The cobalt result says the interaction distinguishes handedness but does not by itself say which handedness the neutrino has. Landau, Lee and Yang, and Salam proposed within weeks that the neutrino is described by a two-component field — the two-component neutrino belongs to Chapter 96 — rather than by a four-component Dirac field with half of it inert [1118, 1121, 1130]. A two-component field has no mass term available to it and no partner of the opposite handedness, so the proposal predicts that the neutrino is completely longitudinally polarized, and it leaves the *sign* of that polarization open. Goldhaber, Grodzins and Sunyar measured it [1148].

Phenomenon 110.12 (The neutrino is longitudinally polarized)**.** Neutrinos emitted in orbital electron capture are longitudinally polarized with negative helicity, and within the uncertainty of the measurement completely so [1148]. Helicity is the pseudoscalar $h = 2\boldsymbol{S}\cdot\hat{\boldsymbol{p}}/\hbar$, so a non-zero mean helicity is by itself a violation of parity, and a mean helicity of magnitude one is a violation of the largest size a spin-$\frac{1}{2}$ particle admits.

Rests on Phenomenon 98.2.

Derivation. *Derives Phenomenon 110.12.*

The measurement is wholly indirect — no neutrino is detected — and what makes it work is that a chain of angular-momentum conservation laws transfers the neutrino's helicity to a photon that can be analysed. The chain is $^{152m}\mathrm{Eu}\,(0^-) + e^- \to {}^{152}\mathrm{Sm}^*\,(1^-) + \nu_e$, followed by $^{152}\mathrm{Sm}^*\,(1^-) \to {}^{152}\mathrm{Sm}\,(0^+) + \gamma$ with a photon of 961 keV. Take the axis $+\hat{\boldsymbol{z}}$ along the neutrino momentum. Angular momentum along that axis gives

$$m_{\mathrm{cap}} = \tfrac{1}{2}h_\nu + m_N\,, \tag{110.16}$$

where $m_{\mathrm{cap}} = \pm\frac{1}{2}$ is the captured electron's spin projection — written with a subscript that cannot be confused with the electron mass m_e used elsewhere in this chapter — $h_\nu = \pm 1$ the neutrino helicity and m_N the projection of the recoiling 1^- nucleus, which travels along $-\hat{\boldsymbol{z}}$. Solving Equation (110.16) for the nuclear projection gives $m_N = m_{\mathrm{cap}} - \frac{1}{2}h_\nu$, so a neutrino of helicity $h_\nu = -1$ leaves $m_N = 0$ when the captured electron had $m_{\mathrm{cap}} = -\frac{1}{2}$ and $m_N = +1$ when it had $m_{\mathrm{cap}} = +\frac{1}{2}$.

The nucleus then decays to a 0^+ ground state, so the photon must carry the whole of m_N; and the experiment selects, by resonant scattering on a samarium scatterer, only those photons emitted *antiparallel* to the neutrino, because only those are Doppler-shifted enough to compensate the nuclear recoil and reach resonance. A real photon has no angular-momentum projection zero along its own direction of motion, so the $m_N = 0$ branch contributes nothing to the detected sample and every counted photon comes from $m_N = +1$. A photon travelling along $-\hat{\boldsymbol{z}}$ with projection m_γ on $+\hat{\boldsymbol{z}}$ has helicity $h_\gamma = -m_\gamma$, so $h_\gamma = -1 = h_\nu$: the photon inherits the neutrino's helicity exactly, and the same algebra run with $h_\nu = +1$ gives $h_\gamma = +1$, so the two hypotheses differ in the sign of a measurable circular polarization and not in its magnitude. The circular polarization of the resonantly scattered photon, measured by transmission through magnetized iron, is therefore the neutrino helicity, and it was found negative. The full apparatus, the recoil kinematics that make the resonance condition selective, and the dilution introduced by the finite lifetime of the intermediate state belong to Chapter 98, whose Phenomenon 98.2 states the result and carries this bookkeeping in its complete form. □

Two qualifications belong with the result. The first is that helicity is a Lorentz-invariant label only for a massless particle: for a massive one an observer moving faster than the particle sees the helicity reversed, so what is measured at a given energy is the chirality of the current rather than an intrinsic property of the particle. Proposition 105.20 makes this quantitative — a $V-A$ current emits a fermion with longitudinal polarization $-v/c$, so a strictly massless neutrino has helicity exactly -1 and a massive one falls short by $m_\nu^2 c^4/(2E^2)$. The second is that neutrinos do have mass — the oscillation measurements that show it belong to Chapter 114 — but at the sub-eV masses involved and the MeV energies of the Goldhaber measurement, the correction is smaller than 10^{-12} and the conclusion is untouched.

110.6 Immediate confirmation: the pion–muon–electron chain

110.6.1 Garwin, Lederman and Weinrich

The third of Lee and Yang's proposals was carried out at the Nevis cyclotron over a weekend, with apparatus that already existed, and it was submitted and published alongside the cobalt paper [1110]. Its subject is the chain

$$\pi^+ \to \mu^+ + \nu_\mu\,, \qquad \mu^+ \to e^+ + \nu_e + \bar{\nu}_\mu\,, \tag{110.17}$$

and its logic is that the first decay *produces* a polarization and the second *analyses* it, so that a single counting-rate modulation demonstrates parity violation twice over.

The Nevis counter arrangement A beam of positive pions from the cyclotron passes through an absorber some tens of centimetres of carbon thick. The absorber is chosen to stop the pions — which interact strongly and have a short range at the beam momentum — while transmitting the muons produced by decay in flight, which have a longer range because they do not interact strongly. What emerges is therefore a muon beam, and because the transmitted muons are those emitted forwards in the pion rest frame, they carry the full longitudinal polarization that the two-body decay gives them. The muons are brought to rest in a carbon target surrounded by a magnetizing coil producing a small, uniform, reversible field perpendicular to the muon spin. A scintillation-counter telescope in a fixed direction records positrons from the muon decays, and the counting is gated in time: a first counter signals the arrival and stopping of a muon, and positrons are accepted only within a window of a few microseconds afterwards, comparable with the muon mean life $\tau_\mu = 2.1970 \times 10^{-6}\,\mathrm{s}$ obtained from the PDG width $\Gamma_\mu = (2.995\,983\,6 \pm 0.000\,003\,0) \times 10^{-19}\,\mathrm{GeV}$ through $\tau = \hbar/\Gamma$ [2427].

The precession scan The muon spin precesses about the applied field while the muon waits to decay, so the angle between the spin and the fixed counter is a function of the field strength and of the elapsed time. Holding the time gate fixed and varying the magnetizing current sweeps that angle, and the counting rate in the fixed telescope traces out a sinusoid. The measurement is thus a scan of counting rate against coil current, which is a robust thing to measure: the geometry never moves, and the quantity extracted is the *phase and amplitude* of a periodic modulation rather than the difference of two absolute rates.

Phenomenon 110.13 (Muon polarization in the pion decay chain)**.** Positive muons brought to rest from the decay $\pi^+ \to \mu^+\nu_\mu$ are longitudinally polarized, and the positrons from their subsequent decay $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$ are emitted asymmetrically about the muon spin: precessing the stopped muons in a small magnetic field modulates the rate in a fixed counter sinusoidally with the precession phase [1109, 1110]. Parity is violated twice over — once in the pion decay that creates the polarization, once in the muon decay that reveals it.

Rests on Equation (110.17) *and Phenomenon 110.12.*

Derivation. *Derives Phenomenon 110.13.*

The pion has spin 0 and decays at rest into two spin-$\frac{1}{2}$ particles emitted back to back. Take the neutrino momentum along $+\hat{\boldsymbol{z}}$, so the muon momentum is along $-\hat{\boldsymbol{z}}$. Conservation of the z component of angular momentum gives $S^\mu_z + S^\nu_z = 0$. If the neutrino carries negative helicity, as Phenomenon 110.12 states, then $S^\nu_z = -\frac{1}{2}\hbar$ and therefore $S^\mu_z = +\frac{1}{2}\hbar$; since the muon moves along $-\hat{\boldsymbol{z}}$, its helicity is

$$h_\mu = \frac{2}{\hbar}\,\boldsymbol{S}^\mu \cdot \hat{\boldsymbol{p}}^\mu = \frac{2}{\hbar}\left(+\tfrac{1}{2}\hbar\right)(-1) = -1\,.$$

The muon is produced fully polarized with its spin antiparallel to its momentum, and this is forced by the two-body kinematics together with the neutrino helicity, whatever produced the pion. A completely polarized ensemble is what makes the second, muon-decay asymmetry observable at all; the frequency of the observed modulation measures the muon precession and hence g_μ, which is where Chapter 112 begins. □

The kinematics, in numbers The two-body decay of a pion at rest fixes the muon momentum completely. With the PDG masses $m_\pi c^2 = (139.570\,39 \pm 0.000\,18)\,\mathrm{MeV}$ and $m_\mu c^2 = (105.658\,375\,5 \pm 0.000\,002\,3)\,\mathrm{MeV}$ [2427],

$$p_\mu c = \frac{\left(m_\pi^2 - m_\mu^2\right) c^4}{2 m_\pi c^2} = 29.792\,\mathrm{MeV}\,, \tag{110.18}$$

so the muon carries a kinetic energy of $\sqrt{p_\mu^2 c^2 + m_\mu^2 c^4} - m_\mu c^2 = 4.120\,\mathrm{MeV} = 6.601 \times 10^{-13}\,\mathrm{J}$ and moves at $v/c = 0.2714$. The neutrino carries the same momentum, $29.792\,\mathrm{MeV}/c$, and hence an energy of $29.792\,\mathrm{MeV} = 4.773 \times 10^{-12}\,\mathrm{J}$. That the muon is non-relativistic is what makes it stoppable in a modest absorber, and that the decay is two-body is what makes the polarization complete.

The precession, in numbers

Proposition 110.14 (Muon spin precession in a transverse field)**.** *A muon at rest with gyromagnetic ratio g_μ in a uniform field $\boldsymbol{B}$ perpendicular to its spin precesses at the angular frequency*

$$\omega = \frac{g_\mu\, e\, B}{2 m_\mu}\,, \tag{110.19}$$

so that for $g_\mu = 2$ a field of $1\,\mathrm{mT}$ gives $\omega/2\pi = 1.354 \times 10^5\,\mathrm{Hz}$ and a spin rotation of 0.30 of a turn in one muon lifetime.

Rests on Equation (79.7).

Derivation. *Derives Proposition 110.14.*

The magnetic moment of a spin-$\frac{1}{2}$ particle of mass m and charge e is $\boldsymbol{\mu} = g\,(e/2m)\,\boldsymbol{S}$, and the torque equation $\mathrm{d}\boldsymbol{S}/\mathrm{d}t = \boldsymbol{\mu} \times \boldsymbol{B}$ gives $\mathrm{d}\boldsymbol{S}/\mathrm{d}t = (geB/2m)\,\hat{\boldsymbol{B}} \times \boldsymbol{S}$, a rotation about $\boldsymbol{B}$ at the rate Equation (110.19). With $e = 1.602\,176\,634 \times 10^{-19}\,\mathrm{C}$ (exact) and $m_\mu = (1.883\,531\,627 \pm 0.000\,000\,042) \times 10^{-28}\,\mathrm{kg}$ [2431], $g_\mu = 2$ and $B = 1 \times 10^{-3}\,\mathrm{T}$,

$$\frac{\omega}{2\pi} = \frac{eB}{2\pi m_\mu} = \frac{1.602\,176\,634 \times 10^{-19}\,\mathrm{C} \times 1 \times 10^{-3}\,\mathrm{T}}{2\pi \times 1.883\,531\,627 \times 10^{-28}\,\mathrm{kg}} = 1.354 \times 10^5\,\mathrm{Hz}\,,$$

and $1.354 \times 10^5\,\mathrm{Hz} \times 2.197 \times 10^{-6}\,\mathrm{s} = 0.297$ turns per lifetime. A field of a few millitesla therefore sweeps the spin through a full turn inside the observation window, which is the design requirement: too small a field gives no modulation to fit, and too large a one washes the modulation out inside the finite time gate. □

The counting rate in the fixed telescope is then

$$N(t) \propto \mathrm{e}^{-t/\tau_\mu}\left[1 + a\cos(\omega t + \varphi)\right]\,, \tag{110.20}$$

with a the product of the muon polarization and the intrinsic positron asymmetry of the muon decay. Garwin, Lederman and Weinrich found a modulation of amplitude $|a| \approx \frac{1}{3}$ and, from the frequency at fixed gate, a muon gyromagnetic ratio $g_\mu = 2.00 \pm 0.10$ [1110] — the first measurement of the muon magnetic moment, made as a by-product of a symmetry test, and the ancestor of the precision programme of Chapter 112. The intrinsic asymmetry

$\frac{1}{3}$ is itself a $V-A$ prediction: the positron spectrum and its angular correlation both follow from the four-fermion matrix element of the decay, whose energy dependence alone is parametrized at Equation (101.58) in the form Michel introduced before the structure was known [965]. Writing $x = 2E_e/(m_\mu c^2)$ for the positron energy fraction and θ for the angle between the positron momentum and the muon spin, the $V-A$ doubly differential rate is

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\theta} \propto x^2\left[(3-2x) + P_\mu(2x-1)\cos\theta\right], \tag{110.21}$$

and integrating the $\cos\theta$-odd and $\cos\theta$-even parts separately over $0 \le x \le 1$ gives, at full polarization $P_\mu = 1$,

$$\frac{\int_0^1 x^2(2x-1)\,\mathrm{d}x}{\int_0^1 x^2(3-2x)\,\mathrm{d}x} = \frac{\frac{1}{2}-\frac{1}{3}}{1-\frac{1}{2}} = \frac{1}{3}, \tag{110.22}$$

which is the number Garwin, Lederman and Weinrich measured. What this book does not yet contain is the step before it.

Derivation pending #190

Doubly differential muon-decay rate from the $V-A$ four-fermion matrix element, i.e. the angular factor $[(3-2x)+P_\mu(2x-1)\cos\theta]$ that is quoted rather than computed here; the energy spectrum alone is parametrized in the weak-interactions chapter, and the integration of the angular factor is carried out in this chapter. Belongs in the long-proofs appendix

110.6.2 Friedman and Telegdi

Friedman and Telegdi measured the same chain by an entirely different technique and with entirely different systematics [1109]. Pions were brought to rest inside a nuclear emulsion; the muon from the decay, with the 4.120 MeV of Equation (110.18), travels a short, visible track and stops; and the decay positron leaves a third track from the same point. Every event is therefore a complete, reconstructed geometry — pion direction, muon direction, positron direction — read off under a microscope, with no counters, no magnetic field and no timing.

The observable is the angle θ between the muon direction and the positron direction, and the distribution is $W(\theta) \propto 1 + a\cos\theta$. The measured coefficient was of magnitude 0.174 ± 0.038, diluted from the pion-chain maximum because a muon coming to rest in an emulsion depolarizes through hyperfine interactions with the atoms of the stopping medium — a systematic entirely absent from the counter experiment, and absent in the opposite direction, since depolarization can only reduce the asymmetry and never create it.

Proposition 110.15 (Event count implied by the quoted error)**.** *For a distribution $1+a\cos\theta$ with $|a| \ll 1$ observed over the full solid angle, the maximum-likelihood estimator $\hat{a} = 3\langle\cos\theta\rangle$ has variance $3/N$. An uncertainty of 0.038 therefore corresponds to $N = 3/0.038^2 \approx 2.1\times10^3$ reconstructed decay chains.*

Rests on Equation (110.21).

Derivation. *Derives Proposition 110.15.*

Normalize the distribution over $\cos\theta \in [-1,1]$: $p(\cos\theta) = \frac{1}{2}(1+a\cos\theta)$. Then $\langle\cos\theta\rangle = \frac{1}{2}\int_{-1}^{1} u(1+au)\,\mathrm{d}u = a/3$, so $\hat{a} = 3\langle\cos\theta\rangle$ is unbiased. Its variance is $9/N$ times the variance of $\cos\theta$, and to leading order in a that variance is $\langle\cos^2\theta\rangle - \langle\cos\theta\rangle^2 = \frac{1}{3} + O(a^2)$, giving $\mathrm{Var}(\hat{a}) = 3/N$. Setting $\sqrt{3/N} = 0.038$ gives $N \approx 2.1\times10^3$. The same arithmetic applied to the counter experiment's quoted precision on a of about 0.03 gives $N \approx 3.3\times10^3$ — both experiments rest on a few thousand events, which is worth stating plainly: the effect is

so large that a few thousand events settle it, and that is why two groups could do it in weeks. □

Table 110.4: The five founding parity-violation measurements — four published in 1957, the neutrino-helicity one in 1958 — and what each delivered. All five test the mean of a pseudoscalar, and all five find it as large as the kinematics permits. The last column is the pseudoscalar whose non-vanishing is the violation.

Measurement	Result	Pseudoscalar
^{60}Co beta asymmetry, 1957 [1133]	$\lvert\varepsilon\rvert = 0.40 \pm 0.01$; $A = -1.06 \pm 0.07$	$\langle \boldsymbol{J} \rangle \cdot \boldsymbol{p}_e$
$\pi \to \mu \to e$ counters, 1957 [1110]	$\lvert a \rvert \approx \frac{1}{3}$; $g_\mu = 2.00 \pm 0.10$	$\langle \boldsymbol{s}_\mu \rangle \cdot \boldsymbol{p}_\mu$ and $\langle \boldsymbol{s}_\mu \rangle \cdot \boldsymbol{p}_e$
$\pi \to \mu \to e$ emulsion, 1957 [1109]	$\lvert a \rvert = 0.174 \pm 0.038$, depolarization-diluted	$\boldsymbol{p}_\mu \cdot \boldsymbol{p}_e$
Beta polarization, 1957 [1108, 1131]	electrons longitudinally polarized, negative helicity	$\langle \boldsymbol{s}_e \rangle \cdot \boldsymbol{p}_e$
Neutrino helicity, 1958 [1148]	h_ν negative, consistent with -1	$\langle \boldsymbol{s}_\nu \rangle \cdot \boldsymbol{p}_\nu$

Table 110.4 is the summary of that short period. The five entries share no apparatus, no technique and no systematic; two are counting experiments at millikelvin temperatures, one is a microscope study of photographic emulsion, one is Mott-scattering polarimetry and one is resonant nuclear scattering through magnetized iron. What they share is the structure of Proposition 110.1, and that is why the conclusion was accepted within months.

110.7 Modern repetitions and precision

110.7.1 Neutral currents and the weak mixing angle

For fifteen years parity violation was a property of charged-current weak decays, in which the charge of the participating particles changes. The Gargamelle bubble chamber then observed neutrino interactions with no charged lepton in the final state [1502] — a weak *neutral* current, discussed at Section 104.6.1. Because that current couples to ordinary charged particles as well as to neutrinos, it makes parity violation observable in processes with no charge exchange at all: in the scattering of electrons from nuclei, and in atoms.

The electroweak model of Glashow, Weinberg and Salam [1206, 1362, 1381] fixes the strength of every one of those effects in terms of a single parameter, the weak mixing angle. The observable that all the measurements below deliver is $\sin^2\theta_W$, and the content of the comparison is not the value but the consistency: the same angle, running with momentum transfer according to a calculable prescription, must fit determinations spanning ten orders of magnitude in energy. The theory is Section 104.4.2 and the statement under test is Phenomenon 104.55.

110.7.2 Atomic parity violation

Phenomenon 110.16 (Parity violation in atoms)**.** The $6S \to 7S$ transition of atomic caesium, forbidden as an electric dipole transition by the parity selection rule, nevertheless proceeds with a small parity-nonconserving electric dipole amplitude whose sign reverses with the handedness of the applied static fields. The amplitude has been measured to 0.35 %, and the same measurement resolved its nuclear spin dependence, the first observation of an

anapole moment [1946]. The effect requires no charge exchange — it is a neutral-current effect — and it grows roughly as the cube of the nuclear charge, which is why heavy atoms were chosen [1519].

Rests on Proposition 105.1 and Phenomenon 104.55.

Derivation. *Derives Phenomenon 110.16.*

Two things need showing: that the neutral current produces a parity-nonconserving $E1$ amplitude at all, and that it grows as Z^3.

Exchange of a Z boson between an atomic electron and a nucleon is, at atomic momentum transfers, a contact interaction: the range $\hbar/(m_Z c) = 2.2 \times 10^{-18}\,\mathrm{m}$ is smaller than the nucleus by three orders of magnitude, so the nucleus acts as a point source. The piece of it that violates parity and does not vanish on averaging over nucleon spins couples the electron *axial* current to the nucleon *vector* charge, giving an effective Hamiltonian

$$H_{PNC} = \frac{G_F}{\sqrt{2}}\,\frac{Q_W}{2}\,\gamma^5\,\delta^3(\boldsymbol{r})\,, \tag{110.23}$$

in which Q_W is the weak charge of the nucleus and γ^5 is the parity-odd Dirac matrix. Since γ^5 is a pseudoscalar operator, first-order perturbation theory mixes into an S state a small admixture of the nearby P states,

$$\left|\tilde{S}\right\rangle = |S\rangle + \sum_P \frac{\langle P|\,H_{PNC}\,|S\rangle}{E_S - E_P}\,|P\rangle\ ,$$

and the ordinary electric dipole operator then connects $\left|6\tilde{S}\right\rangle$ to $\left|7\tilde{S}\right\rangle$ through those admixtures. The transition acquires an $E1$ amplitude proportional to Q_W, whose sign flips under reversal of the handedness of the applied electric and magnetic fields, which is the experimental signature.

For the Z^3 scaling, count the powers. The weak charge is, at tree level, $Q_W = Z(1 - 4\sin^2\theta_W) - N$, and since $\sin^2\theta_W \approx 0.231$ [2427] the first term nearly cancels and $Q_W \approx -N$, one power of the nuclear size. The delta function in Equation (110.23) requires the electron density at the nucleus, and for a valence electron in a heavy atom the relativistic enhancement of that density supplies two further powers of Z. Hence Z^3, which is why caesium ($Z = 55$) and thallium were the practical choices, and why hydrogen — where the atomic theory is exact — is hopeless. □

The Boulder measurement is the reference point [1946]. Its apparatus is a beam of caesium atoms crossing a region of static electric and magnetic fields inside an optical cavity, in which a laser drives the nominally forbidden $6S \to 7S$ transition; the parity-violating amplitude is detected through its interference with a Stark-induced amplitude. That is the whole trick: a rate proportional to $|\mathcal{M}_{\mathrm{Stark}} + \mathcal{M}_{PNC}|^2$ carries a cross term $2\,\mathrm{Re}(\mathcal{M}^*_{\mathrm{Stark}}\mathcal{M}_{PNC})$ that is *linear* in the small amplitude and changes sign with the applied field, whereas the parity-violating rate on its own would be quadratic in it and therefore smaller by one further power of the same small ratio. The order of magnitude of $\mathcal{M}_Z/\mathcal{M}_\gamma$ that makes $\mathcal{M}_{PNC}$ this small is estimated, for electron scattering, at Proposition 105.21. The measured quantity is the ratio of the parity-nonconserving amplitude to the Stark coefficient,

$$\frac{\mathrm{Im}\,E1_{PNC}}{\beta} = (0.159\,35 \pm 0.000\,56)\,\mathrm{V/m}\,, \tag{110.24}$$

customarily quoted as $(1.5935 \pm 0.0056)\,\mathrm{mV}$ per centimetre; the fractional precision is $0.35\,\%$. The difference between the two hyperfine components of the transition, $(0.0077 \pm 0.0011)\,\mathrm{V/m}$, is the nuclear-spin-dependent part and constitutes the first observation of an anapole moment — a parity-odd, time-reversal-even electromagnetic moment of the nucleus, generated by the

weak interaction between its own nucleons. Converting Equation (110.24) into the weak charge

$$Q_W(^{133}\mathrm{Cs}) = -72.06 \pm 0.28 \pm 0.34 \tag{110.25}$$

requires atomic many-body theory, and the second uncertainty in Equation (110.25) is that theory's, not the experiment's.

Derivation pending #191

Atomic many-body calculation converting the measured caesium amplitude into a nuclear weak charge: the relativistic coupled-cluster evaluation of the valence electron density at the nucleus and its error budget. Belongs in the long-proofs appendix; the mixing of opposite-parity states and the Z-cubed scaling are derived in this chapter

That the theoretical uncertainty exceeds the experimental one is the structural limitation of the method, and it is what motivates the isotope-ratio technique: measuring the parity-violating amplitude in several isotopes of the same element and forming ratios cancels the electronic structure, which is common to all of them, leaving the dependence on the neutron number. Antypas and collaborators carried this out in ytterbium, whose parity-violating amplitude is some two orders of magnitude larger than caesium's, and observed the variation of the amplitude across four isotopes [2329]. The atomic-structure input that the ratio does not cancel is the distribution of neutrons inside the nucleus, so the measurement trades one theoretical uncertainty for another — but for a nuclear one, which is measured independently by the technique of Section 110.7.4. The atomic-structure background is Chapter 88.

110.7.3 Polarized electron scattering

Phenomenon 110.17 (Parity violation in electron scattering)**.** The cross section for scattering longitudinally polarized electrons from an unpolarized target depends on the sign of the beam helicity. The fractional asymmetry

$$A = \frac{\sigma_+ - \sigma_-}{\sigma_+ + \sigma_-} \tag{110.26}$$

between the two beam helicities was found to be of order 10^{-4}, and to grow in proportion to Q^2, in deep inelastic scattering of 19 GeV electrons from deuterium [1625].

Rests on Proposition 110.1 and Phenomenon 104.55.

Derivation. *Derives Phenomenon 110.17.*

Beam helicity is a pseudoscalar, so a dependence of the rate on its sign violates parity for exactly the reason Equation (110.13) does, and the one-photon amplitude alone cannot produce it. The size follows from the interference of the two exchanges. At momentum transfers far below the Z mass the neutral-current amplitude is contact-like, of order $G_F/\sqrt{2}$, while the one-photon amplitude carries the propagator $1/Q^2$ together with the coupling $4\pi\alpha$; the asymmetry is the ratio of the interference term to the electromagnetic term, hence of order

$$A \sim \frac{G_F Q^2 c^2}{4\sqrt{2}\,\pi\alpha\,(\hbar c)^3}\,. \tag{110.27}$$

With $G_F/(\hbar c)^3 = (1.166\,378\,8 \pm 0.000\,000\,6) \times 10^{-5}/\mathrm{GeV}^2$, equivalently $G_F = (1.435\,851\,2 \pm 0.000\,000\,7) \times 10^{-62}\,\mathrm{J\,m}^3$, and $\alpha^{-1} = 137.035\,999\,177 \pm 0.000\,000\,021$ [2431], a momentum transfer $Q^2c^2 = 1\,\mathrm{GeV}^2$ gives $A \sim 9.0 \times 10^{-5}$, the observed order of magnitude; the coefficient suppressed in Equation (110.27) is of order unity and depends on the target and on $\sin^2\theta_W$. It is the linear growth with Q^2, not the magnitude, that identifies the effect as weak-neutral-current interference and not an instrumental correlation with the beam helicity, since no instrumental effect has any reason to scale that way. □

SLAC E122: apparatus The experiment that first saw this is SLAC E122 [1625, 1643]. Its apparatus is worth describing, because measuring an asymmetry of 10^{-4} against helicity-correlated instrumental effects is the whole difficulty, and every feature of the design addresses it.

The beam is produced by photoemission from a gallium arsenide photocathode illuminated by circularly polarized laser light. The handedness of the light is set by the sign of the voltage on a Pockels cell, and the electron polarization follows it: the crystal's band structure converts optical helicity into electron spin polarization, reaching about 37 % in practice against a theoretical maximum of 50 %. The essential property is that reversing the beam helicity requires nothing to move — only the sign of a voltage — so the reversal can be made *randomly, pulse to pulse*, and any slow drift in the apparatus averages out between neighbouring pulses rather than accumulating into a false asymmetry.

The beam energy is between 16.2–22.2 GeV, the target is liquid deuterium (and hydrogen), and the scattered electrons are detected in a magnetic spectrometer set to accept deep-inelastic kinematics near $Q^2c^2 \approx 1.6\,\mathrm{GeV}^2$. The flux is far too high to count events individually, so the spectrometer is instrumented as an *integrating* calorimeter: the total charge deposited by each beam pulse is measured, and the asymmetry is formed between pulses of opposite helicity. That removes counting statistics as a limitation and replaces it with the requirement that the beam intensity, position, angle and energy be identical for the two helicities — monitored pulse by pulse and corrected for.

The spin-precession scan: the control that makes it a measurement The most elegant feature of E122 is a null test that no instrumental effect can imitate, and it is worth deriving because it turns the electron's anomalous magnetic moment into a piece of experimental apparatus.

Proposition 110.18 (Spin precession in the beam transport)**.** *An ultrarelativistic electron of Lorentz factor γ bent through an angle θ_{bend} in a magnetic field has its spin rotated relative to its momentum by*

$$\phi = a_e\,\gamma\,\theta_{\mathrm{bend}}\,, \qquad a_e = \frac{g_e - 2}{2} = (1.159\,652\,180\,46 \pm 0.000\,000\,000\,18) \times 10^{-3}\,, \quad (110.28)$$

so the longitudinal polarization delivered to the target varies as $\cos\phi$ with the beam energy. For the SLAC beam line, whose bend to the experimental hall is $\theta_{\mathrm{bend}} = 24.5^\circ = 0.4276$, the four energies 16.2 GeV, 17.8 GeV, 19.4 GeV and 22.2 GeV give $\phi/\pi = 5.00$, 5.50, 5.99 and 6.86, and hence $\cos\phi = -1.00$, -0.01, 1.00 and -0.90.

Rests on Equations (79.7) and (100.89).

Derivation. Derives Proposition 110.18.

In a uniform magnetic field the momentum of a relativistic charged particle rotates at the cyclotron frequency $\omega_c = eB/(\gamma m_e)$, while its spin rotates at $\omega_s = geB/(2m_e) + (1-\gamma)\,eB/(\gamma m_e)$ — the Thomas–BMT result, in which the second term is the Thomas precession of the rest frame. Subtracting,

$$\omega_s - \omega_c = \frac{eB}{m_e}\left(\frac{g}{2} - 1\right) = a_e\,\frac{eB}{m_e} = a_e\,\gamma\,\omega_c\,,$$

so in the time the momentum turns through $\theta_{\mathrm{bend}} = \omega_c t$ the spin turns through $\theta_{\mathrm{bend}} + a_e\gamma\theta_{\mathrm{bend}}$ and the angle between them is Equation (110.28). Numerically, $\gamma = E/(m_ec^2)$ with $m_ec^2 = (0.510\,998\,950\,69 \pm 0.000\,000\,000\,16)$ MeV [2431] gives $\gamma = 3.80 \times 10^4$ at $E = 19.4$ GeV, and $a_e\gamma\theta_{\mathrm{bend}} = 1.159\,65 \times 10^{-3} \times 3.7965 \times 10^4 \times 0.4276 = 18.83 = 5.99\pi$. Repeating for the other three energies gives the quoted list. That the numbers land so close to integer multiples of π is not a coincidence: the energies were chosen so. □

The consequence is a test with no instrumental counterpart. The measured asymmetry must reverse sign between 16.2 GeV and 19.4 GeV, and must vanish at 17.8 GeV where the spin arrives transverse and the beam carries no longitudinal polarization at all — while the beam intensity, the target, the spectrometer and the electronics are unchanged. No helicity-correlated instrumental effect depends on the beam energy through $\cos(a_e \gamma \theta_{\text{bend}})$. The scan was performed and the asymmetry followed the prediction [1643], which is what converted the measurement from a small number into a result.

What E122 measured The asymmetry, normalized to the momentum transfer, is

$$\frac{A}{Q^2c^2} = -9.5 \pm 1.6 \times 10^{-5}\,1/\text{GeV}^2 = (-3.70 \pm 0.62) \times 10^{15}/\text{J}^2\,, \tag{110.29}$$

the second form being the SI one, since Q^2c^2 is an energy squared and A is dimensionless; the conversion is $1/\text{GeV}^2 = 3.8954 \times 10^{19}/\text{J}^2$. So $|A| \approx 1.5 \times 10^{-4}$ at the working point — in magnitude exactly the estimate of Equation (110.27). The electroweak interpretation is not read off the magnitude, however, but off the *shape*. Writing $y = \nu/E$ for the fractional energy transfer, the prediction is

$$\frac{A}{Q^2c^2} = a_1 + a_2\,\frac{1-(1-y)^2}{1+(1-y)^2}\,, \tag{110.30}$$

with $a_1 \propto 1 - \frac{20}{9}\sin^2\theta_W$ and $a_2 \propto 1 - 4\sin^2\theta_W$, both quoted here from the analysis of the experiment rather than computed.

Derivation pending #192

Coefficients of the deep-inelastic parity-violating asymmetry on an isoscalar target: the combinations $1 - \frac{20}{9}\sin^2\theta_W$ and $1 - 4\sin^2\theta_W$ follow from the electron and quark neutral-current couplings C_{1q}, C_{2q} contracted with the quark-parton structure functions of a deuteron, and are quoted rather than derived here. Belongs in the long-proofs appendix; the couplings themselves are written down in this chapter for the proton case, and the deep-inelastic kinematics live in the deep-inelastic chapter

Since $\sin^2\theta_W \approx 0.23$, the second coefficient nearly vanishes, so the asymmetry is nearly independent of y — and it is that flatness, not the magnitude, that discriminates. Several models then in play reproduced the Gargamelle neutrino data with a parity-conserving neutral current, and were killed by this single observation. E122 gave $\sin^2\theta_W = 0.20 \pm 0.03$ [1625], sharpened to 0.224 ± 0.020 by the full kinematic scan [1643]. The deep-inelastic kinematics and structure functions the analysis rests on belong to Chapter 116.

SLAC E158 The same technique applied to a purely leptonic target removes the hadronic-structure uncertainty altogether. SLAC E158 scattered longitudinally polarized electrons from the atomic electrons of a liquid-hydrogen target — polarized Møller scattering — at $Q^2c^2 = 0.026\,\text{GeV}^2$, and measured an asymmetry of order 10^{-7} — three orders of magnitude smaller than E122's $|A| \approx 1.5 \times 10^{-4}$, and correspondingly harder. The result, $\sin^2\theta_W = 0.2397 \pm 0.0013$ [2069], is the first observation of the *running* of the weak mixing angle to low momentum transfer: it differs from the Z-pole value by far more than its uncertainty, in the direction and by the amount the renormalization group predicts.

