choosing δ small enough that the quadratic remainder is smaller than half the linear decay rate on the ball of radius δ, the norm is still strictly decreasing there, which gives both conditions of Definition 32.11. The instability statement follows from the same estimate applied on the unstable eigendirection. □

Remark 32.14 (Two pieces of mathematics quoted here)*.* Theorem 32.13 was stated for diagonalizable A because that is the case Part II supports. The general case—A with a non-trivial Jordan block, whose solutions carry polynomial prefactors $t^k \mathrm{e}^{\lambda t}$—needs the Jordan normal form, which Chapter 5 does not contain. Nothing in this chapter uses the degenerate case: every Jacobian evaluated below is diagonalizable at the parameter values quoted.

Theorem 32.15 (Hartman–Grobman, restated from Part II)**.** *Near a hyperbolic fixed point the flow of Equation (32.1) is topologically conjugate to the flow of its linearization Equation (32.4): there is a homeomorphism of a neighbourhood of $\boldsymbol{x}^*$ onto a neighbourhood of the origin carrying trajectories of the one onto trajectories of the other and preserving both the direction and the parametrization of time [1183]; in particular the fixed point is unstable whenever some eigenvalue of the Jacobian has positive real part. This is Theorem 9.32, written in the notation of this chapter.*

Rests on Theorem 9.32 and Definitions 6.7 and 32.12.

Remark 32.16 (Hartman–Grobman is quoted, not proved)*.* Theorem 32.15 is a theorem of ordinary differential equations and belongs with the Picard–Lindelöf theory of Chapter 9, which states it as Theorem 9.32 and records there, in Remark 9.33, why it is quoted rather

than derived. It is restated here because it is what licenses reading a phase portrait off the eigenvalues, and it is used below only in that qualitative role. Its content is exactly that linearization is trustworthy *and no more than that*: the conjugacy is a homeomorphism, not a diffeomorphism, so it preserves the topology of the portrait—which trajectories go where—but not rates or angles, and it says nothing at all at a non-hyperbolic point. Every bifurcation in Section 32.1.3 happens precisely at a non-hyperbolic point, which is why bifurcation theory cannot be done by linearization alone.

Proposition 32.17 (Classification of planar fixed points)**.** *For $n = 2$ write $\tau = \operatorname{tr} A$ and $\Delta = \det A$. The eigenvalues are*

$$\lambda_{\pm} = \tfrac{1}{2}\left(\tau \pm \sqrt{\tau^2 - 4\Delta}\right), \tag{32.6}$$

and the fixed point is classified as in Table 32.1.

Rests on Definition 32.12 and Theorem 5.67.

Proof. *Derives Proposition 32.17.*

The characteristic polynomial of a 2×2 matrix is $\lambda^2 - \tau\lambda + \Delta$, whose roots (Theorem 5.67) are Equation (32.6). If $\Delta < 0$ the discriminant exceeds τ^2, so the roots are real with opposite signs: a saddle, unstable in one direction and stable in the other. If $\Delta > 0$ and $\tau^2 > 4\Delta$ the roots are real with the sign of τ: a node. If $\Delta > 0$ and $\tau^2 < 4\Delta$ they are a complex conjugate pair with real part $\tau/2$: a focus, spiralling in for $\tau < 0$ and out for $\tau > 0$. If $\tau = 0$ and $\Delta > 0$ they are purely imaginary and the linearized orbits are closed: a centre. Theorem 32.13 then assigns the stabilities. □

Table 32.1: Classification of a hyperbolic fixed point of a planar flow by the trace τ and determinant Δ of its Jacobian, from Equation (32.6). The last row is the one case in which the linearization decides nothing—see Example 32.18.

Condition	Type	Stability
$\Delta < 0$	saddle	unstable
$\Delta > 0$, $\tau^2 > 4\Delta$, $\tau < 0$	node	asymptotically stable
$\Delta > 0$, $\tau^2 > 4\Delta$, $\tau > 0$	node	unstable
$\Delta > 0$, $\tau^2 < 4\Delta$, $\tau < 0$	focus	asymptotically stable
$\Delta > 0$, $\tau^2 < 4\Delta$, $\tau > 0$	focus	unstable
$\Delta > 0$, $\tau = 0$	centre (linear)	undecided

Example 32.18 (A linear centre that is really a stable focus)**.** Take

$$\dot{x} = -y - x^3, \qquad \dot{y} = x - y^3.$$

The Jacobian at the origin is $A = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$, with $\tau = 0$ and $\Delta = 1$: a linear centre. But with $\rho = \tfrac{1}{2}(x^2 + y^2)$,

$$\dot{\rho} = x\dot{x} + y\dot{y} = x(-y - x^3) + y(x - y^3) = -\left(x^4 + y^4\right) < 0$$

everywhere except the origin, so every trajectory spirals in and the origin is asymptotically stable. Changing the sign of the cubic terms makes it unstable, again without touching A. A centre is not hyperbolic, so Theorem 32.15 does not apply, and this is what its hypothesis is protecting against.

Rests on Proposition 32.17 and Theorem 32.15.

Lyapunov's second, or *direct*, method dispenses with linearization altogether [253]. It is the method that survives at a non-hyperbolic point, and in mechanics it is usually the energy.

Definition 32.19 (Lyapunov function)**.** A continuously differentiable V on a neighbourhood N of a fixed point $\boldsymbol{x}^*$ is a *Lyapunov function* if $V(\boldsymbol{x}^*) = 0$, $V > 0$ on $N \setminus \{\boldsymbol{x}^*\}$, and

$$\dot{V} = \boldsymbol{\nabla} V \cdot \boldsymbol{f} \leq 0 \qquad \text{on } N\,. \tag{32.7}$$

It is *strict* if the inequality is strict off $\boldsymbol{x}^*$.

Rests on Definitions 7.65 and 32.10.

Theorem 32.20 (Lyapunov's direct method)**.** *If a Lyapunov function exists on N then $\boldsymbol{x}^*$ is stable; if it is strict, $\boldsymbol{x}^*$ is asymptotically stable.*

Rests on Definitions 32.11 and 32.19.

Proof. *Derives Theorem 32.20.*

Given $\varepsilon > 0$, choose the ball $B_\varepsilon \subseteq N$ and let $m = \min\{V(\boldsymbol{x}) : |\boldsymbol{x} - \boldsymbol{x}^*| = \varepsilon\}$, which is positive because V is positive and continuous on a compact set (Theorem 7.24). By continuity there is $\delta > 0$ with $V < m$ on the ball of radius δ. By Equation (32.7) V never increases along a trajectory, so a trajectory starting inside that ball can never reach the sphere of radius ε, on which $V \geq m$: that is stability. If $\dot{V} < 0$ strictly, then V decreases monotonically along the trajectory and is bounded below, so it converges to some $V_\infty \geq 0$; were $V_\infty > 0$, the trajectory would remain in the compact annulus $\{V_\infty \leq V \leq V(\boldsymbol{x}_0)\}$ on which $\dot{V} \leq -c < 0$, forcing V to fall below V_∞ in finite time. Hence $V_\infty = 0$ and $\boldsymbol{x} \to \boldsymbol{x}^*$. □

Example 32.21 (The damped pendulum)**.** A pendulum of mass m and length ℓ with linear viscous damping of coefficient b (SI units $\mathrm{kg\,m^2/s}$) obeys

$$m\ell^2\ddot{\theta} + b\dot{\theta} + mg\ell\sin\theta = 0\,. \tag{32.8}$$

Take V to be the mechanical energy measured from the hanging position,

$$V = \tfrac{1}{2}m\ell^2\dot{\theta}^2 + mg\ell\,(1 - \cos\theta)\ ,$$

which is positive for $0 < |\theta| < \pi$ and vanishes at the fixed point $(\theta, \dot{\theta}) = (0, 0)$. Differentiating along Equation (32.8),

$$\dot{V} = m\ell^2\dot{\theta}\ddot{\theta} + mg\ell\dot{\theta}\sin\theta = -b\dot{\theta}^2 \leq 0\,,$$

so the hanging position is stable by Theorem 32.20. The inequality is not strict—it fails on the whole line $\dot{\theta} = 0$—so asymptotic stability needs the extra remark that the only trajectory lying entirely in $\{\dot{\theta} = 0\}$ is the fixed point itself, since Equation (32.8) then forces $\sin\theta = 0$. With $b = 0$ the energy is exactly conserved, V is a first integral, and the fixed point is a centre: the isochronous small oscillation of Chapter 28, measured in Chapter 34.

Rests on Theorem 32.20 and Equation (28.8).

32.1.3 Bifurcations

Definition 32.22 (Bifurcation)**.** Let $\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}; \mu)$ depend on a control parameter μ. A *bifurcation* occurs at $\mu = \mu_c$ if the qualitative structure of the phase portrait—the number, type or stability of its invariant sets—differs on the two sides of μ_c. By Theorem 32.15 this can happen only where some fixed point or periodic orbit fails to be hyperbolic.

Rests on Definition 32.3 and Theorem 32.15.

The one-dimensional bifurcations come in three normal forms, and the list is short for a reason: expanding $f(x; \mu)$ about the non-hyperbolic point and discarding what does not matter leaves only these possibilities.

Proposition 32.23 (Saddle-node bifurcation)**.** *The system $\dot{x} = \mu - x^2$ has two fixed points $x^* = \pm\sqrt{\mu}$ for $\mu > 0$, of which $+\sqrt{\mu}$ is stable and $-\sqrt{\mu}$ unstable; they merge at $\mu = 0$ and there is no fixed point for $\mu < 0$. The distance between them grows as $\sqrt{\mu}$, and the relaxation rate towards the stable one vanishes as $\sqrt{\mu}$.*

Rests on Definition 32.22 and Theorem 32.13.

Proof. *Derives Proposition 32.23.*

$\mu - x^2 = 0$ has the two real roots $\pm\sqrt{\mu}$ for $\mu > 0$, a double root at $\mu = 0$ and none for $\mu < 0$. The linearization is $f'(x) = -2x$, equal to $-2\sqrt{\mu} < 0$ at $+\sqrt{\mu}$ and $+2\sqrt{\mu} > 0$ at $-\sqrt{\mu}$; Theorem 32.13 in one dimension gives the two stabilities and identifies $2\sqrt{\mu}$ as the relaxation rate, which vanishes at the bifurcation. The slowing down at $\mu \to 0^+$ is generic and observable: it is the *critical slowing down* that announces a saddle-node in a real system before the fixed points actually collide. □

Proposition 32.24 (Transcritical and pitchfork bifurcations)**.** *(i) $\dot{x} = \mu x - x^2$ has fixed points $x^* = 0$ and $x^* = \mu$ for all μ; they exchange stability at $\mu = 0$. (ii) $\dot{x} = \mu x - x^3$ has the single fixed point $x^* = 0$, stable, for $\mu < 0$, and for $\mu > 0$ has $x^* = 0$ unstable together with a symmetric pair $x^* = \pm\sqrt{\mu}$, both stable (*supercritical *pitchfork). (iii) $\dot{x} = \mu x + x^3$ has an unstable pair $x^* = \pm\sqrt{-\mu}$ for $\mu < 0$ which annihilates the stable origin at $\mu = 0$, leaving nothing stable beyond (*subcritical *pitchfork).*

Rests on Definition 32.22 and Theorem 32.13.

Proof. *Derives Proposition 32.24.*

(i) $x(\mu - x) = 0$ gives the two branches; $f'(x) = \mu - 2x$ equals μ at the origin and $-\mu$ at $x^* = \mu$, so the signs are opposite on either side of $\mu = 0$ and the stabilities are exchanged there. (ii) $x(\mu - x^2) = 0$ gives the origin always and $\pm\sqrt{\mu}$ for $\mu > 0$; $f'(x) = \mu - 3x^2$ equals μ at the origin and $-2\mu < 0$ on the outer pair. (iii) is (ii) with $x^3 \to -x^3$: $f' = \mu + 3x^2$ equals μ at the origin and $-2\mu > 0$ on the pair, which therefore exists only for $\mu < 0$ and is unstable. □

The distinction in Proposition 32.24 between the supercritical and subcritical cases is the whole practical content of bifurcation theory in the laboratory. A supercritical transition is continuous and reversible: the new state grows out of the old like $\sqrt{\mu - \mu_c}$, and sweeping the parameter back retraces the same curve. A subcritical transition is discontinuous and hysteretic: the old state loses stability with nothing nearby to fall onto, the system jumps to a distant state, and it stays there when the parameter is swept back past μ_c. Euler buckling (Phenomenon 30.52) is the textbook supercritical pitchfork, its symmetry being the left–right symmetry of the strut; the loss of the convecting rolls in Section 32.5.1 is subcritical, and that is why the Lorenz trajectory has nowhere local to go.

Theorem 32.25 (Hopf bifurcation, quoted)**.** *Let $\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}; \mu)$ in $\mathbb{R}^2$ have a fixed point whose Jacobian has a complex conjugate pair of eigenvalues $\lambda_\pm(\mu) = \alpha(\mu) \pm \mathrm{i}\omega(\mu)$ with $\alpha(\mu_c) = 0$, $\omega(\mu_c) \neq 0$ and $\alpha'(\mu_c) \neq 0$. Then, generically, a one-parameter family of periodic orbits is born at μ_c, of period tending to $2\pi/\omega(\mu_c)$ and of amplitude growing as $\sqrt{|\mu - \mu_c|}$ [866].*

Rests on Proposition 32.17 and Definition 32.22.

Proposition 32.26 (The Hopf normal form)**.** *In polar coordinates the normal form of a Hopf bifurcation is*

$$\dot{\rho} = \mu\rho - a\rho^3\,, \qquad \dot{\vartheta} = \omega + b\rho^2\,. \tag{32.9}$$

For $a > 0$ (supercritical) a stable limit cycle of radius $\rho^* = \sqrt{\mu/a}$ exists for $\mu > 0$; for $a < 0$ (subcritical) an unstable cycle of radius $\sqrt{\mu/a}$ exists for $\mu < 0$ and there is nothing local beyond $\mu = 0$.

Rests on Theorem 32.25.

Proof. *Derives Proposition 32.26.*

The radial equation is decoupled and is exactly the pitchfork of Proposition 32.24 restricted to $\rho > 0$: its non-zero fixed point is $\rho^* = \sqrt{\mu/a}$ and its linearization there is $\mu - 3a\rho^{*2} = -2\mu$, negative for $\mu > 0$ when $a > 0$. The angular equation then gives a periodic orbit of angular frequency $\omega + b\mu/a$, which tends to ω as $\mu \to 0$. The $\sqrt{\mu}$ growth of the amplitude in Theorem 32.25 is the $\sqrt{\mu/a}$ here. □

Remark 32.27 (What the Hopf theorem adds, and where its proof lives). Proposition 32.26 is an exact statement about Equation (32.9); Theorem 32.25 is the assertion that a general system satisfying the eigenvalue conditions can be brought to that form by a smooth change of coordinates near the fixed point. That reduction is a theorem of normal-form theory and belongs with the ordinary-differential-equation material of Chapter 9; it is quoted here from [866]. It also requires the implicit function theorem, to follow the fixed point as μ varies; that one *is* available, as Theorem A.286, so the normal-form reduction is the only piece owed. Every Hopf bifurcation located in this chapter is located by the eigenvalue condition $\alpha(\mu_c) = 0$ directly, computed from the actual Jacobian, so none of the derivations below depends on the reduction.

Remark 32.28 (Structural stability and the bifurcation diagram). A system is *structurally stable* if every sufficiently small smooth perturbation of $\boldsymbol{f}$ has a topologically conjugate phase portrait. Hyperbolic fixed points and hyperbolic limit cycles are structurally stable, by Theorem 32.15 and its analogue for periodic orbits; centres and the exact normal forms above are not, which is why a bifurcation is a codimension-one event—it is seen by sweeping one parameter, and not otherwise. What is plotted against that parameter is the *bifurcation diagram*: the location and stability of every invariant set as a function of μ. It is the experimental deliverable of the whole subject. Every measurement in Section 32.7 is a bifurcation diagram in disguise—the Rayleigh number swept in a convection cell, the rotation rate in a Couette cell, the drive amplitude in a circuit—and the universal numbers of Section 32.6.2 are properties of its geometry, not of the system that produced it.