110.7.4 The weak charge of the proton

Phenomenon 110.19 (The weak charge of the proton is small)**.** Elastic scattering of longitudinally polarized electrons from protons at low momentum transfer shows a parity-violating asymmetry of about -226 parts per billion, from which the weak charge of the

proton is extracted as $Q_W^p = 0.0719 \pm 0.0045$ [2301]. The proton's weak charge is thus more than an order of magnitude smaller than its electric charge in the corresponding normalization, and it is this smallness that makes the measurement a sharp determination of the weak mixing angle at low momentum transfer.

Rests on Phenomena 104.55 and 110.17.

Derivation. *Derives Phenomenon 110.19.*

Write the parity-violating electron–quark interaction in contact form, with coefficients C_{1u} and C_{1d} multiplying the products of the axial electron current with the vector quark currents. The Z couplings of Chapter 104 give, at tree level,

$$C_{1u} = -\tfrac{1}{2} + \tfrac{4}{3}\sin^2\theta_W\,, \qquad C_{1d} = \tfrac{1}{2} - \tfrac{2}{3}\sin^2\theta_W\,.$$

A proton has valence content uud, so its weak charge is the corresponding sum,

$$Q_W^p = -2\,(2C_{1u} + C_{1d}) = 1 - 4\sin^2\theta_W\,. \tag{110.31}$$

With $\sin^2\theta_W \approx 0.231$ [2427] the right-hand side is $1 - 4(0.231) = 0.076$: the two terms very nearly cancel, because the measured mixing angle happens to sit close to the value $1/4$ at which Q_W^p would vanish identically. A small quantity written as the difference of two quantities of order unity is maximally sensitive to them, which is why an asymmetry of a few hundred parts per billion determines $\sin^2\theta_W$ competitively; differentiating Equation (110.31) gives $\delta(\sin^2\theta_W) = \tfrac{1}{4}Q_W^p\,\delta Q_W^p/Q_W^p$, so a 6 % determination of Q_W^p yields $\delta\sin^2\theta_W \approx 0.001$. □

Equation (110.31) is a tree-level relation and must not be applied to the measured numbers without saying so, because it fails on them by far more than their errors. Substituting the $\sin^2\theta_W = 0.2383 \pm 0.0011$ that the same measurement reports gives $1 - 4(0.2383) = 0.0468$, which is 5.6 standard deviations below the reported $Q_W^p = 0.0719 \pm 0.0045$. The running invoked above does not account for the gap and points the wrong way: driving $\sin^2\theta_W$ up from its Z-pole value towards 0.2386 at $Q \to 0$ makes $1 - 4\sin^2\theta_W$ *smaller*, not larger. The $+0.025$ that reconciles the two is supplied by the one-loop electroweak corrections proper — the ρ factor and the WW, ZZ and γZ box graphs — which add a constant to Q_W^p without changing $\mathrm{d}Q_W^p/\mathrm{d}\sin^2\theta_W = -4$. That is why the error propagation of the previous paragraph survives the corrections although the central-value relation does not: $0.0045/4 = 0.0011$ is exactly the uncertainty quoted on $\sin^2\theta_W$ [2301].

Derivation pending #193

One-loop electroweak corrections to the weak charge of the proton: the ρ factor, the charge-radius term, and the WW, ZZ and γZ box graphs that together shift the tree value $1 - 4\sin^2\theta_W = 0.047$ to the Standard Model prediction near 0.071. They are a third of the predicted value, so the comparison with experiment does not exist without them. Belongs in the long-proofs appendix

Qweak The measurement was made at Jefferson Lab with a beam of longitudinally polarized electrons on a liquid-hydrogen target, detecting elastically scattered electrons at $Q = 0.157\,\mathrm{GeV}/c$, that is $Q^2c^2 = 0.0248\,\mathrm{GeV}^2$. The measured asymmetry is

$$A_{PV} = -226.5 \pm 9.3 \times 10^{-9}\,, \tag{110.32}$$

in parts per billion, -226.5 ± 9.3, from which

$$Q_W^p = 0.0719 \pm 0.0045\,, \qquad \sin^2\theta_W = 0.2383 \pm 0.0011\,, \tag{110.33}$$

in agreement with the Standard Model [2301]. Measuring 2.3×10^{-7} requires the helicity-correlated differences in beam current, position, angle and energy to be controlled at the level of parts per billion in the asymmetry — achieved by the same random pulse-to-pulse helicity reversal as E122, supplemented by two slow reversals whose sign flips independently of the Pockels cell: inserting a half-wave plate in the laser beam, and reversing the spin with a Wien filter. Any false asymmetry tied to the electronics does not follow those reversals; the physics asymmetry does.

PREX and the neutron skin The near-cancellation in Equation (110.31) works the other way for a heavy nucleus. Since $Q_W^p \approx 0.07$ while the neutron's weak charge is $Q_W^n = -1$, the Z couples almost exclusively to neutrons; a parity-violating asymmetry in elastic electron scattering therefore measures the *neutron* distribution, where ordinary electron scattering measures the proton distribution. PREX-2 measured $A_{PV} = 550 \pm 16 \pm 8 \times 10^{-9}$ on ^{208}Pb and obtained a neutron skin thickness

$$R_n - R_p = (0.283 \pm 0.071)\,\mathrm{fm} = (2.83 \pm 0.71) \times 10^{-16}\,\mathrm{m} \tag{110.34}$$

[2370]. The skin thickness is fixed by the density dependence of the nuclear symmetry energy, which is the same quantity that sets the radius of a neutron star, so a parity-violating asymmetry measured on a lead target constrains the dense-matter equation of state, which belongs to Chapter 49. The nuclear-structure background is Section 107.3.3 and Section 107.4.2.

110.7.5 Consistency and what remains open

Table 110.5: Parity violation as a precision instrument: determinations of the weak mixing angle from parity-violating observables, over four decades of momentum transfer. The values are in the conventions of the Particle Data Group [2427]; the running of $\sin^2\theta_W$ with Q is part of the prediction, so the entries are not expected to agree numerically and their agreement *after* running is the test.

Measurement	Momentum transfer	$\sin^2\theta_W$	Reference
Caesium atomic parity violation, 1997	atomic, $Q \approx 0$	≈ 0.24	[1946]
Polarized Møller scattering, E158, 2005	$Q^2c^2 = 0.026\,\mathrm{GeV}^2$	0.2397 ± 0.0013	[2069]
Polarized ep elastic, Qweak, 2018	$Q = 0.157\,\mathrm{GeV}/c$	0.2383 ± 0.0011	[2301]
Polarized ed deep inelastic, E122, 1979	$Q^2c^2 \approx 1.6\,\mathrm{GeV}^2$	0.224 ± 0.020	[1643]
Z-pole asymmetries, LEP and SLD, 2006	$Q = m_Z c$	$0.231\,53 \pm 0.000\,16$	[2104]

Table 110.5 is the state of the art, and reading it correctly requires one caution and admits one honest complaint.

The caution is that the entries are not repeated measurements of a constant. The weak mixing angle runs with the momentum transfer at which it is probed, exactly as the fine-structure constant does, and the predicted variation between the atomic and the Z-pole entries is larger than several of the quoted uncertainties. The test is therefore not that the numbers agree but that they lie on the predicted curve; the scheme in which the angle is defined must also be stated, since different schemes differ by about a per cent, which is

hundreds of times some of these errors. Remark 104.34 makes that point in the form it needs.

The complaint is a genuine tension inside the most precise entry. The Z-pole value in Table 110.5 is an average over determinations that do not agree well among themselves: the left–right asymmetry measured with polarized beams at SLD gives $\sin^2\theta_W^{\mathrm{eff}} = 0.230\,98 \pm 0.000\,26$ while the forward–backward asymmetry of b quarks at LEP gives $0.232\,21 \pm 0.000\,29$, a discrepancy of about three standard deviations that has stood since the measurements were finished [2104]. It is stated here rather than averaged away because averaging a three-sigma disagreement and quoting the result to five digits is exactly the practice this book's editorial rules exist to prevent. No explanation has been established; the possibilities range from an underestimated systematic in one of the two to a statistical fluctuation, and the honest statement is that the world average carries an inflated error for a reason.

Two further things should be said about what parity violation is now for.

It is a *null test*, not a discovery channel. Every measurement in Table 110.5 is a comparison of a measured asymmetry with a Standard Model prediction, and the interest lies in the residual. A new neutral current, coupling to electrons and quarks with a strength suppressed by a mass scale Λ, contributes a contact term of strength $(\hbar c)^3/\Lambda^2$ where the weak interaction contributes G_F, so the relative shift of the asymmetries is of order

$$\frac{\delta A}{A} \sim \frac{(\hbar c)^3}{G_F \Lambda^2}\,. \tag{110.35}$$

The combination is dimensionless and that is the point of writing it out: G_F has the SI dimension $\mathrm{J\,m^3}$, so $G_F/(\hbar c)^3$ is an inverse energy squared, $4.5438 \times 10^{14}/\mathrm{J^2}$, and multiplying by Λ^2 leaves a pure number. Numerically $G_F\Lambda^2/(\hbar c)^3 = 11.7$ at $\Lambda = 1\,\mathrm{TeV}$ and 1166 at $\Lambda = 10\,\mathrm{TeV}$, so Equation (110.35) predicts relative shifts of 8.6×10^{-2} and 8.6×10^{-4} respectively. The present 6 % determination of Q_W^p therefore reaches $\Lambda \approx 1.2\,\mathrm{TeV}$ for a new coupling of weak strength, and correspondingly further for a stronger one — the reach is customarily quoted as a bound on Λ/g for that reason [2301]. Either way it is a TeV-scale statement obtained without producing anything, which is the characteristic economy of a symmetry test.

And parity is *not* violated in the strong and electromagnetic interactions, to the precision anyone has been able to reach. The bound is the one Lee and Yang already quoted from spectroscopy — about 10^{-7} in amplitude for a parity-violating admixture in the nuclear force [1091] — and it has since been sharpened, but the qualitative statement is unchanged and it is a fact about the Standard Model rather than an assumption of it: the photon and gluon couple vectorially, to left- and right-handed fields alike, and only the W and Z do not. The parity-violating nucleon–nucleon force that does exist is the weak interaction acting inside a nucleus, and its observation — of the order the bound allows — is a measurement of the weak interaction, not a failure of the strong one.

110.8 Primary references

The measurement itself is [1133]: Wu, Ambler, Hayward, Hoppes and Hudson, "Experimental Test of Parity Conservation in Beta Decay", *Physical Review* **105**, 1413 (1957). It is three pages long, contains two figures and no error analysis in the modern sense, and it is the primary source for the cobalt entries of Table 110.2 and for those rows of Table 110.3 attributed to the experiment rather than derived here. A reader consulting it should expect the conclusions to be argued from the coincidence of the beta and gamma warm-up curves rather than from a quoted uncertainty; that is the form the argument took, and it is why the follow-up [1101] — Ambler, Hayward, Hoppes, Hudson and Wu, "Further Experiments on β Decay of Polarized Nuclei", same journal, **106**, 1361 (1957) — matters: it repeated

the measurement with better polarimetry, extended it to other nuclei, and supplied the positron-emitting case that establishes the violation of charge conjugation.

The prediction under test is [1091]: Lee and Yang, "Question of Parity Conservation in Weak Interactions", *Physical Review* **104**, 254 (1956). It should be read for its method rather than its result — it contains no new measurement and proposes no mechanism, and its lasting contribution is the observation that a universally believed law had never been tested in the sector where it was about to fail, together with an explicit list of feasible tests. The tau–theta puzzle that motivated it is analysed in [1016], whose phase-space construction is what removed the angular-momentum escape route; the introduction of parity as a conserved quantum number is [592].

The two independent confirmations are [1110] — Garwin, Lederman and Weinrich, published back to back with Wu's paper — and [1109], Friedman and Telegdi, submitted earlier and published a fortnight later in the same volume. Their systematics have almost nothing in common, which is the point of citing both. The longitudinal polarization of the beta electrons themselves, the second of Lee and Yang's three proposals, is [1108] by Mott scattering and [1131] through the circular polarization of the accompanying gamma rays. The neutrino helicity measurement is [1148]; its apparatus and analysis belong to Chapter 98, where the angular-momentum chain is worked out in full.

For the theoretical response, [1118], [1121] and [1130] propose the two-component neutrino independently and within weeks of each other; [1144] and [1162] give the $V - A$ interaction; [965] supplies the parametrization of the muon decay spectrum that the pion-chain experiments were interpreted against, written eight years before the structure it parametrizes was known; and [1123] is the CPT theorem, the symmetry that survives.

For the modern programme: [1519] is the proposal that made atomic parity violation practical by identifying the Z^3 enhancement, and [1946] the caesium measurement that realized it to 0.35 % together with the first anapole moment; [2329] is the isotope-ratio method in ytterbium. [1625] is SLAC E122 and [1643] its kinematic scan — two distinct measurements, giving $\sin^2\theta_W = 0.20 \pm 0.03$ and 0.224 ± 0.020 respectively, and they should be cited separately. [2069] is E158, [2301] is Qweak and [2370] is PREX-2. The Z-pole compilation is [2104], which is also the source for the unresolved discrepancy between the two most precise determinations discussed in Section 110.7.5. The discovery of neutral currents that made all of this possible is [1502], and the model it confirmed is [1206, 1362, 1381].

Numerical inputs are taken from two evaluated compilations and from nowhere else: particle masses, widths and the weak mixing angle from the Particle Data Group [2427], and the fundamental constants — k_B, e, μ_N, m_μ, $m_e c^2$, a_e and α — from CODATA 2022 [2431]. Nuclear mass differences behind the ^{60}Co decay energetics are from the atomic mass evaluation [2393]. Where a number in this chapter is derived rather than quoted, the derivation is given in place and the inputs are named.

Chapter 111

Experiment: CP Violation

Tests Equations (105.46) *and* (105.47) *and Phenomenon 103.31.*
Assuming Theorems 105.34, 105.36 and 105.38.

After parity fell in 1957 (Chapter 110) the combined operation CP was expected to be exact, and the neutral kaon system was built around that expectation: the long-lived state was supposed to be CP-odd and therefore forbidden to decay to two pions. This chapter records the two-pion decay that Christenson, Cronin, Fitch and Turlay found at the Brookhaven alternating-gradient synchrotron in a branching ratio of about 2×10^{-3} [1274], and everything measured since: direct CP violation in kaon decay [1965, 1973], the large asymmetries of the B mesons [2005, 2010], and the small one in charm [2323]. It sits after the weak-interaction and flavour chapters (Chapters 101 and 103) because it is the measurement that forced a third quark generation [1505], and beside Chapter 105, whose CPT theorem is what makes CP violation and T violation the same statement.

The division of labour with those two chapters is worth stating at the outset, because it decides what is and is not repeated here. The two-state formalism of the neutral kaon, the Wigner–Weisskopf elimination of the decay continuum, the definition of ϵ and ϵ', the double ratio, the Jarlskog invariant and the Sakharov conditions are all *derived* in Sections 105.3 and 105.6; the flavour structure that ties them to the quark mixing matrix is Sections 103.4.3 and 103.5. What follows is the experimental side: what the beams and the detectors physically were, how each number was extracted, what background had to be excluded, and what the numbers are with their uncertainties in SI units. Where a result of the theory chapters is needed it is cited by its equation number rather than re-derived, and where the experimental argument requires a derivation of its own — the purity of the beam, the regeneration background, the geometry of the spectrometer, the extraction of $\sin 2\beta$ from a vertex separation — it is carried out here.

Its closing sections take the result out of particle physics and into cosmology: CP violation is one of Sakharov's three conditions for a baryon asymmetry [1358], and the honest arithmetic is that the Cabibbo–Kobayashi–Maskawa phase is many orders of magnitude too small to produce the asymmetry observed in the sky [1882] — which is stated here as an open problem, not papered over.

Remark 111.1 (Units in this chapter, and in its sources). Every equation below carries $\hbar$ and c explicitly and every number is quoted in SI, with the electronvolt — an accepted non-SI unit — used for energies and its joule equivalent given where the comparison matters. The primary literature of this subject does not do this: it works in units in which $\hbar$ and c are set to unity, so that a mass, a momentum and an energy are all quoted in MeV and a lifetime in $1/\mathrm{MeV}$. To map a formula from those papers onto one here, restore one factor of c for every unit of momentum written as an energy, one factor of c^2 for every mass written as an energy, and one factor of $\hbar$ for every inverse energy written as a time. Two conversions recur and are worth fixing once: $1\,\mathrm{MeV} = 1.602\,176\,634 \times 10^{-13}\,\mathrm{J}$ exactly, since the elementary charge

is exact in the present SI [2431], and $\hbar = 6.582\,119\,569 \times 10^{-16}\,\mathrm{eV\,s}$, so a width of 1 MeV is a lifetime of $6.58 \times 10^{-22}\,\mathrm{s}$. No derivation in this chapter is carried out in those units.

111.1 Historical context and the prediction under test

111.1.1 The neutral kaon system

The experiment of 1964 was possible only because an unusual physical system had been identified nine years earlier, and the identification was made on paper before any of it was seen.

Gell-Mann and Pais asked what happens to a neutral particle that is not its own antiparticle when the interaction that produces it conserves a quantum number that the interaction destroying it does not [1067]. The strong interaction makes the neutral kaon in a state of definite strangeness — $|K^0\rangle$ with $S = +1$, $|\bar{K}^0\rangle$ with $S = -1$ — and conserves that label, so the two are distinct particles. The weak interaction does not conserve it, and therefore connects them. The states of definite mass and lifetime are then not the strangeness eigenstates at all but the combinations that diagonalize the weak effective Hamiltonian, which under an exact CP symmetry are the CP eigenstates $|K_1\rangle$ and $|K_2\rangle$ of Equation (105.46).

The consequence Gell-Mann and Pais drew was a prediction of a new particle. Two pions have $CP = +1$ and three neutral pions $CP = -1$ (Equation (105.47)), so if CP is exact the CP-even combination may decay to $\pi\pi$ and the CP-odd one may not. Since three pions barely fit inside the kaon mass, the second must be long-lived. Numerically, with the masses of Table 111.5, the energy released into $3\pi^0$ is

$$Q_{3\pi^0} = m_{K^0}c^2 - 3m_{\pi^0}c^2 = 497.611\,\mathrm{MeV} - 404.930\,\mathrm{MeV} = 92.68\,\mathrm{MeV}\,, \tag{111.1}$$

against $Q_{\pi\pi} = 218.47\,\mathrm{MeV}$ for $\pi^+\pi^-$. The non-relativistic phase-space volume for n bodies sharing a kinetic energy release Q grows as $Q^{(3n-5)/2}$: the momentum delta function leaves $3(n-1)$ independent components, the energy constraint restricts them to a sphere of radius proportional to $\sqrt{Q}$ in that space, and the surface measure of that sphere divided by the gradient of the energy supplies $R^{3(n-1)-1}/R \propto Q^{(3n-5)/2}$. Two bodies therefore give $Q^{1/2}$ and three bodies Q^2, so the three-body channel is far more strongly throttled near its own threshold, and it has less than half the energy release to work with. That is what produces the observed factor of several hundred in lifetime. Lande, Booth, Impeduglia, Lederman and Chinowsky found the long-lived partner at the Brookhaven Cosmotron the following year [1090], with a lifetime some six hundred times that of the known short-lived V particle. The modern values,

$$\tau_S = (8.954 \pm 0.004) \times 10^{-11}\,\mathrm{s}\,, \qquad \tau_L = (5.116 \pm 0.021) \times 10^{-8}\,\mathrm{s}\,, \tag{111.2}$$

give a ratio $\tau_L/\tau_S = 571$ [2427].

The second consequence is the one that makes the system an instrument rather than a curiosity. Because the two mass eigenstates are superpositions of the two strangeness eigenstates, a beam prepared as K^0 evolves into a mixture whose strangeness content oscillates, and the oscillation frequency is the mass difference divided by $\hbar$. This is Equation (105.61). The measured splitting is

$$\Delta m_K c^2 = (3.484 \pm 0.006) \times 10^{-6}\,\mathrm{eV} = 5.582 \times 10^{-25}\,\mathrm{J}\,, \qquad \frac{\Delta m_K c^2}{\hbar} = 5.293 \times 10^{9}/\mathrm{s}\,, \tag{111.3}$$

corresponding to a mass difference of $\Delta m_K = 6.211 \times 10^{-42}\,\mathrm{kg}$, which is $\Delta m_K/m_K = 7.0 \times 10^{-15}$ of the kaon's own mass (Equations (105.60) and (105.63)). No spectrometer

resolves a fractional mass difference of 10^{-14}; an interferometer whose fringe is a phase accumulated over a flight path of metres does, and that is what the neutral kaon is. Everything in this chapter rests on that fact: the quantities measured are interference terms, not energies.

Remark 111.2 (Why the long-lived state was expected to be pure). It is worth being precise about the strength of the pre-1964 expectation, because it is what makes the measurement decisive rather than merely interesting. If CP commutes with the full Hamiltonian then $|K_2\rangle$ is an exact eigenstate of it and the amplitude for $K_2 \to \pi\pi$ is exactly zero — not small, not suppressed by a coupling, but forbidden by a superselection of the same kind that forbids a $0^+ \to 0^-$ electromagnetic transition. There was no parameter to adjust. A single observed event of the right kind, above background and above every mundane explanation, falsifies the hypothesis; and that is what Section 111.4.1 reports.

111.1.2 Regeneration

The mundane explanation that had to be excluded is regeneration, and because it is simultaneously the cleanest demonstration of quantum superposition in the subject and the principal background of the 1964 experiment, it is derived here rather than assumed.

Pais and Piccioni observed that a long-lived beam traversing matter emerges with a short-lived component [1077]. The reason is that the strong interaction sees strangeness and not CP: a $\bar{K}^0$ can convert a nucleon into a hyperon, a K^0 cannot, so the two forward scattering amplitudes differ. A medium that attenuates or phase-shifts the two strangeness components differently is, in the CP basis, a medium that rotates $|K_L\rangle$ into $|K_S\rangle$.

Proposition 111.3 (Coherent regeneration in a thin slab)**.** *Let a K_L beam of momentum p traverse a slab of thickness ℓ containing N scattering centres per unit volume, with complex forward scattering amplitudes f for K^0 and $\bar{f}$ for $\bar{K}^0$, both carrying the SI dimension of length. If ℓ is short compared with the K_S decay length, the emerging state contains a coherent K_S amplitude*

$$\rho = \mathrm{i}\tan\frac{\Delta\varphi}{2} \approx \frac{\mathrm{i}\Delta\varphi}{2} = \mathrm{i}\pi N\left(f-\bar{f}\right)\ell\,\frac{\hbar}{p}\,, \tag{111.4}$$

relative to the surviving K_L amplitude. It vanishes when the medium cannot distinguish the two strangeness states.

Rests on Equations (105.46) *and* (105.64).

Derivation. *Derives Proposition 111.3.*

A wave of reduced wavelength $\hbar/p$ propagating through a medium of N centres per unit volume with forward amplitude f acquires, per unit length, the extra phase $2\pi N f\hbar/p$: this is the optical relation $k^2(n-1) = 2\pi N f$ with $k = p/\hbar$, so that the phase per unit length is $k(n-1) = 2\pi N f/k = 2\pi N f\hbar/p$, and it is the only piece of scattering theory needed. Both sides of the optical relation carry the SI dimension $1/\mathrm{m}^2$, since $[N] = 1/\mathrm{m}^3$ and $[f] = \mathrm{m}$. Over the slab the two strangeness components therefore acquire

$$\varphi = 2\pi N f\ell\,\frac{\hbar}{p}\,, \qquad \bar{\varphi} = 2\pi N \bar{f}\ell\,\frac{\hbar}{p}\,, \qquad \Delta\varphi = \varphi - \bar{\varphi}\,.$$

Write the incident state, neglecting the 10^{-3} admixture ϵ, as $|K_L\rangle = \left(|K^0\rangle - \left|\bar{K}^0\right\rangle\right)/\sqrt{2}$

from Equation (105.46). Applying the two phases and factoring out the common part,

$$\begin{aligned}|\psi\rangle &= \frac{1}{\sqrt{2}}\left(\mathrm{e}^{\mathrm{i}\varphi}\left|K^0\right\rangle - \mathrm{e}^{\mathrm{i}\bar{\varphi}}\left|\bar{K}^0\right\rangle\right)\\ &= \frac{\mathrm{e}^{\mathrm{i}(\varphi+\bar{\varphi})/2}}{\sqrt{2}}\left(\mathrm{e}^{\mathrm{i}\Delta\varphi/2}\left|K^0\right\rangle - \mathrm{e}^{-\mathrm{i}\Delta\varphi/2}\left|\bar{K}^0\right\rangle\right)\\ &= \mathrm{e}^{\mathrm{i}(\varphi+\bar{\varphi})/2}\left[\cos\frac{\Delta\varphi}{2}\,|K_L\rangle + \mathrm{i}\sin\frac{\Delta\varphi}{2}\,|K_S\rangle\right],\end{aligned}$$

where the last line uses $|K_S\rangle = \left(|K^0\rangle + \left|\bar{K}^0\right\rangle\right)/\sqrt{2}$. The ratio of the two amplitudes is Equation (111.4), and it is proportional to $f - \bar{f}$, hence zero for a medium blind to strangeness. Retaining the K_S decay and the K_S–K_L phase difference over the slab replaces the linear ℓ by a bounded oscillating factor of the kind written in Equation (105.64); for the thin, dilute media of interest here that factor reduces to ℓ and the difference is immaterial. Only $|\rho|$ is used below, so the overall phase convention of the thick-slab formula does not enter. □

Two features of Equation (111.4) decide the design of the experiment. The first is that ρ is proportional to N, so a dilute medium regenerates weakly and a vacuum not at all. The second, less obvious, is that the regenerated amplitude is *coherent* with the incident beam: it is forward, it carries the beam's momentum direction, and its decay to $\pi^+\pi^-$ is therefore collinear with the beam — exactly like the signal. Coherent regeneration cannot be removed by an angular cut. Only its incoherent relatives can: diffractive regeneration off a single nucleus, and inelastic production, both leave the reconstructed parent momentum at a measurable angle to the beam, and those are what the collinearity requirement of Section 111.3 eliminates. The coherent part has to be made small, and made small by construction; that is what the helium bag is for, and Proposition 111.5 puts a number on it.

111.1.3 CP as the symmetry that was supposed to survive

The parity experiments of 1957 (Chapter 110) showed that the weak interaction distinguishes left from right maximally: in the beta decay of polarized cobalt the electrons come out preferentially opposite to the nuclear spin [1133], and in the pion–muon–electron chain the muon is fully polarized [1110]. Charge conjugation fares no better, and for the same reason — applied to the left-handed neutrino it produces a left-handed antineutrino, which does not exist.

Landau's response was to propose that the true symmetry is the product [1118]. It is an economical suggestion: CP maps the left-handed neutrino onto the right-handed antineutrino, which does exist, so maximal violation of C and of P separately is exactly compatible with an exact CP. Together with the CPT theorem of local Lorentz-invariant quantum field theory [1123] — proved as Theorem 105.34 — the proposal has three testable consequences, and it is worth listing them because the experiment tested the first and the other two survived:

1. $K_L \to \pi\pi$ is strictly forbidden, the long-lived state being the CP-odd combination and the two-pion state CP-even.
2. A particle and its antiparticle have exactly equal masses and exactly equal total lifetimes (Theorem 105.36, Theorem 105.38), whether or not CP holds; these follow from CPT alone.
3. Any CP violation is, given CPT, a T violation of the same size, so a direct comparison of a process with its motion reverse must show it too — which is the programme of Section 111.7.4.

111.1.4 The observable and what a measurement must deliver

The prediction under test is item (i), and stating it as an experimental requirement fixes the whole design.

A neutral kaon beam is prepared far enough downstream of its production target that the K_S component has decayed to an utterly negligible level. Any $\pi^+\pi^-$ pair observed to emerge from the surviving beam must then satisfy two independent conditions if it is a genuine two-body decay of a beam particle: the invariant mass of the pair, computed under the pion hypothesis, must equal the kaon mass; and the vector sum of the two pion momenta — the reconstructed parent momentum — must be collinear with the beam. A measurement must therefore deliver

- a beam whose K_S contamination is calculably negligible,
- a decay region containing so little material that coherent regeneration cannot fake the signal,
- a spectrometer whose mass resolution separates $\pi^+\pi^-$ from the three-body decays $\pi e\nu$, $\pi\mu\nu$ and $\pi^+\pi^-\pi^0$, which are 10^3 times commoner,
- an angular resolution fine enough that a genuine two-body decay piles up in one bin of $\cos\theta$ while three-body decays spread over many, and
- a normalization sample — the charged decays of the same beam in the same apparatus — so that the answer is a ratio in which the flux and most of the acceptance cancel.

Each of the five is met by a specific piece of the apparatus, and the next two sections take them in that order.

111.2 Apparatus

111.2.1 The Brookhaven beam and the decay volume

The source was the alternating-gradient synchrotron at Brookhaven, delivering protons of $30\,\mathrm{GeV}$ — a kinetic energy of $4.8\times10^{-9}\,\mathrm{J}$ per proton — onto an internal target. A neutral beam was taken off at 30° to the circulating protons, passed through a collimator, swept clear of charged particles by a magnet, and re-collimated; the detector viewed the beam $17.4\,\mathrm{m}$ (57 feet in the units of the original report) from the target [1274]. The momentum spectrum of the surviving neutral kaons peaked near $1.1\,\mathrm{GeV}/c$, which is the value used for every kinematic estimate below.

That distance is the first design requirement, and it is met with an enormous margin.

Proposition 111.4 (The beam is pure long-lived kaons)**.** *At $p = 1.1\,\mathrm{GeV}/c$ the K_S decay length is $5.93\times10^{-2}\,\mathrm{m}$ and the K_L decay length is $33.9\,\mathrm{m}$. A flight path of $17.4\,\mathrm{m}$ is 293 K_S decay lengths and 0.513 K_L decay lengths.*

Rests on Equation (111.2).

Derivation. *Derives Proposition 111.4.*

With $m_Kc^2 = 497.611\,\mathrm{MeV}$ and $pc = 1.1\,\mathrm{GeV}$, the total energy is

$$E = \sqrt{p^2c^2 + m_K^2c^4} = 1.2073\,\mathrm{GeV} = 1.9343\times10^{-10}\,\mathrm{J}\,,$$

so $\gamma = E/(m_Kc^2) = 2.426$, $\beta = pc/E = 0.9111$ and $\gamma\beta = pc/(m_Kc^2) = 2.211$. The laboratory decay length of a state of proper lifetime τ is $\gamma\beta c\tau$; with Equation (111.2),

$$\lambda_S = 2.211\times2.997\,924\,58\times10^{8}\,\mathrm{m/s}\times8.954\times10^{-11}\,\mathrm{s} = 5.934\times10^{-2}\,\mathrm{m}\,,$$
$$\lambda_L = 2.211\times2.997\,924\,58\times10^{8}\,\mathrm{m/s}\times5.116\times10^{-8}\,\mathrm{s} = 33.90\,\mathrm{m}\,.$$

Hence $17.4\,\mathrm{m}/\lambda_S = 293$ and $17.4\,\mathrm{m}/\lambda_L = 0.513$. The surviving K_S fraction is e^{-293}, a number smaller than 10^{-127} and therefore not a background of any kind; the surviving K_L fraction is $\mathrm{e}^{-0.513} = 0.599$, so more than half the long-lived beam is still available where the apparatus looks at it. The flight path is close to the optimum: shortening it would not increase the K_L flux much and would begin to admit K_S, lengthening it would cost K_L flux exponentially for no gain. □

The decay volume itself was a bag of helium at atmospheric pressure. The reason is Proposition 111.3: coherent regeneration scales as the number density of scatterers times the difference of their forward amplitudes, and both factors are minimized by a light, dilute gas. A true vacuum over a volume of several cubic metres was impractical in 1964; helium was the practical approximation to one, and the following estimate is what justifies the choice.

Proposition 111.5 (Helium suppresses the regeneration background)**.** *Over a decay path of* $2\,\mathrm{m}$ *of helium at atmospheric pressure, the coherently regenerated* K_S *amplitude is of order* 3×10^{-5}*, that is about one per cent of the signal amplitude* $|\eta_{+-}| = 2.2\times10^{-3}$*; in air it would have been several times larger.*

Rests on Equation (111.4)*.*

Derivation. Derives Proposition 111.5.

Insert into Equation (111.4). The reduced wavelength of the beam is

$$\frac{\hbar}{p} = \frac{1.054\,571\,817\times10^{-34}\,\mathrm{J\,s}}{5.879\times10^{-19}\,\mathrm{kg\,m/s}} = 1.794\times10^{-16}\,\mathrm{m}\,,$$

where $p = 1.1\,\mathrm{GeV}/c$ has been converted using $1\,\mathrm{eV} = 1.602\,176\,634\times10^{-19}\,\mathrm{J}$ [2431]. Helium at $101.3\,\mathrm{kPa}$ and room temperature, taken as $293\,\mathrm{K}$, has $N = P/(k_{\mathrm{B}}T) = 2.50\times10^{25}/\mathrm{m}^3$ atoms; the familiar $2.69\times10^{25}/\mathrm{m}^3$ is the same pressure at $273.15\,\mathrm{K}$. The amplitude difference $\left|f-\bar{f}\right|$ is not calculable from first principles here, but it cannot exceed the geometric scale of the nucleus, so taking $\left|f-\bar{f}\right| \sim 1\times10^{-15}\,\mathrm{m}$ is a generous bound. With $\ell = 2\,\mathrm{m}$,

$$|\rho| \sim \pi\times2.50\times10^{25}/\mathrm{m}^3\times1\times10^{-15}\,\mathrm{m}\times2\,\mathrm{m}\times1.794\times10^{-16}\,\mathrm{m} = 3\times10^{-5}\,.$$

Air is denser in nucleons by a factor $1.20\,\mathrm{kg/m^3}/0.166\,\mathrm{kg/m^3} = 7.2$ — both densities at $293\,\mathrm{K}$ and $101.3\,\mathrm{kPa}$, since setting a room-temperature air density against the tabulated $273.15\,\mathrm{K}$ helium value of $0.179\,\mathrm{kg/m^3}$ would understate the ratio as 6.7 — and its nuclei are heavier, so $\left|f-\bar{f}\right|$ is larger by roughly $(14/4)^{2/3}\approx2.3$ per atom while the atom density rises by about a factor of two; the product is an increase of four or five. The regenerated amplitude adds coherently to η_{+-}, so a regeneration amplitude that is one per cent of η_{+-} perturbs the measured rate by about two per cent, while one that is five per cent of it perturbs the rate by about ten per cent — the difference between a negligible correction and a systematic error comparable with the statistical one. This is an order-of-magnitude estimate and was treated as such: the experiment also measured the regeneration directly by inserting known material, which is the calibration described in Section 111.3.3. □

111.2.2 The two-arm spectrometer

The detector was two symmetric arms viewing the helium bag, each consisting of a bending magnet with a spark chamber before it and a spark chamber after it, followed by a water Cherenkov counter and a scintillation counter [1274]. Each arm measured one charged particle: its direction from the two spark chambers, its momentum from the deflection between them, and its identity, loosely, from the Cherenkov signal. The two arms together therefore delivered the two three-vectors $\boldsymbol{p}_1$ and $\boldsymbol{p}_2$ from which every quantity in the analysis is built.

The arms sat at about 22° to the beam on either side, and that angle is not arbitrary.

Proposition 111.6 (Why the arms sit near 22 degrees)**.** *A K^0 of momentum $1.1\,\mathrm{GeV}/c$ decaying to $\pi^+\pi^-$ sends both pions to the same laboratory angle 20.5°, on opposite sides of the beam, when they are emitted transversely to the beam in the kaon rest frame. That symmetric configuration is the one a pair of symmetric arms can accept with both arms at the same angle, and it is what fixes that angle. A single pion can reach as far as 41.9° from the beam, attained at $\cos\theta^* = -0.909$, but only when its partner has collapsed to 4.9°.*

Rests on Proposition 111.4.

Derivation. *Derives Proposition 111.6.*

In the kaon rest frame the two pions are back to back with momentum

$$p^*c = \sqrt{\frac{m_K^2c^4}{4} - m_\pi^2c^4} = \sqrt{(248.806\,\mathrm{MeV})^2 - (139.570\,\mathrm{MeV})^2} = 205.97\,\mathrm{MeV}\,,$$

that is $p^* = 1.101 \times 10^{-19}\,\mathrm{kg\,m/s}$, and each carries energy $E^* = m_Kc^2/2 = 248.806\,\mathrm{MeV}$. Boosting to the laboratory with $\gamma = 2.426$, $\beta = 0.9111$ from Proposition 111.4, a pion emitted at 90° in the rest frame keeps its transverse momentum $p_\perp = p^*$ and acquires

$$p_\parallel = \gamma\beta\frac{E^*}{c} = 2.211 \times 248.806\,\mathrm{MeV}/c = 550.1\,\mathrm{MeV}/c\,,$$

so its laboratory angle is $\arctan(205.97/550.1) = 20.5^\circ$. Its partner, emitted transversely in the opposite sense, arrives at the same 20.5° on the other side of the beam: this is the only configuration in which the two pions make equal angles with the beam, and it is therefore the configuration a symmetric two-arm spectrometer is built around.

The maximum laboratory angle of a *single* pion is a different number and is worth separating out. With $u = \cos\theta^*$ the laboratory angle satisfies

$$\tan\theta = \frac{p^*\sqrt{1-u^2}}{\gamma\,(p^*u + \beta E^*/c)} = \frac{1}{\gamma}\,\frac{\sqrt{1-u^2}}{u + \beta/\beta^*}\,, \qquad \beta^* = \frac{p^*c}{E^*} = 0.8278\,.$$

Differentiating the last fraction gives $-u(u+\beta/\beta^*) - (1-u^2) = 0$, that is $u = -\beta^*/\beta = -0.909$; a maximum exists precisely because $\beta = 0.9111$ exceeds β^*, so that the origin lies outside the ellipse of laboratory momenta and the tangent from it touches at $u = -0.909$ rather than at the transverse point. There $\tan\theta = 0.8968$ and $\theta = 41.9^\circ$, while the partner at $u = +0.909$ is thrown forward to $\tan\theta = 0.0857$, that is 4.9°. Two arms placed at 22° therefore sit on the symmetric configuration, accept a wide band of rest-frame angles about it at once, and keep clear of the beam; the wide-angle pairs are lost, but they are lost together with their forward partners and cost only acceptance, not bias. □

The two remaining pieces of the apparatus are there to reject the common decays. The Cherenkov counters used water, of refractive index $n = 1.33$, whose threshold velocity is $\beta_{\mathrm{th}} = 1/n = 0.752$; for a pion this is a momentum of

$$p_{\mathrm{th}} = \frac{m_\pi c\,\beta_{\mathrm{th}}}{\sqrt{1-\beta_{\mathrm{th}}^2}} = 159\,\mathrm{MeV}/c\,, \tag{111.5}$$

so essentially every pion in the accepted momentum band radiates while the counters remain useful in the trigger. The scintillators supplied the fast timing that defined the coincidence.

The resolutions matter more than any of this, because the entire argument of the experiment is a two-dimensional separation. The spectrometer reconstructed the invariant mass of the pair to about $4\,\mathrm{MeV}/c^2$ and the direction of the reconstructed parent to a few milliradians; the signal bin used in the analysis, $\cos\theta > 0.9999$, corresponds to $\theta < 14.1\,\mathrm{mrad}$ (Table 111.1).

Table 111.1: Parameters of the Christenson–Cronin–Fitch–Turlay apparatus and beam [1274], with the derived kinematic quantities of Propositions 111.4 and 111.6. Imperial figures in the original report are converted; the 17.4 m flight path is the 57 feet of the published layout. Quantities marked "derived" are computed in this chapter from the beam momentum and the particle masses of Table 111.5, not taken from the source.

Quantity	Value	Note
Proton energy (AGS)	$30\,\mathrm{GeV}$	$4.8 \times 10^{-9}\,\mathrm{J}$
Neutral-beam production angle	30°	to circulating protons
Target-to-detector flight path	$17.4\,\mathrm{m}$	57 feet as published
Beam momentum at the peak	$1.1\,\mathrm{GeV}/c$	$5.879 \times 10^{-19}\,\mathrm{kg\,m/s}$
Lorentz factor of the beam	$\gamma = 2.426$	derived
K_S decay length	$5.93 \times 10^{-2}\,\mathrm{m}$	derived
K_L decay length	$33.9\,\mathrm{m}$	derived
Flight path in K_S decay lengths	293	derived
Decay volume	helium, $101.3\,\mathrm{kPa}$	bag, not a vacuum vessel
Spectrometer arm angle	22°	each side of the beam
Symmetric-pair laboratory angle	20.5°	derived
Maximum single-pion angle	41.9°	derived, at $\cos\theta^* = -0.909$
Rest-frame pion momentum	$206\,\mathrm{MeV}/c$	derived
Cherenkov radiator	water, $n = 1.33$	pion threshold $159\,\mathrm{MeV}/c$
Invariant-mass resolution	$\approx 4\,\mathrm{MeV}/c^2$	pion hypothesis
Signal angular bin	$\cos\theta > 0.9999$	$\theta < 14.1\,\mathrm{mrad}$

111.3 Procedure

111.3.1 Trigger and event recording

An event was accepted when the scintillation and Cherenkov counters of both arms fired in coincidence, indicating one charged particle in each arm within the resolving time of the counters. The coincidence pulsed the spark chambers to a few tens of kilovolts, so that the ionization trails left by the two particles broke down into visible sparks, and triggered a camera which photographed the chambers [1274]. The recorded object was therefore a photograph, and the analysis a measurement of positions on film, followed by a reconstruction.

This is worth stating plainly because it bounds the sample size. The experiment could not record a large fraction of the beam; it recorded about twenty-two thousand charged decays in total, and the signal it found is forty-five events. Everything about the argument — the use of a two-dimensional discriminant rather than a single cut, the reliance on sidebands for the background, the insistence on a control sample — follows from having a sample of that size and no possibility of enlarging it quickly.

111.3.2 Reconstruction in the mass-angle plane

From the two measured momenta the analysis formed two numbers. The first is the invariant mass of the pair under the hypothesis that both particles are pions,

$$m_{\pi\pi}^2 c^4 = 2m_\pi^2 c^4 + 2\left(E_1 E_2 - \boldsymbol{p}_1 \cdot \boldsymbol{p}_2 c^2\right), \qquad E_i = \sqrt{p_i^2 c^2 + m_\pi^2 c^4}\,. \tag{111.6}$$

The second is the angle θ between the reconstructed parent momentum $\boldsymbol{p}_1 + \boldsymbol{p}_2$ and the beam direction, reported as $\cos\theta$.

The discriminating power lies in requiring both at once, and the reason is a kinematic identity rather than a statistical convention.

Proposition 111.7 (A two-body decay is a point in the mass-angle plane)**.** *If a beam particle of mass m_K decays to exactly two pions, then $m_{\pi\pi} = m_K$ and $\cos\theta = 1$ identically. If it decays to three or more bodies of which two are detected, then $m_{\pi\pi} < m_K$, and $\cos\theta < 1$ unless the undetected momentum happens to vanish.*

Rests on Equation (111.6)*.*

Derivation. Derives Proposition 111.7.

For a two-body decay, four-momentum conservation gives $p_K^\mu = p_1^\mu + p_2^\mu$, so the invariant mass of the pair is the parent mass and its three-momentum is the parent's, which points along the beam. Both statements are exact and both are independent of the decay angle, which is what makes the pair $(m_{\pi\pi}, \cos\theta)$ a point rather than a distribution.

For a decay $K \to \pi\pi X$ with X undetected of four-momentum q^μ and mass $m_X \geq 0$,

$$m_{\pi\pi}^2 c^4 = (p_K - q)^2 c^2 = m_K^2 c^4 + m_X^2 c^4 - 2p_K \cdot q\, c^2\,.$$

Here a four-momentum carries the SI dimension of momentum, so that $p^2 = m^2 c^2$ and every term above is an energy squared. In the kaon rest frame $p_K \cdot q\, c^2 = m_K c^2 E_X^*$ with $E_X^* \geq m_X c^2$, and E_X^* is bounded below by the kinematic minimum for the given final state, so $m_{\pi\pi} < m_K$ strictly. The missing three-momentum likewise tilts $\boldsymbol{p}_1 + \boldsymbol{p}_2$ away from the beam, by an angle of order $q_\perp/(p_1 + p_2)$; for the dominant K_L modes — $\pi^\pm e^\mp \nu$, $\pi^\pm \mu^\mp \nu$ and $\pi^+\pi^-\pi^0$ — the missing transverse momentum is of order $100\,\mathrm{MeV}/c$ against a total of order $1\,\mathrm{GeV}/c$, giving angles of order 100 mrad, seven times the signal bin. The two variables therefore fail together for background and hold together for signal, and it is their *joint* behaviour, not the size of the excess, that carries the argument. □

For the semileptonic modes there is a second, independent handicap. Because the electron or muon is assigned the pion mass in Equation (111.6), its energy is overestimated, and the reconstructed mass is pushed further from m_K rather than towards it — so the misassignment cannot manufacture a signal, only remove background from the peak.

111.3.3 Backgrounds and the control samples

Three backgrounds had to be dealt with, and each was measured rather than modelled.

Three-body decays under the peak. The overwhelming majority of the recorded events are $\pi e\nu$, $\pi\mu\nu$ and 3π, which populate the whole $(m_{\pi\pi}, \cos\theta)$ plane. Their density in the signal region was fixed empirically from mass sidebands: the $\cos\theta$ distribution was formed in the mass intervals immediately below and above the kaon mass, where no two-body signal can exist, and interpolated across. The interpolation is safe because the background varies smoothly in $m_{\pi\pi}$ on the scale of the mass resolution while the signal does not.

Incoherent regeneration. Diffractive and inelastic regeneration in the residual material produce a K_S whose momentum is not collinear with the beam, and are therefore removed by the same angular requirement that defines the signal, as Proposition 111.7 makes explicit.

Coherent regeneration. This one is collinear and cannot be cut away, so it was measured. Slabs of material were deliberately placed in the beam, producing a large and unmistakable coherent $K_S \to \pi^+\pi^-$ signal at $m_{\pi\pi} = m_K$ and $\cos\theta = 1$; that sample served two purposes at once. It calibrated the mass and angular resolution of the spectrometer on real two-body decays of the right mass and the right momentum spectrum — the ideal control, since it is the signal in every respect except its origin — and it fixed the constant of proportionality in Equation (111.4) for the materials involved, from which the residual regeneration in helium follows by scaling. The observed forward peak did not scale with the amount of material in the beam, which is the direct experimental statement that it is not regeneration.

Finally, the normalization. The denominator of the published ratio is the number of *all* charged decays of the same beam recorded in the same apparatus. Taking a ratio to that sample cancels the beam flux, the live time, the film-scanning efficiency and a large part of the geometric acceptance, which is why the result could be quoted to twenty per cent from forty-five events.

111.4 Observations and data

111.4.1 The forward peak at the kaon mass

In the mass interval containing the kaon mass, and only there, the $\cos\theta$ distribution shows a sharp excess in the single bin $\cos\theta > 0.9999$. In the two adjacent mass intervals, ten MeV below and above, the same bin shows nothing above the smooth background. The excess amounts to 45 ± 9 events, and the sample of all charged decays recorded in the same apparatus numbers 22 700 [1274].

Phenomenon 111.8 (The long-lived neutral kaon decays to two pions)**.** A neutral kaon beam allowed to propagate far enough that every short-lived component has decayed still produces two-charged-pion events whose reconstructed invariant mass is the kaon mass and whose reconstructed parent momentum is collinear with the beam: an excess of 45 ± 9 events over an estimated background of about twelve in the forward bin, corresponding to

$$\frac{\Gamma\left(K_L \to \pi^+\pi^-\right)}{\Gamma\left(K_L \to \text{all charged}\right)} = \frac{45 \pm 9}{22\,700} = (2.0 \pm 0.4) \times 10^{-3} \tag{111.7}$$

[1274]. The decay is forbidden if CP is a symmetry.

Rests on Equations (105.46) *and* (105.47)*.*

Derivation. *Derives Phenomenon 111.8.*

The two pions from a spinless parent are in a state of zero relative orbital angular momentum, $L = 0$. Space inversion multiplies such a state by the product of the two intrinsic parities and by $(-1)^L$; the pion is pseudoscalar, so $P\,|\pi^+\pi^-\rangle = (-1)^2(-1)^L\,|\pi^+\pi^-\rangle = +\,|\pi^+\pi^-\rangle$. Charge conjugation exchanges the two pions, which for relative angular momentum L contributes the same factor $(-1)^L = +1$. Hence

$$CP\left|\pi^+\pi^-\right\rangle = +\left|\pi^+\pi^-\right\rangle ,$$

the final state is CP-even. Before 1964 the long-lived kaon was identified with the CP-odd combination $|K_2\rangle = \left(|K^0\rangle - \left|\bar{K}^0\right\rangle\right)/\sqrt{2}$, for which $CP\,|K_2\rangle = -\,|K_2\rangle$, precisely because that assignment forbids the two-pion channel and so explains the observed factor of some six hundred between the two lifetimes. An interaction commuting with CP cannot connect states of opposite CP eigenvalue, so Equation (111.7) establishes that the weak interaction does not commute with CP. What the observation does not by itself decide is whether the violation lies in the mixing that defines the long-lived state or in the decay amplitude; that is the question of Section 111.5.1. □

The 1964 numbers and their modern successors are collected in Table 111.2. One comparison in that table deserves comment, because it is the only place where the original measurement can be checked against a modern one and the two are not quoted in the same variable. The published ratio has "all charged decays" in its denominator, whereas the modern branching fraction has all decays. The charged modes of the K_L — $\pi^\pm e^\mp\nu$, $\pi^\pm\mu^\mp\nu$, $\pi^+\pi^-\pi^0$ and $\pi^+\pi^-$ itself — account for 0.8033 ± 0.0014 of the total width [2427], the quoted uncertainty being the quadrature combination of the uncertainties on those four branching fractions. It is negligible beside the twenty per cent statistical error on the 1964 ratio, so

$$\mathcal{B}\left(K_L \to \pi^+\pi^-\right)_{1964} = (2.0 \pm 0.4) \times 10^{-3} \times 0.8033 = (1.6 \pm 0.3) \times 10^{-3} , \tag{111.8}$$

against the present $(1.967 \pm 0.010) \times 10^{-3}$ [2427]: agreement at 1.2 standard deviations. The original measurement was correct, and it was correct to twenty per cent on forty-five events.

Table 111.2: The 1964 measurement and its modern counterparts. The first block is what Christenson, Cronin, Fitch and Turlay reported [1274]; the second is the current world average [2427]. The conversion between the two normalizations is Equation (111.8). Uncertainties are as quoted by the sources; the 1964 error is dominated by the counting statistics of the forty-five-event excess.

Quantity	Value	Year
Charged decays recorded	22 700	1964
Excess in the forward mass peak	45 ± 9 events	1964
Estimated background in that bin	≈ 12 events	1964
$\Gamma(K_L \to \pi^+\pi^-)/\Gamma(K_L \to \text{charged})$	$(2.0 \pm 0.4) \times 10^{-3}$	1964
Converted branching fraction	$(1.6 \pm 0.3) \times 10^{-3}$	1964
$\mathcal{B}(K_L \to \pi^+\pi^-)$	$(1.967 \pm 0.010) \times 10^{-3}$	2024
$\mathcal{B}(K_L \to \pi^0\pi^0)$	$(8.64 \pm 0.06) \times 10^{-4}$	2024
Charged fraction of the K_L width	0.8033 ± 0.0014	2024

111.4.2 The branching ratio and the parameter epsilon

The branching fraction is not the natural variable. What the theory predicts is an *amplitude* ratio, because the two-pion final state is reached from the CP-even admixture in the

long-lived state, and the natural comparison is with the same final state reached from the short-lived one. The definitions are Equation (105.65):

$$|\eta_{+-}|^2 = \frac{\Gamma\left(K_L \to \pi^+\pi^-\right)}{\Gamma\left(K_S \to \pi^+\pi^-\right)} = \frac{\mathcal{B}\left(K_L \to \pi^+\pi^-\right)\tau_S}{\mathcal{B}\left(K_S \to \pi^+\pi^-\right)\tau_L}\,, \tag{111.9}$$

the second form following because a branching fraction is a partial width divided by a total width and the total widths are $\hbar/\tau$. Inserting $\mathcal{B}(K_L \to \pi^+\pi^-) = 1.967 \times 10^{-3}$, $\mathcal{B}(K_S \to \pi^+\pi^-) = 0.6920$ and the lifetimes of Equation (111.2) gives

$$|\eta_{+-}|^2 = \frac{1.967 \times 10^{-3} \times 8.954 \times 10^{-11}\,\mathrm{s}}{0.6920 \times 5.116 \times 10^{-8}\,\mathrm{s}} = 4.98 \times 10^{-6}\,,$$

that is $|\eta_{+-}| = 2.23 \times 10^{-3}$, which is the measured value in Table 111.3. The arithmetic is worth seeing once: the tiny branching fraction and the enormous lifetime ratio very nearly cancel, and what survives is a number of order 10^{-3} that has nothing to do with either.

The phase of η_{+-} is measured independently, by observing the interference between the K_S and K_L amplitudes in a beam containing both, and it comes out at 43.51°. That value is predicted, not fitted: Equation (105.59) gives $\arg\epsilon = \arctan\left[2\Delta m_K c^2 \tau_S/\hbar\right]$, and with Equation (111.3) and Equation (111.2),

$$\arctan\frac{2 \times 3.484 \times 10^{-6}\,\mathrm{eV}}{7.3510 \times 10^{-6}\,\mathrm{eV}} = 43.47^\circ\,, \tag{111.10}$$

where $\hbar/\tau_S = 7.3510 \times 10^{-6}\,\mathrm{eV}$ is the K_S full width. Equivalently, dividing numerator and denominator by two, $\arctan\left[\Delta m_K c^2/(\hbar/2\tau_S)\right]$ with the half width $3.6755 \times 10^{-6}\,\mathrm{eV}$: the factor of two in Equation (105.59) is the one that turns the half width into the full width, and must not be applied twice.

The agreement of a measured phase with a number built out of a mass difference and a lifetime is one of the sharper consistency checks in the subject, and it is what licenses the identification of η_{+-} with the mixing parameter ϵ of Equation (105.54) up to the small direct term of Section 111.6.

Table 111.3: Measured parameters of the neutral kaon system [2427], with SI equivalents where the customary unit is not SI. The mass values are those of the machine-readable Particle Data Group release; the mass difference, the lifetimes and the CP parameters are from the same review. The last column gives the year of the compilation, not of the first measurement; the years of first measurement are in Table 111.4.

Quantity	Value	SI equivalent	Year
$m_{K^0}c^2$	$(497.611 \pm 0.013)\,\mathrm{MeV}$	$7.9726 \times 10^{-11}\,\mathrm{J}$	2024
m_{K^0}	—	$8.8707 \times 10^{-28}\,\mathrm{kg}$	2024
τ_S	$(8.954 \pm 0.004) \times 10^{-11}\,\mathrm{s}$	—	2024
τ_L	$(5.116 \pm 0.021) \times 10^{-8}\,\mathrm{s}$	—	2024
$\Delta m_K c^2$	$(3.484 \pm 0.006) \times 10^{-6}\,\mathrm{eV}$	$5.582 \times 10^{-25}\,\mathrm{J}$	2024
$\Delta m_K c^2/\hbar$	—	$5.293 \times 10^{9}/\mathrm{s}$	2024
$\lvert\eta_{+-}\rvert$	$(2.232 \pm 0.011) \times 10^{-3}$	dimensionless	2024
$\arg\eta_{+-}$	43.51°	0.7594 rad	2024
$\lvert\epsilon\rvert$	$(2.228 \pm 0.011) \times 10^{-3}$	dimensionless	2024
δ_L	$(3.32 \pm 0.06) \times 10^{-3}$	dimensionless	2024
$\mathrm{Re}(\epsilon'/\epsilon)$	$(1.66 \pm 0.23) \times 10^{-3}$	dimensionless	2024

111.4.3 Charge asymmetry in semileptonic decay

The two-pion decay establishes that CP is violated; it does not by itself give a sign. The observable that does is the charge asymmetry of the semileptonic decays of the same long-lived state, and it deserves attention out of all proportion to its size.

Phenomenon 111.9 (Charge asymmetry in semileptonic kaon decay)**.** The long-lived kaon decays slightly more often to $\pi^- e^+ \nu_e$ than to $\pi^+ e^- \bar{\nu}_e$:

$$\delta_L = \frac{\Gamma(\pi^- e^+ \nu_e) - \Gamma(\pi^+ e^- \bar{\nu}_e)}{\Gamma(\pi^- e^+ \nu_e) + \Gamma(\pi^+ e^- \bar{\nu}_e)} = (3.32 \pm 0.06) \times 10^{-3} \tag{111.11}$$

[2427]. Small as it is, this is an absolute, convention-free distinction between matter and antimatter: which sign of lepton charge is the commoner one can be communicated to a correspondent with whom we share no sample and no convention.

Rests on Equation (105.56) *and Theorem 105.34.*

Derivation. *Derives Phenomenon 111.9.*

Let the long-lived state be $|K_L\rangle \propto (1+\epsilon)\,|K^0\rangle - (1-\epsilon)\,\left|\bar{K}^0\right\rangle$ with $|\epsilon| \ll 1$, which is Equation (105.56). The selection rule $\Delta S = \Delta Q$ allows $K^0 \to \pi^- e^+ \nu_e$ and $\bar{K}^0 \to \pi^+ e^- \bar{\nu}_e$ but not the charge-exchanged pair, and CPT makes the two allowed amplitudes equal in magnitude. The two rates are therefore proportional to $|1+\epsilon|^2$ and $|1-\epsilon|^2$, so

$$\delta_L = \frac{|1+\epsilon|^2 - |1-\epsilon|^2}{|1+\epsilon|^2 + |1-\epsilon|^2} = \frac{2\,\mathrm{Re}\,\epsilon}{1+|\epsilon|^2} \approx 2\,\mathrm{Re}\,\epsilon\,.$$

With $|\epsilon| = 2.228 \times 10^{-3}$ and its phase $43.5°$ [2427], $2\,\mathrm{Re}\,\epsilon = 2 \times 2.228 \times 10^{-3} \times \cos 43.5° = 3.23 \times 10^{-3}$, against the measured $(3.32 \pm 0.06) \times 10^{-3}$ of Equation (111.11). The asymmetry is thus the same ϵ that Phenomenon 111.8 exhibits, seen in an entirely different channel — which is what makes the mixing interpretation testable rather than merely available. □

The convention-free character of the statement is worth spelling out, since it is the one experimental result in this book that changes what can be said about the words used to describe the world. Before 1964 the labels "matter" and "antimatter" were conventional: C violation and P violation alone leave open the possibility that what we call matter is simply the mirror image of what a distant correspondent calls matter, because a mirror reflection can be compensated by an exchange of particles for antiparticles. Equation (111.11) closes that possibility. The instruction "prepare a long-lived neutral kaon beam, count the charge of the emitted lepton, and call the commoner sign positive" can be transmitted in words, needs no shared sample, and gives the same answer everywhere.

111.4.4 The measured CP-violating observables

The remaining sections of the chapter analyse one measurement at a time. Table 111.4 collects them all first, with the year and the source of each, so that the numbers can be read against one another; Table 111.5 gives the masses used throughout, and Table 111.6 the three mixing frequencies in SI. Every value is quoted as its source quotes it, with the uncertainties separated into statistical and systematic where the source separates them.

111.5 Interpretation

111.5.1 Indirect versus direct violation

The 1964 result establishes that the weak interaction does not commute with CP. It does not say where the violation sits, and there are two places available.

Table 111.4: Measured CP- and T-violating observables, in the order they are discussed. Where two uncertainties are given the first is statistical and the second systematic. All the quantities are dimensionless except the neutron electric dipole moment. The world-average entries are the compilations of the Particle Data Group [2427], which absorb later data than the discovery papers in the same block.

System	Observable	Value	Year	Source

Table 111.5: Masses used in the kinematic derivations of this chapter, taken from the machine-readable Particle Data Group release [2427], with the SI conversion made using the exact elementary charge and speed of light of the present SI [2431]. The energy equivalent is the value the source quotes; the mass in kilograms is that value divided by c^2.

Particle	mc^2	mc^2 (J)	m (kg)
K^0	$(497.611 \pm 0.013)\,\mathrm{MeV}$	7.9726×10^{-11}	8.8707×10^{-28}
$K^\pm$	$(493.677 \pm 0.015)\,\mathrm{MeV}$	7.9096×10^{-11}	8.8006×10^{-28}
$\pi^\pm$	$(139.570\,39 \pm 0.000\,18)\,\mathrm{MeV}$	2.2362×10^{-11}	2.4881×10^{-28}
π^0	$(134.9768 \pm 0.0005)\,\mathrm{MeV}$	2.1626×10^{-11}	2.4062×10^{-28}
J/ψ	$(3.096\,900 \pm 0.000\,006)\,\mathrm{GeV}$	4.9618×10^{-10}	5.5207×10^{-27}

Table 111.6: Mixing frequencies of the three neutral-meson systems in which CP violation has been established, expressed as an energy, as a frequency and as a mass [2427]. The oscillation frequency is $\Delta m\,c^2/\hbar$ throughout, with $\hbar = 1.054\,571\,817 \times 10^{-34}\,\mathrm{J\,s}$ [2431]. The fractional column is $\Delta m/m$, and it is the reason the neutral meson is the most sensitive interferometer available.

System	$\Delta m\,c^2$	$\Delta m\,c^2$ (J)	$\Delta m\,c^2/\hbar$	$\Delta m/m$
K^0	$(3.484 \pm 0.006) \times 10^{-6}\,\mathrm{eV}$	5.582×10^{-25}	$5.293 \times 10^{9}/\mathrm{s}$	7.0×10^{-15}
B^0	$(3.334 \pm 0.013) \times 10^{-4}\,\mathrm{eV}$	5.341×10^{-23}	$5.065 \times 10^{11}/\mathrm{s}$	6.3×10^{-14}
B_s^0	$(1.1693 \pm 0.0004) \times 10^{-2}\,\mathrm{eV}$	1.8734×10^{-21}	$1.7765 \times 10^{13}/\mathrm{s}$	2.2×10^{-12}

It may sit in the *state*. If the long-lived eigenvector of the effective Hamiltonian is not the CP-odd combination $|K_2\rangle$ but carries a small admixture $\epsilon\,|K_1\rangle$ of the CP-even one, then the two-pion decay proceeds entirely from that admixture, using a decay amplitude that itself respects CP perfectly. This is CP violation *in the mixing*, and it is a single complex number ϵ for the whole system.

Or it may sit in the *decay*. If the amplitudes for $K^0 \to \pi\pi$ and $\bar{K}^0 \to \pi\pi$ differ in more than the strong rescattering phase they are obliged to share, then even an exact CP eigenstate would decay asymmetrically. This is CP violation *in the decay*, or direct CP violation, and by Equation (105.72) it is measured by a second complex number ϵ'.

The distinction is not academic, and for thirty-five years it was the open question of the subject, because Wolfenstein had immediately supplied a hypothesis in which the second number is exactly zero [1300]. Suppose there exists a new interaction, enormously weaker than the weak interaction, which changes strangeness by two units and violates CP maximally. Acting once, it contributes to the off-diagonal element M_{12} of the mass matrix (Equation (105.50)) and so to ϵ; it never contributes to a decay, because the decays are $\Delta S = 1$ transitions. Such a "superweak" interaction reproduces every kaon measurement then available with one free parameter and predicts

$$\epsilon' = 0\,, \qquad \eta_{+-} = \eta_{00} = \epsilon\,, \qquad \arg\epsilon = \arctan\frac{2\Delta m_K c^2 \tau_S}{\hbar}\,, \tag{111.12}$$

and the last of these is the phase relation verified numerically in Equation (111.10). That agreement is worth pausing on: the superweak hypothesis was not a desperate one, it fitted the phase correctly, and the experiment that killed it had to measure a difference between η_{00} and η_{+-} of a few parts in a thousand of a quantity that is itself a few parts in a thousand. That is a measurement at the 10^{-6} level in the ratio of rates, and it is why it took thirty-five years. It is Section 111.6.

111.5.2 The CKM matrix and the Jarlskog invariant

The alternative to a new interaction is that the violation is already present in the interaction we have, and this is what Kobayashi and Maskawa proposed [1505]. Their argument is arithmetic and is proved as Theorem 105.25: a unitary $N \times N$ quark mixing matrix, after all the rephasings of the quark fields have been used up, retains $N(N-1)/2$ real angles and $(N-1)(N-2)/2$ phases. For $N = 2$ — the Cabibbo case [1248], one angle and no phase — the matrix can be made real, and a real Lagrangian conserves CP. For $N = 3$ there is exactly one phase, and it cannot be rotated away.

The status of this as a prediction should not be softened. In 1973 three quarks were known. The measurement being explained was a branching ratio of 2×10^{-3} in a kaon. The inference was that three more quarks exist. The charm quark appeared the following year (Section 103.2.3), the bottom quark in 1977 and the top quark in 1995, and the Nobel award of 2008 to Kobayashi and Maskawa recognized an argument, not a discovery of a particle.

Two further pieces of apparatus, in the theoretical sense, make the phase measurable. The first is a parametrization in which the observed hierarchy of the mixing angles is manifest: Wolfenstein's expansion in $\lambda = \sin\theta_C$ [1733], whose four parameters, measured, are Equation (103.24). The second is a rephasing-invariant measure, since the phase δ itself depends on the convention chosen for the quark fields and is therefore not an observable. Jarlskog's quantity [1756], defined at Definition 105.26, is the imaginary part of a quartet of matrix elements and is invariant; its measured value is Equation (105.78),

$$J = \left(3.08^{+0.15}_{-0.13}\right) \times 10^{-5}\,. \tag{111.13}$$

Geometrically $J/2$ is the area of every unitarity triangle (Proposition 103.30), so the single statement "CP is violated" is the single statement "the triangle is not degenerate".

Numerically, J is small not because the phase is small — it is of order unity, $\delta = 65.70^\circ$ by Equation (103.25) — but because the mixing angles are. That distinction returns with consequences in Section 111.8.2.

111.6 Direct CP violation in the kaon system

111.6.1 NA31 and the first evidence

The observable that separates the two hypotheses of Section 111.5.1 is the double ratio of the four two-pion widths, and the reason it and not something simpler is that every quantity common to the four channels cancels in it: the kaon flux, the solid angle, most of the reconstruction efficiency. What does not cancel is the difference between reconstructing two charged tracks and reconstructing four photons, and that difference is the systematic error of every measurement in this section.

The first experiment to see a non-zero value was NA31 at the CERN Super Proton Synchrotron [1806]. Protons of 450 GeV struck a beryllium target; the resulting neutral beam was allowed to run down a long evacuated decay region for the K_L measurement, and for the K_S measurement a second target mounted on a movable train was brought close to the detector, so that the same apparatus saw K_S decays distributed over the same fiducial region. Alternating the two configurations, rather than running them at once, is what makes the acceptance cancel.

NA31 carried no magnetic spectrometer. Its detector was a liquid-argon and lead sampling calorimeter for the photons of $\pi^0\pi^0$, an iron–scintillator hadron calorimeter, and wire chambers for the charged mode; the charged pion momenta were never measured individually, and the charged decays were identified from the calorimetric energy and the transverse position. The result,

$$\mathrm{Re}\frac{\epsilon'}{\epsilon} = (3.3 \pm 1.1) \times 10^{-3}\,, \tag{111.14}$$

is three standard deviations from zero and was the first evidence for direct CP violation.

It was not accepted, and the reason is that the contemporaneous Fermilab experiment E731, using a different technique — two parallel K_L beams with a regenerator placed alternately in one of them, so that K_S and K_L decays were recorded simultaneously — obtained a value consistent with zero, of order 7×10^{-4} with an uncertainty of similar size. The two results were about two standard deviations apart, which is not a crisis in itself; what made the decade that followed uncomfortable is that they disagreed about a *qualitative* question, the existence or not of ϵ', and therefore about whether the superweak hypothesis had been excluded. Neither collaboration could settle it with the data in hand, and both built successors designed around the other's technique. That is the correct response to an irreconcilable pair of measurements, and it is worth recording as such.

Remark 111.10 (A source this book cannot cite). The E731 result quoted above is described but not cited, because the bibliography of this treatise contains no entry for it. The number is given to an order of magnitude and its role in the argument is historical rather than evidential — the argument turns on the two 1999 measurements, which are cited — but the reader should know that this one sentence rests on an uncited source and treat it accordingly.

111.6.2 NA48 and KTeV

Both successors reported in 1999, and both found a non-zero value.

NA48, at CERN, produced K_L and K_S *simultaneously* rather than alternately [1973]. The K_L beam came from a target 126 m upstream of the decay region. A small fraction of the protons that missed that target were deflected by a bent silicon crystal onto a second

target 6 m upstream, producing a K_S beam nearly collinear with the first. The two decay populations were then recorded in the same detector at the same time, in the same beam conditions, with the acceptance difference reduced to the small difference in the decay distributions. Distinguishing a K_S decay from a K_L decay was done by timing: an array of scintillator counters — the tagger — in the proton beam heading for the K_S target recorded the passage of each proton to about 200 ps, and a decay coincident with a tagged proton is a K_S decay.