32.2 Limit cycles

32.2.1 The Poincaré–Bendixson theorem

Definition 32.29 (Limit cycle)**.** A *limit cycle* is an isolated closed orbit: a periodic trajectory some neighbourhood of which contains no other closed orbit. It is *attracting* (stable) if all nearby trajectories approach it as $t \to +\infty$, and repelling if they do so as $t \to -\infty$.

Rests on Corollary 32.5 and Definition 32.8.

The isolation is the whole point, and it is what separates a limit cycle from the continuous family of closed orbits surrounding a centre. A conservative system has families; only a system that dissipates in one region and pumps in another can have an isolated one. Limit cycles were named and first analysed in the second instalment of Poincaré's memoir [220].

Theorem 32.30 (Poincaré–Bendixson, restated from Part II)**.** *Let $\boldsymbol{f}$ be continuously differentiable on an open subset of the plane, and let a trajectory of Equation (32.1) remain, for all $t \geq t_0$, inside a compact region containing no fixed point. Then that trajectory either is a closed orbit or approaches one [220, 298]. This is Theorem 9.34, written in the notation of this chapter.*

Rests on Theorem 9.34, Corollary 32.5, and Definition 6.9.

Remark 32.31 (Poincaré–Bendixson is quoted, not proved). The proof is planar topology—a transversal segment, and the Jordan curve theorem, from which the monotonicity of

successive crossings along that segment follows because a trajectory arc together with the chord joining its ends bounds a region the flow cannot re-enter—and it is mathematics that belongs with the ordinary differential equations of Chapter 9, which states it as Theorem 9.34 and sets out in Remark 9.35 exactly which planar facts the proof rests on and which of them this treatise does not carry. It is restated here because the entire architecture of this chapter rests on its corollary: the theorem is what makes the plane too small for chaos, and therefore what sends the subject into three dimensions and into maps.

Corollary 32.32 (No chaos in a planar flow)**.** *A bounded trajectory of a continuously differentiable autonomous flow in the plane cannot be chaotic: as $t \to \infty$ it converges to a fixed point, to a closed orbit, or to a cycle of connecting trajectories between fixed points. Deterministic chaos in a continuous autonomous flow therefore requires at least three phase-space dimensions.*

Rests on Theorem 32.30 and Remark 32.9.

Proof. *Derives Corollary 32.32.*

A bounded trajectory has compact closure. If that closure contains no fixed point, Theorem 32.30 gives convergence to a closed orbit. If it contains fixed points, the limit set consists of those fixed points together with trajectories connecting them, since by Corollary 32.5 nothing else can accumulate without self-intersection in a plane. In neither case do nearby trajectories separate exponentially forever while remaining bounded, which is what Phenomenon 32.72 requires. In three dimensions the argument fails at its first step: a curve may wander indefinitely in a bounded region without crossing itself, because the plane no longer separates it. □

Proposition 32.33 (Bendixson's negative criterion)**.** *If $\boldsymbol{\nabla}\cdot\boldsymbol{f}$ has one strict sign throughout a simply connected region D of the plane, then Equation (32.1) has no closed orbit lying entirely in D [298].*

Rests on Theorem 7.99 and Definition 6.17.

Proof. *Derives Proposition 32.33.*

Let C be a closed orbit in D bounding the region S. Green's theorem (Theorem 7.99) gives

$$\int_S \boldsymbol{\nabla}\cdot\boldsymbol{f}\,\mathrm{d}^2x = \oint_C (f_1\,\mathrm{d}x_2 - f_2\,\mathrm{d}x_1) = \oint_C (f_1\dot{x}_2 - f_2\dot{x}_1)\,\mathrm{d}t = 0\,,$$

because $\dot{x}_1 = f_1$ and $\dot{x}_2 = f_2$ on the orbit make the integrand vanish identically. The left-hand side cannot be zero if the integrand has one strict sign, so no such C exists. The criterion is only negative: it excludes cycles, it never produces one—for that one needs a trapping region and Theorem 32.30. □

Remark 32.34 (Index arguments). A second exclusion principle is topological. The *index* of a closed curve C containing no fixed point is the winding number (Definition 6.20) of the vector field $\boldsymbol{f}$ around it; it is an integer, unchanged by continuous deformation of C (Lemma 6.22), equal to $+1$ for a node, focus or centre and -1 for a saddle, and it is the sum of the indices of the fixed points enclosed. Since a closed orbit is everywhere tangent to $\boldsymbol{f}$, its own index is $+1$. Hence every closed orbit encloses at least one fixed point, and the fixed points it encloses have indices summing to $+1$: a limit cycle cannot surround a single saddle and nothing else, and it cannot lie in a region with no fixed point at all.

32.2.2 Relaxation oscillations: van der Pol

The paradigm of a system with a limit cycle came from radio engineering. A triode circuit in which the effective resistance is negative at small amplitude and positive at large amplitude

obeys, for the voltage v across the tuned circuit,

$$\ddot{v} - \alpha\left(1 - \frac{v^2}{v_0^2}\right)\dot{v} + \omega_0^2 v = 0\,, \qquad \omega_0^2 = \frac{1}{LC}\,, \tag{32.10}$$

in which α has SI units 1/s, v_0 is the voltage at which the damping changes sign, and ω_0 is the resonant angular frequency of the inductance L and capacitance C [555]. Scaling to the dimensionless amplitude $u = v/v_0$ and the dimensionless time $s = \omega_0 t$ puts it in the form used everywhere below,

$$\frac{\mathrm{d}^2 u}{\mathrm{d}s^2} - \varepsilon\left(1 - u^2\right)\frac{\mathrm{d}u}{\mathrm{d}s} + u = 0\,, \qquad \varepsilon = \frac{\alpha}{\omega_0}\,, \tag{32.11}$$

with the single dimensionless control parameter ε. Every statement made about Equation (32.11) converts back by $v = v_0 u$ and $t = s/\omega_0$.

Phenomenon 32.35 (Self-sustained oscillation)**.** A triode circuit whose damping changes sign with amplitude settles into a periodic oscillation whose amplitude and period belong to the circuit alone: started from an arbitrarily small disturbance the oscillation grows until it reaches that amplitude, and started from a larger one it decays to the same amplitude [555]. This is qualitatively unlike the linear oscillator of Chapter 28, whose amplitude is set by the initial conditions and is therefore arbitrary, and unlike a driven resonance, since nothing periodic is applied. In the strongly nonlinear regime the waveform is not sinusoidal at all but a relaxation oscillation of slow charging and abrupt discharge, whose period is set by the slow stage and so scales with the nonlinearity rather than with the resonant frequency of the circuit [555].

Rests on Equation (32.10) *and Definition 32.29.*

Derivation. *Derives Phenomenon 32.35.*

Weak nonlinearity. For $\varepsilon \ll 1$ write Equation (32.11) as a perturbed harmonic oscillator and follow the energy $E = \tfrac{1}{2}(\dot{u}^2 + u^2)$, where the overdot now means $\mathrm{d}/\mathrm{d}s$. Along a solution,

$$\dot{E} = \dot{u}\ddot{u} + u\dot{u} = \varepsilon\left(1 - u^2\right)\dot{u}^2\,. \tag{32.12}$$

Over one cycle the solution is nearly $u = a\cos\psi$ with $\dot{u} = -a\sin\psi$ and ψ advancing by 2π, so averaging Equation (32.12) with $\langle\sin^2\psi\rangle = \tfrac{1}{2}$ and $\langle\cos^2\psi\sin^2\psi\rangle = \tfrac{1}{8}$ gives

$$\left\langle \dot{E} \right\rangle = \varepsilon\left(\frac{a^2}{2} - \frac{a^4}{8}\right)\,,$$

and since $E = a^2/2$ this is an equation for the slowly varying amplitude,

$$\frac{\mathrm{d}a}{\mathrm{d}s} = \frac{\varepsilon a}{2}\left(1 - \frac{a^2}{4}\right)\,. \tag{32.13}$$

Equation (32.13) is the supercritical pitchfork of Proposition 32.24 in the radial variable: for any $a > 0$ the amplitude moves monotonically to $a = 2$, from below if it starts below and from above if it starts above. That is exactly the observation, and in physical variables the cycle has amplitude $v = 2v_0$—twice the voltage at which the damping changes sign, independent of how the oscillation was started and independent of α. Its angular frequency is ω_0 to leading order.

Strong nonlinearity. For $\varepsilon \gg 1$ use the Liénard variable $w = \dot{u}/\varepsilon + F(u)$ with $F(u) = u^3/3 - u$, which turns Equation (32.11) into the first-order pair

$$\dot{u} = \varepsilon\left(w - F(u)\right)\,, \qquad \dot{w} = -\frac{u}{\varepsilon}\,. \tag{32.14}$$

Since ε is large, u moves fast unless $w \approx F(u)$; the trajectory therefore jumps horizontally onto a branch of the cubic $w = F(u)$ in a time of order ε^{-1} and then crawls along it. A branch is attracting when $\partial\dot{u}/\partial u = -\varepsilon F'(u)$ is negative, that is when $F'(u) = u^2 - 1 > 0$: the two outer branches $u > 1$ and $u < -1$. On such a branch $\dot{w} = F'(u)\dot{u} = (u^2 - 1)\dot{u}$ equals $-u/\varepsilon$, so

$$\frac{\mathrm{d}s}{\mathrm{d}u} = -\frac{\varepsilon\,(u^2 - 1)}{u}\,.$$

On the branch $u > 1$ the trajectory enters at $u = 2$—where the previous jump deposited it, since $F(2) = F(-1) = 2/3$—and creeps down to the fold at $u = 1$, at which the branch turns and it jumps across to $u = -2$, because $F(-2) = F(1) = -2/3$. The time for one slow stage is therefore

$$s_{\mathrm{slow}} = \varepsilon \int_1^2 \frac{u^2 - 1}{u}\,\mathrm{d}u = \varepsilon \left[\frac{u^2}{2} - \ln u\right]_1^2 = \varepsilon\left(\frac{3}{2} - \ln 2\right).$$

By the symmetry $u \to -u$, $w \to -w$ of Equation (32.14) the cycle consists of two such stages and two jumps, and the jumps together with the turning regions at the folds contribute only at order $\varepsilon^{-1/3}$. Hence

$$s_{\mathrm{period}} = (3 - 2\ln 2)\,\varepsilon + \mathcal{O}(\varepsilon^{-1/3})\,, \qquad T = \frac{(3 - 2\ln 2)\,\alpha}{\omega_0^2}\,, \tag{32.15}$$

using $3 - 2\ln 2 = 1.6137$. The physical period grows in proportion to the nonlinearity α and falls as the *inverse square* of the resonant angular frequency—it is not the resonant period $2\pi/\omega_0$ at all, which is the observation stated. The waveform is likewise not sinusoidal: two slow ramps of duration $\propto \varepsilon$ separated by jumps of duration $\propto \varepsilon^{-1}$. □

Remark 32.36 (Existence and uniqueness of the cycle). The derivation above establishes the cycle asymptotically at each end of the range of ε. That Equation (32.11) has exactly one closed orbit, attracting every trajectory but the fixed point at the origin, and for *every* $\varepsilon > 0$, is Liénard's theorem (A. Liénard, *Revue générale de l'électricité* **23** (1928) 901–912 and 946–954). **That paper is not in this bibliography and the statement is therefore uncited here**; the reader should treat the global uniqueness as quoted, while the amplitude Equation (32.13) and the period Equation (32.15) are derived above and stand on their own. Note that the key entry `Lienard:1898` in this bibliography is Liénard's electrodynamics paper on the potentials of a moving charge, a different work by the same author, and must not be cited for this theorem.

Phenomenon 32.37 (Frequency demultiplication and the first heard chaos)**.** A neon-tube relaxation oscillator driven by a sinusoidal voltage does not follow the drive: it locks to a submultiple of the drive frequency, and as a circuit parameter is varied smoothly the observed frequency descends in a staircase of whole-number ratios—van der Pol and van der Mark followed it from the fundamental down to one fortieth. At the transitions between two adjacent steps "often an irregular noise is heard in the telephone receivers before the frequency jumps to the next lower value" [590]. That noise is not a defect of the apparatus and not thermal: it is the first recorded laboratory encounter with deterministic chaos.

Rests on Phenomenon 32.35.

Derivation. *Derives Phenomenon 32.37.*

The staircase follows from the mechanism of the oscillator. A neon tube in parallel with a capacitance C charged through a resistance R from a supply V_s has capacitor voltage

$$v(t) = V_s + (V_e - V_s)\,\mathrm{e}^{-t/RC}$$

after each discharge, where V_e is the extinction voltage. The tube fires when v reaches the breakdown voltage V_b, so the free period is

$$T_0 = RC \ln\!\left(\frac{V_s - V_e}{V_s - V_b}\right), \tag{32.16}$$

proportional to C, which is the parameter van der Pol and van der Mark varied. Superposing a small sinusoidal voltage of period T_d modulates the instant at which the threshold is reached: the tube can only fire near a maximum of the drive, so the realized period is an integer multiple nT_d, with n the number of drive periods needed for the ramp to reach V_b. As C is increased, T_0 grows continuously by Equation (32.16) while n can only change by whole numbers, so the observed frequency $1/(nT_d)$ falls in steps: the demultiplication. Each step is a locked periodic orbit, stable over a finite interval of C—the entrainment band, or Arnold tongue, of Section 32.6.3.

The irregular noise sits at the boundaries, where two locking ratios n and $n+1$ are both marginal. There the return map of Section 32.3.1 has no stable fixed point of either period, and the sequence of firing phases neither repeats nor converges. The full account of that regime needs the circle map and is given in Section 32.6.3; what is derived here is the staircase, and the location of the noise at its risers. □

Entrainment of this kind is generic to limit-cycle oscillators and is the nonlinear counterpart of the linear resonance of Chapter 28: a linear oscillator responds at the drive frequency and at no other, whereas a limit-cycle oscillator has a frequency of its own and either captures the drive, is captured by it, or does neither.

32.3 Poincaré sections and discrete dynamics

32.3.1 The return map

Definition 32.38 (Poincaré section and return map)**.** Let Σ be a hypersurface of dimension $n-1$ in the phase space of Equation (32.1), transverse to the flow (that is, $\boldsymbol{f}$ is nowhere tangent to Σ). The *first-return*, or *Poincaré*, *map* $\boldsymbol{P} : \Sigma \to \Sigma$ sends a point $\boldsymbol{x} \in \Sigma$ to the point at which the trajectory through $\boldsymbol{x}$ next meets Σ in the same sense [255]. A fixed point of $\boldsymbol{P}$ is a periodic orbit of the flow; a period-k orbit of $\boldsymbol{P}$ is a periodic orbit piercing Σ k times.

Rests on Definition 32.3 and Corollary 32.5.

This is the device that trades a flow for a map one dimension down, and with it the whole theory of iterated maps becomes available for continuous systems. It is also what makes the numerics of the subject tractable and the figures readable: a three-dimensional flow becomes a scatter of points in a plane.

Proposition 32.39 (Stability of a periodic orbit)**.** *Let $\boldsymbol{x}^* \in \Sigma$ be a fixed point of $\boldsymbol{P}$ and let $\mu_1, \dots, \mu_{n-1}$ be the eigenvalues of $D\boldsymbol{P}(\boldsymbol{x}^*)$, the* characteristic multipliers *of the corresponding periodic orbit. If $|\mu_i| < 1$ for all i the orbit is asymptotically stable; if $|\mu_i| > 1$ for some i it is unstable.*

Rests on Definition 32.38 and Theorem 5.73.

Proof. *Derives Proposition 32.39.*

Linearizing $\boldsymbol{P}$ about $\boldsymbol{x}^*$ as in Definition 32.12 gives $\delta\boldsymbol{x}_{k+1} = D\boldsymbol{P}\,\delta\boldsymbol{x}_k$ to first order, so $\delta\boldsymbol{x}_k = (D\boldsymbol{P})^k \delta\boldsymbol{x}_0$. Expanding in an eigenbasis of $D\boldsymbol{P}$ the i-th component is μ_i^k times its initial value, which tends to zero for $|\mu_i| < 1$ and diverges for $|\mu_i| > 1$. The passage from the linearized map to the full one repeats the estimate at the end of the proof of Theorem 32.13, with the quadratic remainder dominated on a small enough neighbourhood. A multiplier crossing the unit circle is a bifurcation of the periodic orbit: at $\mu = +1$ a saddle-node

of cycles, at $\mu = -1$ a *period-doubling*—the orbit that will drive Section 32.6—and at a complex conjugate pair crossing, the birth of a two-torus. □

Proposition 32.40 (A Hamiltonian section preserves area)**.** *For an autonomous Hamiltonian system with two degrees of freedom, a Poincaré section taken inside a fixed energy surface has a two-dimensional return map that preserves area.*

Rests on Theorems 22.22 and 24.21.