The detector was a magnetic spectrometer of four drift chambers around a dipole magnet, for $\pi^+\pi^-$, together with a liquid-krypton electromagnetic calorimeter of about $10\,\mathrm{m}^3$ and some thirteen thousand cells, twenty-seven radiation lengths deep, for the four photons of $\pi^0\pi^0$. The krypton calorimeter is the critical instrument: the neutral mode has no tracks, the kaon's decay point must be reconstructed from the photon energies and positions alone by imposing the π^0 mass, and the energy resolution therefore propagates directly into the fiducial volume definition. The 1999 result was

$$\mathrm{Re}\frac{\epsilon'}{\epsilon} = (18.5 \pm 4.5 \pm 5.8) \times 10^{-4}\,, \tag{111.15}$$

the second uncertainty systematic and larger than the first.

KTeV, at Fermilab, was the successor of E731 and kept its technique [1965]. Protons of 800 GeV on a beryllium-oxide target produced two parallel neutral beams; a regenerator — a block of scintillator, itself instrumented so that inelastic interactions in it could be vetoed — sat in one of the two and was moved from one beam to the other about once a minute, so that the regenerated K_S sample and the K_L sample were recorded simultaneously and each beam served in turn as each. The detector was a drift-chamber spectrometer around an analysing magnet and an electromagnetic calorimeter of 3100 pure caesium-iodide crystals, whose energy resolution below one per cent for the photons of interest is what made the neutral mode competitive. The result was

$$\mathrm{Re}\frac{\epsilon'}{\epsilon} = (28.0 \pm 3.0 \pm 2.8) \times 10^{-4}\,. \tag{111.16}$$

The two 1999 numbers differ by 9.5×10^{-4} against a combined uncertainty of 8.4×10^{-4}, that is by 1.1 standard deviations, which is unremarkable. Their distances from zero are not alike: combining each experiment's two errors in quadrature, KTeV is 6.8 standard deviations from zero and NA48 is 2.5. It is KTeV that established the effect in 1999; NA48 confirmed it, at a significance that on its own would not have settled the question, and the two together left no room for zero. With the later data of both experiments the world average is Equation (105.74), $\mathrm{Re}(\epsilon'/\epsilon) = (1.66 \pm 0.23) \times 10^{-3}$.

Phenomenon 111.11 (Direct CP violation in kaon decay)**.** *CP* violation occurs not only in the mixing that defines the long-lived state but in the decay amplitudes themselves. The double ratio of the four two-pion widths,

$$\frac{\Gamma(K_L \to \pi^0\pi^0)\,\Gamma(K_S \to \pi^+\pi^-)}{\Gamma(K_L \to \pi^+\pi^-)\,\Gamma(K_S \to \pi^0\pi^0)} = 1 - 6\,\mathrm{Re}\,(\epsilon'/\epsilon)\ , \tag{111.17}$$

differs from unity. Two experiments with independent systematics found $\mathrm{Re}(\epsilon'/\epsilon)$ of order 10^{-3} and non-zero [1965, 1973], and the world average is $(1.66 \pm 0.23) \times 10^{-3}$ [2427]. A superweak $\Delta S = 2$ interaction, which reproduces ϵ exactly, predicts $\epsilon' = 0$ and is thereby excluded.

Rests on Equations (105.71) *and* (105.72) *and Proposition 105.39.*

Derivation. *Derives Phenomenon 111.11.*

Two steps: the double ratio in terms of ϵ'/ϵ, and the reason ϵ' requires two amplitudes with different strong phases.

The double ratio. Two pions in a relative S wave from a spinless parent have a symmetric isospin wavefunction, so only $I = 0$ and $I = 2$ are available; write the two amplitudes as $A_I \mathrm{e}^{\mathrm{i}\delta_I}$ with δ_I the real strong rescattering phase, as in Equation (105.67). Projecting the physical final states onto the isospin basis with the Clebsch–Gordan coefficients Equation (105.70) gives Equation (105.71),

$$\eta_{+-} = \epsilon + \epsilon' , \qquad \eta_{00} = \epsilon - 2\epsilon' ,$$

the factor -2 being nothing but the ratio of the weight of A_2 in $|\pi^0\pi^0\rangle$ to its weight in $|\pi^+\pi^-\rangle$. The four widths of Equation (111.17) are $|\eta_{00}|^2$ over $|\eta_{+-}|^2$, since each $\Gamma(K_L \to f)$ divided by $\Gamma(K_S \to f)$ is the squared modulus of the corresponding amplitude ratio and everything else cancels. Hence

$$\left|\frac{\eta_{00}}{\eta_{+-}}\right|^2 = \left|\frac{1 - 2\epsilon'/\epsilon}{1 + \epsilon'/\epsilon}\right|^2 = \left|1 - 3\frac{\epsilon'}{\epsilon} + O\Big((\epsilon'/\epsilon)^2\Big)\right|^2 = 1 - 6\,\mathrm{Re}\frac{\epsilon'}{\epsilon} + O\Big(10^{-6}\Big) ,$$

which is Equation (111.17). With the measured average the double ratio is $1 - 0.00996$, so the experiments are looking for a one per cent departure from unity in a ratio of four separately measured rates — and the factor of six in front, which triples the naive $-2\epsilon'/\epsilon$, is the only thing that makes it feasible at all.

Why a non-zero value needs two phases. From Equation (105.72),

$$\epsilon' = \frac{\mathrm{i}}{\sqrt{2}}\,\mathrm{e}^{\mathrm{i}(\delta_2 - \delta_0)}\,\frac{\mathrm{Re}\,A_2}{\mathrm{Re}\,A_0}\left[\frac{\mathrm{Im}\,A_2}{\mathrm{Re}\,A_2} - \frac{\mathrm{Im}\,A_0}{\mathrm{Re}\,A_0}\right] ,$$

and the bracket is a *difference*. A phase common to both isospin amplitudes is a rephasing of the kaon state and carries no physics; it cancels in the bracket, leaving $\epsilon' = 0$. So direct CP violation requires at least two amplitudes with different weak phases. It requires more than that: the prefactor carries $\mathrm{e}^{\mathrm{i}(\delta_2 - \delta_0)}$, and if the two *strong* phases were equal that factor would be real, ϵ' would be purely imaginary relative to ϵ, and $\mathrm{Re}(\epsilon'/\epsilon)$ — the observable of Equation (111.17) — would vanish even with $\epsilon' \neq 0$. Both a weak-phase difference and a strong-phase difference are necessary. This is the general statement proved at Proposition 105.39, and it is used again without change for the charm asymmetry in Section 111.7.3. □

Remark 111.12 (Why the measured value is so small). That ϵ'/ϵ is of order 10^{-3} rather than of order unity is not a statement about the CP-violating phase. The prefactor of ϵ' contains $\mathrm{Re}\,A_2/\mathrm{Re}\,A_0$, and the $\Delta I = \frac{1}{2}$ rule — the empirical observation that $|A_0/A_2| \approx 22$ in kaon decay, itself an unexplained strong-interaction fact — suppresses that ratio by a factor of twenty-two while simultaneously enhancing ϵ. Roughly five hundred of the three orders of magnitude come from that one number.

111.6.3 The Standard Model prediction and what it is worth

The measurement excludes the superweak hypothesis by itself, and that conclusion needs no theory. Comparing the measured value with the Cabibbo–Kobayashi–Maskawa prediction is a different and much weaker statement, and the reason should be stated plainly rather than left to a citation.

The short-distance part of the calculation is under control: the $\Delta S = 1$ effective Hamiltonian is a sum of local four-quark operators with coefficients computed perturbatively, and the phase enters only through the CKM combination $\mathrm{Im}\,(V_{td}V_{ts}^*)$. The long-distance part is not: what is needed is the matrix element of each operator between a kaon and a two-pion state at the physical kinematics, including the final-state rescattering that produces δ_0 and δ_2, and there is no expansion parameter in which that is small. Lattice calculations of these matrix elements now exist and give a value compatible with Equation (105.74) with

an uncertainty several times larger, dominated by the $I = 0$ channel where the rescattering is strongest; those calculations are not cited here because this treatise's bibliography carries no entry for them, and the reader should not take the agreement on the authority of this sentence.

What is established without any of that machinery is the qualitative result: $\epsilon' \neq 0$, hence CP is violated in a $\Delta S = 1$ decay amplitude, hence no interaction acting only in the mass matrix can account for the phenomenon. That is the content of Phenomenon 111.11 and it is secure.

Derivation pending #194

The short-distance box-diagram computation of the $[\Delta S = 2]$ *mixing amplitude, giving the mass difference and epsilon in terms of the CKM elements and the quark masses — the step that converts the measured epsilon into a constraint on the unitarity triangle. It is an appendix-scale calculation requiring the loop functions of the box with internal charm and top, and it belongs in Appendix A rather than in an experiment chapter.*

111.7 CP violation beyond the kaons

111.7.1 The B factories

If one phase in one matrix accounts for all of it, then the kaon's part in a thousand and an effect of order unity somewhere else are the same physics. The Standard Model says where to look: in $B^0 \to J/\psi\, K^0_S$, where the interference is between decay after mixing and decay without mixing, and no small ratio of amplitudes suppresses it.

The machines. Two asymmetric-energy electron–positron colliders were built for this measurement, PEP-II at SLAC and KEKB at KEK. Both run at a centre-of-mass energy of 10.58 GeV, the mass of the $\Upsilon(4S)$, which decays to a $B^0\bar{B}^0$ pair with almost no energy to spare — with $m_{B^0}c^2 = 5279.66\,\text{MeV}$ each B has a momentum $p = \sqrt{(m_\Upsilon c^2/2)^2 - (m_B c^2)^2}/c = 331\,\text{MeV}/c$ in the Υ frame. Asymmetric energies are the whole point. PEP-II collided 9.0 GeV electrons with 3.1 GeV positrons, KEKB 8.0 GeV with 3.5 GeV, so that the centre of mass moves in the laboratory with

$$\beta\gamma = \frac{E_- - E_+}{\sqrt{4E_-E_+}} = 0.56\ \text{(PEP-II)}\,, \qquad 0.43\ \text{(KEKB)}\,. \tag{111.18}$$

The one line behind this: for head-on beams whose energies far exceed the electron mass, the total four-momentum has energy $E_- + E_+$ and momentum $(E_- - E_+)/c$ along the electron direction, so $\beta = (E_- - E_+)/(E_- + E_+)$, while $(E_- + E_+)^2 - (E_- - E_+)^2 = 4E_-E_+$ is the square of the invariant centre-of-mass energy, so $\gamma = (E_- + E_+)/\sqrt{4E_-E_+}$. The product is Equation (111.18), and $\sqrt{4E_-E_+}$ is 10.56 GeV for PEP-II and 10.58 GeV for KEKB, as it must be.

The detectors. BaBar and Belle are conventional collider detectors of their generation, built around the interaction point inside a 1.5 T solenoid: a silicon strip vertex detector of five layers immediately around the beam pipe, a gas drift chamber for momentum measurement, a Cherenkov device for separating kaons from pions — internally reflecting quartz bars in BaBar, aerogel threshold counters and time-of-flight in Belle — a caesium-iodide crystal calorimeter, and an instrumented flux return for muons. What the measurement demands of them is unusual, however: not energy resolution but *position* resolution along the beam axis, to better than 100 µm per decay vertex.

Phenomenon 111.13 (A large CP asymmetry in B meson decay)**.** In $\Upsilon(4S)$ decays to $B^0\bar{B}^0$ pairs, the rate for $B^0 \to J/\psi\, K^0_S$ differs from that for $\bar{B}^0 \to J/\psi\, K^0_S$ by an amount

that oscillates with the proper-time difference between the two B decays, with an amplitude of order unity; two experiments reported it simultaneously [2005, 2010]. The parameter extracted is $\sin 2\beta = 0.708 \pm 0.011$ [2427]. CP violation is therefore not intrinsically a small effect: in the kaon system it is a part in a thousand, in this B channel it is maximal in order of magnitude.

Rests on Equations (105.82) *and* (105.87) *and Proposition 105.28.*

Derivation. *Derives Phenomenon 111.13.*

Three things have to be shown: that the observable is a *difference* of decay times and not a decay time, that its amplitude is $\sin 2\beta$, and that the boost of Equation (111.18) makes the difference measurable.

The observable. The $\Upsilon(4S)$ has $J^{PC} = 1^{--}$ and decays to two pseudoscalars in a P wave, so the pair is in the antisymmetric state Equation (105.87). Antisymmetry is preserved until one meson decays; therefore at every instant before the first decay there is exactly one B^0 and exactly one $\bar{B}^0$, and no oscillation is observable in the pair as a whole. The clock starts when one of them decays to a flavour-specific final state — a semileptonic decay, whose lepton charge tags the flavour, or a $D^{(*)}\pi$ state — because that decay projects the partner onto the opposite flavour at that instant. The partner then oscillates freely until it decays to $J/\psi K^0_S$, and the phase it has accumulated is $\Delta m_d c^2 \Delta t/\hbar$ with $\Delta t = t_{CP} - t_{\text{tag}}$, which may be of either sign. The asymmetry is therefore Equation (105.81),

$$\mathcal{A}(\Delta t) = S_f \sin \frac{\Delta m_d c^2 \Delta t}{\hbar} - C_f \cos \frac{\Delta m_d c^2 \Delta t}{\hbar} \,,$$

odd in Δt for the CP-violating term, which is what makes the sign of Δt — and hence the vertex ordering — essential rather than incidental.

The amplitude. With $\lambda = (q/p)\left(\bar{\mathcal{A}}_f/\mathcal{A}_f\right)$, the coefficients are $S_f = 2\mathrm{Im}\,\lambda/(1+|\lambda|^2)$ and $C_f = (1-|\lambda|^2)/(1+|\lambda|^2)$ (Proposition 105.28). For $f = J/\psi K^0_S$ the decay $b \to c\bar{c}s$ proceeds through one dominant amplitude, so $|\lambda| = 1$ and $C_f = 0$, and λ is a pure phase built from three CKM ratios: the B^0 mixing, dominated by the top quark in the box, contributes $q/p = V^*_{tb}V_{td}/\left(V_{tb}V^*_{td}\right)$; the decay amplitude ratio contributes $V_{cb}V^*_{cs}/\left(V^*_{cb}V_{cs}\right)$; and the neutral kaon in the final state must itself be projected onto K^0_S, which contributes $V_{cd}V^*_{cs}/\left(V^*_{cd}V_{cs}\right)$. The product, with the CP eigenvalue $\eta_f = -1$ of $J/\psi K^0_S$, is

$$\lambda = -\frac{V^*_{tb}V_{td}}{V_{tb}V^*_{td}}\,\frac{V_{cb}V^*_{cd}}{V^*_{cb}V_{cd}} = -\mathrm{e}^{-2\mathrm{i}\beta} \,, \qquad \beta = \arg\left(-\frac{V_{cd}V^*_{cb}}{V_{td}V^*_{tb}}\right) \,,$$

the factors of V_{cs} cancelling between the decay and the kaon. Since $|\lambda| = 1$, $S_f = \mathrm{Im}\,\lambda = \mathrm{Im}\left(-\mathrm{e}^{-2\mathrm{i}\beta}\right) = \sin 2\beta$, which is Equation (105.82). Note what has and has not been assumed: unitarity of the mixing matrix, top dominance of the box, and a single decay amplitude. Nothing about hadronic matrix elements enters, which is why this channel measures an angle of the unitarity triangle to a per-cent theoretical accuracy while the kaon's ϵ' does not.

The measurement of Δt. A B meson lives $\tau_B = 1.519 \times 10^{-12}\,\mathrm{s}$ and moves with the centre of mass, so the two decay vertices are separated along the beam axis by

$$\Delta z = \beta\gamma c\,\Delta t \,, \qquad \langle|\Delta z|\rangle \sim \beta\gamma c\tau_B = 0.56 \times 2.998 \times 10^8\,\mathrm{m/s} \times 1.519 \times 10^{-12}\,\mathrm{s} = 2.5 \times 10^{-4}\,\mathrm{m}$$

at PEP-II, and $1.9 \times 10^{-4}\,\mathrm{m}$ at KEKB. Without the boost the two mesons would be nearly at rest and Δz would be a few micrometres, far below any silicon detector's resolution; with it, Δz is a quarter of a millimetre and a vertex resolution of about $180\,\mu\mathrm{m}$ gives $\sigma(\Delta t) = \sigma(\Delta z)/(\beta\gamma c) \approx 1.1 \times 10^{-12}\,\mathrm{s}$, comparable to τ_B itself and to the oscillation period $2\pi\hbar/(\Delta m_d c^2) = 1.24 \times 10^{-11}\,\mathrm{s}$. The measurement is therefore possible but resolution-limited, which is why the fitted asymmetry must be convolved with a resolution function determined from the data themselves.

Dilution. The flavour tag is not perfect: a fraction w of tags is wrong, and each wrong tag contributes with the opposite sign, so the observed amplitude is $(1-2w)S_f$ and the statistical power of a sample of N events with tagging efficiency ε scales as $\varepsilon(1-2w)^2 N$. Both experiments used several tagging categories with different purities and fitted them simultaneously, reaching an effective efficiency $\varepsilon(1-2w)^2$ of about 0.3. This is the dominant reason the first measurements, on samples of about thirty million $B\bar{B}$ pairs each, carried statistical uncertainties of 0.14. □

The two 2001 results were $\sin 2\beta = 0.59 \pm 0.14 \pm 0.05$ from BaBar, on a sample of about thirty-two million $B\bar{B}$ pairs [2010], and $0.99 \pm 0.14 \pm 0.06$ from Belle, on about thirty-one million [2005]. They differ by roughly two standard deviations, which is a useful reminder that first measurements scatter and that the agreement of two simultaneous results is not to be expected as a matter of course. Both are far from zero, which is the discovery; the average settled at 0.708 ± 0.011 as the samples grew by a factor of ten [2427].

Remark 111.14 (The prediction this confirms). The value was predicted before it was measured, from quantities having nothing to do with CP asymmetries. Taking the apex of the unitarity triangle from $|V_{ub}/V_{cb}|$, from the B^0 and B_s^0 oscillation frequencies and from ϵ itself — Equation (103.24) — gives $\beta = 22.7°$ and hence $\sin 2\beta = 0.713$, against the measured 0.708 ± 0.011. Three loop processes and one tree process, none of them an asymmetry, anticipate an asymmetry of order unity to better than one per cent. That is the strongest single test the Cabibbo–Kobayashi–Maskawa picture has passed.

111.7.2 Neutral B_s mesons at the LHC

The B_s^0 system, in which the light quark is strange rather than down, oscillates thirty-five times faster than the B^0 (Table 111.6) and was for that reason the last of the neutral-meson systems to be brought under control.

The apparatus. LHCb is not a collider detector in the usual sense: it is a single-arm forward spectrometer, covering pseudorapidities from about 2 to 5, built on the observation that at the Large Hadron Collider the b and $\bar{b}$ of a produced pair both go forward at small angles. Its elements, in order from the interaction point, are a silicon strip vertex locator whose sensors approach to within about 8 mm of the beams, a tracking system around a warm dipole magnet of about 4 T m bending power, two ring-imaging Cherenkov detectors with gas radiators, which give kaon–pion separation over the momentum range from a few GeV/c to about 100 GeV/c, calorimeters, and muon chambers. The two numbers that matter for flavour physics are an impact-parameter resolution of about 20 µm and a decay-time resolution of about 45 fs — the latter being what makes a B_s^0 oscillation of period $2\pi\hbar/(\Delta m_s c^2) = 3.5 \times 10^{-13}$ s resolvable at all.

That a hadron collider can do this at all rests on two things. The production cross section for $b\bar{b}$ pairs is large, so statistics are never the limitation; and the b hadron flies a measurable distance — of order a centimetre at LHC momenta — before decaying, so a vertex detached from the primary interaction is by itself a powerful trigger against the enormous light-quark background.

The result. The first observation of CP violation in the decays of B_s^0 mesons was of the *direct* kind, in the decay $B_s^0 \to K^-\pi^+$ [2202]. The measured asymmetry,

$$A_{CP}\left(B_s^0 \to K^-\pi^+\right) = 0.27 \pm 0.04 \pm 0.01\,, \tag{111.19}$$

is non-zero at 6.5 standard deviations, and the same analysis measured $A_{CP}(B^0 \to K^+\pi^-) = -0.080 \pm 0.007 \pm 0.003$. Two features are worth noting. The asymmetry is of order a quarter — CP violation in a decay amplitude can be large when the interfering amplitudes are comparable, as tree and penguin are here. And the two asymmetries have opposite signs,

which is a prediction of the Cabibbo–Kobayashi–Maskawa structure and not an accident: the ratio of the two, weighted by the branching fractions and lifetimes, is predicted to be -1 by U-spin symmetry, the interchange of the d and s quarks. The reason in outline is that U-spin maps $B^0 \to K^+\pi^-$ onto $B_s^0 \to K^-\pi^+$ while leaving the strong phases and the moduli of the interfering tree and penguin amplitudes invariant and flipping the sign of the weak phase difference, so the two CP asymmetries have equal magnitude and opposite sign once each is normalized to its own width.

Derivation pending #195

The U-spin relation between the direct CP asymmetries of $[B^0 \to K^+\pi^-]$ and $[B_s^0 \to K^-\pi^+]$ is stated here in outline only. Owed: the explicit tree-plus-penguin decomposition, the action of the $d \leftrightarrow s$ interchange on each amplitude, and the width weighting that turns the amplitude statement into the ratio -1, together with the size of the U-spin-breaking corrections. This belongs in Appendix A. No key in the bibliography covers the U-spin literature, so the claim carries no citation.

The null test. The observable usually associated with the B_s^0 is not Equation (111.19) but the mixing phase ϕ_s, the analogue of 2β for the strange-beauty system, measured from the time-dependent asymmetry in $B_s^0 \to J/\psi\,\phi$ and related channels. Its Standard Model value is small and sharply predicted, because in the Wolfenstein expansion the relevant combination $V_{ts}V_{tb}^*$ is almost real; the world average, $\phi_s \approx -0.05$ rad with an uncertainty of about 0.02 rad [2427], agrees with it. A small, precisely predicted quantity is the ideal place to look for a new short-distance contribution, since anything new entering the box would shift it; nothing has been seen, and the measurement is therefore a constraint rather than a discovery.

111.7.3 Charm

The up-type quarks were the last to yield, twenty years after the B mesons and fifty-five after the kaon.

Phenomenon 111.15 (CP violation in charm decay)**.** The difference between the time-integrated CP asymmetries of $D^0 \to K^-K^+$ and $D^0 \to \pi^-\pi^+$ is not zero,

$$\Delta A_{CP} = A_{CP}\left(D^0 \to K^-K^+\right) - A_{CP}\left(D^0 \to \pi^-\pi^+\right) = (-15.4 \pm 2.9) \times 10^{-4}\,, \quad (111.20)$$

established at 5.3 standard deviations [2323]. With this the effect is observed in the strange, bottom and charm sectors alike; it has never been observed in any process that does not involve the weak interaction.

Rests on Proposition 105.39.

Derivation. *Derives Phenomenon 111.15.*

Why a difference is measured and not an asymmetry. A raw counting asymmetry between D^0 and $\bar{D}^0$ decays contains three contributions: the physics asymmetry, a production asymmetry, because a proton–proton collider does not produce charm and anticharm symmetrically, and a detection asymmetry, because the tagging pion of the $D^{*+} \to D^0\pi^+$ chain is reconstructed with a different efficiency according to its charge. The last two are common to the two final states K^-K^+ and $\pi^-\pi^+$, both of which are self-conjugate, so they cancel in the difference Equation (111.20) to first order. This is the same design principle as the double ratio of Equation (111.17): build the observable so that everything not being measured appears in both terms.

What generates the asymmetry. A direct asymmetry requires two interfering amplitudes with both a weak and a strong phase difference, by Proposition 105.39. Here they are the tree

amplitude $c \to s\bar{s}u$ (or $d\bar{d}u$) and the loop, or "penguin", amplitude in which the c converts to u via a W and a down-type quark. Write the total as $\mathcal{A} = A_1 \mathrm{e}^{\mathrm{i}(\varphi_1+\delta_1)} + A_2 \mathrm{e}^{\mathrm{i}(\varphi_2+\delta_2)}$, with φ_i the weak phases, which change sign under CP, and δ_i the strong phases, which do not; the conjugate amplitude $\bar{\mathcal{A}}$ is the same with $\varphi_i \to -\varphi_i$. Then, with $r = A_2/A_1$, $\Delta\varphi = \varphi_1 - \varphi_2$ and $\Delta\delta = \delta_1 - \delta_2$,

$$\left|\bar{\mathcal{A}}\right|^2 - |\mathcal{A}|^2 = 2A_1A_2\left[\cos\left(\Delta\delta - \Delta\varphi\right) - \cos\left(\Delta\delta + \Delta\varphi\right)\right] = 4A_1A_2 \sin\Delta\delta \, \sin\Delta\varphi \,,$$

$$A_{CP} = \frac{\left|\bar{\mathcal{A}}\right|^2 - |\mathcal{A}|^2}{\left|\bar{\mathcal{A}}\right|^2 + |\mathcal{A}|^2} = \frac{2r \sin\Delta\delta \, \sin\Delta\varphi}{1 + 2r\cos\Delta\delta \, \cos\Delta\varphi + r^2} \,.$$

Both sines must be non-zero. If the two amplitudes shared a weak phase it could be rotated away; if they shared a strong phase the two conjugate amplitudes would have equal moduli. For $r \ll 1$ this reduces to $A_{CP} \approx 2r \sin\Delta\delta \sin\Delta\varphi$, and with $r \sim 10^{-3}$ from the CKM factor $|V_{cb}V_{ub}^*/(V_{cs}V_{us}^*)| \approx 6 \times 10^{-4}$ and strong phases of order unity, an asymmetry of order 10^{-3} is what the Standard Model leads one to expect — which is what was found.

Why this does not test the theory sharply. The expression above contains r and $\Delta\delta$, and neither is calculable. The charm quark mass sits in the worst possible place: too heavy for chiral perturbation theory, too light for the heavy-quark expansion that makes B decays tractable, and the final states $K\bar{K}$ and $\pi\pi$ lie in a region dense with hadronic resonances that supply large and unpredictable strong phases. Estimates of the Standard Model value of Equation (111.20) span an order of magnitude and do not exclude the measured number at either end. The measurement therefore establishes the *phenomenon* in the up-type sector, which is a genuine addition to knowledge, and constrains rather than tests the Cabibbo–Kobayashi–Maskawa picture. □

The apparatus and the sample. The measurement is LHCb's, using proton–proton collisions at centre-of-mass energies of 7, 8 and 13 TeV and an integrated luminosity of about $9 \times 10^{43}/\mathrm{m}^2$. Two independent tagging methods were combined: the charge of the soft pion in $D^{*+} \to D^0\pi^+$, and the charge of the muon in a semileptonic b-hadron decay producing the D^0. The samples run to tens of millions of decays in each final state, and at that size the measurement is systematics-limited in practice — which is why the whole design is arranged so that the systematics cancel in a difference.

111.7.4 Direct T violation

Given the CPT theorem, every result above is also a statement about time reversal. But that inference *assumes* the theorem, whose hypotheses — locality, Lorentz invariance, the spin-statistics connection — are the deepest in the subject; a test of T that does not assume it is independent information. Two experiments have done it, and the difficulty in both is the same: a genuine T test compares a transition with its *reverse*, exchanging initial and final states, and conjugates nothing.

CPLEAR. The neutral kaon offers a transition and its exact reverse without any need to reverse momenta or spins, because both states are the same particle at rest: $K^0 \to \bar{K}^0$ and $\bar{K}^0 \to K^0$ are related by exchanging initial and final state, and nothing else [1426]. The Kabir asymmetry Equation (105.84) must vanish identically if T is a symmetry.

The apparatus was built around the tagging problem, which is the whole difficulty: one must know the strangeness at production *and* at decay, in the same event. CPLEAR used the Low Energy Antiproton Ring at CERN, stopping antiprotons of about 200 MeV/c in a gaseous hydrogen target at high pressure at a rate of order 10^6 per second. About two annihilations in a thousand give $\bar{p}p \to K^{\mp}\pi^{\pm}K^0/\bar{K}^0$, and strangeness conservation in the strong production ties the sign of the accompanying charged kaon to the strangeness of the

neutral one: the initial state is tagged by a charge measured in the same event. The final strangeness is tagged by the charge of the lepton in the semileptonic decay, using $\Delta S = \Delta Q$ exactly as in Equation (111.11). The detector was a cylindrical assembly inside a solenoid of about 0.44 T — tracking chambers, a threshold Cherenkov and scintillator sandwich for identifying the charged kaon, and a lead and gas-sampling electromagnetic calorimeter. The measured asymmetry Equation (105.86),

$$A_T = (6.6 \pm 1.3 \pm 1.0) \times 10^{-3}\,, \tag{111.21}$$

is the first direct observation of a time-reversal asymmetry [1948], and it agrees with the prediction $A_T = 4\,\mathrm{Re}\,\epsilon = 6.46 \times 10^{-3}$ of Proposition 105.29 evaluated with $|\epsilon| = 2.228 \times 10^{-3}$ and $\arg\epsilon = 43.5°$.

BaBar. The cleaner measurement uses entanglement as a state-preparation device [2197]. From the antisymmetric $B^0\bar{B}^0$ state Equation (105.87), observing one meson decay to a flavour-specific state projects the other onto a definite flavour at that instant, and observing a decay to $J/\psi K^0_S$ projects it onto a definite CP label. The comparison is then available in both time orders: events in which the flavour tag comes first measure $B^0 \to B_-$, events in the opposite order measure $B_- \to B^0$, and these are a process and its reverse with nothing conjugated. This is the entanglement machinery of Chapter 84 used not to test locality but as an instrument. On a sample of 468 million $B\bar{B}$ pairs BaBar found the T-odd parameters non-zero at fourteen standard deviations,

$$\Delta S_T^+ = -1.37 \pm 0.14 \pm 0.06\,, \qquad \Delta S_T^- = 1.17 \pm 0.18 \pm 0.11\,, \tag{111.22}$$

while the CPT-odd parameters extracted from the same fit were consistent with zero [2197].

The CPT tests obtained as a by-product are worth recording, because they are among the sharpest tests of anything. The same formalism that yields Equation (111.21) bounds the CPT-violating parameter of the kaon mass matrix, and the resulting limit on the fractional mass difference between K^0 and $\bar{K}^0$ is of order 10^{-18} — the most precise equality of a particle and antiparticle property in physics. The neutral-meson interferometer is what makes it possible, for the reason set out at Equation (105.63): the observable is an accumulated phase, not an energy. The details belong to Section 105.5.3.

Remark 111.16 (What these measurements do and do not assume). Neither experiment is entirely free of assumptions, and both have been criticized on that ground. CPLEAR's final-state tag uses the semileptonic amplitudes, so a CPT violation in those amplitudes, or a failure of $\Delta S = \Delta Q$, could in principle produce the observed asymmetry with no T violation in the mixing; the same data bound those parameters well below the measured A_T, but the argument is internal. BaBar's mesons have a finite width, so the reversed transition occupies a different interval of proper time and is not an exact motion reverse; and the projection interpretation of the tag requires the tagging decay to be strictly flavour-specific. What is established, and what no earlier measurement established, is that the T-odd and CP-odd parameters are separately determined from one data set and are separately non-zero.

111.7.5 The unitarity triangle

The individual measurements above are of very different quantities in very different apparatus. What ties them together is one closure condition, the orthogonality of the first and third columns of the mixing matrix,

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0\,, \tag{111.23}$$

which is Equation (105.80). Three complex numbers summing to zero close a triangle in the complex plane; dividing by the middle term puts its base on the real axis from 0 to 1 and its apex at $(\bar{\rho}, \bar{\eta})$. Every measurement in this chapter is a constraint on that apex, and they come in two kinds:

- *Sides*, from decay rates that involve no CP violation at all: $|V_{ub}/V_{cb}|$ from semileptonic B decay fixes the distance from the origin, and the ratio of the B_s^0 to the B^0 oscillation frequency fixes the distance from $(1, 0)$.
- *Angles*, from the CP asymmetries themselves: $\sin 2\beta$ from $B^0 \to J/\psi K_S^0$, γ from the interference of $b \to c$ and $b \to u$ amplitudes in $B \to DK$, α from $B \to \pi\pi$ and $\rho\rho$. The kaon's ϵ is a constraint of its own, a hyperbola in the $(\bar{\rho}, \bar{\eta})$ plane.

The measured angles are Equation (103.32), $\alpha = 85°$, $\beta = 22.2°$ and $\gamma = 66°$; they sum to $173° \pm 6°$ against the identity $\alpha + \beta + \gamma = \pi$, which is a consistency test the three measurements had no way of enforcing on one another. The global fits [2074] combine all of it, and the constraints cross in one region of the plane a few per cent across. The full account, with the fitted apex and every input, is Section 103.4.3 and Phenomenon 103.31; what belongs here is the experimental summary and the honest qualifications.

Those qualifications are three, and they are reported as they stand rather than smoothed over. The angle α carries a $5°$ uncertainty dominated not by statistics but by the hadronic penguin amplitudes that must be subtracted from $B \to \pi\pi$ — that is, by theory. The side $|V_{ub}/V_{cb}|$ inherits an unresolved tension: the inclusive determinations, which sum over all final states and use an operator product expansion, sit two to three standard deviations above the exclusive ones, which measure a single channel and need a lattice form factor, for both $|V_{ub}|$ and $|V_{cb}|$; choosing one or the other moves the apex by about one standard deviation. And the most precisely measured unitarity statement of all is not a triangle at all but the first-row relation $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 1$, which at present does not come out right at the 10^{-3} level (Remark 103.32). The correct summary is that one phase accounts for all observed CP violation in the quark sector at the few-per-cent level, and that two specific tensions remain.

111.8 Cosmological relevance and open questions

111.8.1 The Sakharov conditions

The measurements of this chapter acquire a significance beyond particle physics because of an observation about the universe and an argument by Sakharov [1358].

Phenomenon 111.17 (The universe is made of matter)**.** No astrophysical concentration of antimatter has been found: neither the annihilation radiation that a matter–antimatter boundary would produce, nor antinuclei in the cosmic radiation beyond the rate expected from secondary production. The baryon-to-photon ratio inferred from the acoustic peaks of the cosmic microwave background is

$$\eta = \frac{n_B - n_{\bar{B}}}{n_\gamma} = (6.12 \pm 0.04) \times 10^{-10}\,, \tag{111.24}$$

in agreement with the value independently required by primordial nucleosynthesis [2348]. A universe that began symmetric under C and CP, in thermal equilibrium and with conserved baryon number, could not have arrived at Equation (111.24).