Proof. *Derives Proposition 32.40.*

Take coordinates (q^1, p_1, q^2, p_2) and let Σ be the surface $q^2 = \text{const}$ within $\mathcal{H} = E$, coordinatized by (q^1, p_1). The flow is canonical, so by Poincaré's invariant (Theorem 22.22) the integral $\int \mathrm{d}q^a\,\mathrm{d}p_a$ over a two-surface carried by the flow is conserved. Take a tube of trajectories whose ends are two regions S_0 and $S_1 = \boldsymbol{P}(S_0)$ of Σ. On Σ the coordinate q^2 is constant, so $\mathrm{d}q^2 = 0$ there and the invariant reduces to $\int \mathrm{d}q^1\,\mathrm{d}p_1$; on the lateral surface of the tube the same invariant vanishes because the surface is generated by trajectories. Hence $\int_{S_0} \mathrm{d}q^1\,\mathrm{d}p_1 = \int_{S_1} \mathrm{d}q^1\,\mathrm{d}p_1$: the map preserves area. Liouville's theorem (Theorem 24.21) is the four-dimensional statement of which this is the section. □

Proposition 32.40 is the reason the surfaces of section of Section 32.4.4 look the way they do: an area-preserving map cannot have an attractor, so the points either lie on invariant curves or wander over an area, and never spiral into anything.

32.3.2 The Smale horseshoe and symbolic dynamics

Chaos in a map has a certified mechanism, and it is geometrical rather than analytical: stretch, fold, and put back.

Definition 32.41 (The horseshoe map)**.** Let Q be the unit square. The *horseshoe map* H stretches Q uniformly by a factor $\lambda > 2$ in one direction, contracts it by $\eta < 1/2$ in the other, bends the resulting strip into a horseshoe, and lays it back across Q so that $H(Q) \cap Q$ consists of two full horizontal strips [1359]. The *invariant set* is

$$\Lambda = \bigcap_{k=-\infty}^{\infty} H^k(Q)\,, \tag{32.17}$$

the set of points whose entire forward and backward orbit stays in Q.

Rests on Definition 32.3.

Theorem 32.42 (The horseshoe is a full shift, quoted)**.** *Λ is a compact, totally disconnected, perfect set—a Cantor set—and H restricted to Λ is topologically conjugate to the two-sided shift σ on the space Σ_2 of bi-infinite binary sequences, $(\sigma s)_k = s_{k+1}$, the conjugacy assigning to each point the record of which of the two strips its orbit occupies at each time [1359].*

Rests on Definitions 6.9 and 32.41.

Proposition 32.43 (What the shift does)**.** *The shift σ on Σ_2 has exactly 2^k points of period k for every $k \geq 1$, hence a countable infinity of periodic orbits; it has orbits that are dense in Σ_2; and it has sensitive dependence, two sequences agreeing on $|j| \leq N$ being separated after N steps.*

Rests on Theorem 32.42.

Proof. *Derives Proposition 32.43.*

A sequence with $\sigma^k s = s$ is determined by the k entries $s_0, \ldots, s_{k-1}$ and there are 2^k of these, each giving one such sequence. For a dense orbit, list the finite binary words in order of length—0, 1, 00, 01, 10, 11, 000, ...—and concatenate them into one half-infinite string, completing it to the left arbitrarily; some forward shift of the result begins with any prescribed finite word, and agreement on a long initial word is exactly closeness in Σ_2. For

sensitivity, take s and s' agreeing on $|j| \le N$ and differing at $j = N+1$: after $N+1$ shifts they differ in the zeroth place, which is the coarsest distinction the metric makes. Under the conjugacy of Theorem 32.42 every one of these statements is a statement about H on Λ. □

Remark 32.44 (Topological entropy, and where horseshoes come from). The count 2^k in Proposition 32.43 is the horseshoe's signature: the number of distinguishable orbit segments of length k grows like e^{hk} with $h = \ln 2$, and that exponential growth rate of distinguishable histories is the *topological entropy*. A positive topological entropy is one of the standard definitions of chaos, and for the horseshoe it is exact.

The reason the construction matters physically is that horseshoes are not rare. Wherever the stable and unstable manifolds of a saddle intersect transversally—a *transverse homoclinic point*—some iterate of the map contains a horseshoe, and therefore all of Proposition 32.43. That is the Smale–Birkhoff homoclinic theorem, quoted here from [1359]. Its importance for this chapter is that Poincaré had already found such an intersection, and its infinitely tangled consequences, in the restricted three-body problem [247]: the tangle of Section 32.4.1 and the horseshoe are the same object, seen sixty years apart.

Remark 32.45 (A measure-theoretic gap). Theorem 32.42 calls Λ a Cantor set, and Section 32.5.4 will assign it a dimension. The construction of the Cantor set, its uncountability, and the fact that it has Lebesgue measure zero are results of real analysis and measure theory that Chapters 6 and 7 do not carry; they are used descriptively here and nothing below depends on more than the counting argument of Proposition 32.43, which is elementary.

32.4 Hamiltonian chaos

32.4.1 The three-body problem

Definition 32.46 (The circular restricted three-body problem)**.** Two *primaries* of masses M_1 and M_2 move on a circular orbit about their common centre of mass with angular velocity $\Omega = \left[G(M_1+M_2)/a^3\right]^{1/2}$, by Equation (27.51). A third body of negligible mass m moves in their field. In the frame rotating with the primaries, in which the two are at rest, the Hamiltonian of the third body is

$$\mathcal{H} = \frac{|\boldsymbol{p}|^2}{2m} - \Omega\, L_z - G M_1 m\,\frac{1}{r_1} - G M_2 m\,\frac{1}{r_2}\,, \tag{32.18}$$

with $L_z = (\boldsymbol{r}\times\boldsymbol{p})_z$ and r_1, r_2 the distances to the primaries. Since Equation (32.18) has no explicit time dependence in that frame, it is conserved; the constant is the *Jacobi integral*, of SI unit J.

Rests on Equations (22.1) and (27.51).

The system has three degrees of freedom and one known constant of motion. By Liouville–Arnold (Theorem 23.31) three independent constants in involution would make it integrable, and the question Poincaré was set—and answered in the negative—was whether the remaining two exist.

Theorem 32.47 (Poincaré's non-integrability, quoted)**.** *For the restricted three-body problem written as an integrable system perturbed at order ε in the mass ratio, there is no first integral, other than a function of $\mathcal{H}$ itself, that is analytic in the phase-space variables and in ε and single-valued in the angles [247]. The perturbation series that would construct such an integral diverges, and the geometric reason is the homoclinic tangle: the stable and unstable manifolds of an unstable periodic orbit intersect transversally, and by Corollary 32.5 each intersection forces infinitely many more, so the manifolds fold into a mesh "so complicated that I shall not even try to draw it" [255].*

Rests on Theorem 23.31 and Remark 32.44.

Remark 32.48 (Why the tangle defeats a series solution). An analytic first integral is constant on every trajectory and therefore constant on the closure of any trajectory. In the tangle the closure of a single unstable manifold contains a whole horseshoe (Remark 32.44), whose orbits by Proposition 32.43 come arbitrarily close to every point of a Cantor set of positive topological entropy. An analytic function constant on such a set, and on the infinitely many distinct periodic orbits it contains, is forced to be constant on an open set and hence—by analytic continuation—a function of the energy alone. The contrast with the two-body Kepler problem of Chapter 27 is total: there the motion is integrable, its level sets are the closed ellipses of Phenomenon 27.32, and the extra constants (angular momentum and the Laplace–Runge–Lenz vector) exist and are polynomial. Adding one more body destroys them.

32.4.2 The KAM theorem

Take an integrable Hamiltonian in the action–angle variables of Definition 23.28 and perturb it:

$$\mathcal{H}(I,\theta) = \mathcal{H}_0(I) + \varepsilon \mathcal{H}_1(I,\theta)\,, \tag{32.19}$$

with $\mathcal{H}_1$ 2π-periodic in each angle and ε dimensionless. The unperturbed motion lies on the invariant tori of Theorem 23.31, each labelled by its actions and carrying the frequencies $\omega^a(I) = \partial \mathcal{H}_0/\partial I_a$ of Equation (23.52).

Proposition 32.49 (The small-denominator obstruction)**.** *Seek a canonical transformation removing the perturbation to first order, generated by $S(I',\theta) = I'\cdot\theta + \varepsilon S_1(I',\theta)$. With the Fourier expansion $\mathcal{H}_1 = \sum_{\boldsymbol{k}\in\mathbb{Z}^f} h_{\boldsymbol{k}}(I)\,\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\theta}$, the generator is*

$$S_1(I,\theta) = \sum_{\boldsymbol{k}\neq\boldsymbol{0}} \frac{\mathrm{i}\,h_{\boldsymbol{k}}(I)}{\boldsymbol{k}\cdot\boldsymbol{\omega}(I)}\,\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\theta}\,, \tag{32.20}$$

which is undefined whenever $\boldsymbol{k}\cdot\boldsymbol{\omega}(I) = 0$ for some $\boldsymbol{k}\neq\boldsymbol{0}$, and arbitrarily large near such a resonance.

Rests on Equations (22.18) *and* (23.52).

Proof. *Derives Proposition 32.49.*

The generating function of the second kind (Equation (22.21)) gives $I_a = \partial S/\partial\theta^a = I'_a + \varepsilon\,\partial S_1/\partial\theta^a$, so the new Hamiltonian is

$$\mathcal{H}'(I') = \mathcal{H}_0(I') + \varepsilon\left[\boldsymbol{\omega}(I')\cdot\frac{\partial S_1}{\partial\theta} + \mathcal{H}_1(I',\theta)\right] + \mathcal{O}(\varepsilon^2)\,,$$

using $\partial\mathcal{H}_0/\partial I_a = \omega^a$. Requiring the bracket to be independent of the angles—and taking the angle average of $\mathcal{H}_1$, $h_{\boldsymbol{0}}$, into $\mathcal{H}'$—leaves $\boldsymbol{\omega}\cdot\partial S_1/\partial\theta = -\sum_{\boldsymbol{k}\neq\boldsymbol{0}} h_{\boldsymbol{k}}\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\theta}$. Inserting the Fourier series for S_1 turns the derivative into a factor $\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{\omega}$ and solving mode by mode gives Equation (32.20). The denominators are the resonance conditions; since the rationals are dense, every neighbourhood of every torus contains resonant tori, and this is the difficulty that defeated celestial mechanics for two centuries. □

Definition 32.50 (Diophantine frequency vector)**.** A frequency vector $\boldsymbol{\omega}\in\mathbb{R}^f$ is *Diophantine* of type (γ,τ) if

$$|\boldsymbol{k}\cdot\boldsymbol{\omega}| \geq \frac{\gamma}{|\boldsymbol{k}|^{\tau}} \qquad \text{for all } \boldsymbol{k}\in\mathbb{Z}^f\setminus\{\boldsymbol{0}\}\,, \tag{32.21}$$

with $\gamma>0$ and $\tau > f-1$. The condition says the frequencies are badly approximable by rationals, so the denominators in Equation (32.20) shrink only polynomially in $|\boldsymbol{k}|$ while the numerators $h_{\boldsymbol{k}}$ of an analytic $\mathcal{H}_1$ shrink exponentially.

Rests on Proposition 32.49.

Theorem 32.51 (Kolmogorov–Arnold–Moser, quoted)**.** *Let $\mathcal{H}_0$ be analytic and non-degenerate, in the sense that* $\det(\partial^2\mathcal{H}_0/\partial I_a \partial I_b) \neq 0$*, and let $\mathcal{H}_1$ be analytic. Then for every γ there is $\varepsilon_0(\gamma) > 0$ such that for $|\varepsilon| < \varepsilon_0$ every unperturbed torus whose frequency vector is Diophantine of type (γ, τ) survives as an invariant torus of the perturbed system, merely deformed, carrying the same frequencies. The surviving tori fill a set whose relative measure tends to* 1 *as $\varepsilon \to 0$, the complement being $\mathcal{O}(\sqrt{\varepsilon})$ [1045, 1238, 1247].*

Rests on Definition 32.50 and Theorem 23.31.

Remark 32.52 (KAM is quoted, and will not be proved here). Theorem 32.51 carries no derivation in this book, and the omission is a decision rather than a debt—the same treatment Part II gives Carleson's theorem in Remark 17.18. What the proof does is worth stating, because it is what makes the theorem believable and it is also what makes it long. One cannot iterate the first-order step of Proposition 32.49: each pass leaves a remainder of order ε^2, then ε^3, and the small denominators of Equation (32.20) force one to work on a domain shrunk at every pass, so the successive corrections lose analyticity faster than they gain smallness and the series diverges. Kolmogorov's device is to replace the ordinary perturbation series by a Newton iteration [1045]: each pass solves the linearized problem exactly and therefore *squares* the remainder, $\varepsilon \to \varepsilon^2 \to \varepsilon^4$, which converges fast enough to survive both the shrinking domains and the growth of the denominators permitted by the Diophantine condition Equation (32.21). Arnold supplied the analytic details [1247] and Moser removed the analyticity hypothesis in favour of finite differentiability [1238].

Three ingredients of that argument have no home in this treatise: the Diophantine estimates themselves, the Cauchy estimates on shrinking complex strips that control each pass, and the measure-theoretic accounting that turns "the resonant set is small for each $\boldsymbol{k}$" into the $\mathcal{O}(\sqrt{\varepsilon})$ complement quoted in Theorem 32.51—the last of which needs the Lebesgue measure that Part II does not carry. None of them appears anywhere else in this book. What *is* derived here is the obstruction the theorem overcomes (Proposition 32.49), the condition under which it can be overcome (Definition 32.50), and—in Section 32.4.3—the quantitative estimate of where the tori actually break, which is Chirikov's overlap criterion and is not a corollary of KAM at all. Every number this chapter quotes about the solar system comes from numerical integration [1732, 1824], not from KAM, which is perturbative and silent at those perturbation strengths.

Remark 32.53 (What KAM does and does not guarantee). Four cautions, each of which is routinely overstated in summaries. First, KAM is perturbative: ε_0 is small, and the theorem says nothing at the perturbation strengths of real celestial mechanics, where the question is settled numerically (Section 32.4.5). Second, the surviving tori form a nowhere dense set of large measure—their complement, the resonant gaps, is dense—so "most initial conditions are regular" and "regular initial conditions form a fat Cantor set riddled with chaotic layers" are both true at once. Third, the theorem is about tori, not about the motion in between: what happens in the gaps is the subject of Section 32.4.3. Fourth, and most importantly, the confinement KAM provides is dimension-dependent. In a system with two degrees of freedom the invariant tori are two-dimensional inside a three-dimensional energy surface, so they separate it and a chaotic orbit is trapped between neighbouring tori forever. With three or more degrees of freedom the tori no longer separate the energy surface, the chaotic layers connect, and slow transport along the resonance web—Arnold diffusion—becomes possible. Its existence is established for constructed examples; its *rate* in a given physical system is not settled by any theorem and must be measured or integrated. The primary reference for the diffusion example is not in this bibliography, and the statement is therefore made here without one.

32.4.3 Resonance overlap and the standard map

The local model of a perturbed resonance is a rotor given a periodic kick.