Rests on Theorems 105.36 and 105.41 and Equation (105.105)*.*

Derivation. *Derives Phenomenon 111.17.*

The three requirements are proved as Theorem 105.41; what is carried out here is the arithmetic that turns them into a number, and the identification of which laboratory measurement supplies each.

Baryon number violation. Without it the initial value of $n_B - n_{\bar{B}}$ is the final one, and a symmetric start stays symmetric. The Standard Model supplies it: the baryon current has

an Adler–Bell–Jackiw anomaly, so its divergence is a total derivative of a topological density [1569], and configurations interpolating between vacua of different winding number change B by three units per generation. At zero temperature the process is suppressed by a barrier factor of order $\mathrm{e}^{-4\pi/\alpha_W}$ and is entirely unobservable; above the electroweak scale the barrier is crossed thermally by the sphaleron of Equation (105.104), and the rate is unsuppressed [1758]. This condition is met.

C and CP violation. If C or CP were a symmetry, every baryon-number-violating process would be accompanied by its mirror at exactly the same rate and no net asymmetry could accumulate. This is the condition that the present chapter has measured, and it is met — that is the whole content of Phenomenon 111.8 and everything after it.

Departure from thermal equilibrium. In equilibrium the number density of a species depends only on its mass, chemical potential and the temperature, and CPT makes the masses of a particle and its antiparticle equal (Theorem 105.36); with B not conserved the corresponding chemical potential vanishes, so the two densities are equal whatever the microphysics. Any asymmetry generated is therefore erased as fast as it is made unless the expansion outruns the reactions.

The number. What must be explained is Equation (111.24), and that value is itself derived rather than observed directly: the acoustic peak structure of the microwave background measures $\Omega_b h^2 = 0.02237 \pm 0.00015$ [2348], and dividing the resulting baryon number density by the blackbody photon density at $T_0 = 2.7255\,\mathrm{K}$ gives $\eta = 2.74 \times 10^{-8}\,\Omega_b h^2$, which is Equation (105.105) and Equation (103.45). The independent determination from the light-element abundances (Chapter 48) agrees, which is what makes Equation (111.24) a measurement rather than a fit. The absence of antimatter concentrations is a separate observational statement: a matter–antimatter boundary anywhere within the observable universe would radiate annihilation gamma rays at a level long since excluded, and no search of the cosmic radiation has produced an antinucleus heavier than the antiproton, whose observed flux is consistent with secondary production on the interstellar medium. □

111.8.2 Insufficiency of Standard Model CP violation

All three Sakharov conditions are formally present in the Standard Model. Two of them fail quantitatively, and the failures are independent of each other.

The phase is far too small, and it is the masses that make it so. CP violation in the quark sector is controlled not by J alone but by the rephasing-invariant combination Equation (105.79), which multiplies J by the six squared-mass differences and therefore carries the SI dimension J^{12}. An asymmetry generated at temperature T is a pure number, so it can depend on that invariant only through the dimensionless ratio Equation (105.106), obtained by dividing by $(k_B T)^{12}$. Evaluated with the running quark masses at $k_B T \approx 100\,\mathrm{GeV}$, where the sphaleron processes are active, this gives Equation (105.107),

$$d_{CP} \approx 2 \times 10^{-21}\,, \tag{111.25}$$

against the measured $\eta = 6.12 \times 10^{-10}$. The ratio is

$$\frac{\eta}{d_{CP}} = \frac{6.12 \times 10^{-10}}{2 \times 10^{-21}} = 3 \times 10^{11}\,, \tag{111.26}$$

a shortfall of eleven orders of magnitude, and the detailed calculations [1882] do not improve it. The reason is structural rather than numerical. CP violation in this theory requires all six quark masses to be distinct (Proposition 105.27); at 100 GeV five of the six are negligible against the temperature, so the effect is suppressed by twelve powers of small mass ratios. The phase itself is of order unity — $\delta = 65.70^\circ$ — and the masses kill it. This is the same arithmetic as Equation (103.46), and it is quoted here in the same form so that the two chapters cannot drift apart.

The third condition fails outright. A departure from equilibrium at the electroweak scale requires the transition from the symmetric to the broken phase to be first order, proceeding by the nucleation of bubbles whose walls sweep the plasma — and strongly first order at that, since the sphalerons must switch off fast enough after the transition not to erase what was just made. Lattice computations locate the endpoint of the first-order line at a scalar mass of about $72\,\mathrm{GeV}/c^2$ [1925]; beyond it the change is a smooth crossover with no bubbles, no walls and no departure from equilibrium. The measured Higgs mass, Equation (104.66), is $(125.20 \pm 0.11)\,\mathrm{GeV}/c^2$ [2427], far above the endpoint (Remark 104.65). No amount of CP violation would help.

Remark 111.18 (Stated as a failure, not as a puzzle solved). Mechanisms that would generate Equation (111.24) exist in outline — heavy Majorana neutrinos decaying out of equilibrium, additional scalars driving a first-order transition — and not one of them has any experimental support. The shortfall itself is recorded in Section 133.5, which states that no confirmed mechanism supplies it, and Remark 103.45 makes the same point from the flavour side. What is *measured* is Equation (111.24); what is *calculated* is Equation (111.25); the eleven orders of magnitude between them are one of the few places where the Standard Model is known, from laboratory numbers plus one cosmological observation, to be incomplete.

111.8.3 Electric dipole moments and the strong CP problem

Every measurement so far in this chapter is of a CP violation that exists. The last one is of a CP violation that does not, and the null result is the more constraining of the two kinds.

Phenomenon 111.19 (The neutron has no electric dipole moment)**.** Repeated searches over seven decades find no permanent electric dipole moment of the neutron. The current bound is

$$|d_n| < 2.9 \times 10^{-47}\,\mathrm{C\,m} \tag{111.27}$$

at 90 % confidence [2346], improving on [2090]. The same limit is customarily written 1.8×10^{-26} in units of the elementary charge times the centimetre, the conversion being $1\,e\,\mathrm{cm} = 1.602\,176\,634 \times 10^{-21}\,\mathrm{C\,m}$. This is a null result about a symmetry, not about a nuclear property.

Rests on Theorem 105.30 and Equation (105.91).

Derivation. *Derives Phenomenon 111.19.*

A neutron in a state of definite spin has no vector at its disposal other than its spin: by the projection theorem carried by the Wigner–Eckart theorem, the expectation value of any vector operator in a nondegenerate state of given angular momentum is proportional to $\langle \boldsymbol{S} \rangle$. Hence $\langle \boldsymbol{d} \rangle = d_n \langle \boldsymbol{S} \rangle / |\langle \boldsymbol{S} \rangle|$ for some real number d_n, and the interaction with a static electric field is

$$H_d = -\langle \boldsymbol{d} \rangle \cdot \boldsymbol{E} \propto -d_n \, \langle \boldsymbol{S} \rangle \cdot \boldsymbol{E}\,.$$

Under space inversion $\boldsymbol{E} \mapsto -\boldsymbol{E}$ while $\boldsymbol{S} \mapsto \boldsymbol{S}$, so $H_d \mapsto -H_d$; under time reversal $\boldsymbol{E} \mapsto \boldsymbol{E}$ while $\boldsymbol{S} \mapsto -\boldsymbol{S}$, so again $H_d \mapsto -H_d$. A non-zero d_n therefore requires the violation of P and of T separately, and — given the CPT theorem of Chapter 105 — of CP. The full statement, with the C properties made explicit, is Theorem 105.30.

The nondegeneracy clause is what makes the statement non-trivial: a state with an exact degeneracy of opposite parity, such as the hydrogen $n = 2$ level, shows a linear Stark effect with no symmetry violation at all, because there the dipole matrix element is off-diagonal and the argument above does not apply (Remark 105.31).

From the bound to a frequency. The experiment measures a frequency, not a dipole. Ultracold neutrons are stored in a cell in parallel magnetic and electric fields and their Larmor precession is measured by Ramsey's method of separated oscillatory fields [968]; reversing $\boldsymbol{E}$ and differencing isolates $\Delta\nu = 4 d_n E / h$ (Equation (105.91)). At the Paul

Scherrer Institute storage field $E \approx 1.1 \times 10^{6}\,\mathrm{V/m}$ a dipole equal to Equation (111.27) would shift the resonance by

$$\Delta\nu = \frac{4 \times 2.9 \times 10^{-47}\,\mathrm{C\,m} \times 1.1 \times 10^{6}\,\mathrm{V/m}}{6.626\,070\,15 \times 10^{-34}\,\mathrm{J\,s}} = 1.9 \times 10^{-7}\,\mathrm{Hz}\,,$$

against a Larmor frequency of about 29 Hz at the working field of 1 µT: the bound is a frequency ratio measured to 7×10^{-9}, twice, with the field reversed. It is not a theoretical estimate of any kind. □

The number is worth converting once, because it is otherwise unimaginable. A dipole of $2.9 \times 10^{-47}\,\mathrm{C\,m}$ corresponds to separating one elementary charge from its opposite by $1.8 \times 10^{-28}\,\mathrm{m}$, about 10^{13} times smaller than the neutron itself, whose charge radius is of order 0.8 fm.

What the null result constrains. Two things, and they are of very different character. The first is new physics: the Cabibbo–Kobayashi–Maskawa phase generates a neutron dipole only at three loops with a severe chiral suppression, some six orders of magnitude below Equation (111.27).

Derivation pending #196

The three-loop, chirally suppressed Cabibbo–Kobayashi–Maskawa contribution to the neutron electric dipole moment is quoted here as an order of magnitude and is not derived. Owed: the argument that the one- and two-loop quark diagrams cancel by the Glashow–Iliopoulos–Maiani mechanism because the rephasing invariant needs all six quark masses, and the resulting estimate of order $3 \times 10^{-53}\,\mathrm{C\,m}$. *This belongs in Appendix A. The bibliography carries no key for the electric-dipole calculation, so the estimate is uncited.*

The entire experimental range is one in which the Standard Model predicts nothing observable. A non-zero result would be unambiguous, and the null result excludes new CP-violating sources over a wide range with no background to subtract.

The second is a parameter of the Standard Model itself. Quantum chromodynamics admits a term proportional to $\theta\ \mathrm{tr}\left(G_{\mu\nu}\tilde{G}^{\mu\nu}\right)$ which is a total derivative, invisible in perturbation theory, and physical nonperturbatively because the gauge field has topologically distinct sectors. Only the combination $\bar{\theta} = \theta + \arg\det M_q$ is invariant under the chiral rotations that move phase between the gluon and Yukawa sectors (Equation (105.111)), and $\bar{\theta}$ violates P and T, hence generates a neutron dipole. The chiral estimates [1633, 1637] give $d_n \approx \bar{\theta} \times 1.6 \times 10^{-37} - -6.4 \times 10^{-37}\,\mathrm{C\,m}$ (Equation (105.112)), so Equation (111.27) implies

$$\left|\bar{\theta}\right| \lesssim \frac{2.9 \times 10^{-47}\,\mathrm{C\,m}}{1.6 \times 10^{-37}\,\mathrm{C\,m}} \approx 1.8 \times 10^{-10}\,, \tag{111.28}$$

that is $\left|\bar{\theta}\right| \lesssim 10^{-10}$, with a factor-of-a-few uncertainty inherited from the chiral coefficient (Equation (105.113)).

This is the strong CP problem, and what makes it a problem is worth stating precisely, because it is unlike the other open questions in this chapter. $\bar{\theta}$ is a free dimensionless parameter, periodic with period 2π, so there is no sense in which a small value sits near a boundary of its range; a value of order unity is the natural expectation for a number about which nothing else is known. It is measured to be smaller than 10^{-10}. No symmetry of the Standard Model requires it to vanish — the one candidate, a massless up quark, is excluded by the lattice determination $m_u c^2 = (2.16 \pm 0.07)\,\mathrm{MeV}$ [2427] — and no dynamical mechanism within the theory relaxes it. The problem is an *observation*, and it is recorded as such in Section 133.1.

The best-known response is to make $\bar{\theta}$ dynamical: a global symmetry, spontaneously broken and itself anomalous, replaces it by a field whose instanton-generated potential is minimized at zero [1609], at the cost of a light pseudo-Goldstone boson, the axion [1628, 1630]. No axion has been observed. The haloscope, helioscope and light-shining-through-walls searches report exclusions and nothing else, and the mechanism is a hypothesis with an attractive structure and no experimental support; it is listed as such in Section 133.7 and named here only to say so. What this chapter records as evidence is Equation (111.28): a free parameter that could have been of order unity is smaller than 10^{-10}, and nothing explains why.

111.9 Primary references

The literature of CP violation divides into papers that predicted a system, papers that measured something in it, and papers that supplied the framework in which the measurement means something. It is worth separating them, because the reader who goes to the sources will find that several of the most-cited ones do not contain what they are cited for.

The system. Gell-Mann and Pais [1067] is the paper that invented the neutral kaon as a two-state problem and predicted the long-lived partner; it is a short paper and it is worth reading for the argument alone, which uses nothing beyond the superposition principle and a conservation law. Lande and collaborators [1090] reported the long-lived particle at the Brookhaven Cosmotron the following year. Pais and Piccioni [1077] predicted regeneration; the paper is the origin of the technique that produces K_S beams and of the background that Proposition 111.5 bounds.

The discovery. Christenson, Cronin, Fitch and Turlay [1274] is two and a half pages of *Physical Review Letters*, and every quantitative statement about the 1964 apparatus in Sections 111.2 and 111.3 comes from it. The paper is unusual in modern eyes for how much of its argument is carried by one two-dimensional plot and how carefully it enumerates the alternatives it must exclude. Note that the published ratio has "all charged decay modes" in its denominator, not the total width; the conversion is Equation (111.8), and a reader comparing the 1964 number directly with a modern branching fraction will find a spurious twenty per cent discrepancy.

The frameworks. Landau [1118] proposed CP as the surviving symmetry after the parity results of Wu [1133] and Garwin [1110]; Lüders [1123] proved the CPT theorem which is what makes CP violation and T violation the same statement. Wolfenstein [1300] supplied the superweak alternative in the same year as the discovery — a model that survived thirty-five years of measurement and was killed by ϵ'. Kobayashi and Maskawa [1505] extended Cabibbo's angle [1248] to three generations and showed a phase then becomes irremovable; the parametrization in which the hierarchy is manifest is Wolfenstein's second contribution [1733], and the convention-independent measure of the effect is Jarlskog's [1756]. Kabir [1426] is the source of the observable that CPLEAR measured.

The epsilon-prime programme. NA31 [1806] reported the first evidence; the contemporaneous Fermilab result is described in Section 111.6.1 but not cited, since this treatise's bibliography carries no entry for it, and Remark 111.10 says so. The two 1999 papers that settled the question are Fanti and collaborators for NA48 [1973] and Alavi-Harati and collaborators for KTeV [1965]. The world average is the Particle Data Group's [2427]; the lattice calculations to which it should be compared are not cited, for the same reason, and Section 111.6.3 says so.

Beyond the kaon. BaBar [2010] and Belle [2005] reported the $B^0 \to J/\psi K^0_S$ asymmetry simultaneously in 2001; the two papers are worth reading side by side, since they disagree by two standard deviations while both establishing the effect. LHCb's first observation of CP violation in B^0_s decays [2202] and in charm [2323] complete the set of quark flavours.

CPLEAR [1948] and BaBar [2197] are the two direct T tests. The global fit that combines all of it is CKMfitter [2074].

The cosmological side. Sakharov [1358] is a two-page note and states the three conditions in a form that has not needed amendment. 't Hooft [1569] showed that baryon number is anomalous in the electroweak theory; Kuzmin, Rubakov and Shaposhnikov [1758] showed that the resulting rate is unsuppressed at high temperature. Gavela and collaborators [1882] carried out the calculation that quantifies the shortfall, and Kajantie and collaborators [1925] showed by lattice computation that the electroweak transition is a crossover for any Higgs mass above about $72\,\mathrm{GeV}/c^2$, which removes the third Sakharov condition independently. The measured baryon-to-photon ratio is Planck's [2348].

The null results. The current neutron electric dipole moment bound is from ultracold neutrons at the Paul Scherrer Institute [2346], improving the Institut Laue-Langevin result [2090]; the technique is Ramsey's [968] and the argument for measuring the quantity at all was made by Purcell and Ramsey [966] at a time when parity was universally assumed. The chiral estimates relating the bound to $\bar{\theta}$ are Baluni [1633] and Crewther, Di Vecchia, Veneziano and Witten [1637]. Peccei and Quinn [1609] proposed the dynamical relaxation of $\bar{\theta}$ and Weinberg [1628] and Wilczek [1630] pointed out the axion that follows; none of it has been observed.

The data. Every world-average number in this chapter is from the Particle Data Group's 2024 Review [2427], and the masses in Table 111.5 are from its machine-readable release, stored with this treatise as evidence. The SI conversions — the elementary charge, the speed of light, the Planck and reduced Planck constants — are CODATA 2022 [2431], likewise stored; in the present SI the first three of those are exact, so the conversions in this chapter carry no uncertainty of their own.

Chapter 112

Experiment: The Electron Anomalous Magnetic Moment

Tests Phenomenon 93.3 and Equation (100.62).

Assuming Theorem 112.9 and Proposition 112.12.

The electron magnetic moment anomaly $a_e = (g-2)/2$ is the most precisely measured quantity in particle physics and the most precisely computed: the Harvard one-electron quantum cyclotron reports

$$a_e = 1.15965218059(13) \times 10^{-3}\,, \tag{112.1}$$

a fractional uncertainty of about 1.1×10^{-10} on the anomaly itself [2419], against a QED series evaluated through tenth order [2330]. That 2023 measurement is the experiment this chapter is built around, and it is the year registered for the chapter in the List of Experiments; the two earlier results from the same apparatus [2101, 2126] are reported alongside it because the systematic budget is cumulative and the three values are not independent. This chapter is the experimental counterpart of the renormalized perturbation theory of Chapter 100: it takes Dirac's $g = 2$ [596], the first measured departure from it [912, 916], and Schwinger's one-loop $a_e = \alpha/2\pi$ [919], and follows the comparison down to the digit at which it currently stops.

Where it stops is the point of the chapter, and it is not where the headline figures suggest. Extracting a_e from theory requires an independently measured fine-structure constant, and the two best determinations — caesium recoil [2316] and rubidium recoil [2363] — disagree with each other by several standard deviations, a discrepancy far larger than either quoted uncertainty. The comparison of measurement with theory is therefore verified only to the precision of the worse-behaved input, and the chapter states that bound explicitly rather than quoting agreement to twelve digits. The same discipline is applied to the muon anomaly, where a genuine measurement–theory tension [2091, 2368, 2416] is entangled with a disagreement between lattice and data-driven evaluations of the hadronic vacuum polarization [2375]. The chapter follows the house experiment pattern of editorial rule 4: apparatus, procedure, observations and data, interpretation, primary references, in that order, with the historical setting and the theoretical prediction placed before the apparatus so that the reader knows what is being tested before meeting the hardware.

Remark 112.1 (Units, and the literature's convention). Everything in this chapter is written in SI. Frequencies are in hertz, fields in tesla, energies in joules with the electronvolt given alongside, and $\hbar$ and c appear explicitly in every equation, including the intermediate steps. The anomaly itself is a pure number, so no unit convention can change it — which is precisely why it is the sharpest comparison available between a measurement and a calculation.

The QED literature computes a_e with $\hbar = c = 1$, in which convention masses, momenta and energies are all quoted in electronvolts and the fine-structure constant is written

$\alpha = e^2/4\pi$ with a rationalized Heaviside–Lorentz charge. To map a formula from that literature onto this chapter, restore one factor of $\hbar$ for each unit of action, one factor of c for each power of velocity, and read the coupling as

$$\alpha = \frac{e^2}{4\pi\varepsilon_0\hbar c} = (7.297\,352\,564\,3 \pm 0.000\,000\,001\,1) \times 10^{-3}\,, \tag{112.2}$$

which is dimensionless in SI as it is in any other system [2431]. No derivation in this chapter is carried out in the natural-units convention; this remark exists only so that a reader holding [2330] open beside the book can align the two.

112.1 Historical context and the prediction under test

112.1.1 Dirac's $g = 2$

A magnetic moment attached to an angular momentum is written

$$\boldsymbol{\mu} = -g\,\frac{\mu_{\mathrm{B}}}{\hbar}\,\boldsymbol{J}\,, \qquad \mu_{\mathrm{B}} = \frac{e\hbar}{2m_e} = (9.274\,010\,065\,7 \pm 0.000\,000\,002\,9) \times 10^{-24}\,\mathrm{J/T}\,, \tag{112.3}$$

the numerical value of the Bohr magneton being the CODATA 2022 recommended one [2431]. The dimensionless factor g is what is at issue. For a classical current loop, or for the orbital motion of a charge in an atom, $g = 1$: this follows from nothing more than the definition of the magnetic moment of a current distribution, $\boldsymbol{\mu} = \frac{1}{2}\int \mathrm{d}^3x\, \boldsymbol{x} \times \boldsymbol{j}$, applied to a charge $-e$ of mass m_e moving on a closed orbit, whose angular momentum is $\boldsymbol{L} = m_e \int \mathrm{d}^3x\, \boldsymbol{x} \times \boldsymbol{v}\, \rho/(-e)$ with ρ the charge density.

Spin is not orbital motion, and the factor is not 1. Uhlenbeck and Goudsmit had to postulate $g = 2$ for the electron's intrinsic angular momentum to make the alkali doublets and the anomalous Zeeman effect come out [532], and Pauli inserted the same factor by hand into the nonrelativistic wave equation [587]. What Dirac's relativistic equation supplies, without being asked, is exactly that factor [596]. The derivation is carried out in full elsewhere in this book — see Phenomenon 93.3, where squaring the minimally coupled Dirac operator produces the term $-(q\hbar/2m_e)\,\boldsymbol{\sigma}\cdot\boldsymbol{B}$ and the factor of two comes entirely from the algebra of $(\boldsymbol{\sigma}\cdot\boldsymbol{a})(\boldsymbol{\sigma}\cdot\boldsymbol{b})$ — and it is not repeated here.

Two features of that result are what make the present chapter possible. First, $g = 2$ is exact in the single-particle theory: it is not fitted, it contains no parameter, and it does not depend on the field strength, the electron's velocity, or anything else that could be adjusted. Second, it is a statement about a *free* electron, so a measurement on a free electron tests it without any intervening atomic structure. Any measured departure from 2 is therefore a measurement of something that the relativistic wave equation does not contain, and the only candidate in a theory built on it is the interaction of the electron with the quantized electromagnetic field. That is why the anomaly is diagnostic rather than merely a correction.

It is worth being explicit about the size of the effect to be found, and about a sign convention that is easy to count twice. In Equation (112.3) the orientation of the moment relative to the spin is carried by the explicit minus sign, so the g written there is a positive number, and the anomaly is defined on that magnitude:

$$a_e := \frac{|g_e| - 2}{2}\,, \qquad \mu_e = (1 + a_e)\,\mu_{\mathrm{B}}\,. \tag{112.4}$$

CODATA 2022 tabulates the g factor with its sign included, $g_e = -2.00231930436092(36)$, the sign recording that the moment is antiparallel to the spin for a negative charge [2431]. Every g written in this chapter is $|g_e|$; inserting the tabulated negative value into Equation (112.4) would apply the same sign twice and give -2.0012 instead of the anomaly. The excess over

the Dirac value is therefore about one part in 860 — large enough to have been found in 1948 with atomic beams, small enough that measuring its own tenth significant figure is a seventy-five-year project.

112.1.2 The hyperfine anomaly and the Kusch–Foley measurement

The excess was not found by measuring the electron moment against an absolute standard. It was found because a set of measurements that assumed $g_S = 2$ failed to be self-consistent.

The atomic beam. Kusch and Foley used the atomic-beam magnetic-resonance method that Rabi's group had developed a decade earlier [798, 819]. An oven produces a thermal beam of neutral atoms — gallium, indium and sodium in the experiments at issue — which passes in vacuum through three magnet regions in series. The first (the A magnet) has a strong transverse gradient and deflects the atoms according to the sign of their effective moment; the third (the B magnet) has a gradient of the opposite sense and refocuses onto a detector exactly those atoms whose effective moment is unchanged. Between them sits the C region: a strong, uniform field $\boldsymbol{B}$ with a small radio-frequency field applied transverse to it. If the radio frequency matches a Zeeman transition frequency of the atom in the C field, the atom changes state, the B magnet no longer refocuses it, and the detected beam intensity drops. The observable is a dip in a beam current as a frequency is swept.

Why a ratio evades the calibration problem. The resonance condition in the C field is

$$h\nu = g_F \, \mu_{\mathrm{B}} \, B \, \Delta m_F \, , \tag{112.5}$$

so an absolute determination of g_F requires knowing B to the same accuracy as ν — and in 1948 a magnetic field could not be measured to anything like a part in 10^4, whereas a radio frequency could be counted to a part in 10^6. The way out is to measure two resonances in the *same* field. The ratio of their frequencies is

$$\frac{\nu_1}{\nu_2} = \frac{g_{F,1} \, \Delta m_{F,1}}{g_{F,2} \, \Delta m_{F,2}} \, , \tag{112.6}$$

in which B, h and μ_{B} have all cancelled. The field need only be stable for the duration of the two sweeps, not known. This is the same structural trick — measure a ratio of frequencies in a common field — that the Penning-trap experiments of Section 112.3.2 carry to a part in 10^{13}, and it is the single most important idea in the whole subject.

The inconsistency. For an atom in Russell–Saunders coupling, the Landé factor of a level with quantum numbers L, S, J is a known function of g_L and g_S,

$$g_J = g_L \, \frac{J(J+1) - S(S+1) + L(L+1)}{2J(J+1)} + g_S \, \frac{J(J+1) + S(S+1) - L(L+1)}{2J(J+1)} \, , \tag{112.7}$$

with the orbital factor $g_L = 1$ up to the known reduced-mass correction.

Derivation. The total moment of the electron shell is the sum of an orbital and a spin part,

$$\boldsymbol{\mu} = -\frac{\mu_{\mathrm{B}}}{\hbar} \left(g_L \boldsymbol{L} + g_S \boldsymbol{S} \right) \, ,$$

which is *not* proportional to $\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}$ unless $g_L = g_S$. Within one level of definite J, however, the Wigner–Eckart theorem makes every vector operator proportional to $\boldsymbol{J}$: for

any vector $\boldsymbol{V}$, $\langle \boldsymbol{V} \rangle = \langle \boldsymbol{V}\cdot\boldsymbol{J}\rangle \, \langle \boldsymbol{J}\rangle / \hbar^2 J(J+1)$. Applying this with $\boldsymbol{V} = g_L \boldsymbol{L} + g_S \boldsymbol{S}$ defines g_J through $\langle \boldsymbol{\mu}\rangle = -g_J(\mu_{\mathrm{B}}/\hbar)\,\langle \boldsymbol{J}\rangle$, so that

$$g_J = \frac{g_L \langle \boldsymbol{L}\cdot\boldsymbol{J}\rangle + g_S \langle \boldsymbol{S}\cdot\boldsymbol{J}\rangle}{\hbar^2 J(J+1)} \, .$$

Squaring $\boldsymbol{S} = \boldsymbol{J} - \boldsymbol{L}$ and $\boldsymbol{L} = \boldsymbol{J} - \boldsymbol{S}$ gives the two scalar products,

$$\boldsymbol{L}\cdot\boldsymbol{J} = \tfrac{1}{2}\left(\boldsymbol{J}^2 + \boldsymbol{L}^2 - \boldsymbol{S}^2\right) , \qquad \boldsymbol{S}\cdot\boldsymbol{J} = \tfrac{1}{2}\left(\boldsymbol{J}^2 + \boldsymbol{S}^2 - \boldsymbol{L}^2\right) ,$$

and inserting the eigenvalues $\hbar^2 J(J+1)$, $\hbar^2 L(L+1)$ and $\hbar^2 S(S+1)$ — the factors of $\hbar^2$ cancelling against the denominator, as they must for g_J to be dimensionless — gives Equation (112.7). □

Because the two coefficients depend on L, S and J, different levels weight g_S and g_L differently: the ${}^2P_{1/2}$ and ${}^2P_{3/2}$ levels of gallium and indium, and the ${}^2S_{1/2}$ ground state of sodium, give three independent combinations. Measuring the ratios of their g factors therefore over-determines the pair (g_L, g_S), and the system has no solution with $g_S = 2g_L$.

Kusch and Foley found that the discrepancy is removed by allowing the electron's spin g factor to exceed twice the orbital one by about 0.12 % [912, 916]. In the modern notation that is $a_e \approx 1.2 \times 10^{-3}$, and the reader should notice how coarse the measurement was by present standards and how decisive it was anyway: the quantity being tested was believed exact, so a departure of one part in 10^3, established at many times its own uncertainty, could not be absorbed into any parameter of the theory. The two 1948 papers are a matched pair — Foley and Kusch [912] carries the interpretation and Kusch and Foley [916] the fuller experimental account — and they are cited together throughout this chapter for that reason.

Phenomenon 112.2 (The electron magnetic moment is not the Dirac value)**.** The magnetic moment of the electron exceeds one Bohr magneton. The excess was first established from the internal inconsistency of atomic-beam magnetic-resonance measurements of hyperfine g-factor ratios in gallium, indium and sodium, which could not be reconciled with $g_S = 2$ and required an electron moment larger by about 0.12 % [912, 916]. The modern value of the anomaly $a_e = (|g_e| - 2)/2$ of Equation (112.4) is

$$a_e = 1.15965218059(13) \times 10^{-3} \, , \tag{112.8}$$

an uncertainty of 0.13 parts per trillion on $g/2$ [2419].

Rests on Equation (112.4) *and Theorem 100.41.*

Derivation. *Derives Phenomenon 112.2.*

The excess is not a fitted parameter but a computed one. At one loop the correction to the electron–photon vertex gives $a_e = \alpha/2\pi = 1.1614 \times 10^{-3}$ [919], which already reproduces Equation (112.8) to three significant figures and accounts for the whole of the 0.12 % excess that Kusch and Foley found; the loop integral is evaluated in full at Theorem 100.41 and is not repeated here. The remaining figures are supplied by the higher orders of the same series, carried to tenth order [2330] and set out term by term in Table 112.2. What limits the comparison is not the series but the input discussed in Section 112.2.3. □

112.1.3 Schwinger's $\alpha/2\pi$

The one-loop correction to the electron–photon vertex splits, by Lorentz invariance and current conservation, into two form factors: $F_1(q^2)$, which renormalizes the charge, and $F_2(q^2)$, which multiplies the tensor structure $\mathrm{i}\sigma^{\mu\nu}q_\nu/2m_e c$ and therefore contributes an extra magnetic coupling. The anomaly is $a_e = F_2(0)$, and at one loop

$$a_e^{(1)} = \frac{\alpha}{2\pi} = \frac{e^2}{8\pi^2 \varepsilon_0 \hbar c} = 1.161\,410 \times 10^{-3} \, . \tag{112.9}$$

This chapter does not repeat that calculation: it is Theorem 100.41, proved in full in Chapter 100, where the loop integral is regularized, the divergence is shown to sit entirely in F_1, and $F_2(0)$ is extracted as a convergent Feynman-parameter integral. What matters here is the epistemic shape of the result, and it is worth stating carefully because it is the reason renormalization became believable rather than merely tolerated.

The one-loop vertex is divergent. The divergence is absorbed into the definition of the electron's charge, which is not predicted by the theory and never was. What is left over, after that absorption, is a pure number times α — no cutoff, no regulator, no scheme dependence, and no adjustable parameter. Schwinger's number was published in 1948, in the same year and in the same journal volume as the Kusch–Foley measurement, and it agreed with it. A theory that had been widely regarded as a formal device for organizing divergences had produced a parameter-free number that matched an experiment nobody had computed it for. Everything in the rest of this chapter is a seventy-five-year continuation of that single comparison, carried from three significant figures to ten.

The second-order term is worth one further remark. Because Equation (112.9) contains no mass, the same number is the one-loop anomaly of the muon and of the tau. Lepton-universality of the leading term is what makes the electron and the muon anomalies complementary rather than redundant: they differ only in the corrections, and the corrections are what carry information about hadrons and about anything heavier (Section 112.2.2).

112.1.4 What a measurement must deliver

Phenomenon 112.3 (The anomaly is a ratio of two frequencies)**.** For a free electron in a uniform magnetic field $\boldsymbol{B}$, the spin precession frequency ν_s and the cyclotron frequency ν_c satisfy

$$a_e = \frac{\nu_s - \nu_c}{\nu_c} = \frac{\nu_a}{\nu_c}\,, \qquad \nu_a := \nu_s - \nu_c\,, \tag{112.10}$$

in which the magnetic field has cancelled identically. The anomaly can therefore be obtained from two frequency measurements in one field, with no absolute magnetometry anywhere in the chain.

Rests on Equations (112.3) *and* (112.4).

Derivation. *Derives Phenomenon 112.3.*

The cyclotron motion of a charge $-e$ of mass m_e in a uniform field $\boldsymbol{B} = B\hat{\boldsymbol{z}}$ is quantized into Landau levels of energy

$$E_n = \left(n + \tfrac{1}{2}\right)\hbar\omega_c\,, \qquad \omega_c = \frac{eB}{m_e}\,, \qquad \nu_c = \frac{\omega_c}{2\pi} = \frac{eB}{2\pi m_e}\,, \tag{112.11}$$

with $\hbar\omega_c$ carrying SI dimensions of joules, ω_c of rad/s and ν_c of hertz. The spin contributes the Zeeman energy $-\boldsymbol{\mu}\cdot\boldsymbol{B}$, which from Equation (112.3) splits the two spin projections $m_s = \pm\frac{1}{2}$ by

$$\Delta E_{\text{spin}} = g\,\mu_{\text{B}} B = g\,\frac{e\hbar B}{2m_e} = \frac{g}{2}\,\hbar\omega_c\,, \tag{112.12}$$

so the spin precession frequency is $\nu_s = \Delta E_{\text{spin}}/h = (g/2)\nu_c$. Hence

$$\frac{\nu_s - \nu_c}{\nu_c} = \frac{g}{2} - 1 = \frac{g-2}{2} = a_e\,,$$

which is Equation (112.10). Both B and the ratio e/m_e have cancelled: the field enters ν_s and ν_c in exactly the same way because the same μ_{B} and the same ω_c appear in both, and that identity is what Equations (112.11) and (112.12) exhibit. The anomaly is the fractional difference of two frequencies measured on one particle in one field. □

The consequences of this structure govern everything that follows, and they are worth setting out before any hardware is described.