Definition 32.54 (The kicked rotor and the standard map)**.** A rigid rotor of moment of inertia I (SI unit $\mathrm{kg\,m^2}$), free except for an impulsive torque applied once every T, has the Hamiltonian

$$\mathcal{H} = \frac{L^2}{2I} + K' T \cos\vartheta \sum_{n\in\mathbb{Z}} \delta(t - nT)\,, \tag{32.22}$$

with L the angular momentum ($\mathrm{J\,s}$) and K' an energy (J). Integrating Hamilton's equations across one kick and along the free flight between kicks gives the exact stroboscopic map

$$L_{n+1} = L_n + K' T \sin\vartheta_n\,, \tag{32.23}$$

$$\vartheta_{n+1} = \vartheta_n + \frac{T}{I} L_{n+1}\,, \tag{32.24}$$

which in the dimensionless action $l_n = T L_n / I$ becomes the *standard map*

$$l_{n+1} = l_n + K \sin\vartheta_n\,, \qquad \vartheta_{n+1} = \vartheta_n + l_{n+1}\,, \qquad K = \frac{K' T^2}{I}\,. \tag{32.25}$$

Rests on Equations (22.3) *and* (22.4).

The map Equation (32.25) is area-preserving—its Jacobian determinant is 1, as Proposition 32.40 requires—and K is the single dimensionless control parameter, built out of the measured kick energy, kick period and moment of inertia.

Proposition 32.55 (Chirikov's resonance-overlap estimate)**.** *Each primary resonance of Equation* (32.25) *sits at $l = 2\pi m$, $m \in \mathbb{Z}$, and has half-width $\Delta l = 2\sqrt{K}$ in the action. Neighbouring resonances therefore touch when $4\sqrt{K} = 2\pi$, that is at*

$$K_{overlap} = \left(\frac{\pi}{2}\right)^2 = 2.47\,, \tag{32.26}$$

above which no invariant curve can span the cylinder and the action diffuses without bound [1636].

Rests on Equations (32.19) *and* (32.25).

Proof. *Derives Proposition 32.55.*

Near $l = 0$ and for small K the map is the stroboscopic image of the pendulum flow $\dot\vartheta = l$, $\dot l = K\sin\vartheta$, whose energy $\tfrac12 l^2 + K\cos\vartheta$ is conserved. Its separatrix passes through $(\vartheta, l) = (0, 0)$ with energy K, and at $\vartheta = \pi$ reaches $\tfrac12 l^2 - K = K$, so the maximum excursion of the separatrix is $l = 2\sqrt{K}$: that is the half-width. The same holds at every $l = 2\pi m$ by the periodicity of the map in l modulo 2π. Two neighbouring separatrices, of half-width $2\sqrt{K}$ each, span the gap 2π between resonance centres when $2 \cdot 2\sqrt{K} = 2\pi$, which is Equation (32.26).

The criterion is a heuristic and is honest about it: it neglects the higher-harmonic resonances that fill the gaps and the deformation of the separatrices by the neighbouring resonance, both of which lower the threshold. Numerically the last invariant curve of Equation (32.25)—the one carrying the golden-mean winding number, the most irrational and therefore the last to break—disappears at $K_c = 0.9716$, so Equation (32.26) overestimates by a factor of about 2.5 [1636]. That is the accuracy the criterion claims for itself, and it is why the criterion is used for an order of magnitude and never for a number. □

Remark 32.56 (Cantori and slow transport). Just above K_c an invariant curve does not simply vanish: it becomes a *cantorus*, an invariant Cantor set with gaps, which no longer blocks transport but still obstructs it. Orbits leak through the gaps at a rate that vanishes as $K \to K_c^+$, so the diffusion of the action is not the free diffusion of a random walk but is throttled by a hierarchy of partial barriers. This is the mechanism behind the very long timescales of Section 32.4.5: a chaotic orbit can behave regularly for many Lyapunov times before it finds a gap.

The physical realizations of Equation (32.25) are the kicked rotor itself, the periodically driven pendulum of Section 32.7.3, and—the case Chirikov was writing for—any resonance of a nearly integrable system, since Equation (32.22) is what Equation (32.19) reduces to near a single resonance.

32.4.4 Numerical discovery: Hénon–Heiles

Definition 32.57 (The Hénon–Heiles Hamiltonian)**.** A star of mass m moving in the meridional plane of an axisymmetric galactic potential, expanded to cubic order about the circular orbit, has

$$\mathcal{H} = \frac{p_x^2 + p_y^2}{2m} + \frac{1}{2} m\omega^2 \left(x^2 + y^2\right) + m\lambda \left(x^2 y - \frac{y^3}{3}\right), \tag{32.27}$$

with ω in 1/s and λ in $1/(\mathrm{m\,s}^2)$ [1281]. Rescaling by $x = (\omega^2/\lambda)\xi$, $y = (\omega^2/\lambda)\eta$ and $t = s/\omega$ reduces it to

$$\tilde{\mathcal{H}} = \frac{1}{2}\left(\tilde{p}_\xi^2 + \tilde{p}_\eta^2\right) + \frac{1}{2}\left(\xi^2 + \eta^2\right) + \xi^2\eta - \frac{\eta^3}{3}, \tag{32.28}$$

measured in units of the energy $E_* = m\omega^6/\lambda^2$.

Rests on Equation (22.1) *and Theorem 7.38.*

Phenomenon 32.58 (Regular and chaotic motion coexist)**.** A slightly perturbed integrable Hamiltonian system does not become wholly chaotic. Surfaces of section computed for the Hénon–Heiles Hamiltonian show, at low energy, closed invariant curves filling the accessible region — the traces of surviving invariant tori — and, as the energy is raised, islands of such curves embedded in a growing sea of points that wander over a two-dimensional area [1281]. Both kinds of orbit occur at the same energy in the same system, and the chaotic fraction grows continuously with the perturbation: there is no energy at which order gives way to disorder all at once [1045, 1238, 1247]. The numerical experiment also settled the astronomical question it was posed for — whether stellar motion in a galactic disc admits a third isolating integral — in the negative for general orbits, while showing that many individual orbits behave as though it existed [1281].

Rests on Equation (32.27) *and Theorem 32.51.*

Derivation. *Derives Phenomenon 32.58.*

Three things have to be established: that the system has a finite range of bounded motion in which the question makes sense, that a closed curve on the surface of section is the trace of an invariant torus, and that a scattered area is not.

The escape energy. The cubic term in Equation (32.28) eventually overwhelms the quadratic one, so the potential $\tilde{V} = \frac{1}{2}(\xi^2 + \eta^2) + \xi^2\eta - \eta^3/3$ is bounded only inside a finite region. Setting $\boldsymbol{\nabla}\tilde{V} = 0$ gives $\xi(1 + 2\eta) = 0$ and $\eta + \xi^2 - \eta^2 = 0$. From $\xi = 0$ the second equation gives $\eta = 0$ (the minimum, $\tilde{V} = 0$) or $\eta = 1$, at which $\tilde{V} = \frac{1}{2} - \frac{1}{3} = \frac{1}{6}$. From $\eta = -\frac{1}{2}$ it gives $\xi^2 = \frac{3}{4}$, and there $\tilde{V} = \frac{1}{2}\left(\frac{3}{4} + \frac{1}{4}\right) - \frac{3}{8} + \frac{1}{24} = \frac{1}{6}$ as well. There are therefore three saddle points at the same height, at the corners of an equilateral triangle, and

$$E_{\mathrm{escape}} = \frac{1}{6} E_* = \frac{m\omega^6}{6\lambda^2}. \tag{32.29}$$

Below this the motion is bounded and the question of integrability is well posed; above it, orbits escape through the three channels.

Reading the section. Take the section $\xi = 0$ with $\pi_\xi > 0$, coordinatized by (η, π_η); by Proposition 32.40 the return map preserves area. If the orbit lies on a two-torus—which is what a third isolating integral would guarantee, by Theorem 23.31—then the intersection of that two-torus with the two-dimensional section inside the three-dimensional energy surface

is a one-dimensional curve, and the successive points must fall on it. Conversely, points that fill a two-dimensional patch cannot lie on any smooth one-dimensional invariant set, so no third integral exists on that orbit. This is what makes the surface of section a decisive diagnostic rather than a picture: the dimension of the point set is the answer.

The measured outcome. At $E = \frac{1}{12}E_*$ the computed section is covered by closed curves and the motion looks integrable; at $E = \frac{1}{8}E_*$ islands of closed curves survive inside a connected region of scattered points; at $E = \frac{1}{6}E_*$ the scattered region occupies almost the whole accessible area, with a few small islands remaining [1281]. The relative area of the scattered region rises continuously from zero, which is the statement of the phenomenon, and Theorem 32.51 is the reason it must: the tori that go first are the resonant ones, and the Diophantine ones of Equation (32.21) survive to larger perturbations, so the transition is graded and not sudden. The astronomical conclusion follows directly: no third isolating integral, analytic in the coordinates, exists for general orbits in such a potential, while the surviving tori explain why so many individual stellar orbits behave as though one did. □

32.4.5 Chaos in the solar system

Phenomenon 32.59 (The solar system is chaotic)**.** The asteroid belt is not populated uniformly: it carries deep gaps at the orbital periods commensurate with Jupiter's — the Kirkwood gaps — and the gap at the 3/1 commensurability coincides with a zone in which the eccentricity of a test asteroid does not oscillate but wanders, on a timescale short against the age of the system, until the orbit crosses those of the inner planets and the body is removed [1732]. The planetary orbits themselves are chaotic in the same sense: numerical integration of the averaged equations gives a positive Lyapunov exponent for the inner solar system, with a Lyapunov time of order 5×10^6 yr, so that an error of 15 m in an initial position grows within about 1×10^8 yr to a distance of the order of the Earth–Sun separation, 1.5×10^{11} m [1824]. The observed regularity of the planets over recorded history is therefore no evidence at all of predictability over the age of the system.

Rests on Equation (32.46) and Theorem 32.51.

Derivation. *Derives Phenomenon 32.59.*

Where the gaps are. Kepler's third law Equation (27.51) with the Sun's mass gives, for a heliocentric orbit, $a = (T/1\,\mathrm{yr})^{2/3}\,\mathrm{au}$. An asteroid in the $p{:}q$ mean-motion resonance with Jupiter has $T = (q/p)\,T_J$ with $T_J = 11.862\,\mathrm{yr}$, so its semi-major axis is fixed by arithmetic alone: Table 32.2 lists the four principal cases against the observed gap positions. The agreement is at the level of the approximation—the derivation used the Sun's mass alone and a circular Jovian orbit—and it identifies the gaps as a resonance phenomenon without yet explaining why a resonance should empty rather than fill.

Why the 3/1 zone empties. At the 3/1 resonance the numerical integration of [1732] shows the eccentricity of a test body not librating but jumping irregularly, in sudden bursts that carry it above $e = 0.3$ on a timescale of order 1×10^6 yr. That range is the one that matters, because Mars has $a_M = 1.5237\,\mathrm{au}$ and $e_M = 0.0934$, hence aphelion $Q_M = a_M(1 + e_M) = 1.666\,\mathrm{au}$; an asteroid at $a = 2.50\,\mathrm{au}$ reaches Mars's orbit when its perihelion $a(1 - e)$ falls to Q_M, that is when

$$e > 1 - \frac{Q_M}{a} = 1 - \frac{1.666}{2.50} = 0.33\,. \tag{32.30}$$

A body that reaches such an eccentricity is removed by a close encounter within an interval negligible against the age of the system, and the gap is the record of that removal. The chaotic zone and the observed gap coincide in width, which is the quantitative content of [1732].

The planets. For the planets themselves the exponent is measured, not derived: [1824] integrates the averaged secular equations for 2×10^8 yr and finds neighbouring solutions

separating exponentially with a Lyapunov time $\lambda^{-1} \approx 5 \times 10^{6}\,\mathrm{yr}$. Feeding that into the horizon formula Equation (32.46), an initial uncertainty $\delta_0 = 15\,\mathrm{m}$ reaches $\Delta = 1.5 \times 10^{11}\,\mathrm{m}$ after

$$T = \lambda^{-1} \ln \frac{\Delta}{\delta_0} = 5 \times 10^{6}\,\mathrm{yr} \times \ln\left(1 \times 10^{10}\right) = 5 \times 10^{6}\,\mathrm{yr} \times 23.0 \approx 1.2 \times 10^{8}\,\mathrm{yr}\,,$$

which is the growth quoted in [1824] to the one significant figure to which the Lyapunov time itself is known. Two conclusions, and only two, follow. Positive λ destroys prediction of the *phase* of the orbits beyond about $1 \times 10^{8}\,\mathrm{yr}$; it does not by itself say that any planet is lost, which is a question about the size of the chaotic zone and not about the exponent, and which the same integrations address separately. The regularity of the planets over the few thousand years of recorded observation is 1×10^{-3} Lyapunov times and constrains nothing. □

Table 32.2: Positions of the principal Kirkwood gaps, computed from Kepler's third law Equation (27.51) with $T_J = 11.862\,\mathrm{yr}$ and no free parameter, against the observed gap centres. The residual reflects the neglect of Jupiter's mass and of the eccentricity of its orbit.

Resonance	T (yr)	a computed (au)	a observed (au)
4:1	2.966	2.06	2.06
3:1	3.954	2.50	2.50
5:2	4.745	2.82	2.82
7:3	5.084	2.96	2.96
2:1	5.931	3.28	3.27

The gap positions in Table 32.2 are arithmetic. What a resonance does to a body sitting in one is dynamics, and the local model is the pendulum of Proposition 32.55 again.

Proposition 32.60 (Libration width of a mean-motion resonance)**.** *Let a test body of mass m_t, negligible beside both other masses, orbit a star of mass M with semi-major axis a, eccentricity e and mean motion $n = \sqrt{GM/a^3}$, perturbed by a planet of mass m on a circular coplanar orbit of mean motion n_J, and let it lie near the p:q commensurability $q\,n = p\,n_J$. Write the single resonant harmonic of the perturbing Hamiltonian as*

$$\mathcal{H}_{res} = -\frac{GMm_t}{a}\,\mu\,S\cos\sigma\,, \qquad \mu = \frac{m}{M}\,, \tag{32.31}$$

with S dimensionless and

$$\sigma = p\lambda_J - q\lambda + (q-p)\varpi \tag{32.32}$$

the resonant angle built from the two mean longitudes and the longitude of pericentre ϖ. Then, while ϖ may be treated as fixed, σ obeys a pendulum equation whose libration angular frequency is

$$\omega_{lib} = q\,n\sqrt{3\mu S}\,, \tag{32.33}$$

and whose separatrix has the half-width

$$\frac{\Delta a}{a} = \frac{4}{\sqrt{3}}\sqrt{\mu S} \tag{32.34}$$

in semi-major axis, independent of p and q except through S. Furthermore S vanishes with the eccentricity as $S = s\,e^{|p-q|}$, with s a function of a/a_J alone and of order unity.

Rests on Proposition 32.55 and Equation (32.19).

Proof. *Derives Proposition 32.60.*

The pendulum. Take as the action conjugate to the mean longitude λ the quantity $\Lambda = m_t\sqrt{GMa}$, for which the Kepler Hamiltonian is $\mathcal{H}_0 = -G^2M^2m_t^3/(2\Lambda^2)$ and

$$\frac{\partial \mathcal{H}_0}{\partial \Lambda} = \frac{G^2M^2m_t^3}{\Lambda^3} = \sqrt{\frac{GM}{a^3}} = n\,, \qquad \frac{\mathrm{d}n}{\mathrm{d}\Lambda} = -\frac{3n}{\Lambda}\,,$$

the second by differentiating the first. Hamilton's equation for Λ picks out the λ dependence of Equation (32.31), which enters only through σ and only as $-q\lambda$:

$$\dot\Lambda = -\frac{\partial \mathcal{H}_{\mathrm{res}}}{\partial \lambda} = -\frac{GMm_t}{a}\mu S\,\sin\sigma\,\frac{\partial\sigma}{\partial\lambda} = q\,\varepsilon\sin\sigma\,, \qquad \varepsilon \equiv \frac{GMm_t}{a}\mu S\,.$$

Differentiating Equation (32.32) twice with ϖ fixed and n_J constant, $\dot\sigma = p\,n_J - q\,n$ and

$$\ddot\sigma = -q\,\frac{\mathrm{d}n}{\mathrm{d}\Lambda}\dot\Lambda = \frac{3q^2n\varepsilon}{\Lambda}\sin\sigma = \omega_{\mathrm{lib}}^2\sin\sigma\,, \tag{32.35}$$

a pendulum with its stable equilibrium at $\sigma = \pi$. Its frequency is Equation (32.33), since $\Lambda = m_t n a^2$ and $\varepsilon = m_t n^2 a^2 \mu S$ give $3q^2n\varepsilon/\Lambda = 3q^2n^2\mu S$.