First, the measurement is a frequency measurement, and frequency is the SI quantity that can be realized best: the second is defined by a caesium hyperfine transition and time intervals are routinely compared to a part in 10^{16}, far beyond what is needed here (Chapter 2). Nothing else in the experiment has to be that good.

Second, the difference $\nu_a = \nu_s - \nu_c = a_e \nu_c$ is smaller than either frequency by three orders of magnitude, so a fractional error ϵ in either ν_s or ν_c produces a fractional error of order $\epsilon / a_e \approx 860\,\epsilon$ in a_e unless it is common to both. This is the reason ν_a is measured *directly*, as the frequency of a transition that flips the spin and lowers the cyclotron quantum number by one, rather than as a difference of two separately measured large numbers. Measured that way, the requirement on ν_c is only that it be known to about a_e times the target precision.

Third, since B does not appear, magnetometry is replaced by a different set of systematic effects: whatever makes the trap's frequencies differ from the free-space ones. Those are the electrostatic confining potential itself, the special-relativistic mass increase, the image charges induced in the electrodes, and — dominantly — the coupling of the cyclotron motion to the modes of the conducting cavity that surrounds it. These four are the whole of the systematic problem, and Sections 112.3.2 and 112.3.3 exist to explain how each is controlled; the published line-by-line error budget is not reproduced in this book and must be read in [2419].

Fourth, and least obviously, the quantity delivered is dimensionless. No SI unit enters the final number at all, which is why a_e can be compared with a calculation without a single conversion factor and why its uncertainty is not limited by the realization of the kilogram, the ampere or the tesla. The uncertainty conventions used to quote it — standard uncertainty, coverage factor 1, correlations propagated explicitly — are those of Chapter 2.

112.2 The theoretical prediction

112.2.1 The QED series through tenth order

Because the one-loop vertex correction of Theorem 100.41 is α times a dimensionless integral, and because every additional loop adds one factor of the coupling and one dimensionless integral, the anomaly of a lepton is a power series in α with pure numbers as coefficients:

$$a_e = \sum_{n \geq 1} C_n \left(\frac{\alpha}{\pi} \right)^n + a_e^{\mu,\tau} + a_e^{\mathrm{had}} + a_e^{\mathrm{weak}} . \tag{112.13}$$

The expansion parameter is written α/π rather than α because a factor $1/\pi$ per loop is what the four-dimensional loop measure $\mathrm{d}^4\ell / (2\pi\hbar)^4$ actually supplies; with $\alpha/\pi = 2.3228 \times 10^{-3}$ the terms fall by a factor of a few hundred at each order, which is why ten significant figures need only five of them. Every C_n is a pure number, and every term in Equation (112.13) is dimensionless in SI, as it must be for the sum to be a g factor.

The coefficients are those adopted in Chapter 100, whose provenance is [2330]:

$$\begin{aligned} &C_1 = \tfrac{1}{2}\,, && C_2 = -0.328478965\ldots\,, && C_3 = +1.181241456\ldots\,, \\ &C_4 = -1.912245\ldots\,, && C_5 = +6.737(159)\,. \end{aligned} \tag{112.14}$$

C_1 is Schwinger's; C_2 and C_3 are known in closed form, in terms of $\zeta(3)$, $\ln 2$ and π^2; C_4 and C_5 are numerical. The counting of Feynman diagrams contributing to the mass-independent part at each order is 1, 7, 72, 891 and 12 672 [2190, 2302, 2330], which is the practical reason the series stops where it does: the tenth-order evaluation is a decade-long numerical project, not an algebraic one.

Two features of Equation (112.14) deserve to be flagged rather than passed over.

The tenth-order term is not negligible, and it is disputed. With the CODATA 2022 value of α the fifth-order term contributes $C_5(\alpha/\pi)^5 = 4.556 \times 10^{-13}$ to a_e, which is *three and a half times* the experimental uncertainty 1.3×10^{-13} of Equation (112.8). The quoted uncertainty on C_5 itself, ± 0.159, propagates to 1.1×10^{-14}, comfortably below the experiment. But that uncertainty is the error of a numerical integration, and an independent recomputation of the largest gauge-invariant subset of the tenth-order diagrams — those without closed lepton loops — does not agree with the published value within the quoted errors [2343]. This is recorded here, as it is in Chapter 100, because a single unverified numerical computation would otherwise be load-bearing in the most precisely tested prediction in physics. It does not currently change the conclusion of Section 112.7, because the α input is a larger limitation than any plausible revision of C_5; it would matter immediately if the α inputs were reconciled.

The mass-dependent terms enter at fourth order. The C_n of Equation (112.14) are the mass-independent coefficients: they are what remains when every internal fermion line is the same lepton as the external one. Diagrams in which a muon or tau loop is inserted into a photon propagator depend on the ratios m_e/m_μ and m_e/m_τ and are collected into $a_e^{\mu,\tau}$. Their leading behaviour is a clean piece of physics and is derived in Section 112.2.2: a loop of mass M decouples from the anomaly of a lepton of mass m_ℓ as $(m_\ell/M)^2$, so muon loops are suppressed in a_e by $(m_e/m_\mu)^2 \approx 2.34 \times 10^{-5}$. The full value from [2330] is

$$a_e^{\mu,\tau} = 2.7478 \times 10^{-12}\,, \tag{112.15}$$

which is twenty times the experimental uncertainty and therefore mandatory. The logarithms $\ln(m_\mu/m_e)$ that accompany such ratios are the mass singularities analysed by Kinoshita [1232]; they are finite here because the internal mass is the larger one.

112.2.2 Hadronic and electroweak contributions

The remaining two terms of Equation (112.13) are not QED. The hadronic term collects diagrams in which the virtual photon converts into quarks and gluons — hadronic vacuum polarization at leading order, and hadronic light-by-light scattering beyond it — and the electroweak term collects diagrams containing a W, a Z or a Higgs boson. For the electron [2330] gives

$$a_e^{\mathrm{had}} = 1.6927 \times 10^{-12}\,, \qquad a_e^{\mathrm{weak}} = 0.030\,53 \times 10^{-12}\,. \tag{112.16}$$

Neither can be computed from first principles in perturbation theory: the hadronic one because the strong coupling is large at the relevant scale (Chapter 102), and it is obtained instead either from measured $e^+e^- \to$ hadrons cross sections through a dispersion relation or from lattice QCD (Remark 102.61). The electroweak one is perturbative but requires the full Standard Model.

Phenomenon 112.4 (Hadronic sensitivity scales as the square of the lepton mass)**.** The hadronic contribution to a lepton anomaly is a small correction for the electron and the dominant theoretical uncertainty for the muon. Numerically the hadronic terms contribute of order 1.7×10^{-12} to a_e [2330] — already an order of magnitude above the experimental uncertainty of Equation (112.8), and therefore no longer negligible — and of order 7×10^{-8} to a_μ [2353].

Rests on Equations (112.8)*,* (112.13) *and* (112.16)*.*

Derivation. Derives Phenomenon 112.4.

The hadronic vacuum polarization enters the anomaly through a dispersion integral over the measured cross section for $e^+e^- \to$ hadrons, weighted by a kernel which, for centre-of-mass energies $\sqrt{s}$ well above the lepton mass, behaves as $K(s) \simeq m_\ell^2 c^4/(3s)$. The integral is

dominated by the hadronic resonances, whose scale is fixed by the strong interaction and is the same whichever lepton is being computed, so the whole contribution scales as m_ℓ^2. The ratio for the two leptons is therefore

$$\frac{a_\mu^{\mathrm{had}}}{a_e^{\mathrm{had}}} \simeq \left(\frac{m_\mu}{m_e}\right)^2 = (206.7683)^2 = 4.28 \times 10^4 \,, \tag{112.17}$$

using the mass ratio built from the CODATA 2022 electron and muon masses $m_e = (9.109\,383\,713\,9 \pm 0.000\,000\,002\,8) \times 10^{-31}\,\mathrm{kg}$ and $m_\mu = (1.883\,531\,627 \pm 0.000\,000\,042) \times 10^{-28}\,\mathrm{kg}$ [2431]; applied to the electron value quoted above this reproduces the muon one. The same m_ℓ^2 scaling governs the electroweak contribution and the sensitivity to any new heavy state, and it is the whole reason the muon is the better probe of physics beyond the Standard Model despite its far worse experimental precision — and the reason the electron anomaly, whose theory is almost purely QED, is the better test of QED itself. □

The same statement can be checked against a case where the heavy mass is known exactly, which is a useful consistency test of the scaling argument just made. The two-loop contribution to a_e from a vacuum polarization loop of a heavier lepton of mass M is

$$\delta a_e = \left(\frac{\alpha}{\pi}\right)^2 \left[\frac{1}{45}\left(\frac{m_e}{M}\right)^2 + O\!\left(\left(\frac{m_e}{M}\right)^4 \ln\frac{M}{m_e}\right)\right] , \tag{112.18}$$

which is dimensionless, as every term in Equation (112.13) must be.

Derivation. At this order the heavy lepton reaches the electron only by polarizing the internal photon of the one-loop vertex, so the dispersive representation of Equation (112.43) applies verbatim with the hadronic $R(s)$ replaced by the contribution of one lepton pair of mass M,

$$R_M(s) = \left(1 + \frac{2M^2c^4}{s}\right)\sqrt{1 - \frac{4M^2c^4}{s}} \,, \qquad s \geq 4M^2c^4 \,, \tag{112.19}$$

which is the usual threshold factor for producing a pair of mass M and is dimensionless, s carrying SI dimensions of J^2. Because $M \gg m_e$ the entire integration region satisfies $s \geq 4M^2c^4 \gg m_e^2c^4$, so the asymptotic kernel $K(s) \to m_e^2c^4/(3s)$ of Equation (112.43) may be used throughout, and

$$\delta a_e = \frac{1}{3}\left(\frac{\alpha}{\pi}\right)^2 \int_{4M^2c^4}^{\infty} \frac{\mathrm{d}s}{s}\, R_M(s)\, \frac{m_e^2c^4}{3s} = \frac{1}{9}\left(\frac{\alpha}{\pi}\right)^2 m_e^2c^4 \int_{4M^2c^4}^{\infty} \frac{R_M(s)}{s^2}\,\mathrm{d}s \,.$$

Substitute $u = 4M^2c^4/s$, which maps the range onto $0 < u \leq 1$ and turns $\mathrm{d}s/s^2$ into $-\mathrm{d}u/(4M^2c^4)$:

$$\int_{4M^2c^4}^{\infty} \frac{R_M(s)}{s^2}\,\mathrm{d}s = \frac{1}{4M^2c^4}\int_0^1 \left(1 + \frac{u}{2}\right)\sqrt{1-u}\,\mathrm{d}u = \frac{1}{4M^2c^4}\left(\frac{2}{3} + \frac{2}{15}\right) = \frac{1}{5M^2c^4} \,,$$

using $\int_0^1 \sqrt{1-u}\,\mathrm{d}u = \frac{2}{3}$ and $\int_0^1 u\sqrt{1-u}\,\mathrm{d}u = \frac{4}{15}$. Hence

$$\delta a_e = \frac{1}{9}\left(\frac{\alpha}{\pi}\right)^2 \frac{m_e^2c^4}{5M^2c^4} = \frac{1}{45}\left(\frac{\alpha}{\pi}\right)^2 \left(\frac{m_e}{M}\right)^2 ,$$

which is the leading term of Equation (112.18). What has been dropped is the correction to the asymptotic kernel, of relative order $m_e^2c^4/s \leq (m_e/2M)^2$, and that is the source of the $O((m_e/M)^4)$ remainder shown. Note that the factor $1/3$ inside the kernel is load-bearing: with $K \to m_e^2c^4/s$ the same integral would give $1/15$, three times too large. □

With $M = m_\mu$, so that $(m_e/m_\mu)^2 = 2.3390 \times 10^{-5}$, this gives $5.3955 \times 10^{-6} \times 5.198 \times 10^{-7} = 2.80 \times 10^{-12}$. The full mass-dependent term of Equation (112.15) is 2.7478×10^{-12}, so the leading $(m_e/M)^2$ piece accounts for it to two per cent — but note the direction: the leading piece *overshoots* the full value, and the residual $2.7478 \times 10^{-12} - 2.8046 \times 10^{-12} = -5.7 \times 10^{-14}$ is negative. The same formula with $M = m_\tau$ adds a tau loop of about $+1 \times 10^{-14}$, which pushes the other way, so the negative sign must come from the three-loop mass-dependent diagrams, which are the only contribution of the right sign at this size. The decoupling of a heavy state as the square of the mass ratio is therefore not an approximation invented for the hadronic estimate; it is a property of the anomaly, verified here against an independently known mass.

Remark 112.5 (What the anomaly can and cannot see). Equation (112.18) sets the reach of the measurement. A new state of mass M coupling to the lepton with roughly electromagnetic strength shifts the anomaly by of order $(\alpha/\pi)(m_\ell c^2/Mc^2)^2$, so an experimental sensitivity δa_ℓ probes

$$Mc^2 \gtrsim m_\ell c^2 \sqrt{\frac{\alpha}{\pi\, \delta a_\ell}}\,. \tag{112.20}$$

The lepton mass in the numerator is why the muon, 206.7683 times heavier, buys a factor 206.7683 in mass reach for the same fractional precision. The square root is why the electron's enormous advantage in precision does not simply transfer: the electron anomaly is measured about 1840 times more precisely than the muon's in fractional terms (1.1×10^{-10} against 2.1×10^{-7}, from Tables 112.1 and 112.4), and a factor 1840 in δa_ℓ buys only $\sqrt{1840} \approx 43$ in mass — less than the mass ratio it is competing against. The two experiments are answering different questions: the electron anomaly tests QED, the muon anomaly searches. Numbers are given in Section 112.7.

112.2.3 The fine-structure constant as an input

Equation (112.13) is a function of α. It predicts a number only when α is supplied, and if α is taken from the anomaly itself the exercise is a definition rather than a test. This subsection sets out where an independent α comes from and how well it is known; Section 112.7 draws the consequence.

The best independent determinations are atom-recoil measurements, and the route is worth deriving because it shows exactly which quantity carries the uncertainty. The Rydberg constant is, by definition,

$$R_\infty = \frac{m_e c\, \alpha^2}{2h} = (10\,973\,731.568\,157 \pm 0.000\,012)/\mathrm{m}\,, \tag{112.21}$$

the value being CODATA 2022 [2431]. Solving for α^2 and inserting the mass of an atom of species X in the obvious place,

$$\alpha^2 = \frac{2R_\infty h}{m_e c} = \frac{2R_\infty}{c}\,\frac{m_X}{m_e}\,\frac{h}{m_X}\,. \tag{112.22}$$

Each of the three factors on the right is separately measurable. The first is Equation (112.21), known to 1.1×10^{-12} fractionally from hydrogen spectroscopy and utterly negligible here. The second, the mass of the atom in units of the electron mass, is a ratio of cyclotron frequencies in a Penning trap — the same instrument as Section 112.3.2, used for a different purpose — and is known to better than 10^{-10}. The third, h/m_X, has the SI dimensions of J s/kg, that is m^2/s, and is what the recoil experiment measures: an atom that absorbs a photon of wavevector $k = 2\pi/\lambda$ recoils with velocity

$$v_{\mathrm{rec}} = \frac{\hbar k}{m_X} = \frac{h}{m_X \lambda}\,, \tag{112.23}$$

and the resulting Doppler shift, accumulated over many photon recoils in an atom interferometer, is counted as a frequency. Since Equation (112.22) gives α as the square root of h/m_X, a fractional uncertainty ϵ on h/m_X becomes $\epsilon/2$ on α: a determination of α at 2.0×10^{-10} requires h/m_X at 4.0×10^{-10}, which is the actual achievement of these experiments.

Phenomenon 112.6 (The two recoil determinations disagree)**.** The fine-structure constant can be obtained from a photon-recoil frequency together with the mass of the recoiling atom in units of the electron mass. Two such determinations,

$$\alpha^{-1} = 137.035999046(27)\ \text{(caesium)}\,, \qquad \alpha^{-1} = 137.035999206(11)\ \text{(rubidium)}\,, \tag{112.24}$$

differ by 1.60×10^{-7}, about five and a half times their combined standard uncertainty [2316, 2363]. The recommended value accordingly carries an inflated uncertainty [2431].

Rests on Equations (112.8) *and* (112.22).

Derivation. *Derives Phenomenon 112.6.*

The consequence for the comparison of Equation (112.8) with theory is arithmetic. To leading order $a_e = \alpha/2\pi$, so $\delta a_e = \delta\alpha/2\pi$ and, fractionally, $\delta a_e/a_e = \delta\alpha/\alpha$. The two inputs of Equation (112.24) differ fractionally by

$$\frac{\delta\alpha}{\alpha} = \frac{1.60 \times 10^{-7}}{137.036} = 1.17 \times 10^{-9}\,,$$

and with $\alpha = 7.2974 \times 10^{-3}$ this is $\delta\alpha = 8.5 \times 10^{-12}$, so that

$$\delta a_e = \frac{\delta\alpha}{2\pi} = 1.4 \times 10^{-12}\,. \tag{112.25}$$

The experimental uncertainty on a_e in Equation (112.8) is 1.3×10^{-13}. The two predictions therefore straddle the measurement by about ten times its own uncertainty, and the honest statement of the test is that quantum electrodynamics is confirmed to the precision of its input — roughly one part in 10^9 of a_e, about nine significant figures — and not to the twelve or thirteen that the quoted precision of a_e alone would suggest [2419]. The alternative reading, in which a_e together with the series is used to *define* α, is internally consistent but defers the test until the two recoil measurements agree. □

The two experiments are not variants of one technique in any way that would make a common systematic likely. Parker and collaborators [2316] used a caesium atom interferometer with Ramsey–Bordé interferometry and Bragg diffraction; Morel and collaborators [2363] used rubidium with Bloch oscillations in an accelerated optical lattice to accumulate hundreds of photon recoils. The atomic species differ, the mass ratios m_X/m_e come from different measurements, and the interferometric schemes differ. That is what makes the disagreement uncomfortable: it is not obviously attributable to one of them, and the CODATA 2022 adjustment therefore inflates the uncertainty of the recommended value $\alpha^{-1} = 137.035999177(21)$ rather than choosing between them [2431]. Note that this recommended value is not independent of a_e — the adjustment uses the anomaly together with the QED series as one of its inputs — which is exactly why it cannot be used to test the series. That distinction is the subject of Section 112.7 and is the single most important statement in this chapter.

112.3 Apparatus

112.3.1 Free-electron precession experiments

The first measurements to use Equation (112.10) directly, on free rather than bound electrons, were made at Michigan by Crane and collaborators over the 1950s and early 1960s, culminating in the precision experiment of Wilkinson and Crane [1268].

The Michigan experiment. Electrons of about 100 keV, that is 1.602×10^{-14} J, of kinetic energy were transversely polarized by Mott scattering from a thin gold foil — the spin–orbit coupling in the Coulomb field of a high-Z nucleus makes the differential cross section depend on the spin projection normal to the scattering plane, so scattering at a fixed angle selects a polarized beam. The polarized electrons were injected into a region of static, nearly uniform magnetic field of order 0.1 T, in which a weak axial gradient provided a shallow magnetic bottle that trapped them in a spiral orbit for a controlled dwell time. They were then ejected onto a second gold foil, and the left–right asymmetry of the Mott scattering measured the angle between the spin and the momentum at the moment of ejection.

Why the method works. This apparatus measures the anomaly by allowing it to accumulate.

Proposition 112.7 (The anomaly accumulates as a turning angle)**.** *An electron that completes N cyclotron orbits in a uniform magnetic field turns its spin, relative to its momentum, through the angle*

$$\theta = 2\pi a_e N \,. \tag{112.26}$$

Rests on Phenomenon 112.3.

Proof. *Derives Proposition 112.7.*

The momentum direction rotates at $\omega_c = eB/m_e$ and the spin precesses at $\omega_s = (g/2)\,\omega_c$, both about $\hat{\boldsymbol{z}}$ and both derived in Phenomenon 112.3. Their difference is

$$\omega_a = \omega_s - \omega_c = \left(\frac{g}{2} - 1\right)\omega_c = a_e\,\omega_c \,,$$

so after a time t the accumulated relative angle is $\theta = a_e \omega_c t$. In N orbits, $\omega_c t = 2\pi N$, which gives Equation (112.26). □

The point is the factor N. A single orbit turns the spin by $2\pi a_e = 7.29 \times 10^{-3}$ radians, far too small to measure against the analysing power of a Mott polarimeter; after $N = 1 \times 10^5$ orbits it is $\theta = 728.6$ rad, which is $a_e N = 116$ full turns — a hundred and more — and the asymmetry oscillates that many times as the dwell time is swept, so the *frequency* of that oscillation — which is ν_a — is what is fitted. The measurement has become a frequency measurement again, and the magnetic field appears only through ν_c, which is measured in the same apparatus. Wilkinson and Crane reached a fractional uncertainty of a few parts in 10^5 on a_e [1268] — their $a_e = 1159.622(27) \times 10^{-6}$ is 2.3×10^{-5} of itself, which on the customary $g/2$ scale is the 2.7×10^{-8} more often quoted. That is enough to test the two-loop coefficient C_2 of Equation (112.14), whose term is 1.5×10^{-3} of a_e and therefore about sixty-five times the uncertainty, and not enough to reach the three-loop term, which is 1.3×10^{-5} of a_e and sits half a standard deviation away.

What limited it. Three things, all structural. The electrons are unconfined radially over a large volume, so B in Equation (112.11) is an average over an orbit whose extent is not precisely known; the trapping bottle needed to hold them is itself a field inhomogeneity; and the polarimetry is destructive and statistically inefficient, so each electron yields one bit and the ensemble must be re-prepared. All three are removed at once by confining a *single* electron in a small, well-characterized volume and reading its state nondestructively — which is the Penning trap.

112.3.2 The Penning trap

A Penning trap confines a charged particle using a uniform magnetic field $\boldsymbol{B} = B\hat{\boldsymbol{z}}$ for radial confinement and a static quadrupole electrostatic potential for axial confinement. A magnetic field alone cannot confine along $\hat{\boldsymbol{z}}$, and by Earnshaw's theorem no static electric field can confine in all three directions; the combination works because the electric field need only confine in one direction while defeating the radial anti-confinement that Laplace's equation forces on it.

The fields. The electrode surfaces are shaped to produce, near the centre,

$$\Phi(\rho, z) = \frac{V_0}{2d^2}\left(z^2 - \frac{\rho^2}{2}\right), \qquad d^2 = \frac{1}{2}\left(z_0^2 + \frac{\rho_0^2}{2}\right), \tag{112.27}$$

where V_0 is the signed potential difference applied between the ring and the endcaps, z_0 is the axial half-spacing and ρ_0 the inner radius; d is the characteristic trap dimension, with SI units of metres. Equation (112.27) satisfies $\nabla^2\Phi = 0$, as it must, and the minus sign in front of $\rho^2/2$ is the price: the potential that confines axially pushes the particle out radially. For a particle of charge $-e$ the axial potential energy is $-e\Phi = -eV_0 z^2/2d^2$ on the axis, so trapping requires $V_0 < 0$; the trap depth is $|V_0|$ and only that magnitude appears in the mode frequencies below.

Theorem 112.8 (The three modes of a Penning trap)**.** *An electron of charge $-e$ and mass m_e in the fields of Equation (112.27) and $\boldsymbol{B} = B\hat{\boldsymbol{z}}$ executes three independent harmonic motions, of angular frequencies*

$$\omega_z = \sqrt{\frac{e\,|V_0|}{m_e d^2}}, \qquad \omega_\pm = \frac{\omega_c}{2} \pm \sqrt{\frac{\omega_c^2}{4} - \frac{\omega_z^2}{2}}, \qquad \omega_c = \frac{eB}{m_e}, \tag{112.28}$$

provided $\omega_c^2 > 2\omega_z^2$. They satisfy

$$\omega_+ + \omega_- = \omega_c, \qquad \omega_+\omega_- = \frac{\omega_z^2}{2}. \tag{112.29}$$

Rests on Equation (112.27).

Proof. *Derives Theorem 112.8.*

The equation of motion is $m_e\ddot{\boldsymbol{r}} = -e\,(-\nabla\Phi) - e\,\dot{\boldsymbol{r}} \times \boldsymbol{B}$, with $-e$ the electron's charge. The axial component decouples:

$$m_e\ddot{z} = e\,\partial_z\Phi = \frac{eV_0}{d^2}\,z = -\frac{e\,|V_0|}{d^2}\,z,$$

the last step using $V_0 < 0$, which is the polarity that traps a negative charge. This is $\ddot{z} = -\omega_z^2 z$ with $\omega_z^2 = e\,|V_0|\,/(m_e d^2)$, manifestly positive, and it is the first of Equation (112.28); its SI check is $[e\,|V_0|\,/m_e d^2] = \mathrm{J}/(\mathrm{kg\,m^2}) = 1/\mathrm{s^2}$, as required.

For the radial motion write $u = x + \mathrm{i}y$. The two transverse components combine into

$$\ddot{u} + \mathrm{i}\omega_c\dot{u} - \frac{\omega_z^2}{2}u = 0,$$

where the $\mathrm{i}\omega_c\dot{u}$ term is the magnetic force and the last term is the radial defocusing of Equation (112.27). Substituting $u = u_0 \mathrm{e}^{-\mathrm{i}\omega t}$ gives the characteristic equation $\omega^2 - \omega_c\omega + \omega_z^2/2 = 0$, whose roots are the $\omega_\pm$ of Equation (112.28). They are real — that is, the motion is bounded — exactly when the discriminant is non-negative, $\omega_c^2 > 2\omega_z^2$. Vieta's formulas for that quadratic are Equation (112.29). □

The fast root ω_+ is the *trap-modified cyclotron* frequency, the slow root ω_- the *magnetron* frequency; expanding Equation (112.28) for $\omega_z \ll \omega_c$,

$$\omega_- \simeq \frac{\omega_z^2}{2\omega_c}\,, \qquad \omega_+ \simeq \omega_c - \omega_-\,. \tag{112.30}$$

The magnetron motion is a slow $\boldsymbol{E}\times\boldsymbol{B}$ drift of the orbit centre around the trap axis. It is a metastable mode: its energy *decreases* as its radius grows, so damping it would expel the electron, and it must instead be driven inwards by sideband coupling to the axial motion. In the Harvard trap the three frequencies are separated by six orders of magnitude, which is what makes them independently addressable. With $B = 5.32\,\mathrm{T}$ and $\nu_z = 200\,\mathrm{MHz}$,

$$\nu_c = \frac{eB}{2\pi m_e} = 148.9\,\mathrm{GHz}\,, \qquad \nu_z = 200\,\mathrm{MHz}\,, \qquad \nu_- = \frac{\nu_z^2}{2\nu_c} = 134\,\mathrm{kHz}\,, \tag{112.31}$$

and the anomaly frequency to be measured is $\nu_a = a_e\nu_c = 172.7\,\mathrm{MHz}$, close to ν_z. That proximity is a design choice and not a coincidence, but the dependence runs one way only: $\nu_a = a_e eB/2\pi m_e$ is fixed by B alone, and V_0 is then chosen so that $\nu_z = \sqrt{e\,|V_0|\,/m_e d^2}/2\pi$ falls near the ν_a that the field has already determined. Only ν_z is set by V_0.

The invariance theorem. A real trap is not the ideal one of Equation (112.27): its magnetic and electric axes are not exactly aligned, and the quadrupole has a small ellipticity. Both perturb ω_+, ω_z and ω_- individually, at a level far above the target precision. What rescues the measurement is that one particular combination is untouched.

Theorem 112.9 (Invariance theorem)**.** *The free-space cyclotron frequency is recovered from the three measured trap frequencies as*

$$\omega_c^2 = \omega_+^2 + \omega_z^2 + \omega_-^2\,, \tag{112.32}$$

and this relation continues to hold, to the order at which it matters, when the trap axis is tilted with respect to $\boldsymbol{B}$ and when the electrostatic quadrupole is elliptical rather than axially symmetric [1769].

Rests on Equation (112.29)*.*

Proof. *Derives Theorem 112.9.*

For the ideal trap the identity is algebraic. By Equation (112.29), $\omega_z^2 = 2\omega_+\omega_-$, so

$$\omega_+^2 + \omega_z^2 + \omega_-^2 = \omega_+^2 + 2\omega_+\omega_- + \omega_-^2 = (\omega_+ + \omega_-)^2 = \omega_c^2\,,$$

the last step being the first of Equation (112.29). That the sum of squares survives a tilt and an ellipticity, whereas each frequency separately does not, is the content of Brown and Gabrielse's analysis, which diagonalizes the quadratic form of the perturbed trap and shows that the trace of the relevant matrix — which is what the sum of squares computes — is fixed by B alone. The derivation of that general case is not reproduced here. □

Derivation pending #197

The invariance theorem for a tilted and elliptical Penning trap: the general Brown–Gabrielse result, that the sum of squares of the three measured mode frequencies equals the squared free-space cyclotron frequency independently of the tilt angle and the ellipticity parameter. Belongs in Appendix A beside the ideal-trap identity proved in this chapter.

Numerically the theorem matters less than it might appear, because in the ideal trap $\omega_+\omega_- = \omega_z^2/2$ lets Equation (112.32) be rewritten as $\omega_c = \omega_+ + \omega_z^2/(2\omega_+)$ with no approximation at all; what the general theorem buys is that the same combination survives a tilt and an ellipticity. The correction term $\nu_z^2/(2\nu_+)$ is 134 kHz out of 148.9 GHz, a fractional shift of 9×10^{-7} — a million times the target precision, so it must be applied, but it depends only on ν_z, which is measured continuously.

The continuous Stern–Gerlach effect. The remaining problem is reading the spin. A single electron emits no light one can collect, and a Stern–Gerlach deflection of a charged particle is defeated by the Lorentz force. Dehmelt's solution is to make the *axial frequency* depend on the spin state, by superimposing on the uniform field a small magnetic bottle

$$\Delta\boldsymbol{B} = B_2\left[\left(z^2 - \frac{\rho^2}{2}\right)\hat{\boldsymbol{z}} - z\rho\,\hat{\boldsymbol{\rho}}\right], \tag{112.33}$$

produced by a ring of ferromagnetic material (nickel) in the trap electrodes. In the Harvard trap $B_2 \approx 1540\,\mathrm{T/m^2}$.

Proposition 112.10 (A spin flip shifts the axial frequency)**.** *In the field of Equation* (112.33)*, a change $\Delta\mu$ in the z-component of the electron's magnetic moment shifts the axial frequency by*

$$\Delta\nu_z = \frac{\Delta\mu\, B_2}{4\pi^2 m_e \nu_z}. \tag{112.34}$$

Both a spin flip and a one-quantum cyclotron excitation change the moment by $\Delta\mu = 2\mu_\mathrm{B}$, and both therefore produce the same shift, $\Delta\nu_z \approx 4\,\mathrm{Hz}$ out of 200 MHz.

Rests on Equations (112.11) *and* (112.33)*.*

Proof. *Derives Proposition 112.10.*

The energy of a magnetic moment μ in the bottle is $U = -\mu\,\Delta B_z = -\mu B_2 z^2$ on the axis, which adds to the axial potential energy $\tfrac12 m_e\omega_z^2 z^2$ a term quadratic in z. The effective spring constant is therefore $k = m_e\omega_z^2 - 2\mu B_2$, and since $\omega_z = \sqrt{k/m_e}$,

$$|\Delta\omega_z| = \left|\frac{\partial\omega_z}{\partial k}\,\Delta k\right| = \frac{1}{2m_e\omega_z}\,|2\,\Delta\mu\, B_2| = \frac{|\Delta\mu|\ B_2}{m_e\omega_z},$$

which is Equation (112.34) after $\omega_z = 2\pi\nu_z$. The sign is fixed by the same expression: a moment aligned so as to lower its energy at large $|z|$ softens the axial spring and lowers ν_z, and the two spin states therefore sit either side of the unperturbed frequency.

For the size of $\Delta\mu$: the cyclotron energy of Equation (112.11) is $E_n = (n+\tfrac12)\hbar eB/m_e$, so the magnetic moment carried by the cyclotron motion is

$$\mu_n = -\frac{\partial E_n}{\partial B} = -\left(n+\tfrac12\right)\frac{e\hbar}{m_e} = -\left(n+\tfrac12\right)2\mu_\mathrm{B},$$

so one cyclotron quantum is worth $2\mu_\mathrm{B}$; and a spin flip changes the spin moment by $g\mu_\mathrm{B} \approx 2\mu_\mathrm{B}$ by Equation (112.3). Inserting $\Delta\mu = 2\mu_\mathrm{B} = 1.8548\times10^{-23}\,\mathrm{J/T}$, $B_2 = 1540\,\mathrm{T/m^2}$, $m_e = 9.109\,383\,713\,9\times10^{-31}\,\mathrm{kg}$ and $\nu_z = 200\,\mathrm{MHz}$,

$$\Delta\nu_z = \frac{1.8548\times10^{-23}\,\mathrm{J/T}\times 1540\,\mathrm{T/m^2}}{4\pi^2\times 9.109\,383\,713\,9\times10^{-31}\,\mathrm{kg}\times 2\times10^{8}\,\mathrm{Hz}} = 3.97\,\mathrm{Hz}.$$

□

Four hertz in two hundred megahertz is two parts in 10^8, and the axial motion can be tracked to far better than that, so a single spin flip of a single electron is a resolved, nondestructive, repeatable observation. The electron is not destroyed by the measurement

and can be interrogated for months. That is what the phrase "quantum jump spectroscopy" in Section 112.4 means.

The same apparatus loads a positron as readily as an electron, and Van Dyck, Schwinberg and Dehmelt compared the two g factors in the same trap, in the same field, with the same readout [1798]. Because everything common to the two measurements cancels in the ratio, the bound on the *difference* is far sharper than the uncertainty on either value — the same structural argument as Equation (112.6). The result and its standing as a CPT test are in Section 112.5.2.

112.3.3 The cylindrical trap and the one-electron quantum cyclotron

The Harvard apparatus that produced Equation (112.8) is a Penning trap with three further properties, each of which removes one item that would otherwise dominate the error budget.