The width. Equation (32.35) conserves $\frac12\dot\sigma^2 + \omega_{\mathrm{lib}}^2\cos\sigma$. The separatrix passes through the unstable point $\sigma = 0$ with $\dot\sigma = 0$, so its constant is ω_{lib}^2, and at $\sigma = \pi$ it reaches $\frac12\dot\sigma^2 = 2\omega_{\mathrm{lib}}^2$: the maximum excursion is $|\dot\sigma| = 2\omega_{\mathrm{lib}}$. This is the same computation as in Proposition 32.55, on a different pair of variables. Converting to the semi-major axis, $\dot\sigma = -q\,(\mathrm{d}n/\mathrm{d}\Lambda)\,\Delta\Lambda = 3qn\,\Delta\Lambda/\Lambda$, so

$$\frac{\Delta\Lambda}{\Lambda} = \frac{2\omega_{\mathrm{lib}}}{3qn} = \frac{2}{\sqrt3}\sqrt{\mu S}\,,$$

and $\Lambda \propto \sqrt{a}$ makes $\Delta a/a = 2\Delta\Lambda/\Lambda$, which is Equation (32.34). The factor q has cancelled.

Why S carries $e^{|p-q|}$. The perturbing Hamiltonian depends on the two orbits only through their relative geometry, so it is unchanged by rotating the whole system: $\lambda \to \lambda + \phi$, $\lambda_J \to \lambda_J + \phi$, $\varpi \to \varpi + \phi$. The combination Equation (32.32) is invariant under exactly that substitution—its three coefficients sum to $p - q + q - p = 0$—which is what selects the admissible harmonics. Now ϖ is undefined at $e = 0$, and the perturbation is a smooth function of the position of the test body, hence of the two elements $e\cos\varpi$ and $e\sin\varpi$, which are smooth where ϖ is not. A term carrying $\mathrm{e}^{\mathrm{i}j\varpi}$ can be assembled from those two only as a polynomial of degree at least $|j|$ in them, so it vanishes at least as $e^{|j|}$. Here $j = q - p$, giving $S = s\,e^{|p-q|}$ with the remaining factor a function of the semi-major-axis ratio alone. □

Remark 32.61 (The 3/1 zone: what the width says, and what is quoted). Put the numbers in for the 3/1 gap, where $p = 3$, $q = 1$ and the resonance is therefore of second order, $S = s\,e^2$. With $\mu = m_J/M_\odot = 9.5458\times10^{-4}$, Equation (32.34) gives

$$\frac{\Delta a}{a} = \frac{4}{\sqrt3}\sqrt{\mu s}\;e = 0.0714\,\sqrt{s}\;e\,,$$

so a body of the typical belt eccentricity $e \approx 0.1$ librates over $\Delta a \approx 0.018\,\mathrm{au}$ about $a = 2.50\,\mathrm{au}$, and the libration period Equation (32.33) is $2\pi/\omega_{\mathrm{lib}} = 74\,\mathrm{yr}/(\sqrt{s}\,e)$, of order $7\times10^2\,\mathrm{yr}$ there. Two features of those formulas do the work. The width grows *with* the eccentricity, so a body whose e is being pumped finds the resonance widening around it rather than escaping from it; and the libration frequency vanishes with e, while the secular precession rate of ϖ—the very quantity the derivation above froze—is of order μn and does *not* vanish with e. Their ratio is

$$\frac{\omega_{\mathrm{lib}}}{|\dot\varpi|} \sim \frac{n\sqrt{3\mu s}\,e}{\mu n} = \sqrt{\frac{3s}{\mu}}\;e \approx 56\,\sqrt{s}\;e\,,$$

which falls below unity for $e \lesssim 0.02$. Below that eccentricity the single-resonance averaging that produced the pendulum is not valid: the resonant and the secular degrees of freedom run at comparable rates, and two comparable resonances that overlap are precisely the configuration Proposition 32.55 identifies as chaotic. The low-eccentricity part of the 3/1 zone is therefore where the pendulum picture must fail, which is the qualitative statement that a body starting on a nearly circular orbit there does not stay on one.

What is *not* derived here is the rest of [1732]: that the eccentricity actually wanders as far as the Mars-crossing value Equation (32.30) rather than to some smaller ceiling, and that it does so in bursts on a timescale of order 1×10^6 yr. Those are numerical results, obtained by integrating an algebraic mapping of the resonance over millions of orbits, and this chapter quotes them. The timescale is worth one comment, because it is easy to misread: it is *not* the Lyapunov time. The only timescale the local model supplies is the libration period, a few hundred years, and a resonance-overlap chaotic layer has a Lyapunov time of that order; the 1×10^6 yr on which the eccentricity jumps is three orders of magnitude longer, and the gap between them is the throttled transport of Remark 32.56. A chaotic orbit can look regular for a thousand Lyapunov times before it finds a way through.

32.5 Strange attractors

32.5.1 The Lorenz system

Definition 32.62 (The Lorenz system)**.** Truncating the Boussinesq equations for a fluid layer of depth d heated from below to one convective mode and two thermal modes gives the three ordinary differential equations

$$\dot{x} = \sigma(y - x)\,, \qquad \dot{y} = x(r - z) - y\,, \qquad \dot{z} = xy - bz\,, \tag{32.36}$$

in which the dot is $\mathrm{d}/\mathrm{d}s$ with $s = \pi^2(1 + a^2)\kappa t/d^2$ a dimensionless time built from the thermal diffusivity κ (m^2/s), x is proportional to the amplitude of the convective roll, y and z to the horizontal and vertical temperature variations, and the three parameters are

$$\sigma = \frac{\nu}{\kappa}\,, \qquad r = \frac{\mathrm{Ra}}{\mathrm{Ra}_c}\,, \qquad b = \frac{4}{1 + a^2}\,, \tag{32.37}$$

with ν the kinematic viscosity, a the dimensionless horizontal wavenumber of the roll, and

$$\mathrm{Ra} = \frac{g\alpha_T\,\Delta T\,d^3}{\nu\kappa} \tag{32.38}$$

the Rayleigh number, built from the acceleration of gravity g, the thermal expansion coefficient α_T (1/K) and the temperature difference ΔT across the layer [1262]. For stress-free boundaries the critical value is $\mathrm{Ra}_c = 27\pi^4/4 = 657.5$, attained at $a^2 = \tfrac{1}{2}$, whence Lorenz's $b = 8/3$; his other values are $\sigma = 10$ and $r = 28$.

Rests on Theorem 32.6 and Definition 32.7.

Full derivation: Appendix A.65 (p. 3146).

Derives Definition 32.62.

Appendix A.65 carries the reduction in full: the Boussinesq equations for a layer of depth d heated from below, the stream-function form that eliminates the pressure, the linear stability analysis that produces the critical Rayleigh number $\mathrm{Ra}_c = 27\pi^4/4$ at $a^2 = \tfrac{1}{2}$ for stress-free boundaries [438], the Galerkin truncation to one velocity mode and two temperature modes, and the scaling that turns what is left into Equation (32.36) with the three parameters Equation (32.37). It is a page of vector calculus and several pages of algebra, which is why it is not reproduced here, and it is what makes each of σ, r and b a ratio of measured fluid properties rather than a dial: σ is the Prandtl number of the working

fluid, r the Rayleigh number in units of its own critical value, and b a pure function of the horizontal wavenumber of the roll. The physical content that follows the truncation—the dissipation rate, the fixed points, the onset of the strange attractor—is derived in this chapter and does not depend on the appendix.

Remark 32.63 (The Lorenz system is a model, not the fluid). Equation (32.36) retains three of the infinitely many modes of a convecting layer, and Lorenz said plainly that the truncation is not quantitatively faithful to convection at $r = 28$, which is far above the range in which a three-mode truncation can be trusted [1262]. What the system is faithful to is the *mechanism*: a dissipative flow, bounded, with an unstable fixed point and no stable alternative nearby. Its evidential standing rests on Section 32.7.1, where a real convection cell reproduces the universal numbers, and not on any claim that Equation (32.36) describes that cell.

Proposition 32.64 (The Lorenz flow contracts volume)**.** *The divergence of Equation* (32.36) *is the negative constant* $-(\sigma + 1 + b)$*, so every phase volume obeys*

$$V(s) = V(0)\,\mathrm{e}^{-(\sigma+1+b)s}\,, \tag{32.39}$$

which at Lorenz's parameters contracts by a factor e *in every* $3/41 = 0.0732$ *of dimensionless time.*

Rests on Theorem 32.6 and Equation (32.36)*.*

Proof. *Derives Proposition 32.64.*

Differentiating each component of Equation (32.36) with respect to its own variable gives $-\sigma$, -1 and $-b$, whose sum is the constant $-(\sigma + 1 + b)$. Equation (32.3) then reads $\dot V = -(\sigma + 1 + b)V$, which integrates to Equation (32.39). At $\sigma = 10$ and $b = 8/3$ the rate is $41/3$ and its reciprocal is $3/41$. □

Proposition 32.65 (Fixed points of the Lorenz system and their stability)**.** *The origin is a fixed point for every* r*; it is asymptotically stable for* $r < 1$ *and a saddle for* $r > 1$*, the transition at* $r = 1$ *being a supercritical pitchfork that creates the pair*

$$C_{\pm} = \left(\pm\sqrt{b(r-1)},\ \pm\sqrt{b(r-1)},\ r-1\right)\,, \tag{32.40}$$

the two steady convecting rolls. For $\sigma > b + 1$ *the pair loses stability at*

$$r_H = \frac{\sigma(\sigma + b + 3)}{\sigma - b - 1}\,, \tag{32.41}$$

which is $470/19 = 24.7368$ *at* $\sigma = 10$*,* $b = 8/3$*.*

Rests on Equation (32.36) *and Theorem 32.13.*

Proof. *Derives Proposition 32.65.*

Setting the right-hand sides of Equation (32.36) to zero gives $y = x$ from the first, then $x(r - 1 - z) = 0$ from the second and $x^2 = bz$ from the third. Either $x = y = z = 0$, or $z = r - 1$ and $x^2 = b(r - 1)$, which is real only for $r \geq 1$: that is Equation (32.40), and the $\sqrt{r-1}$ growth of the amplitude identifies the pitchfork of Proposition 32.24(ii), the symmetry being the $(x, y) \to (-x, -y)$ invariance of Equation (32.36).

At the origin the Jacobian is block diagonal, with the entry $-b$ and the 2×2 block

$$B = \begin{pmatrix} -\sigma & \sigma \\ r & -1 \end{pmatrix}\,.$$

The block has $\tau = -(\sigma + 1) < 0$ and $\Delta = \sigma(1 - r)$, so by Proposition 32.17 it is a stable node for $r < 1$ and a saddle for $r > 1$.

At $C_\pm$, writing $x_0 = \pm\sqrt{b(r-1)}$, the Jacobian is

$$A = \begin{pmatrix} -\sigma & \sigma & 0 \\ 1 & -1 & -x_0 \\ x_0 & x_0 & -b \end{pmatrix},$$

whose trace is $-(\sigma+1+b)$, whose determinant is $-2\sigma x_0^2 = -2\sigma b(r-1)$, and whose sum of principal 2×2 minors is $0 + \sigma b + (b + x_0^2) = b(\sigma + r)$. Hence

$$\lambda^3 + (\sigma+1+b)\lambda^2 + b(\sigma+r)\lambda + 2\sigma b(r-1) = 0\,. \tag{32.42}$$

A Hopf bifurcation needs a purely imaginary pair. Substituting $\lambda = \mathrm{i}\omega$ in Equation (32.42) and separating real and imaginary parts gives

$$2\sigma b(r-1) = (\sigma+1+b)\,\omega^2\,, \qquad \omega^2 = b(\sigma+r)\,,$$

and eliminating ω^2 leaves $(\sigma+1+b)(\sigma+r) = 2\sigma(r-1)$. Expanding, $\sigma^2+b\sigma+3\sigma+r(1+b-\sigma) = 0$, which solves to Equation (32.41); it is positive only for $\sigma > b+1$. With $\sigma = 10$ and $b = 8/3$, $r_H = 10\cdot\frac{47}{3}/\frac{19}{3} = 470/19$. □

Remark 32.66 (Why $r = 28$ has nowhere to go). Proposition 32.65 places $r = 28$ above $r_H = 24.74$, so all three fixed points are unstable there. The Hopf bifurcation at r_H is subcritical: the periodic orbits it involves exist *below* r_H and are unstable, so they are swallowed by $C_\pm$ rather than emitted by them, in the manner of Proposition 32.24(iii). Above r_H there is therefore no local attractor of any kind, while Proposition 32.64 forces all volumes to zero and a trapping argument keeps trajectories bounded. Something of zero volume and no local structure must attract them: that is the strange attractor of Phenomenon 32.68, and the argument just given is the whole reason to expect one.

32.5.2 Strange attractors and the Ruelle–Takens proposal

Definition 32.67 (Strange attractor)**.** An attractor (Definition 32.8) is *strange* if the dynamics on it has sensitive dependence on initial conditions, that is a positive largest Lyapunov exponent (Definition 32.73). It is a *fractal* attractor if in addition its dimension (Definition 32.79) is not an integer. The two properties are logically independent, and the term coined by Ruelle and Takens [1453] covers the sets—the common case—that have both.

Rests on Definition 32.8 and Phenomenon 32.72.

Phenomenon 32.68 (Strange attractors)**.** A dissipative chaotic system settles onto an attracting set of zero phase-space volume which is nevertheless neither a point, nor a closed curve, nor a smooth surface: it is a set of non-integer dimension, measured from experimental and numerical time series by counting the pairs of points lying closer than a given separation [1720]. The Lorenz system is the standard case: its trajectories are drawn onto a bounded set of two sheets on which they never repeat, and the correlation dimension of that set is measured to be a little above two [1720]. Sets of this kind are what Ruelle and Takens named strange attractors, and their geometry is that of the fractals [1453, 1696].

Rests on Definition 32.67 and Proposition 32.64.

Derivation. *Derives Phenomenon 32.68.*

The zero-volume half of the statement is Proposition 32.64: every volume decays like $\mathrm{e}^{-(\sigma+1+b)s}$, so the attractor can contain no three-dimensional region whatever.

It is equally not a point and not a closed curve. By Remark 32.66 no fixed point and no local periodic orbit is stable at $r = 28$; and on the attractor neighbouring trajectories separate exponentially, by Equation (32.44), while the motion remains bounded, so the set is stretched in one direction and folded back on itself without end. Nor can it be a

smooth surface: a two-dimensional invariant surface in a three-dimensional flow would confine trajectories to a plane-like region in which Corollary 32.32 forbids the observed sensitivity.

What remains is fixed quantitatively by the exponents. The Lorenz attractor at $\sigma = 10$, $b = 8/3$, $r = 28$ has computed Lyapunov spectrum $\lambda_1 = 0.906$, $\lambda_2 = 0$, $\lambda_3 = -14.572$ per unit dimensionless time, whose sum is $-13.667 = -(\sigma + 1 + b)$ exactly as Proposition 32.76 requires—a check on the numbers that costs nothing and is worth making. The Kaplan–Yorke estimate $D = 2 + \lambda_1 / |\lambda_3| = 2.06$ then predicts a dimension just above two, and the correlation dimension measured from the trajectory by pair counting is 2.05 ± 0.01 [1720]. The measured value is what settles the statement; the derivation establishes only that it must lie strictly between two and three. □

Remark 32.69 (The Ruelle–Takens proposal and what displaced Landau). Landau's account of the onset of turbulence had each instability add one incommensurate frequency, so that the flow became turbulent by accumulating an unbounded number of them. Ruelle and Takens proposed instead that after a small number of bifurcations the motion settles on an attractor which is strange in the sense of Definition 32.67, with a continuous power spectrum and sensitive dependence [1453]. The two pictures differ in a directly measurable quantity—the shape of the power spectrum—and that is what the Taylor–Couette measurement of Section 32.7.2 was able to decide.

Example 32.70 (The Hénon map)**.** The tractable prototype is the two-dimensional map

$$x_{n+1} = 1 - \hat{a} x_n^2 + y_n \,, \qquad y_{n+1} = \hat{b} x_n \,, \tag{32.43}$$

with $\hat{a} = 1.4$ and $\hat{b} = 0.3$ [1581]. Its Jacobian matrix is $\begin{pmatrix} -2\hat{a}x & 1 \\ \hat{b} & 0 \end{pmatrix}$, whose determinant is the constant $-\hat{b}$: the map contracts areas by the exact factor 0.3 at every step, whatever the point, which makes it the cleanest available caricature of a dissipative flow. Its largest Lyapunov exponent is $\lambda_1 = 0.419$ per iterate, so $\lambda_2 = \ln \hat{b} - \lambda_1 = -1.623$ and the Kaplan–Yorke estimate is $1 + \lambda_1 / |\lambda_2| = 1.26$; the measured correlation dimension is 1.21 ± 0.01 [1720]. The two differ, as they generally do—the correlation dimension is a lower bound on the information dimension that the Kaplan–Yorke formula estimates—and quoting either as "the" dimension of the attractor without saying which is measured would misreport both.

Rests on Definitions 32.38 and 32.67.

Remark 32.71 (Hyperbolicity, and an honest limit). The horseshoe of Section 32.3.2 is *uniformly hyperbolic*: at every point of its invariant set the tangent space splits into a uniformly contracting and a uniformly expanding direction, and that is what makes its symbolic description exact. Real attractors are not uniformly hyperbolic. The Lorenz attractor contains a fixed point, at which the expansion rate differs from that on the rest of the set, and the Hénon attractor has tangencies between stable and unstable manifolds. That the Lorenz equations possess an attractor at all—rather than a very long transient, or a periodic orbit of enormous period—was for four decades a conjecture, settled eventually by a computer-assisted proof whose primary reference is not in this bibliography and which is therefore not cited here. The practical consequence for a reader is worth stating plainly: the numbers quoted in this section are measurements on trajectories, and their status is that of measurements.

32.5.3 Sensitive dependence and Lyapunov exponents

Phenomenon 32.72 (Sensitive dependence on initial conditions)**.** In a chaotic system two initial states differing by an unmeasurably small amount separate at an exponential rate:

on the attractor the separation of nearby trajectories grows on average as

$$|\delta \boldsymbol{x}(t)| \sim |\delta \boldsymbol{x}(0)|\, \mathrm{e}^{\lambda t}\,, \qquad \lambda > 0\,, \tag{32.44}$$

with λ — the largest Lyapunov exponent — a property of the attractor and not of the particular trajectory followed [1378]. The effect was established in a numerical model of thermal convection, in which two solutions started from imperceptibly different data were followed until they bore no resemblance to one another [1262], and a positive λ is now extracted routinely from a single measured scalar time series [1766]. Determinism is untouched by this; what is destroyed is prediction, on the finite horizon of Equation (32.46).

Rests on Equation (32.4) *and Theorem 32.74.*

Derivation. *Derives Phenomenon 32.72.*

Linearize the flow $\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x})$ about a reference trajectory: an infinitesimal separation obeys the variational equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\,\delta \boldsymbol{x} = D\boldsymbol{f}\big(\boldsymbol{x}(t)\big)\,\delta \boldsymbol{x}\,, \tag{32.45}$$

whose solution is $\delta \boldsymbol{x}(t) = M(t)\,\delta \boldsymbol{x}(0)$ for a fundamental matrix M depending on the reference trajectory alone. For a flow with an invariant measure the multiplicative ergodic theorem (Theorem 32.74) guarantees that the limit

$$\lambda\big(\delta \boldsymbol{x}(0)\big) = \lim_{t\to\infty} \frac{1}{t} \ln \frac{|\delta \boldsymbol{x}(t)|}{|\delta \boldsymbol{x}(0)|}$$

exists for almost every initial point and takes one of finitely many values, the largest of which is attained for every $\delta \boldsymbol{x}(0)$ outside a set of lower dimension [1378]. That is Equation (32.44), and it is why λ can be quoted as a number for the system rather than for the run.

The consequence is quantitative. Suppose the initial state is known to within δ_0 and the prediction is useful while the error stays below a tolerance Δ. Solving $\delta_0 \mathrm{e}^{\lambda T} = \Delta$ gives the horizon

$$T = \frac{1}{\lambda} \ln \frac{\Delta}{\delta_0}\,. \tag{32.46}$$

It depends on the measurement precision only through its *logarithm*: improving the initial data by a factor of ten buys the fixed extra time $\lambda^{-1} \ln 10$ and no more, however great the effort. A system with $\lambda > 0$ is therefore not one whose equations are unknown — Equation (32.45) used them — but one in which prediction is bought at an exponentially rising price. □

Definition 32.73 (Lyapunov spectrum)**.** The *Lyapunov exponents* of a trajectory are the n numbers $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$ giving the exponential growth rates of the principal axes of an infinitesimal ball carried by Equation (32.45); equivalently $\lambda_i = \lim_{t\to\infty} t^{-1} \ln \mu_i(t)$ with μ_i the singular values of the fundamental matrix $M(t)$. They carry SI units of 1/s for a flow and are dimensionless per iterate for a map. A bounded, aperiodic trajectory with $\lambda_1 > 0$ is called *chaotic*.

Rests on Equation (32.45)*.*

Theorem 32.74 (Oseledets, quoted)**.** *Let φ_t preserve a probability measure supported on a compact invariant set, and let $\boldsymbol{f}$ be continuously differentiable. Then for almost every point with respect to that measure the limits in Definition 32.73 exist, are the same for almost all points of an ergodic component, and the tangent space at each point splits into subspaces on which the growth rate is exactly λ_i [1378].*

Rests on Definitions 32.8 and 32.73.

Remark 32.75 (Oseledets is quoted, not proved). The multiplicative ergodic theorem is a theorem of ergodic theory, resting on measure theory, on Birkhoff's pointwise ergodic theorem and on the subadditive ergodic theorem. Part II contains none of these: Chapter 11 is built on discrete and Riemann-integrable probability and says so. The theorem is quoted here because it is what converts "two runs diverged" into "the system has an exponent", and every numerical exponent quoted in this chapter relies on it for its meaning. The two propositions that follow are independent of it and are proved.

Proposition 32.76 (The exponents sum to the mean divergence)**.** *For a flow with an ergodic invariant measure on its attractor,*

$$\sum_{i=1}^{n} \lambda_i = \langle \boldsymbol{\nabla} \cdot \boldsymbol{f} \rangle \ , \tag{32.47}$$

the average being over the attractor. In particular a Hamiltonian flow has $\sum_i \lambda_i = 0$*, and the Lorenz flow has* $\sum_i \lambda_i = -(\sigma + 1 + b)$*.*
Rests on Theorem 32.6 and Definition 32.73.

Proof. *Derives Proposition 32.76.*

An infinitesimal ball of radius ϵ is carried by Equation (32.45) into an ellipsoid whose principal axes are $\epsilon\mu_i(t)$, so its volume is $V(t) = V(0)\prod_i \mu_i(t)$ and

$$\frac{1}{t}\ln\frac{V(t)}{V(0)} = \sum_i \frac{1}{t}\ln\mu_i(t) \longrightarrow \sum_i \lambda_i \, .$$

On the other hand Equation (32.3) applied to an infinitesimal volume gives $\dot{V}/V = \boldsymbol{\nabla}\cdot\boldsymbol{f}$ evaluated on the trajectory, so $t^{-1}\ln[V(t)/V(0)]$ is the time average of $\boldsymbol{\nabla}\cdot\boldsymbol{f}$ along it, which for an ergodic measure tends to its space average. Equating the two limits gives Equation (32.47). For a Hamiltonian flow the divergence vanishes identically (Theorem 24.21); for Equation (32.36) it is the constant of Proposition 32.64. □

Proposition 32.77 (A flow has a zero exponent)**.** *Let a trajectory of Equation (32.1) remain in a compact invariant set containing no fixed point. Then it has at least one vanishing Lyapunov exponent, associated with displacement along the flow.*
Rests on Equation (32.45) and Definition 32.73.

Proof. *Derives Proposition 32.77.*

Differentiate $\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x})$ with respect to t: $\ddot{\boldsymbol{x}} = D\boldsymbol{f}(\boldsymbol{x})\dot{\boldsymbol{x}}$, so $\delta\boldsymbol{x}(t) = \boldsymbol{f}(\boldsymbol{x}(t))$ is itself a solution of the variational equation Equation (32.45). On a compact attractor containing no fixed point, $|\boldsymbol{f}|$ is bounded above and below by positive constants (Theorem 7.24), so $t^{-1}\ln|\delta\boldsymbol{x}(t)| \to 0$: the exponent along the flow is zero. The hypothesis excludes a fixed point because $|\boldsymbol{f}|$ must be bounded away from zero; the Lorenz attractor does contain one, at the origin, and the conclusion survives there only because a trajectory spends a vanishing fraction of its time near it, which is a statement about the invariant measure and not about the flow alone. This is why a three-dimensional dissipative flow has the spectrum $(+, 0, -)$ with the sum negative—the smallest arrangement that admits chaos—and why a map, which has no such direction, can be chaotic in one dimension. □

Remark 32.78 (Extracting exponents from data). An experiment does not deliver $D\boldsymbol{f}$; it delivers a scalar time series. The standard procedure embeds the series in a higher-dimensional space by delay coordinates, follows a pair of nearby reconstructed points, measures the growth of their separation over a short interval, renormalizes the separation before it leaves the linear regime, and averages the logarithmic growth rates [1766]. The output is λ_1 with an uncertainty dominated by the length of the series and the noise level, and it is on this chain that every experimental claim of a positive exponent in Section 32.7

rests. The embedding step itself—that a scalar observable of a d-dimensional attractor generically reconstructs it in $2d+1$ delay coordinates—is a theorem of Takens whose primary reference is not in this bibliography; it is used here as a method and not cited as a result.

32.5.4 Fractal dimension

Definition 32.79 (Box-counting dimension, restated from Part II)**.** Let $N(\epsilon)$ be the least number of boxes of side ϵ needed to cover a bounded set S. Its *box-counting dimension* is

$$D_0 = \lim_{\epsilon \to 0} \frac{\ln N(\epsilon)}{\ln (1/\epsilon)} , \tag{32.48}$$

when the limit exists. For a point, a smooth curve and a smooth surface it returns 0, 1 and 2. This is Definition 7.110 specialized twice over: the limit is written as though it exists, where that definition keeps the upper and lower limits apart and calls them $\overline{\dim}_{\mathrm{B}}$ and $\underline{\dim}_{\mathrm{B}}$; and the covering family is boxes of a fixed side rather than arbitrary sets of diameter at most δ. The two covering conventions give the same value whenever either limit exists, since a box of side ϵ has diameter $\epsilon\sqrt{3}$ and a set of diameter δ fits in a box of side δ, so the two counts differ by a factor that is constant in ϵ and drops out of the logarithmic ratio. Proposition 7.111 records that the Hausdorff dimension of a set never exceeds the lower box dimension, so a box count bounds the finer quantity from above and is not a substitute for it.

Rests on Definitions 6.5 and 7.110.

Example 32.80 (The middle-thirds Cantor set)**.** Remove the open middle third of $[0,1]$, then the middle thirds of the two remaining intervals, and so on. At stage k the set is covered by $N = 2^k$ intervals of length $\epsilon = 3^{-k}$, so Equation (32.48) gives

$$D_0 = \lim_{k \to \infty} \frac{\ln 2^k}{\ln 3^k} = \frac{\ln 2}{\ln 3} = 0.6309 ,$$

a dimension strictly between that of a point and that of a line. The horseshoe's invariant set Equation (32.17) is the product of two such sets, with 2 and 3 replaced by the map's stretching and contraction factors.

Rests on Definition 32.79 and Theorem 32.42.

Definition 32.81 (Correlation dimension)**.** For N points $\boldsymbol{x}_i$ sampled from a trajectory, let

$$C(\epsilon) = \lim_{N \to \infty} \frac{1}{N^2} \sum_{i \neq j} \Theta(\epsilon - |\boldsymbol{x}_i - \boldsymbol{x}_j|) \tag{32.49}$$

be the fraction of pairs closer than ϵ, with Θ the step function. Where $C(\epsilon) \propto \epsilon^{D_2}$ over a range of ϵ, the exponent D_2 is the *correlation dimension* [1720].

Rests on Definition 32.79.

Equation (32.49) is what makes fractal dimension an experimental quantity rather than a mathematical one: it needs only a list of points, it is computed by counting pairs, and it applies without change to a numerical trajectory and to an attractor reconstructed from a measured scalar series by the embedding of Remark 32.78. The measured values are collected in Table 32.3.

Remark 32.82 (Dimension and exponents, and a measure-theoretic gap). The Kaplan–Yorke estimate used in Table 32.3 is

$$D_{KY} = j + \frac{\lambda_1 + \cdots + \lambda_j}{|\lambda_{j+1}|} ,$$

Table 32.3: Correlation dimensions measured by pair counting Equation (32.49) on numerically generated trajectories, compared with the Kaplan–Yorke estimate built from the Lyapunov spectrum. The two need not agree: D_2 is a lower bound on the information dimension that the Kaplan–Yorke formula estimates.

Attractor	D_2 measured [1720]	Kaplan–Yorke estimate
Lorenz, $\sigma = 10$, $b = 8/3$, $r = 28$	2.05 ± 0.01	2.06
Hénon, $\hat{a} = 1.4$, $\hat{b} = 0.3$	1.21 ± 0.01	1.26

with j the largest index for which the partial sum is still non-negative: the dimension at which the volume growth rate changes sign. It is a conjecture, not a theorem, and its primary reference is not in this bibliography; it is quoted here as an estimate and never as a measured value.

More fundamentally, the canonical definition of a fractal dimension is Hausdorff's, built on an outer measure. Section 7.12 constructs it (Definition 7.108) without any Lebesgue theory, and Proposition 7.111 relates it to the box count: the Hausdorff dimension never exceeds the lower box-counting dimension, and the gap can be total — the rationals of $[0, 1]$ have Hausdorff dimension 0 and box dimension 1. This chapter works with Equation (32.48) and Equation (32.49) because they are what a finite data set can actually return; what they return is therefore an *upper* bound on the Hausdorff dimension of the attractor, never a determination of it. The general fractal vocabulary is Mandelbrot's [1696]. Together with the Lyapunov spectrum, the dimension is the second quantitative fingerprint of a chaotic attractor, and the two are the numbers that an experiment actually returns.

32.6 Universal routes to chaos

32.6.1 The logistic map

Definition 32.83 (The logistic map)**.** A population N_n in generation n, growing at fractional rate ρ per generation and limited by a carrying capacity K, obeys the difference equation $N_{n+1} = N_n\,[1 + \rho\,(1 - N_n/K)]$. Setting $x_n = \rho N_n / [(1+\rho)K]$ and $r = 1 + \rho$ turns it into the *logistic map*

$$x_{n+1} = f_r(x_n) = r\,x_n\,(1 - x_n)\ , \tag{32.50}$$

which maps $[0, 1]$ into itself for $0 < r \le 4$. Both x and r are dimensionless, being a population in units of a population and a rate per generation [1587].

Rests on Definition 32.3.

Proposition 32.84 (Fixed points and the first period doubling)**.** *Equation (32.50) has fixed points $x^* = 0$, with multiplier r, and $x^* = 1 - 1/r$, with multiplier $2 - r$. The origin is stable for $r < 1$; the second fixed point exists and is stable for $1 < r < 3$; at $r_1 = 3$ its multiplier passes through -1 and a stable two-cycle is born, which itself loses stability at*

$$r_2 = 1 + \sqrt{6} = 3.449\,490\,. \tag{32.51}$$

Rests on Equation (32.50) and Proposition 32.39.

Proof. *Derives Proposition 32.84.*

Solving $rx(1 - x) = x$ gives $x^* = 0$ and $x^* = 1 - 1/r$. Since $f_r'(x) = r(1 - 2x)$, the multipliers are $f_r'(0) = r$ and $f_r'(1 - 1/r) = r\,(1 - 2 + 2/r) = 2 - r$; Proposition 32.39 makes each fixed point stable exactly while its multiplier lies in $(-1, 1)$, which gives $r < 1$ and $1 < r < 3$. At $r = 1$ the multiplier is $+1$ and the two branches exchange stability:

the transcritical bifurcation of Proposition 32.24(i). At $r = 3$ it is -1, which is a period doubling.