Cylindrical electrodes, so the cavity is calculable. The classical Penning trap uses hyperboloidal electrodes, which generate Equation (112.27) exactly but whose enclosed volume is a cavity whose electromagnetic modes cannot be written down. The Harvard trap instead uses a stack of right circular cylinders — a ring, two endcaps and two compensation electrodes, gold-plated, of inner radius about 4.6 mm and comparable total length — with the compensation electrodes tuned so that the leading anharmonic term of the potential vanishes and Equation (112.27) is recovered near the centre. The price is a slightly less perfect potential; the prize is that the enclosed volume is a right circular cylindrical cavity, whose TE and TM modes are Bessel functions with analytically known frequencies. The cavity shift of the cyclotron frequency can therefore be *calculated* and corrected, rather than merely bounded [2101].

That shift is not small on the scale of the measurement. The cyclotron motion is a harmonic oscillator coupled to the modes of its enclosure, and the coupling both damps it and shifts its frequency. The damping is easily estimated. In free space a cyclotron orbit radiates at the Larmor rate, giving a damping constant

$$\gamma_c = \frac{4}{3}\,\frac{r_e\,\omega_c^2}{c}\,, \qquad r_e = \frac{e^2}{4\pi\varepsilon_0 m_e c^2} = 2.8179\times10^{-15}\,\mathrm{m}\,, \tag{112.35}$$

where r_e is the classical electron radius, itself built from the same combination $e^2/4\pi\varepsilon_0$ that appears in $\alpha = e^2/(4\pi\varepsilon_0\hbar c)$.

Derivation. A nonrelativistic charge of acceleration a radiates at the Larmor power $P = e^2a^2/(6\pi\varepsilon_0 c^3)$, in watts. On a circular orbit of angular frequency ω_c and speed v the acceleration is $a = \omega_c v$, and the kinetic energy is $E = \tfrac{1}{2}m_e v^2$, so $v^2 = 2E/m_e$ and

$$\frac{\mathrm{d}E}{\mathrm{d}t} = -P = -\frac{e^2\omega_c^2 v^2}{6\pi\varepsilon_0 c^3} = -\frac{e^2\omega_c^2}{3\pi\varepsilon_0 m_e c^3}\,E =: -\gamma_c E\,.$$

The energy therefore decays exponentially at the rate γ_c, and writing $e^2/4\pi\varepsilon_0 = r_e m_e c^2$ turns that rate into $\gamma_c = 4r_e m_e c^2\omega_c^2/(3m_e c^3) = \tfrac{4}{3}r_e\omega_c^2/c$, which is Equation (112.35). Its SI dimension is $\mathrm{m}\times 1/\mathrm{s}^2\times\mathrm{s/m} = 1/\mathrm{s}$, as a rate must be. The argument is classical, but the rate is also the spontaneous-emission rate of the $n = 1$ Landau level, because for a harmonic oscillator the classical energy-damping constant and the one-quantum decay rate coincide. □

With $\omega_c = 2\pi\times 148.9\,\mathrm{GHz}$ this gives $\gamma_c = 11.0/\mathrm{s}$, a free-space lifetime of 0.091 s for the first excited cyclotron state. Inside the cavity, when ν_c is detuned from every mode, the density of states into which the electron can radiate is suppressed and the lifetime is lengthened by an order of magnitude. This is inhibited spontaneous emission — the

counterpart of Purcell's cavity enhancement [893], observed directly for a Rydberg atom between conducting plates [1755] — and it is used here as an instrument rather than studied. Its general treatment belongs to the cavity-QED section of Chapter 122, which reserves the heading but does not yet carry the derivation. A cyclotron excited state that survives for seconds can be observed by watching the axial frequency, which is the whole measurement.

The frequency shift is the dispersive counterpart of the same coupling and is of order a part in 10^9 of ν_c, i.e. of order 10^{-6} of a_e: enormous compared with the target. Because the mode structure of a cylinder is known, the shift can be mapped by measuring the cyclotron damping rate as a function of B — the rate peaks where ν_c crosses a mode — and the measurement is then made at fields chosen to sit between modes. The cavity shift and its correction remain the largest single systematic of the experiment; this book does not reproduce the published line-by-line budget, which is in [2126, 2419].

A dilution refrigerator, so the cyclotron motion is in its ground state. The trap is operated at about 100 mK in a dilution refrigerator, with the electrodes, the vacuum enclosure and the detection amplifier all at that temperature.

Proposition 112.11 (The electron is in the cyclotron ground state)**.** *At* $B = 5.32\,\mathrm{T}$ *and* $T = 100\,\mathrm{mK}$ *the mean thermal occupation of the cyclotron oscillator is* $\bar{n} \approx 9 \times 10^{-32}$*.*

Rests on Equations (112.11) *and* (112.35)*.*

Proof. *Derives Proposition 112.11.*

The level spacing of Equation (112.11) is

$$\hbar\omega_c = h\nu_c = 6.626\,070\,15\times10^{-34}\,\mathrm{J\,s}\times1.4892\times10^{11}\,\mathrm{Hz} = 9.8675\times10^{-23}\,\mathrm{J} = 6.159\times10^{-4}\,\mathrm{eV}\,,$$

using the exact SI value of the Planck constant [2431]. In temperature units this is $h\nu_c/k_\mathrm{B} = 7.147\,\mathrm{K}$, with $k_\mathrm{B} = 1.380\,649\times10^{-23}\,\mathrm{J/K}$ exact. The Bose–Einstein occupation at $T = 0.100\,\mathrm{K}$ is

$$\bar{n} = \frac{1}{\mathrm{e}^{h\nu_c/k_\mathrm{B}T} - 1} \simeq \mathrm{e}^{-71.47} = 9\times10^{-32}\,.$$

□

The consequence is that the electron sits in $n = 0$ and stays there: a thermally excited cyclotron quantum appears roughly once in 10^{31} attempts, so any observed excitation was driven. This is what converts a classical oscillator into a two-level system that can be addressed one quantum at a time, and it is the difference between the 100 mK apparatus and the 4 K traps that preceded it. The same Bose–Einstein formula at $T = 4.0\,\mathrm{K}$ gives $\bar{n} = 1/(\mathrm{e}^{7.147/4.0} - 1) = 0.201$, and at $T = 4.2\,\mathrm{K}$ it gives 0.223: about one excitation in five, so the oscillator spends a fifth of its time out of the ground state and the cyclotron frequency is smeared by the thermally fluctuating relativistic mass shift. Two tenths is not a small number when the shift per quantum is $\delta = 179\,\mathrm{Hz}$, and it is the factor 2×10^{30} between 0.201 and 9×10^{-32} — the exponential $\mathrm{e}^{-7.147/T}$ read at the two temperatures — that turns the oscillator into a two-level system.

The same cryogenics supply the vacuum. The trap can is sealed at room temperature and cooled; every residual gas except helium freezes onto the walls, and the pressure falls below about $1\times10^{-14}\,\mathrm{Pa}$. At that pressure the collision rate with background gas is such that a single electron has been held and interrogated continuously for months, which is what makes an experiment consisting of hundreds of thousands of individual quantum jumps possible at all.

A self-excited oscillator, so the axial frequency is read continuously. The axial motion induces an image current in the endcap electrodes, which is amplified and, in the Harvard implementation, fed back to the electrode with a controlled phase and an amplitude-limiting gain. The electron's axial motion then self-oscillates at its own frequency, at a large and stable amplitude, and ν_z is read out as the frequency of a strong signal rather than inferred from a weak damped ring-down. The signal-to-noise gain is what allows the 4 Hz shift of Proposition 112.10 to be detected in a fraction of a second, and it is one of the refinements separating [2126] from [2101].

The 2023 measurement [2419] adds no new principle to this list. Its improvement by a factor of 2.2 over 2008 comes from better thermal isolation and control of the trap electrodes, longer averaging, a more thorough mapping of the cavity modes, and the accumulated understanding of an apparatus that had by then been operated for two decades. That is worth saying plainly: the most precise measurement in physics was improved not by a new idea but by twenty years of attention to the same one.

112.4 Procedure

Loading exactly one electron. Electrons are produced by a field-emission point held at the trap electrode potential, or by driving a sharp tungsten tip until it emits; a burst of them is captured by pulsing the endcap potential. The resulting cloud contains an unknown number N of electrons, and the next step is to reduce it to one. The image current driven in the detection circuit by the axial motion is proportional to N, so the amplitude of the axial resonance signal falls in *discrete, equal steps* as the trap depth is lowered and electrons are ejected one at a time. The last step before the signal vanishes identifies $N = 1$ unambiguously: this is a counting measurement, not an inference from a calibrated amplitude, and it is one of the reasons the experiment can claim to be about a single particle.

Cooling the three modes. Each mode is brought under control by a different mechanism, and all three must be cold because each couples back to the frequencies being measured through the magnetic bottle of Equation (112.33).

- *Cyclotron.* Damped radiatively into the cavity at the rate of Equation (112.35), as modified by the mode structure. Since the cavity walls are at 100 mK, the motion thermalizes to the ground state by Proposition 112.11, in a few seconds.

- *Axial.* Damped resistively by the image current it drives through the detection resistor, which is also at 100 mK; the damping time is of order 0.2 s. This is also the readout channel.

- *Magnetron.* Cannot be damped — see the discussion after Equation (112.30) — and is instead cooled by driving the axial sideband at $\nu_z + \nu_-$, which couples the two motions so that axial damping removes magnetron action, shrinking the magnetron orbit towards the trap axis.

Quantum jump spectroscopy. The electron sits in the ground state $\left|n = 0, m = -\tfrac{1}{2}\right\rangle$, with m labelling the two spin projections and the level scheme as in Equation (112.37). Two drives are applied and the axial frequency is watched for the 4 Hz step of Proposition 112.10:

- a microwave drive near $\bar{\nu}_+ = 148.9$ GHz, injected through a waveguide, which raises the cyclotron quantum number by one at fixed m;

- an anomaly drive near $\bar{\nu}_a = 172.7\,\mathrm{MHz}$, applied as an oscillating potential on a trap electrode, which drives the electron axially through the bottle field of Equation (112.33). In the electron's frame this is an oscillating transverse magnetic field at $\bar{\nu}_a$, and it drives the simultaneous transition $\left|1,-\tfrac{1}{2}\right\rangle \to \left|0,+\tfrac{1}{2}\right\rangle$ — a spin flip accompanied by the loss of one cyclotron quantum.

A spin flip is the signature, because it alone leaves the axial frequency permanently shifted while the cyclotron excitation decays back. The cyclotron line entering the denominator of Equation (112.36) is the one measured with the spin in the upper state, $\left|0,+\tfrac{1}{2}\right\rangle \to \left|1,+\tfrac{1}{2}\right\rangle$; that choice is what fixes the coefficient of the relativistic correction there at $\tfrac{3}{2}\delta$ rather than $\tfrac{1}{2}\delta$, as the proof of Proposition 112.12 shows. Each attempt yields one bit: jump or no jump. The drive frequency is stepped, several hundred attempts are made at each step, and the fraction that produce a jump traces the resonance line. Because the electron is not consumed, the same electron supplies every point of every line, which removes the particle-to-particle systematics that limited Section 112.3.1.

The lineshape, which is the dominant modelling input. The magnetic bottle that makes the readout possible also broadens the lines. The axial motion samples the bottle, so the field the cyclotron and spin motions experience is $B + B_2\langle z^2\rangle$, and $\langle z^2\rangle$ fluctuates with the axial energy. The result is a resonance whose width is set by the axial temperature and whose shape is *asymmetric*, with a tail on the high-frequency side, because $\langle z^2\rangle \geq 0$ can only raise the field. The line centre is therefore not the line maximum, and extracting it requires the lineshape model of [1769], in which the frequency executes a random walk driven by the axial energy's thermal fluctuations. Two limits of that model are used and their difference is taken as a systematic uncertainty. This is the single largest piece of theory entering the *experimental* number and the honest place to look for an unrecognized error.

Interleaving, so that field drift cancels. The superconducting solenoid drifts. Its field is regulated and the apparatus is temperature-stabilized, but a drift of a part in 10^9 over an hour would still swamp the target. The two drives are therefore interleaved on a timescale of minutes, so that $\bar{\nu}_a$ and $\bar{\nu}_+$ are measured in what is effectively the same field, and the ratio of Equation (112.10) is formed from contemporaneous data. A residual linear drift is fitted and removed; the check is that the extracted a_e is independent of the interleaving period.

The working formula. What is measured is not ν_s and ν_c but $\bar{\nu}_a$, $\bar{\nu}_+$ and $\bar{\nu}_z$, and the free-space ν_c has to be reconstructed from them.

Proposition 112.12 (The measured anomaly)**.** *In terms of the three measured trap frequencies,*

$$\frac{g}{2} = 1 + \frac{\bar{\nu}_a - \bar{\nu}_z^2/2\bar{\nu}_+}{\bar{\nu}_+ + \tfrac{3}{2}\delta + \bar{\nu}_z^2/2\bar{\nu}_+ + \Delta\nu_{\mathrm{cav}}}\,, \qquad \delta := \frac{h\nu_c}{m_e c^2}\,\nu_c\,, \tag{112.36}$$

where δ is the relativistic shift per cyclotron quantum and $\Delta\nu_{\mathrm{cav}}$ the cavity shift of Section 112.3.3.

Rests on Theorem 112.9 and Equations (112.10) and (112.29).

Proof. *Derives Proposition 112.12.*

Start from Equation (112.10), $g/2 = 1 + \nu_a/\nu_c$, and express both free-space frequencies through measured ones.

For the denominator, the invariance theorem Equation (112.32) together with $\nu_- \ll \nu_z \ll \nu_+$ gives

$$\nu_c = \sqrt{\bar{\nu}_+^2 + \bar{\nu}_z^2 + \bar{\nu}_-^2} = \bar{\nu}_+ + \frac{\bar{\nu}_z^2}{2\bar{\nu}_+}\,.$$

This is an identity, not a truncation, and it is worth saying why, because expanding the square root suggests otherwise. The second of Equation (112.29) gives $\bar{\nu}_- = \bar{\nu}_z^2/2\bar{\nu}_+$ exactly, so

$$\bar{\nu}_+^2 + \bar{\nu}_z^2 + \bar{\nu}_-^2 = \bar{\nu}_+^2 + 2\bar{\nu}_+\bar{\nu}_- + \bar{\nu}_-^2 = \left(\bar{\nu}_+ + \frac{\bar{\nu}_z^2}{2\bar{\nu}_+}\right)^2 ,$$

and the $-\frac{1}{8}\bar{\nu}_z^4/\bar{\nu}_+^3$ that the binomial expansion produces is cancelled term for term by $\bar{\nu}_-^2/2\bar{\nu}_+$; at the operating point of Equation (112.31) the two are $\mp 6.06 \times 10^{-2}\,\mathrm{Hz}$ and their sum is zero to machine precision. What is actually neglected is not a power of $\bar{\nu}_z/\bar{\nu}_+$ but the departure of the measured $\bar{\nu}_-$ from $\bar{\nu}_z^2/2\bar{\nu}_+$ in a tilted and elliptical trap, which is second order in the misalignment and is the content of Theorem 112.9.

Next the relativistic correction. The cyclotron levels are not exactly equally spaced, because the electron's mass grows with its energy. Expanding $E = \sqrt{(pc)^2 + (m_e c^2)^2}$ to first order beyond the nonrelativistic term and evaluating in the Landau basis gives the level scheme [1769]

$$\frac{E(n,m)}{h} = \left(n + \tfrac{1}{2}\right)\nu_c + \frac{g}{2}\,m\,\nu_c - \frac{\delta}{2}\left(n + \tfrac{1}{2} + m\right)^2 , \tag{112.37}$$

with $m = \pm\frac{1}{2}$ the spin projection and $\delta/\nu_c = h\nu_c/m_e c^2$ the ratio of one cyclotron quantum to the electron rest energy. Everything relativistic sits in the last term, which is quadratic in the total excitation $n + \frac{1}{2} + m$ because the leading correction to $E = \sqrt{(pc)^2 + (m_e c^2)^2}$ is $-p^4/8m_e^3c^2$, that is, minus the square of the nonrelativistic energy divided by $2m_e c^2$.

Evaluate it on the two transitions actually driven. The cyclotron line used for the denominator connects $(0, +\frac{1}{2}) \to (1, +\frac{1}{2})$, so the bracket $(n + \frac{1}{2} + m)^2$ runs from 1^2 to 2^2 and

$$\bar{\nu}_+\big|_{\mathrm{rel}} = \nu_c - \frac{\delta}{2}\left(2^2 - 1^2\right) = \nu_c - \frac{3}{2}\delta\,.$$

The anomaly drive connects $(1, -\frac{1}{2}) \to (0, +\frac{1}{2})$, for which the bracket takes the value 1^2 at *both* ends, so the relativistic term cancels identically and the anomaly transition is unshifted — which is the reason the correction appears in the denominator of Equation (112.36) and not in the numerator. Adding $\frac{3}{2}\delta$ back to $\bar{\nu}_+$ in the denominator and leaving the numerator alone therefore reconstructs ν_c and ν_a respectively, and finally $\nu_a = \bar{\nu}_a + \bar{\nu}_+ - \nu_c = \bar{\nu}_a - \bar{\nu}_z^2/2\bar{\nu}_+$ because the anomaly drive is referred to the trap cyclotron frequency, not the free-space one. Collecting the pieces and adding the cavity shift as an explicit correction to ν_c gives Equation (112.36). □

The sizes are worth recording, because they show which corrections matter. At $B = 5.32\,\mathrm{T}$, $h\nu_c/m_e c^2 = 1.21 \times 10^{-9}$, so $\delta = 179\,\mathrm{Hz}$ and $\frac{3}{2}\delta = 269\,\mathrm{Hz}$, against $\bar{\nu}_+ = 148.9\,\mathrm{GHz}$: a fractional correction of 1.8×10^{-9}, which is 1.6×10^{-6} of a_e and four orders of magnitude above the target. The magnetron term $\bar{\nu}_z^2/2\bar{\nu}_+ = 134\,\mathrm{kHz}$ is larger still. Neither is a source of uncertainty, because both are computed from measured quantities; the cavity shift is, because it is computed from a model of the cavity.

Blind analysis. An unknown offset, drawn from a distribution wide compared with the expected uncertainty and unknown to the analysts, is added in software to the extracted $\bar{\nu}_a$. All lineshape choices, cuts, drift models and systematic corrections are fixed with the offset in place; only then is it removed and the value revealed. This protects against the specific failure mode of a measurement whose expected answer is known to ten digits in advance, which is otherwise very hard to guard against and which the 2008 and 2023 analyses both took seriously [2126, 2419].

112.5 Observations and data

112.5.1 The measured electron anomaly

Table 112.1: Determinations of the electron magnetic moment anomaly $a_e = (g-2)/2$. The first two entries are historical and are quoted to the precision their methods supported. The last three come from the same Harvard apparatus and are *not* independent: each supersedes its predecessor, and the systematic analysis is cumulative. The final row is not a measurement but the CODATA 2022 least-squares adjustment, which combines the measurements with the QED series and with the recoil determinations of α. "Fractional" is the standard uncertainty divided by a_e itself; note that the experimental papers customarily quote instead the uncertainty on $g/2$, which is smaller by the factor $a_e/(1+a_e) \approx 1/863$.

year	method	$a_e \times 10^3$	fractional	source
1948	atomic beam resonance	≈ 1.2	$\sim 10^{-2}$	[912, 916]
1963	free-electron precession	1.159622(27)	2.3×10^{-5}	[1268]
2006	one-electron quantum cyclotron	1.15965218085(76)	6.6×10^{-10}	[2101]
2008	one-electron quantum cyclotron	1.15965218073(28)	2.4×10^{-10}	[2126]
2023	one-electron quantum cyclotron	1.15965218059(13)	1.1×10^{-10}	[2419]
2022	CODATA adjustment	1.15965218046(18)	1.6×10^{-10}	[2431]

Table 112.1 is the chapter's primary data, and three features of it need comment.

Two different fractional precisions are in circulation. The experimental papers quote parts per trillion *on* $g/2$; this book quotes the fractional uncertainty *on* a_e, because that is what is compared with a calculation. The two differ by the factor $(g/2)/a_e = (1+a_e)/a_e = 863$. So [2419]'s "0.13 parts per trillion" is 1.3×10^{-13} absolute, which is 1.1×10^{-10} of a_e — about 0.11 parts per billion. Likewise [2126]'s 0.28 parts per trillion is 0.24 parts per billion of a_e, and [2101]'s 0.76 parts per trillion is 0.66 parts per billion. Quoting the smaller number is not wrong, but a reader who compares it against the theoretical uncertainty — which is naturally expressed on a_e — without converting will be out by nearly three orders of magnitude.

The three Harvard values are consistent and correlated. The 2023 value lies 1.4×10^{-13} below the 2008 value, about half of the 2008 standard uncertainty, and 2.6×10^{-13} below the 2006 value, a third of its uncertainty. They are not independent measurements that happen to agree: the same trap, the same solenoid and much of the same systematic analysis are shared, so the correct statement is that the successive refinements did not move the number, which is a weaker but still meaningful check.

The CODATA value is not an independent measurement. The 2022 adjustment value $1.15965218046(18) \times 10^{-3}$ [2431] sits 1.3×10^{-13} below [2419], within the combined uncertainty. It must not be used to test the QED series, because the series is one of the inputs from which it was derived. This is the circularity that Section 112.7 is about.

Table 112.2 makes the structure of the prediction visible, and the count of figures each order buys is worth doing rather than guessing. Comparing each running sum with the measured $1.15965218059 \times 10^{-3}$: one loop is off by 1.5×10^{-3} fractionally, so it agrees to three significant figures; two loops by 1.3×10^{-5}, five figures; three loops by 4.4×10^{-8}, seven figures. Beyond that the terms themselves say where they land. The fourth-order term

Table 112.2: The theoretical value of a_e, term by term, evaluated at the CODATA 2022 fine-structure constant $\alpha^{-1} = 137.035999177(21)$ [2431] with the coefficients of Equation (112.14). The expansion parameter is $\alpha/\pi = 2.322\,819\times10^{-3}$. Every entry is dimensionless. The last column is the running sum, and the comparison with the measured $1.15965218059(13) \times 10^{-3}$ is made in Section 112.7.

order	term	value	running sum
α^1	$C_1(\alpha/\pi)$	$+1.1614097321 \times 10^{-3}$	$1.1614097321 \times 10^{-3}$
α^2	$C_2(\alpha/\pi)^2$	$-1.7723050605 \times 10^{-6}$	$1.1596374270 \times 10^{-3}$
α^3	$C_3(\alpha/\pi)^3$	$+1.4804203632 \times 10^{-8}$	$1.1596522312 \times 10^{-3}$
α^4	$C_4(\alpha/\pi)^4$	$-5.5667966898 \times 10^{-11}$	$1.1596521756 \times 10^{-3}$
α^5	$C_5(\alpha/\pi)^5$	$+4.5555816 \times 10^{-13}$	$1.1596521760 \times 10^{-3}$
—	$a_e^{\mu,\tau}$	$+2.7478 \times 10^{-12}$	$1.1596521788 \times 10^{-3}$
—	a_e^{had}	$+1.6927 \times 10^{-12}$	$1.1596521805 \times 10^{-3}$
—	a_e^{weak}	$+0.0305 \times 10^{-12}$	$1.1596521805 \times 10^{-3}$

is 4.8×10^{-8} of a_e and therefore occupies the eighth figure; the muon-loop and hadronic terms (2.4×10^{-9} and 1.5×10^{-9} of a_e) the ninth; the fifth-order term (3.9×10^{-10}) the tenth, which is where the experiment's own 1.1×10^{-10} now lives; and the electroweak term (2.6×10^{-11}) the eleventh, below it. Notice that $a_e^{\mu,\tau} + a_e^{\text{had}} = 4.44\times10^{-12}$ is *thirty-four times* the experimental uncertainty: the electron anomaly is no longer a pure QED observable, and a comparison that omitted the hadronic term would fail by an amount easily resolved.

Table 112.3: Independent determinations of the fine-structure constant, and the CODATA 2022 recommended value. The two recoil measurements use different atomic species, different interferometric schemes and different atom-to-electron mass ratios, and they disagree by 1.60×10^{-7} in α^{-1}, about 5.5 times their combined standard uncertainty. The last column is the resulting standard uncertainty on the *predicted* a_e, computed as $\delta a_e = \delta\alpha/2\pi$ from Equation (112.25), and is to be compared with the experimental 1.3×10^{-13}.

year	method	α^{-1}	δa_e	source
2018	caesium recoil, atom interferometer	137.035999046(27)	2.29×10^{-13}	[2316]
2020	rubidium recoil, Bloch oscillations	137.035999206(11)	9.32×10^{-14}	[2363]
2022	CODATA adjustment (not independent)	137.035999177(21)	1.78×10^{-13}	[2431]

112.5.2 Positrons and the CPT test

Phenomenon 112.13 (Electron and positron moments agree)**.** The g factors of the electron and of the positron, measured in the same Penning trap with the same field and the same readout, agree to about two parts in 10^{12} [1798]. No difference between the magnetic moment of a lepton and that of its antilepton has ever been observed.

Rests on Theorem 105.37 and Equation (112.36)*.*

Derivation. *Derives Phenomenon 112.13.*

That the two moments must have equal magnitude and opposite sign is not an assumption of this chapter but a theorem, proved in Theorem 105.37 from the transformation of the electromagnetic current operator under the antiunitary CPT operator: the magnetic moment operator $\hat{\boldsymbol{\mu}} = \frac{1}{2}\int \mathrm{d}^3x\, \boldsymbol{x} \times \boldsymbol{j}$ is CPT-even, because the sign the current picks up is cancelled

by the reflection of its spatial argument, while the state of maximal spin projection maps to the antiparticle state of *opposite* spin projection — so the moment per unit spin reverses. The companion statement that the masses are equal is Theorem 105.36. Both rest only on locality, Lorentz invariance and the positivity of the energy spectrum, which is what gives a null result here its unusual weight: a nonzero difference would falsify one of those three.

The experimental value is a ratio, and it is sharper than either absolute measurement for the reason already used at Equation (112.6). Writing g_- and g_+ for the electron and positron g factors measured in the same field B, each is extracted from Equation (112.36) using frequencies measured in that field; forming

$$\frac{g_- - g_+}{g_{\mathrm{avg}}}$$

cancels the cavity shift, the relativistic correction, the lineshape model and the field itself to the extent that they are common to the two species — and they are common, because the two particles differ only in the sign of the charge and therefore occupy the same trap with the same geometry. Van Dyck, Schwinberg and Dehmelt bounded this ratio at about 2×10^{-12} [1798], which is where the entry in Table 105.2 comes from. It remains the sharpest lepton CPT test of this type; the kaon rest-energy comparison of Chapter 111 is often quoted as sharper, but the two numbers are normalized by different quantities and are not directly comparable — a point made carefully in Section 105.5.3. □

112.6 The muon anomaly

The muon anomaly is included in this chapter as a contrast, not as a digression. It is the same observable computed from the same series, measured by an entirely different technique, and its status is the opposite of the electron's: the experiment is nearly two thousand times less precise in fractional terms (2.1×10^{-7} against 1.1×10^{-10}, from Tables 112.1 and 112.4), the theory is far less certain, and the comparison currently does not agree. Setting the two side by side is the clearest way to show what a precision test actually consists of.

112.6.1 CERN and Brookhaven

A muon lives for

$$\tau_\mu = \frac{\hbar}{\Gamma_\mu} = \frac{1.054\,571\,817 \times 10^{-34}\,\mathrm{J\,s}}{4.800 \times 10^{-29}\,\mathrm{J}} = 2.197 \times 10^{-6}\,\mathrm{s}\,, \tag{112.38}$$

the width $\Gamma_\mu = 2.995\,983\,6 \times 10^{-19}\,\mathrm{GeV} = 4.800 \times 10^{-29}\,\mathrm{J}$ being the PDG value [2427]. Two microseconds is not long enough to trap a muon and interrogate it for months, so the whole strategy of Section 112.3.2 is unavailable. Instead the muon is stored relativistically in a ring, and the anomaly is read out exactly as in Proposition 112.7: as an angle that accumulates between the spin and the momentum.

Storage rings at CERN. Three generations of muon storage ring were built at CERN between 1961 and 1977. The final one stored polarized muons of both signs at a momentum of about $3.1\,\mathrm{GeV}/c$ in a ring of 14 m diameter, and reported the anomaly to about seven parts per million — together with a direct measurement of relativistic time dilation, using the same stored muons, which is written up as an experiment in its own right at Section 41.4 [1592, 1632]. The readout exploits the parity violation of the weak interaction (Chapter 110): in the decay $\mu^+ \to e^+ \nu_e \bar{\nu}_\mu$ the highest-energy positrons are emitted preferentially along the muon spin, so counting decay positrons above an energy threshold as a function of time gives a decaying exponential with a superimposed oscillation, and the oscillation frequency is ν_a.

The magic momentum. A ring needs electrostatic quadrupoles for vertical focusing, and an electric field spoils Equation (112.10): a moving magnetic moment in an electric field precesses too. The Bargmann–Michel–Telegdi equation [1165] gives the precession of the spin relative to the momentum, for a particle of charge q and mass m moving with $\boldsymbol{\beta} = \boldsymbol{v}/c$ perpendicular to $\boldsymbol{B}$, as

$$\boldsymbol{\omega}_a = -\frac{q}{m}\left[a\,\boldsymbol{B} - \left(a - \frac{1}{\gamma^2 - 1}\right)\frac{\boldsymbol{\beta}\times\boldsymbol{E}}{c}\right], \tag{112.39}$$

with $\gamma = (1-\beta^2)^{-1/2}$ and a the anomaly of the particle in question. Both terms have SI dimensions of rad/s: qB/m is a cyclotron frequency, and $q\beta E/(mc)$ is the same thing with E/c playing the part of a magnetic field, which is the correct SI statement of the fact that $\boldsymbol{E}/c$ and $\boldsymbol{B}$ are components of one field tensor.

Proposition 112.14 (The magic momentum)**.** *The electric field drops out of Equation* (112.39) *at the Lorentz factor*

$$\gamma_{\text{magic}} = \sqrt{1 + \frac{1}{a_\mu}} = 29.3034\,, \tag{112.40}$$

corresponding to a muon momentum of $p = \gamma_{\text{magic}}\beta\, m_\mu c = 3.094\,\text{GeV}/c = 1.6537 \times 10^{-18}\,\text{kg m/s}$.

Rests on Equation (112.39).

Proof. *Derives Proposition 112.14.*

The bracket in Equation (112.39) loses its electric term when $a_\mu = 1/(\gamma^2-1)$, that is $\gamma^2 = 1 + 1/a_\mu$, which is Equation (112.40); with the CODATA 2022 muon anomaly $a_\mu = (1.165\,920\,62 \pm 0.000\,000\,41) \times 10^{-3}$ [2431] this gives $1 + 1/a_\mu = 858.69$ and $\gamma_{\text{magic}} = 29.3034$, hence $\beta = 0.9994175$. The momentum follows from $p = \gamma\beta m_\mu c$ with the PDG muon rest energy $m_\mu c^2 = (0.105\,658\,375\,5 \pm 0.000\,000\,002\,3)$ GeV [2427]:

$$pc = 29.3034 \times 0.9994175 \times 0.105\,658\,375\,5\,\text{GeV} = 3.0944\,\text{GeV}\,,$$

so $p = 3.0944\,\text{GeV}/c$, which in SI base units is $3.0944 \times 10^9\,\text{eV} \times 1.602\,176\,634 \times 10^{-19}\,\text{J/eV} / 2.997\,924\,58 \times 10^8\,\text{m/s} = 1.6537 \times 10^{-18}\,\text{kg m/s}$. □

At that momentum, with the ring's magnetic field and radius, the kinematics is fixed and can be checked against itself. Brookhaven's E821 — and, later, Fermilab's E989, which reuses the same magnet — has a storage radius $r = 7.112\,\text{m}$ and a field $B = 1.4513\,\text{T}$, and the momentum a ring of that geometry selects is

$$p = eBr = 1.602\,176\,634 \times 10^{-19}\,\text{C} \times 1.4513\,\text{T} \times 7.112\,\text{m} = 1.6537 \times 10^{-18}\,\text{kg m/s}\,, \tag{112.41}$$

which is Proposition 112.14 to five figures. The ring was built to the magic momentum, and the agreement of Equation (112.41) with Proposition 112.14 is a consistency check on the numbers quoted here rather than an independent fact.

Brookhaven's E821 measured a_μ to 0.54 parts per million and reported a value about 2.5 standard deviations above the Standard Model evaluation then current [2091]. That discrepancy is what motivated everything in Sections 112.6.2 and 112.6.3.

112.6.2 Fermilab E989

The E821 storage ring — a 14.2 m diameter superconducting magnet, too large to disassemble — was transported intact from Brookhaven to Fermilab in 2013 and rebuilt there with a far more intense and cleaner muon beam, a completely new detector system, and roughly a threefold improvement in field uniformity. The experimental scales are worth listing, since each is derived above:

- cyclotron period $T_c = 2\pi r/\beta c = 149\,\text{ns}$;
- anomalous precession period $1/\nu_a = 4.37\,\mu\text{s}$, from $\nu_a = a_\mu eB/2\pi m_\mu = 229\,\text{kHz}$, so the spin turns once relative to the momentum every 29 turns of the ring;
- dilated muon lifetime $\gamma\tau_\mu = 29.3034 \times 2.197\,\mu\text{s} = 64.4\,\mu\text{s}$, giving about 15 anomalous precession cycles per lifetime and a usable observation window of several hundred microseconds.

Two frequencies are measured. The first is ω_a, from the oscillation in the decay-positron time spectrum described above. The second is not B but ω_p, the Larmor precession frequency of a free proton in the same field, measured by pulsed nuclear magnetic resonance in water-based probes on a trolley that is driven around the storage region to map the field, cross-calibrated against a spherical-water standard. The anomaly is then extracted as

$$a_\mu = \frac{\omega_a}{\omega_p} \cdot \frac{\mu_p}{\mu_e} \cdot \frac{m_\mu}{m_e} \cdot \frac{|g_e|}{2}\,, \tag{112.42}$$

a product of one measured ratio with three externally known ones, each taken as a magnitude in the sense of Equation (112.4). Note what has happened: the field has again cancelled, and the price is that the muon anomaly depends on the proton-to-electron moment ratio, the muon-to-electron mass ratio and the electron g factor — the last of which is the subject of the rest of this chapter. The two measurements are not as independent as they look.

As at Harvard, the analysis is blind: a frequency offset unknown to the analysis teams is applied to the reference clock in hardware, and the several independent analysis groups agree their result before it is removed. The published values are 0.46 parts per million from the first data set [2368] and 0.20 parts per million from the second and third [2416]; they agree with each other and with Brookhaven.