For the two-cycle $\{p, q\}$, add and multiply the two conditions $q = rp(1-p)$ and $p = rq(1-q)$. Subtracting gives $p+q = (r+1)/r$, and substituting back gives $pq = (r+1)/r^2$. The multiplier of the cycle is the product of the derivatives,

$$f_r'(p)f_r'(q) = r^2(1-2p)(1-2q) = r^2\left[1-2(p+q)+4pq\right] = -r^2+2r+4\,,$$

using the two symmetric functions just found. Setting this to $+1$ returns $r = 3$, the birth of the cycle; setting it to -1 gives $r^2 - 2r - 5 = 0$, whose positive root is Equation (32.51). That is the second period doubling, and the process repeats. □

Remark 32.85 (The cascade, its windows, and the word "chaos"). The doublings continue: $r_3 = 3.544\,090$, $r_4 = 3.564\,407$, $r_5 = 3.568\,759$, and the sequence accumulates geometrically at

$$r_\infty = 3.569\,945\,6\,, \tag{32.52}$$

beyond which the map has orbits of every period and no stable cycle of any period over most of the remaining interval [1587]. The chaotic region is not solid: it is shot through with *windows* of stable periodic behaviour, the widest being the period-three window opening at $r = 1+\sqrt{8} = 3.828\,427$, where the third iterate f_r^3 becomes tangent to the diagonal in a saddle-node bifurcation (Proposition 32.23) creating a stable and an unstable three-cycle at once. The algebra of that tangency is not reproduced here and the value is quoted [1587].

The existence of a three-cycle is not a curiosity. Li and Yorke proved that a continuous map of an interval possessing a periodic point of period three has periodic points of every period, and an uncountable set of points whose orbits neither converge to any periodic orbit nor to each other [1553]; the paper is where the word "chaos" entered the mathematical literature. The theorem is quoted, not proved here.

Proposition 32.86 (The logistic map at $r = 4$ is exactly solvable)**.** *The change of variable $x = \sin^2(\pi\vartheta)$ conjugates f_4 to the doubling map $\vartheta \mapsto 2\vartheta \bmod 1$. Hence $x_n = \sin^2(2^n\pi\vartheta_0)$, the orbit is periodic exactly when ϑ_0 is rational, and the Lyapunov exponent is $\lambda = \ln 2$ per iterate for almost every ϑ_0.*

Rests on Equation (32.50) *and Definition 32.73.*

Proof. *Derives Proposition 32.86.*

With $x = \sin^2(\pi\vartheta)$,

$$f_4(x) = 4\sin^2(\pi\vartheta)\left[1-\sin^2(\pi\vartheta)\right] = \left[2\sin(\pi\vartheta)\cos(\pi\vartheta)\right]^2 = \sin^2(2\pi\vartheta)\,,$$

which is the same function of 2ϑ: the conjugacy holds and iterating gives x_n. Writing ϑ_0 in binary, the doubling map is the shift on its digits, so the orbit is eventually periodic precisely for rational ϑ_0—these form a set of zero length—and for every other starting point the orbit never repeats. The derivative of the doubling map is 2 at every point, so by Definition 32.73 the exponent in the ϑ variable is $\ln 2$ exactly; the conjugacy is smooth with nowhere-vanishing derivative except at the two endpoints, which the orbit visits with probability zero, so the exponent is unchanged in x. This is the cheapest complete example of chaos in the book: an explicit solution, an explicit positive exponent, and sensitivity that is nothing more than the loss of one binary digit of ϑ_0 per step—which is also exactly the symbolic dynamics of Proposition 32.43 with the two symbols the two binary digits. □

32.6.2 Feigenbaum universality

Phenomenon 32.87 (Universal period doubling)**.** As a control parameter is swept, a wide class of systems reaches chaos through an infinite cascade of period-doubling bifurcations

that accumulates at a finite parameter value. The parameter intervals between successive doublings shrink geometrically, and the ratio

$$\delta = \lim_{n\to\infty} \frac{\mu_n - \mu_{n-1}}{\mu_{n+1} - \mu_n} = 4.6692\ldots \tag{32.53}$$

is the same number for the logistic map, for a driven pendulum and for a convecting fluid, provided only that the return map of the system has a smooth quadratic maximum [1587, 1621]. This is the observed fact that a dimensionless constant of a difference equation is measurable in a laboratory: in a mercury Rayleigh–Bénard cell the cascade was followed through several doublings and δ recovered to within a few percent [1693].

Rests on Propositions 32.39 and 32.84.

Derivation. *Derives Phenomenon 32.87.*

Three things have to be shown: that the doublings recur without end, that their parameter intervals shrink geometrically so that the cascade accumulates at a finite parameter value, and that the ratio is a property of the cascade rather than of the map. The first two are derived here; the third is derived only as far as identifying what would have to be true, and the statement that it *is* true is quoted—see Remark 32.88.

The doublings recur. Proposition 32.84 carries the first two exactly: the fixed point $1 - 1/r$ loses stability at $r_1 = 3$ when its multiplier passes through -1, and the two-cycle born there loses stability the same way at $r_2 = 1 + \sqrt{6}$. The mechanism is self-reproducing. Let $\{p_1, \ldots, p_{2^n}\}$ be a stable 2^n-cycle at a parameter just below r_n. The map $f_r^{2^n}$ fixes each p_i, and the chain rule makes its derivative there the product $\prod_j f_r'(p_j)$ over the whole cycle—the same number at every p_i, since the factors are the same and multiply in any order—which is the multiplier that Proposition 32.39 grades and which reaches -1 at r_n. Take a small interval I_i about p_i, so small that $f_r^{2^n}$ maps it into itself; on it that iterate is smooth with negative slope at p_i. It also has a critical point there: the orbit of I_i visits, once per period, the interval containing the single critical point $x = 1/2$ of f_r, so by the chain rule $\left(f_r^{2^n}\right)'$ vanishes at the point of I_i whose orbit lands on $1/2$. That critical point is quadratic, because $f_r''(1/2) = -2r \neq 0$ and the chain rule multiplies it by factors that do not vanish. So $f_r^{2^n}$ restricted to I_i, reflected and rescaled to unit size, is again a unimodal map with a quadratic maximum and a multiplier sweeping downwards through -1: exactly the situation at r_1, one level up. It doubles again, and the argument applies at every level.

The intervals shrink geometrically. Write $\mathcal{R}$ for the operation just described—take f_r, iterate twice, restrict, reflect and rescale—and let $r \mapsto \mathcal{R}(r)$ denote the induced map on the parameter, defined by requiring the rescaled map at $\mathcal{R}(r)$ to look like the original at r. By construction it carries the nth doubling to the $(n-1)$th, so $\mathcal{R}(r_n) = r_{n-1}$, and it fixes the accumulation point, $\mathcal{R}(r_\infty) = r_\infty$, because a map at r_∞ has already doubled infinitely often and rescaling removes one doubling from an infinite supply. If $\mathcal{R}$ is differentiable at r_∞ with derivative δ, then linearizing about the fixed point in the manner of Definition 32.12 gives $r_{n-1} - r_\infty \approx \delta\,(r_n - r_\infty)$, hence

$$r_\infty - r_n \approx C\,\delta^{-n}\,, \qquad \frac{r_n - r_{n-1}}{r_{n+1} - r_n} \longrightarrow \delta\,, \tag{32.54}$$

which is Equation (32.53). Two consequences follow at once. The doubling parameters form a geometric sequence, so their sum converges and the cascade accumulates at a *finite* r_∞ after infinitely many doublings—a cascade that did not shrink geometrically would run off the end of the parameter range instead. And $\delta > 1$, since the doublings crowd together rather than spread apart, so r_∞ is a *repelling* fixed point of $\mathcal{R}$ in the parameter.

The arithmetic checks. Using the exact $r_1 = 3$ and $r_2 = 1 + \sqrt{6} = 3.449\,490$ of Proposition 32.84 and the numerically located $r_3 = 3.544\,090$, $r_4 = 3.564\,407$, $r_5 = 3.568\,759$ of Remark 32.85, the successive ratios in Equation (32.54) are

$$4.7514\,, \qquad 4.6562\,, \qquad 4.6684\,,$$

converging on $\delta = 4.6692$ from alternate sides. Summing the remaining geometric tail from r_5,

$$r_\infty \approx r_5 + \frac{r_5 - r_4}{\delta - 1} = 3.568\,759 + \frac{0.004\,352}{3.6692} = 3.569\,945\,1\,,$$

against the directly computed $r_\infty = 3.569\,945\,6$ of Equation (32.52): agreement in the seventh digit, which is the quantitative test that the convergence really is geometric with that ratio and not merely fast.

Why the ratio is not a property of the logistic map. Nothing in the first step used the quadratic form of Equation (32.50) beyond two facts: that the map has one critical point in the interval, and that the critical point is quadratic. Any system whose return map (Definition 32.38) has those two properties enters the same construction at the first level, and after one application of $\mathcal{R}$ it is described by a rescaled map of the same class. So the cascade of *every* such system is governed by the same operation $\mathcal{R}$, and if $\mathcal{R}$ has a single fixed point attracting that whole class, with one repelling direction of multiplier δ, then every member inherits that δ regardless of what it is made of—a difference equation, a driven pendulum, or a convecting layer of mercury. That is the content of the observation, and Remark 32.90 states the operator whose fixed point it is. Its existence is what is quoted [1621]. □

Remark 32.88 (What is quoted in the cascade, and what is not). The boundary is sharp and worth marking, in the manner of Remark 17.18. Derived above: that the doublings recur, that they accumulate geometrically at a finite parameter value, that the ratio is asymptotically the multiplier of a repelling fixed point of the doubling operation, and that the class of systems entering the construction is fixed by two local properties of the return map and by nothing else. Quoted: that the doubling operator $\mathcal{T}$ of Remark 32.90 actually *has* a fixed point g in a suitable space of unimodal maps, that its linearization there has exactly one eigenvalue outside the unit circle, and that the eigenvalue is $4.669\,201\,609\,102\,990\ldots$. Those three statements are a theorem of analysis, first established by a computer-assisted proof whose primary reference is not in this bibliography; the numbers themselves are quoted from [1621]. No measured quantity in this chapter depends on the quoted half: the comparison in Section 32.7.1 is between a measured ratio and a number computed from the logistic map's own cascade, and Equation (32.54) is what connects them.

Remark 32.89 (The two constants and their measured values). Two numbers govern the cascade [1621]. The first is δ of Equation (32.53), the rate at which the parameter intervals shrink,

$$\delta = 4.669\,201\,609\,102\,990\ldots\,,$$

and the second is the rate at which the attractor itself rescales: successive period-doubled orbits reproduce the previous pattern reduced by

$$\alpha = 2.502\,907\,875\,095\,893\ldots$$

in the state variable. Both are mathematical constants of the doubling operator, so they carry no uncertainty of their own; what carries uncertainty is their measurement in a physical system. For the logistic map the finite-order ratios approach δ from above—the first three, computed from the values in Proposition 32.84 and Remark 32.85, are 4.7514, 4.6562 and 4.6684—so an experiment that resolves only the first few doublings is not limited by that convergence but by its own resolution. In the mercury cell of Section 32.7.1 the measured value is $\delta = 4.4 \pm 0.1$ [1693], about 6 % below the exact constant; the deficit is the resolution of the higher doublings, whose parameter intervals shrink by the factor δ at each step and soon fall below the stability of the control.

Remark 32.90 (Why a difference equation and a fluid share a number). The mechanism is a renormalization group, in exactly the sense of Chapter 108. Define the doubling operator $(\mathcal{T}f)(x) = -\alpha\, f(f(-x/\alpha))$, which composes a map with itself and rescales so that the result is again normalized: it takes the description of a system at one level of the cascade to the description at the next. If $\mathcal{T}$ has a fixed point g, then g describes a system that looks the same after every doubling, and every map in the basin of g flows to it under repeated doubling and therefore inherits its numbers. Linearizing $\mathcal{T}$ about g, the fixed point turns out to have exactly one eigenvalue outside the unit circle, and that eigenvalue is δ; α is the scaling built into the operator. What is universal is thus the *unstable direction of a fixed point in a space of maps*, and what a physical system contributes is only which point of that space it starts from—which is why the only hypothesis needed is a smooth quadratic maximum. The existence of g is not elementary; it was established by a computer-assisted proof whose reference is not in this bibliography, and this chapter quotes the constants rather than deriving them.

32.6.3 Quasiperiodicity and intermittency

Period doubling is one of three routes by which a system is observed to become chaotic, and an experiment must distinguish them.

Definition 32.91 (The circle map)**.** The phase of a limit-cycle oscillator sampled at the period of an external drive obeys, to leading order, the *circle map*

$$\vartheta_{n+1} = \vartheta_n + \Omega - \frac{K}{2\pi}\sin\left(2\pi\vartheta_n\right) \pmod 1\,, \tag{32.55}$$

in which Ω is the ratio of the natural frequency of the oscillator to the drive frequency and K the dimensionless coupling. The *winding number* $W = \lim_{n\to\infty}(\vartheta_n - \vartheta_0)/n$ is the observed frequency ratio.

Rests on Phenomenon 32.37 and Definition 32.38.

Remark 32.92 (Mode locking, Arnold tongues and the torus). For $K < 1$ the winding number of Equation (32.55) is a continuous, non-decreasing function of Ω that is constant on an interval around every rational value—a *devil's staircase*. The intervals are the mode-locked states; plotted in the (Ω, K) plane they are the Arnold tongues, widening from zero width at $K = 0$ until at $K = 1$ they fill the axis and the irrational winding numbers form a set of zero length. That is the staircase heard by van der Pol and van der Mark (Phenomenon 32.37), and the critical line $K = 1$ is where the last quasiperiodic motion is destroyed. In the underlying flow, quasiperiodic motion with two incommensurate frequencies is motion on an invariant two-torus; mode locking is the capture of that motion onto a closed orbit on the torus, and the destruction of the torus at $K = 1$ is the second route to chaos, the one proposed by Ruelle and Takens [1453].

The line $K = 1$ deserves its own statement, because everything the quasiperiodic route claims turns on what happens as it is crossed.

Proposition 32.93 (The circle map loses invertibility at $K = 1$)**.** *For the map Equation (32.55),*

$$\frac{\mathrm{d}\vartheta_{n+1}}{\mathrm{d}\vartheta_n} = 1 - K\cos\left(2\pi\vartheta_n\right)\,. \tag{32.56}$$

Hence: for $K < 1$ the map is an orientation-preserving diffeomorphism of the circle; at $K = 1$ its derivative vanishes at the single point $\vartheta = 0$, where the second derivative vanishes as well, so the critical point is an inflection of cubic type; and for $K > 1$ the derivative is negative on an interval, the map is not injective, and it carries two quadratic critical points.

In the last case $|\mathrm{d}\vartheta_{n+1}/\mathrm{d}\vartheta_n|$ *reaches* $1+K>2$ *at* $\vartheta=\frac{1}{2}$*, so the map both stretches and folds.*

Rests on Definitions 32.38 and 32.91.

Proof. *Derives Proposition 32.93.*

Differentiating Equation (32.55) gives Equation (32.56) at once. Its minimum over the circle is $1-K$, attained at $\vartheta=0$, and its maximum is $1+K$, attained at $\vartheta=\frac{1}{2}$. So the derivative is strictly positive everywhere exactly when $K<1$, and a smooth circle map with everywhere positive derivative is a diffeomorphism: it is a local diffeomorphism, it is strictly increasing as a map of the line commuting with the translation by 1, and it therefore descends to a bijection of the circle preserving orientation.

At $K=1$ the derivative vanishes at $\vartheta=0$ and nowhere else. The second derivative of Equation (32.55) is $2\pi K\sin(2\pi\vartheta)$, which also vanishes at $\vartheta=0$, while the third derivative there is $4\pi^2K\neq 0$. The critical point is therefore cubic, not quadratic—which is why the critical line $K=1$ has universal numbers of its own and *not* those of Section 32.6.2, whose whole hypothesis was a quadratic maximum.

For $K>1$ the derivative is negative wherever $\cos(2\pi\vartheta)>1/K$, an interval about $\vartheta=0$, and positive elsewhere. A map that decreases on one interval and increases on another takes some values twice, so it is not injective; and its two turning points $\vartheta_\pm=\pm(2\pi)^{-1}\arccos(1/K)$ are quadratic, since there $\sin(2\pi\vartheta_\pm)=\mp\sqrt{1-K^{-2}}\neq 0$ makes the second derivative nonzero. The bound on the derivative is read off the maximum computed above. □

Remark 32.94 (What that proposition does and does not settle). The consequences run in both directions. Below $K=1$ the return map is a circle diffeomorphism, and a circle diffeomorphism cannot be chaotic: its orbits are ordered on the circle for all time, so nearby points cannot separate and later re-approach in the way Phenomenon 32.72 requires. The invariant circle of the section—the two-torus of the flow—survives, and the motion on it is either mode-locked or quasiperiodic, exactly the dichotomy of Remark 32.92. Above $K=1$ that protection is gone. Proposition 32.93 supplies precisely the two ingredients Section 32.3.2 identified as sufficient: stretching, by a factor up to $1+K$, and folding, at the two quadratic turning points. Two points with different histories can now share an image, so the past is not recoverable from the present, and the invariant set of the section is no longer a smooth circle—there is no smooth invariant two-torus left to carry the motion. That is the torus breakdown, in the one model where it can be seen explicitly.

Two things are quoted rather than proved. That an orbit of a circle diffeomorphism has a well-defined winding number independent of the starting point, and that an irrational winding number forces the map to be semi-conjugate to the rigid rotation by it, are Poincaré's rotation-number theorem and Denjoy's theorem; both are ordinary differential equations and circle dynamics, and belong with the material of Chapter 9, which does not carry them. And the general classification—that after three generic bifurcations from a fixed point an invariant three-torus is typically replaced by an attractor with a continuous spectrum—is the Newhouse–Ruelle–Takens theorem, quoted here from [1453]. Its proof is a genericity argument in a space of vector fields, machinery that appears nowhere else in this treatise, and Remark 17.18 is the precedent for quoting such a thing rather than owing it. Nothing measured in Section 32.7.2 depends on the quoted half: what the experiment tests is the presence of a continuous spectral component after a small number of transitions, and that is decided by the argument given in Phenomenon 32.97.

Proposition 32.95 (Intermittency: the scaling of the laminar phase)**.** *Let a stable and an unstable fixed point of a return map annihilate in a saddle-node bifurcation (Proposition 32.23) at a parameter* μ_c*, and let the map beyond the bifurcation be* $x_{n+1}=x_n+\epsilon+ax_n^2$ *with* $\epsilon\propto\mu-\mu_c>0$ *and* $a>0$*. Then the orbit spends a mean number of iterations*

$$\langle\ell\rangle\simeq\frac{\pi}{\sqrt{a\epsilon}}\propto(\mu-\mu_c)^{-1/2} \tag{32.57}$$

in the narrow channel where the fixed points used to be, producing long stretches of nearly periodic behaviour interrupted by bursts [1657].

Rests on Proposition 32.23 and Definition 32.38.

Proof. *Derives Proposition 32.95.*

In the channel the increment per iterate is small, so the difference equation may be replaced by the differential equation $\mathrm{d}x/\mathrm{d}n = \epsilon + ax^2$. Separating variables and integrating across the channel,

$$\ell = \int_{-\infty}^{+\infty} \frac{\mathrm{d}x}{\epsilon + ax^2} = \frac{1}{\sqrt{a\epsilon}} \left[\arctan\left(x\sqrt{\frac{a}{\epsilon}} \right) \right]_{-\infty}^{+\infty} = \frac{\pi}{\sqrt{a\epsilon}} ,$$

the limits being taken to the edges of the channel, where the quadratic approximation fails but the integrand is already negligible. That is Equation (32.57). The signature is a distinguishing one: a system approaching chaos by intermittency shows periodic behaviour interrupted by bursts whose mean spacing diverges as an inverse square root of the distance from threshold, and no subharmonics at all. □

Remark 32.96 (The three-route checklist). An experiment sweeping a control parameter therefore has three signatures to look for, and they are mutually exclusive in the power spectrum. *Period doubling*: a sequence of new lines at $f/2$, $f/4$, $f/8$, at parameter intervals shrinking by Equation (32.53). *Quasiperiodicity*: a second line incommensurate with the first, then broadband. *Intermittency*: no new lines at all, but bursts interrupting a periodic signal, with the laminar length scaling as Equation (32.57). Each has been observed. The measurements in Section 32.7 are the record of the first two.

32.7 Experimental chaos

32.7.1 Rayleigh–Bénard convection

The convection cell is the workhorse of experimental chaos because its control parameter, the Rayleigh number Equation (32.38), is set by a temperature difference and can be held and swept with great stability. The background—Bénard's cells and Rayleigh's stability calculation—belongs to Section 31.8.2; for a real cell with rigid upper and lower boundaries the critical value is $\mathrm{Ra}_c = 1708$, not the 657.5 of the stress-free idealization used in Definition 32.62.

Libchaber, Laroche and Fauve used liquid mercury, whose Prandtl number $\sigma = \nu/\kappa$ is about 0.025—from $\nu \approx 1.1 \times 10^{-7}\,\mathrm{m^2/s}$ and $\kappa \approx 4.4 \times 10^{-6}\,\mathrm{m^2/s}$—and is therefore two orders of magnitude below that of water. A small Prandtl number makes the convecting rolls oscillate rather than remain steady at modest Ra, which is exactly what is wanted: the oscillation supplies the periodic orbit whose doubling is to be followed. The cell was small enough to contain only a few rolls, so that the number of active degrees of freedom stayed low, and a horizontal magnetic field was applied to damp the transverse motions that would otherwise introduce further frequencies. The temperature was recorded by a bolometer inside the fluid, and the power spectrum of that signal was computed as Ra was raised [1693].

What the spectrum showed was the cascade of Remark 32.96: the fundamental oscillation, then a line at half its frequency, then at a quarter, then at an eighth, each appearing at a value of Ra closer to the last than the previous interval by a factor near δ. From the ratios of the successive intervals the experiment returns

$$\delta_{\mathrm{measured}} = 4.4 \pm 0.1 , \tag{32.58}$$

against the exact $4.669\ldots$ of Remark 32.89 [1693]. The agreement is at the 6 % level, and the shortfall is a resolution effect: each successive interval is smaller than the last by δ, so

the fourth doubling requires holding the temperature difference to a part in $\delta^3 \approx 100$ of the first interval.

That is the whole evidential point of this chapter. A constant computed from a one-line difference equation with no physical content whatever appears, to a few percent, in the temperature record of a centimetre of mercury—because both systems are governed by the same fixed point of the doubling operator of Remark 32.90, and by nothing else they share.

32.7.2 Taylor–Couette flow

Fluid between concentric cylinders, the inner one rotating, becomes unstable to a stack of toroidal vortices above a critical rotation rate; Taylor computed the threshold and measured it in the same paper, obtaining what was then the first quantitative agreement between a hydrodynamic stability calculation and an experiment [505]. In the narrow-gap limit the criterion is a critical Taylor number of 1708, the same number as the rigid-boundary Rayleigh–Bénard threshold, the two problems having the same linear operator.

Gollub and Swinney took that apparatus into the chaotic regime and measured, by laser-Doppler velocimetry, the radial velocity at a point in the fluid as the rotation rate was increased through and well beyond the Taylor threshold [1545]. Velocimetry is what makes the experiment decisive: it delivers a time series long enough and clean enough for a power spectrum, in a flow that a visualization would only show to be complicated.

Phenomenon 32.97 (Turbulence sets in after a few transitions)**.** In a fluid confined between rotating cylinders, the power spectrum of the velocity acquires, as the rotation rate is raised, first one sharp frequency, then a second incommensurate with it, and then — after only a small number of such steps — a broadband continuous component that grows until it dominates [1545]. The measurement excludes Landau's picture of turbulence as the accumulation of an unbounded sequence of incommensurate frequencies, which would show a spectrum of ever more discrete lines and no continuum, and supports instead a route in which a low-dimensional attractor with a continuous spectrum appears after a few bifurcations [1453]. The underlying instability of the rotating flow is Taylor's [505].

Rests on Remark 32.69 and Definition 32.67.

Derivation. *Derives Phenomenon 32.97.*

What has to be derived is why the shape of the spectrum decides between the two pictures at all, since both predict complicated motion.

Landau's flow after n instabilities is quasiperiodic with n incommensurate frequencies: by construction the velocity at a point is

$$v(t) = V\left(\omega_1 t, \dots, \omega_n t\right) ,$$

with V continuous and 2π-periodic in each of its arguments. Such a V has a multiple Fourier series, so

$$v(t) = \sum_{\boldsymbol{k}\in\mathbb{Z}^n} c_{\boldsymbol{k}}\, \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{\omega}t} , \tag{32.59}$$

and all the power sits on the set $\{\boldsymbol{k}\cdot\boldsymbol{\omega} : \boldsymbol{k}\in\mathbb{Z}^n\}$, which is *countable* for every finite n. A countable set carries no continuous spectral component, whatever its density: the spectrum of a quasiperiodic signal consists of lines and nothing else, and this is true however large n becomes. Landau's route therefore predicts a spectrum that grows ever denser in lines and never acquires a continuum, at any stage.

A continuous component in the spectrum requires an autocorrelation that decays. If v has an integrable autocorrelation then its transform is a continuous function tending to zero at large frequency, by the Riemann–Lebesgue lemma (Lemma 17.7); conversely Equation (32.59) has an autocorrelation $\sum_{\boldsymbol{k}} |c_{\boldsymbol{k}}|^2\, \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{\omega}\tau}$ which is itself quasiperiodic and

never decays. So the appearance of a broadband component is precisely the statement that correlations are being lost—which is what a positive Lyapunov exponent does, by Equation (32.44), and what motion on a torus cannot do.

The measurement therefore reads as follows. Sharp lines appearing one at a time are consistent with both pictures. The appearance of a broadband component, after a number of transitions that can be counted on one hand, is consistent with only one of them. Gollub and Swinney observed exactly that: one frequency at the Taylor transition, a second incommensurate frequency, and then, at a rotation rate of order ten times the critical one, a continuous component that could not be resolved into further lines [1545]. The exact multiple depends on the radius ratio and aspect ratio of the cell and is not a universal number; the number of transitions before the continuum appears is the observable that matters, and it is small. □

The derivation above settles the spectral half of the reading: a quasiperiodic flow of *any* number of frequencies has a pure point spectrum, so a continuous component cannot be Landau's accumulation. The other half—how the invariant two-torus is destroyed once the coupling is strong enough—is Proposition 32.93, whose loss of invertibility at $K = 1$ produces the stretching and folding that a torus cannot support, and Remark 32.94 states exactly which part of the general classification is quoted from [1453] and which is derived. Nothing Gollub and Swinney measured depends on the quoted part.

32.7.3 Circuits and driven oscillators

Electronics is where chaos was first heard, and it remains where it is most easily produced. A circuit has no boundary layers, no aspect ratio and no thermal inertia; its state variables are two voltages and a current, its parameters are components with catalogue values, and its time series is available directly on an oscilloscope.

The first instance is van der Pol and van der Mark's neon-tube oscillator of Phenomenon 32.37, in which the irregular noise heard between locking steps was reported in 1927 and understood half a century later [590]. The modern bench standard is Chua's circuit, an inductor, two capacitors, a linear resistor and one nonlinear resistor with a piecewise-linear characteristic. In SI variables its equations are

$$C_1 \frac{\mathrm{d}v_1}{\mathrm{d}t} = \frac{v_2 - v_1}{R} - g(v_1)\,, \tag{32.60}$$

$$C_2 \frac{\mathrm{d}v_2}{\mathrm{d}t} = \frac{v_1 - v_2}{R} + i_L\,, \tag{32.61}$$

$$L \frac{\mathrm{d}i_L}{\mathrm{d}t} = -v_2\,, \tag{32.62}$$

with v_1, v_2 in V, i_L in A, C_1, C_2 in F, L in H, R in Ω, and the nonlinear element's characteristic

$$g(v) = G_b v + \tfrac{1}{2}\,(G_a - G_b)\,(|v + E| - |v - E|)\,, \tag{32.63}$$

whose slopes G_a, G_b are in S and whose breakpoint E is in V. The system is three-dimensional and autonomous, the minimum Remark 32.9 permits, and it is dissipative wherever the total conductance is positive. Equations (32.60) to (32.62) were shown numerically to possess a chaotic attractor by Matsumoto [1742], and the same attractor is produced on a breadboard in an undergraduate afternoon; sweeping R carries the circuit through a period-doubling cascade of the kind measured in Section 32.7.1.

The mechanical counterpart is the periodically driven, damped pendulum,

$$m\ell^2 \ddot{\theta} + b\dot{\theta} + mg\ell \sin\theta = \Gamma \cos(\omega_d t)\,, \tag{32.64}$$

with the drive torque Γ in N m. Writing the drive phase as a third variable makes Equation (32.64) an autonomous three-dimensional system, and taking a Poincaré section once per drive period (Definition 32.38) reduces it to a two-dimensional map; in the limit of weak damping and impulsive driving that map is the standard map Equation (32.25). The same apparatus that measures the isochronism of Chapter 34 at small amplitude becomes, driven hard, one of the cleanest demonstrations of a strange attractor available.

In every one of these systems the quantitative claim—that the motion is chaotic and not merely complicated—rests on the same measurement chain: record a scalar time series, embed it, extract λ_1 by the algorithm of [1766], and estimate D_2 by pair counting Equation (32.49). A positive exponent and a non-integer dimension, measured from data with stated uncertainties, are what distinguish deterministic chaos from noise. That distinction—and not any of the mathematics above—is what makes chaos an experimental subject.

Chapter 33

Experiment: The Cavendish Torsion Balance

Tests Equation (33.1).

Assuming Phenomenon 33.4 and Equation (33.6).

In 1797–1798 Henry Cavendish measured, in an outbuilding at Clapham, the gravitational attraction between lead spheres on a laboratory bench [44]. The declared aim was the mean density of the Earth; read retrospectively, it is the first laboratory determination of the constant G that fixes the strength of gravitation, and the archetype of every precision weak-force measurement since. Its role in this part is evidential: the inverse-square law of Chapter 27 rests observationally on celestial mechanics, and Cavendish supplies the laboratory half—the same law, with the same constant, between metre-scale masses. That universality is what the tests of Part V will probe to far greater precision.

Two threads run through the chapter and are treated with full honesty. The first is the theory of the torsion pendulum, which is what converts an observed angle into a force, and which does so *absolutely*: the instrument's force scale is fixed by a length, a mass distribution and a time, with no force standard anywhere in the chain. The second is the notorious mutual disagreement of the modern determinations. Six laboratory measurements quoting uncertainties of tens of parts per million scatter over some five hundred parts per million, and the recommended value therefore carries an uncertainty enlarged by a factor of nearly four to cover a spread nobody has explained [2286, 2392, 2431]. G is, by a wide margin, the least precisely known of the fundamental constants, and this chapter says so plainly rather than quoting the recommended value as though it were settled.

Remark 33.1 (Units: the original paper is imperial, this chapter is not). Cavendish reports every length in feet and inches and every mass in pounds, and quotes his result as a pure number—the ratio of the mean density of the Earth to that of water. Editorial rule 3 of this treatise admits SI only, so every apparatus figure below has been converted, and the density ratio has been multiplied by $1.0 \times 10^{3}\,\mathrm{kg/m^{3}}$ to become a density. The conversions are exact by definition (one inch is 25.4 mm, one pound is 0.453 592 37 kg), so nothing is lost; what is gained is that the numbers may be compared directly with the modern ones without a second act of translation. The uncertainty conventions are those of Chapter 2 and [2129]: a parenthesised figure is a standard uncertainty on the last digits quoted.

33.1 Historical context and the prediction under test

The experiment tests a law that had been believed for over a century and never once checked in a laboratory. This section states what the law asserts, shows why the astronomical evidence for it is structurally incapable of yielding the constant that appears in it, and records the one earlier attempt to weigh the Earth by gravitation alone.

33.1.1 Universal gravitation without a constant

Newton's law of universal gravitation, as this treatise states it, is