Table 112.4: The muon anomaly: measurements, the recommended value, and the Standard Model evaluation. The four measurements are independent experiments and agree; the disagreement is between the measurements as a group and the prediction. The last two rows show that the prediction depends on which evaluation of the leading hadronic vacuum polarization is used — the data-driven dispersive one or the lattice one — and that the two do not agree with each other. See the text: the tension is currently between two theoretical evaluations of one hadronic quantity, and no claim of physics beyond the Standard Model follows from it.

year	source of the number	$a_\mu \times 10^3$	reference
1979	CERN muon storage ring	1.165924(9)	[1632]
2006	BNL E821 (0.54 ppm)	1.16592089(63)	[2091]
2021	FNAL E989, first data set	1.16592040(54)	[2368]
2023	FNAL E989, later data sets	1.16592055(24)	[2416]
2022	CODATA recommended	1.16592062(41)	[2431]
2020	Standard Model, data-driven HVP	1.16591810(43)	[2353]
2021	the same, with lattice HVP	$\approx$ 1.16591954(57)	[2375]

112.6.3 Hadronic vacuum polarization: lattice versus data-driven

By Phenomenon 112.4 the hadronic contribution to a_μ is some 4.3×10^4 times that to a_e, which puts it at about 7×10^{-8} — three hundred times the experimental uncertainty of Table 112.4. It is therefore the dominant theoretical uncertainty, and since it cannot be computed perturbatively (Chapter 102) it must be obtained some other way.

The dispersive route. The photon self-energy is an analytic function of $s = (pc)^2$ with a cut along the positive real axis, and the discontinuity across the cut is fixed by the optical theorem to be the total cross section for the photon to make hadrons — which is measured, in e^+e^- annihilation, as the ratio $R(s)$ of Phenomenon 102.15. A dispersion relation then converts the measured cross section into the contribution to the anomaly:

$$a_\ell^{\mathrm{HVP,LO}} = \frac{1}{3}\left(\frac{\alpha}{\pi}\right)^2 \int_{s_{\mathrm{th}}}^{\infty} \frac{\mathrm{d}s}{s}\, R(s)\, K(s)\,, \qquad K(s) \to \frac{m_\ell^2 c^4}{3s} \quad \text{for } s \gg m_\ell^2 c^4\,, \tag{112.43}$$

with $s_{\mathrm{th}} = 4m_\pi^2 c^4$ the two-pion threshold, R and K both dimensionless, and s carrying SI dimensions of J^2. The asymptotic form of the kernel is where the m_ℓ^2 scaling of Equation (112.17) comes from, and the $1/s$ weighting is why the integral is dominated by the lowest resonances: about 73 % of the muon integral comes from the ρ resonance region, that is from $e^+e^- \to \pi^+\pi^-$ below 1 GeV, equivalently 1.602×10^{-10} J. The factor $1/3$ in the asymptotic kernel is the same one that carried the derivation of Equation (112.18), where the known two-loop coefficient $1/45$ fixes it independently.

Derivation pending #198

The dispersive representation of the hadronic vacuum-polarization contribution to a lepton anomaly: analyticity of the photon self-energy, the optical theorem relating its discontinuity to the total hadronic cross section, and the derivation of the kernel $[K(s)]$ from the one-loop vertex with a dressed photon propagator. Belongs in Appendix A.

The two evaluations disagree. Carrying out Equation (112.43) over the compiled world data gives the leading-order hadronic term $a_\mu^{\mathrm{HVP,LO}} = 693.1(4.0) \times 10^{-10}$ [2353], which is the input to the data-driven prediction in Table 112.4. Computing the same quantity directly from the Euclidean correlator on the lattice, without any cross-section data, gives $707.5(5.5) \times 10^{-10}$ [2375]. The difference, $14.4(6.8) \times 10^{-10}$, is about 2.1 standard deviations between two calculations of one number, and it is nearly the whole of the measurement–prediction gap. Substituting the lattice value moves the prediction from the $1.16591810(43) \times 10^{-3}$ of Table 112.4 to about $1.16591954 \times 10^{-3}$, and against the Fermilab measurement $1.16592055(24) \times 10^{-3}$ of that same table [2416] the difference falls from 2.45×10^{-9}, which is 5.0 combined standard deviations, to 1.01×10^{-9}, which is 1.6. No world average is used here: both numbers are rows of Table 112.4, so the arithmetic can be checked against the table.

And the input data are themselves in conflict. The CMD-3 experiment at Novosibirsk measured the $e^+e^- \to \pi^+\pi^-$ cross section from threshold to 1.2 GeV, that is 1.923×10^{-10} J, and obtained a result several per cent above every previous measurement in the dominant ρ region [2426]. Used in Equation (112.43) it would raise the data-driven $a_\mu^{\mathrm{HVP,LO}}$ towards the lattice value and remove much of the discrepancy — but it is inconsistent with the earlier data sets, so it cannot simply be averaged in. The honest description of the present situation is therefore a chain of three disagreements: between two theoretical evaluations of the hadronic term, between two sets of hadronic cross-section measurements, and between the resulting prediction and the muon measurement. Only the last of these would be evidence of anything new, and it cannot be assessed until the first two are settled.

The subleading hadronic light-by-light term, of order 9×10^{-10}, carries an uncertainty of about 2×10^{-10} [2353]: smaller than the vacuum polarization discrepancy, but not negligible, and it is not constrained by any dispersion relation as directly.

112.6.4 Status

Three things would settle the question, and none of them is a new theory.

1. *Independent lattice computations of the same quantity.* The lattice result [2375] is one collaboration's. The sharpest way to test it is not to recompute the whole integral but to compare restricted "window" observables — the correlator integrated over a bounded range of Euclidean time — which are cleaner on the lattice and can also be extracted from the cross-section data. Several groups now do this, and it localizes the disagreement in Euclidean time rather than merely confirming it.

2. *A resolution of the two-pion cross-section conflict.* Either the CMD-3 measurement [2426] or the earlier body of data is wrong, and the discrepancy is large enough that it should be resolvable by further measurements with different systematics.

3. *The complete Fermilab data set.* The measurement in Table 112.4 uses part of the collected data; the final analysis roughly halves the experimental uncertainty again. This sharpens the comparison but cannot resolve it, because the limitation is theoretical.

A fourth route deserves mention because it is orthogonal to all three: measuring the hadronic contribution to the running of α directly in elastic muon–electron scattering, which would give $a_\mu^{\mathrm{HVP,LO}}$ from a single spacelike measurement with systematics unrelated to either the annihilation data or the lattice. A proposal of this kind exists at CERN; no primary reference for it is available in this book's bibliography, and the claim is therefore made without a citation rather than with an invented one.

What must not be said is that the muon anomaly shows physics beyond the Standard Model. Under this book's first editorial rule the tension is reported, not interpreted: the measurements agree with one another, the theoretical evaluations do not agree with one another, and the difference between the two theoretical evaluations is comparable to the difference between theory and experiment. The open problems chapter Chapter 133 collects the questions this book regards as unresolved; the muon anomaly is not among the entries currently written there, and on the reading given here it does not yet qualify — it is an unresolved *calculation*, not an unexplained observation.

112.7 Interpretation

The question this section answers is: how many digits are actually verified? The headline numbers invite the answer "twelve", and that answer is wrong. The comparison has to be run in both directions before it can be stated honestly.

112.7.1 Direction one: theory plus α against the measured a_e

Evaluate Equation (112.13), with the coefficients of Equation (112.14) and the non-QED terms of Equations (112.15) and (112.16), at each of the independently measured values of α in Table 112.3, and subtract the measured a_e of Equation (112.8).

Table 112.5 is the chapter's central result, and it should be read slowly. The same measurement, the same series and the same non-QED corrections give a discrepancy of 3.9 standard deviations with one input for α and 2.1 with the other. Neither is a comfortable agreement; they are on opposite sides of the measurement; and the difference between the two rows is entirely due to the disagreement between two atom-recoil experiments, which is a problem in atomic physics and has nothing whatever to do with QED.

Table 112.5: The test of quantum electrodynamics, run three ways. Each row evaluates the QED series at one determination of α and compares the result with the measured $a_e = 1.15965218059(13) \times 10^{-3}$ [2419]. The combined uncertainty adds in quadrature the experimental one, the propagated uncertainty of the α input from Table 112.3, and about 2×10^{-14} for the truncation of the series and the hadronic term. The verdict of the test depends on which α is used, which is the point of this section. The third row is shown for completeness and is *not* a test: the CODATA adjustment uses a_e and the QED series as inputs, so the comparison is circular.

α input	source	$a_e^{\mathrm{th}} \times 10^3$	$a_e^{\mathrm{exp}} - a_e^{\mathrm{th}}$	deviation
caesium 2018	[2316]	1.1596521816	-1.02×10^{-12}	3.9σ
rubidium 2020	[2363]	1.1596521803	$+3.36 \times 10^{-13}$	2.1σ
CODATA 2022	[2431]	1.1596521805	$+9.05 \times 10^{-14}$	0.4σ (circular)

Phenomenon 112.15 (The test is limited by its input, not by the measurement)**.** The comparison of the measured electron anomaly with its calculated value confirms quantum electrodynamics to a fractional precision of about 1.2×10^{-9} in a_e — roughly nine significant figures — and not to the eleven or twelve figures that the experimental precision alone would allow. The limitation is the independent determination of α [2316, 2363, 2419].

Rests on Equation (112.25).

Derivation. *Derives Phenomenon 112.15.*

The spread in the predicted a_e produced by the two α inputs is $\delta a_e = 1.4 \times 10^{-12}$ by Equation (112.25). Fractionally,

$$\frac{\delta a_e}{a_e} = \frac{1.4 \times 10^{-12}}{1.15965 \times 10^{-3}} = 1.2 \times 10^{-9}\,,$$

which is nine significant figures. The experimental uncertainty is 1.3×10^{-13}, or 1.1×10^{-10} fractionally — eleven figures — and the series truncation and hadronic uncertainty together contribute about 2×10^{-14}, or twelve figures. The largest of the three is the α input, by a factor of ten over the experiment, so it is the α input that sets the verdict. A test is only as sharp as its least well known ingredient, and quoting the sharpest ingredient instead is the specific error this chapter exists to avoid. □

112.7.2 Direction two: the measurement plus theory against α

The same three ingredients can be arranged differently. Take the QED series as correct, insert the measured a_e, and solve Equation (112.13) for α. Inverting the series numerically with the coefficients of Equation (112.14) at the measured value of Equation (112.8) gives

$$\alpha^{-1}\,(a_e) = 137.035999166(15)\,, \tag{112.44}$$

the uncertainty being the experimental 1.3×10^{-13} on a_e propagated back through $\delta\alpha = 2\pi\,\delta a_e$. That is a fractional uncertainty of 1.1×10^{-10}, and it is worth checking that figure against Table 112.3 rather than repeating the claim usually attached to it. The three fractional uncertainties on α^{-1} are $1.5 \times 10^{-8}/137.036 = 1.09 \times 10^{-10}$ here, $2.7 \times 10^{-8}/137.036 = 1.97 \times 10^{-10}$ for the caesium recoil [2316], and $1.1 \times 10^{-8}/137.036 = 8.03 \times 10^{-11}$ for the rubidium one [2363]. So the anomaly route is 1.8 times sharper than caesium and 1.4 times *blunter* than rubidium: it is competitive with the best recoil measurement, not better than it, and Table 112.3 says so already in its δa_e column, where the rubidium entry 9.32×10^{-14} sits below the experimental 1.3×10^{-13} that this paragraph propagates.

It is also not a test of anything. Equation (112.44) assumes the QED series in order to produce α; using it to check the QED series would be circular, and the same is true of the CODATA recommended value, which is an adjustment containing Equation (112.44) as one of its inputs. This is the distinction the chapter has been building towards, and it can now be stated flatly:

- If α is taken from the anomaly itself, the exercise is a *definition*. It produces the best available value of α and tests nothing.
- If α is taken from an independent measurement — and atom recoil is the only method currently competitive — the exercise is a *test*, and its sharpness is bounded by Phenomenon 112.15.

Notice, incidentally, that Equation (112.44) lies between the caesium and rubidium values and is closer to the rubidium one, differing from it by 4.0×10^{-8} and from the caesium one by 1.2×10^{-7}. That is a statement about which recoil experiment is more likely to be in error *if* QED is right; it is not evidence about QED.

112.7.3 What the agreement bounds

Whatever else is true, the electron anomaly agrees with a parameter-free calculation to about 10^{-12} in absolute terms, and that constrains anything not in the calculation.

Electron substructure. If the electron were a bound state of constituents held together at a scale Λ, the anomaly would acquire a contribution of order $(m_e c^2/\Lambda)^2$ from the compositeness. Requiring it to be smaller than the $\delta a_e = 1.4 \times 10^{-12}$ of Equation (112.25),

$$\Lambda \gtrsim \frac{m_e c^2}{\sqrt{\delta a_e}} = \frac{0.510\,998\,950\,69\,\mathrm{MeV}}{\sqrt{1.4 \times 10^{-12}}} = 432\,\mathrm{GeV} = 6.92 \times 10^{-8}\,\mathrm{J}\,, \tag{112.45}$$

using the CODATA electron rest energy [2431]. The electron is pointlike down to a distance $\hbar c/\Lambda \approx 4.6 \times 10^{-19}\,\mathrm{m}$, less than a thousandth of the proton charge radius $(8.4075 \pm 0.0064) \times 10^{-16}\,\mathrm{m}$ [2431].

New particles coupling at loop level. The weaker but more generic bound applies to a state that couples to the electron with roughly electromagnetic strength and therefore contributes only at one loop. Equation (112.20) then gives

$$Mc^2 \gtrsim m_e c^2 \sqrt{\frac{\alpha}{\pi\,\delta a_e}} = 20.8\,\mathrm{GeV} = 3.33 \times 10^{-9}\,\mathrm{J}\,,$$

using $\delta a_e = 1.4 \times 10^{-12}$ again. The muon's sensitivity in the same sense is read off Table 112.4 as the combined uncertainty of the comparison there, $\delta a_\mu = \sqrt{(2.4 \times 10^{-10})^2 + (4.3 \times 10^{-10})^2} = 4.9 \times 10^{-10}$, the two entries being the Fermilab measurement and the data-driven Standard Model evaluation. The same expression with the muon's mass then gives $Mc^2 \gtrsim 230\,\mathrm{GeV} = 3.69 \times 10^{-8}\,\mathrm{J}$. The muon reaches about eleven times higher while being some 350 times *less* sensitive in δa, two and a half orders of magnitude, because the reach grows only as $\delta a^{-1/2}$: the factor 350 costs $\sqrt{350} \approx 19$ in mass, and the mass ratio 206.7683 more than repays it. That is Remark 112.5 made numerical. The two anomalies are not competitors: the electron's is the test of QED, the muon's is the search.

What it does not bound. The agreement says nothing about physics that does not couple to the electron's magnetic moment, and nothing about the parts of the Standard Model that do not enter at this order — the electroweak contribution to a_e is 3×10^{-14}, below the experimental uncertainty, so the electron anomaly does not test the electroweak sector of Chapter 104 at all. It is a test of quantum electrodynamics specifically, and it is the sharpest one there is.

112.7.4 A closing accounting

Set out plainly, the state of the comparison is this. The measurement is secure to 1.3×10^{-13} and has been improved twice by the same group without moving. The QED series is computed to fifth order, contributes at the eleventh figure, and its fifth-order coefficient is disputed by an independent recomputation [2343] at a level that does not currently matter but would if the input improved. The hadronic contribution is thirteen times the experimental uncertainty and is taken from the muon programme's dispersive machinery, so the electron anomaly is no longer purely a QED observable. And the fine-structure constant, the one ingredient that must come from elsewhere, is known from two experiments that disagree by five and a half standard deviations.

The correct summary sentence is therefore not "QED has been verified to twelve significant figures". It is: *the measured and calculated electron anomalies agree to about nine significant figures, which is the precision of the best independent fine-structure constant, and the remaining three figures of experimental precision are waiting for atomic physics to resolve a discrepancy of its own.* That is a less impressive sentence and a true one.

112.8 Primary references

The chapter rests on four groups of sources, and they are of different kinds.

The prediction. Dirac's 1928 paper [596] is where $g = 2$ appears, as a consequence rather than an assumption; the derivation reproduced in this book is at Phenomenon 93.3. Schwinger's 1948 letter [919] is the one-loop anomaly, a page long, and it is the founding calculation of renormalized quantum field theory as a predictive rather than a formal enterprise; the full derivation is Theorem 100.41. For the modern series the standing reference is Aoyama, Kinoshita and Nio's review [2330], which supersedes the same group's earlier tenth-order papers [2190, 2302] and is the source of every coefficient in Equation (112.14) and of the mass-dependent, hadronic and electroweak terms. It should be read together with Volkov's independent five-loop computation [2343], which does not agree with it; citing the review alone would misrepresent the state of the calculation, which is why both appear wherever the fifth-order coefficient is used. Kinoshita's analysis of mass singularities [1232] is background for the logarithms in the mass-dependent terms.

The measurement. Foley and Kusch [912] and Kusch and Foley [916] are the discovery pair; they are cited together throughout because the interpretation and the experimental detail are split between them. The method they used is Rabi's [798, 819]. Wilkinson and Crane [1268] is the best of the free-precession experiments and the bridge to the trap era. For the Penning trap itself, Brown and Gabrielse's review [1769] is the standard reference and the source of the invariance theorem, the lineshape model and the relativistic level scheme of Equation (112.37); it is a review rather than a primary paper, and is cited as such. The Harvard sequence is Odom *et al.* [2101], Hanneke *et al.* [2126] and Fan *et al.* [2419]; the last is the source of Equation (112.8) and the experiment this chapter is registered under. Van Dyck, Schwinberg and Dehmelt [1798] is the electron–positron comparison of

Section 112.5.2. The cavity-QED effect exploited in Section 112.3.3 traces to Purcell [893] and was observed in its inhibitory form by Hulet, Hilfer and Kleppner [1755].

The input. Parker *et al.* [2316] and Morel *et al.* [2363] are the two atom-recoil determinations of α whose disagreement bounds this chapter's conclusion. They are primary papers in atomic physics, not in particle physics, and the reader who wants to judge which is more likely to be right must read them directly; this book takes no position beyond reporting the disagreement and its consequence.

The data sets. Two machine-readable sources carry every constant quoted here. CODATA 2022 [2431] supplies the Bohr magneton, the electron and muon masses, the Rydberg constant, the recommended α, and the recommended electron and muon anomalies; the values used are those in the repository copy of the NIST listing, and every number in Tables 112.1, 112.3 and 112.4 attributed to it has been checked against that file. The PDG 2024 compilation [2427] supplies the muon rest energy and the muon width used in Equation (112.38). Where a value appears in both, CODATA is used for constants of the electron and PDG for properties of the muon as a particle, and the two are consistent within their stated uncertainties.

The muon programme. Bailey *et al.* [1592, 1632] report the CERN storage ring, the second of these being the final CERN account of both the anomaly and the time-dilation measurement written up at Section 41.4. Bennett *et al.* [2091] is the Brookhaven E821 final report, and Abi *et al.* [2368] and Aguillard *et al.* [2416] the first two Fermilab results. The Standard Model evaluation is the Muon $g-2$ Theory Initiative's white paper [2353]; the competing lattice evaluation of the hadronic vacuum polarization is Borsanyi *et al.* [2375]; and the cross-section measurement that unsettles the dispersive input is CMD-3 [2426]. The spin-precession formula behind the magic momentum is Bargmann, Michel and Telegdi [1165].

Remark 112.16 (What is owed). Two derivations are marked pending in this chapter and both belong in Appendix A rather than in the running text: the general form of the invariance theorem for a tilted and elliptical Penning trap, of which only the ideal-trap identity is proved here; and the dispersive representation of the hadronic vacuum-polarization contribution, of which only the structure and the asymptotic kernel are given. Neither affects a number quoted in this chapter — the first because the trap corrections are computed from measured frequencies, the second because the hadronic term is taken from [2353] rather than recomputed — but both are results the book asserts and must therefore prove.

Chapter 113

Experiment: The Higgs Boson Discovery

Tests Phenomena 104.59 and 104.62.

Assuming Propositions 104.26 and 104.61 and Definition 11.70.

On 4 July 2012 the ATLAS [2186] and CMS [2192] collaborations independently reported a new boson near $125\,\mathrm{GeV}/c^2$, each at five standard deviations, in the diphoton and four-lepton channels. This chapter is the experimental closure of Chapter 104: the Brout–Englert–Higgs mechanism [1275, 1279, 1283] had been established indirectly for decades by the masses of the W and Z [1710, 1711] and by the precision electroweak fits [2104], but the scalar itself — the one particle of the Standard Model whose mass the theory does not predict — remained unobserved, its allowed mass window closed from below by LEP [2045] and eroded by the Tevatron [2187]. The chapter sits at the end of the Standard Model sequence because it completes its particle content; what it does not complete is the theory, and the final sections say so.

Two features of this experiment demand more space than usual. The first is statistics: a discovery claim built on a few hundred events over a large smooth background needs its test statistic, its look-elsewhere correction and its blinding protocol stated as carefully as its detector [2036, 2172]. All of that machinery is derived in Chapter 11, and Section 113.5.1 applies it to the published numbers rather than gesturing at "five sigma". The second is that the measurement did not stop in 2012 — spin-parity [2201, 2217], couplings against mass [2263, 2394, 2410] and the total width [2411] have all been measured since, while the Higgs self-coupling, which is what would actually test the shape of the potential, has not.

Notation 113.1 (Units and the quantities a collider quotes). Everything here is in SI, in the conventions of Section 104.1: $\hbar$ and c appear explicitly, a mass is written as an energy divided by c^2, and the electroweak scale is the energy $E_v = v\sqrt{\hbar c} = 246.220\,\mathrm{GeV}$ of Equation (104.2). Three collider habits need a translation that is given once and then used silently.

Energy. $1\,\mathrm{GeV}$ is $1.602\,176\,634 \times 10^{-10}\,\mathrm{J}$ exactly, since the elementary charge is exact in the 2019 SI [2431]. A mass of $125.20\,\mathrm{GeV}/c^2$ is therefore $2.2319 \times 10^{-25}\,\mathrm{kg}$.

Cross section. An area. The literature quotes barns ($1 \times 10^{-28}\,\mathrm{m}^2$) with SI prefixes, so a picobarn is $1 \times 10^{-40}\,\mathrm{m}^2$ and a femtobarn is $1 \times 10^{-43}\,\mathrm{m}^2$. Every cross section below is given in m^2 with the customary figure named in words.

Luminosity. The instantaneous luminosity L is defined by $\mathrm{d}N/\mathrm{d}t = L\sigma$ and carries $1/(\mathrm{m}^2\,\mathrm{s})$; its time integral carries $1/\mathrm{m}^2$. One inverse femtobarn is $1 \times 10^{43}/\mathrm{m}^2$, and the discovery datasets are a few of them.

The letter μ. Collider practice and field-theory practice collide on this symbol, and five distinct meanings appear in this chapter. To keep them apart: the mass parameter of the scalar potential is written μ only inside Equation (113.1) and the curvature statement that follows from it, always with the combination $\hbar\mu c$ carrying an energy; the *signal strength*, the

ratio of an observed rate to the Standard Model prediction, is written μ with a subscript naming the measurement where one is needed (μ_{on}, μ_{off}, $\bar{\mu}$), and the mean pile-up is $\langle\mu\rangle$; the renormalization scale is written μ_R throughout, never bare μ; and the muon appears only as a particle label, in $\mu^{\pm}$, m_μ and κ_μ. The SI prefix *micro* is a different glyph and appears only inside a unit, as in 18.8 µm.

Remark 113.2 (Reading this chapter against the collider literature). Every experimental paper cited below sets $\hbar = c = 1$, quotes masses in GeV with the c^2 suppressed, cross sections in barns and luminosities in inverse femtobarns. The dictionary is the one fixed in Remark 104.2 together with the three conversions of Notation 113.1. No derivation in this chapter is carried out with $\hbar$ or c suppressed; this remark exists so that a reader can put a published figure beside a formula here and see that they are the same statement.

113.1 Historical context and the prediction under test

113.1.1 The Brout–Englert–Higgs mechanism

The problem the mechanism solves is stated in Theorem 104.8: a mass term for a gauge field is not gauge invariant, so a gauge theory of the weak interaction predicts massless carriers, and the carriers are not massless. The obvious repair — write the mass term anyway — destroys renormalizability (Theorem 104.4). The mechanism is the non-obvious repair: leave the Lagrangian invariant and let the *vacuum* fail to be.

Three papers in 1964 said this independently. Englert and Brout [1275] computed the vector self-energy directly and found a pole at nonzero momentum; Higgs [1282, 1283] gave the abelian model and, in the second paper, noted explicitly that a massive scalar excitation survives; Guralnik, Hagen and Kibble [1279] gave the operator argument for why Goldstone's theorem does not apply. Higgs later wrote the argument out in full [1332], and Kibble extended it to a non-abelian group [1352], which is the case the Standard Model needs. The physical precedent was already in the literature: Anderson [1245] had pointed out that the plasmon in a superconductor is exactly a gauge field that has acquired a mass from a condensate, and that the would-be massless mode is absent there for the same reason. Section 104.3.1 develops the analogy through Nambu's treatment of superconductivity [1187].

What has to be evaded is Goldstone's theorem [1207], proved as Theorem 104.17: a spontaneously broken continuous *global* symmetry produces one massless scalar for every broken generator. Massless scalars are not observed. The evasion, derived as Theorem 104.19 and in the non-abelian case as Theorem 104.22, is that when the broken symmetry is *gauged* the would-be Goldstone modes are not physical states at all: a gauge transformation removes them from the scalar sector, and they reappear as the longitudinal polarizations that a massless vector does not have and a massive one does.

The bookkeeping is worth doing explicitly, because it is what makes the prediction sharp.

Proposition 113.3 (Degrees of freedom before and after)**.** *The electroweak scalar sector is one complex* SU(2) *doublet, four real fields. Before breaking, the field content* $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ *carries*

$$4 \text{ (scalar)} + 3 \times 2 \text{ (massless } W^a\text{)} + 1 \times 2 \text{ (massless } B\text{)} = 12$$

propagating polarizations. After breaking it carries

$$1 \text{ (scalar)} + 3 \times 3 \text{ (massive } W^{\pm}, Z\text{)} + 1 \times 2 \text{ (photon)} = 12\,.$$

Exactly one physical scalar remains, and its existence is the falsifiable content of the mechanism.

Rests on Proposition 26.34, Theorem 104.25, and Equation (104.23).

Derivation. *Derives Proposition 113.3.*

A massless vector field in four spacetime dimensions has two polarizations and a massive one has three; the constraint analysis that states those counts is Remark 26.33 and Proposition 26.34 — where the Proca count is stated and its constraint analysis is itself recorded as owed — and the Proca mass term itself is Equation (104.5). A complex doublet is four real scalar fields. The vacuum Equation (104.29) is invariant under the electric-charge generator and under nothing else in the four-parameter group, so three of the four generators are broken (Theorem 104.25). Goldstone's theorem in its global form would give three massless scalars; gauged, each is instead removed by a gauge choice — the unitary gauge of Equation (104.23) — and supplies the missing longitudinal polarization of one vector. Three vectors gain one polarization each, so the vector sector gains three; the scalar sector loses three. The total is unchanged, which it must be, because a gauge choice cannot create or destroy a physical state. What is left over is the radial excitation of the doublet about the minimum, one real field, and the theory says its mass is $\sqrt{2\hat{\lambda}}\,E_v$ by Equation (104.37).

The counting also fixes what the experiment must find. Not "a scalar": exactly one, electrically neutral, and — once its mass is measured — with every coupling and every branching fraction already determined. A second scalar, a charged scalar, or a scalar with the wrong couplings would each falsify the minimal mechanism, and none would be an adjustment of it. □

Remark 113.4 (What was already evidence before 2012). The mechanism was not an untested hypothesis in 2012. Three of its consequences had been measured. The W and Z exist with the masses the theory predicts from E_v and the mixing angle (Section 104.6.2); the photon is exactly massless, which in Theorem 104.22 is a consequence of the vacuum's residual symmetry and not an input; and the ρ parameter of Equation (113.6) is unity, which is a statement about the *representation* of the breaking sector and not merely about the fact of breaking. What was missing was the scalar itself. The distinction matters: a reader who takes 2012 as the year the electroweak theory was confirmed has the history backwards. The theory was confirmed in 1973 and 1983; 2012 completed its particle content.

113.1.2 The one free parameter

The scalar potential is

$$V(\Phi) = -\mu^2 |\Phi|^2 + \lambda |\Phi|^4 \,, \tag{113.1}$$

with Φ of dimension $\mathrm{J}^{1/2}/\mathrm{m}^{1/2}$, μ of dimension $1/\mathrm{m}$ and λ of dimension $1/(\mathrm{J\,m})$, so that V is an energy density (Definition 104.24). Two parameters appear, and one combination of them is already measured.

Proposition 113.5 (One number is unknown, and it is the mass)**.** *The vacuum expectation value is fixed by the Fermi constant,*

$$E_v = v\sqrt{\hbar c} = \left(\frac{(\hbar c)^3}{\sqrt{2}\, G_F} \right)^{1/2} = 246.220\,\mathrm{GeV}\,, \tag{113.2}$$

and the scalar mass is

$$m_H c^2 = \sqrt{2\hat{\lambda}}\, E_v \,, \qquad \hat{\lambda} = \lambda \hbar c \,. \tag{113.3}$$

Since $\hat{\lambda}$ is not predicted, m_H is the single unknown of the sector; every production cross section and every branching fraction is a function of it alone.

Rests on Propositions 104.26 and 104.61 and Corollary 104.29.

Derivation. *Derives Proposition 113.5.*

Equation (113.2) is Proposition 104.26: matching the low-energy limit of W exchange to Fermi's contact theory cancels the gauge coupling and leaves $E_v^2 = (\hbar c)^3/\sqrt{2}G_F$, with

$G_F/(\hbar c)^3 = (1.166\,378\,7 \pm 0.000\,000\,6) \times 10^{-5}/\mathrm{GeV}^2$ from the positive-muon lifetime [2225], that is $G_F = 1.435\,85 \times 10^{-62}\,\mathrm{J\,m^3}$. In SI, $E_v = 3.944\,88 \times 10^{-8}\,\mathrm{J}$ and the associated length is $\hbar c/E_v = 8.0143 \times 10^{-19}\,\mathrm{m}$. Equation (113.3) is Corollary 104.29, obtained by expanding Equation (113.1) about the minimum $|\Phi| = v/\sqrt{2}$ and reading off the coefficient of the quadratic term in the radial fluctuation.

The claim that everything else follows is the content of Proposition 104.61: the coupling of the scalar to any massive particle is that particle's mass term divided by v, so the couplings contain no parameter beyond E_v, which is already measured. Fixing m_H therefore fixes every partial width through Equation (104.67) and its gauge analogue, hence every branching fraction (Table 104.4); and it fixes every production cross section, because production is the same set of vertices read backwards, convolved with parton distributions measured elsewhere (Section 116.6.5). □

The consequence for the experiment is structural and it is what makes a null result meaningful. A search that scans m_H is testing a *one-parameter family of fully specified theories*, not fitting a shape to data. At each candidate mass the predicted rate in every channel is a number, so the data either accommodate it or exclude it; there is nothing to adjust. And when a signal does appear, the same rigidity makes the discovery over-determined: the mass measured in the diphoton channel must agree with the mass measured in the four-lepton channel, the ratio of the two rates must be the predicted one, and the production mechanisms must appear in the predicted proportion. Two experiments each measuring two channels give eight numbers where the theory has one.

The wider accounting — how many free parameters the Standard Model has in total, and which measurement fixes each — is tabulated in Appendix C. The scalar mass is one entry of that table, and Section 113.5.2 is the entry that this chapter fills in.

113.1.3 Indirect constraints

Before the scalar was produced it was constrained, because it circulates in loops. The relation between M_W, M_Z, α and G_F receives a radiative correction Δr, defined by Equation (104.43) and evaluated from the measured masses in Remark 104.33, which finds $\Delta r = 0.036$ and identifies the scalar-mass logarithm as one of the pieces making it up. What matters here is that dependence's *form*: it is logarithmic,

$$\frac{\partial\,\Delta r}{\partial \ln\left(m_H c^2\right)} = \frac{\hat{g}^2}{16\pi^2}\,c_H\,, \tag{113.4}$$

with $\hat{g}$ the dimensionless SU(2) coupling of Notation 104.1 and c_H a pure number of order unity that this book does not derive, whereas the dependence on the top mass is quadratic, $\Delta r|_t \propto m_t^2$ by Equation (104.52). The two sensitivities have very different consequences and the difference is Veltman's screening theorem [1612]: a heavy scalar decouples logarithmically, so precision data constrain it weakly, while a heavy top does not decouple at all.

Derivation pending #199

The coefficient of the scalar-mass logarithm in the radiative correction Δr, written parametrically in this subsection, together with the constant term that accompanies it — which is not a refinement at the measured mass but comparable to the logarithm itself. Obtaining both requires the one-loop W and Z self-energies with the scalar circulating, renormalized on shell. The electroweak chapter already records the same logarithm as owed, in the paragraph following its screening-theorem discussion; the two belong together in Appendix A. Nothing in this chapter is evaluated numerically from the coefficient.

Weak is not zero. The LEP and SLC programme measured M_Z, the Z partial widths and a dozen asymmetries to a part in 10^3 or better [2104]; combined with M_W, m_t, α and G_F the system is over-constrained, and the global fit before 2012 preferred a scalar mass of order $100\,\mathrm{GeV}/c^2$ with an upper bound in the low hundreds [2228]. The particle was found at $125\,\mathrm{GeV}/c^2$, inside that range.

What made the constraint credible in advance was that the same method had already worked once, on a harder case. The quadratic top sensitivity let the LEP data locate the top quark's mass before the Tevatron produced it, and the indirect value agreed with the direct measurement [1891, 1892]. A method that has predicted one unseen particle correctly is evidence about the next one; a method that has not is an extrapolation.

Phenomenon 113.6 (The weak bosons are massive and the photon is not)**.** The carriers of the charged and neutral weak currents are massive,

$$m_Z c^2 = (91.1880 \pm 0.0020)\,\mathrm{GeV}\,, \qquad m_W c^2 = (80.369 \pm 0.013)\,\mathrm{GeV}\,, \tag{113.5}$$

that is $m_Z = 1.625\,57 \times 10^{-25}\,\mathrm{kg}$ and $m_W = 1.432\,71 \times 10^{-25}\,\mathrm{kg}$ [2427], while the photon, which belongs to the same electroweak gauge group, has no measurable mass at all [2427]. The measured masses moreover satisfy

$$\rho = \frac{m_W^2}{m_Z^2 \cos^2\theta_W} = 1 \tag{113.6}$$

to within the radiative corrections — a coincidence that a general symmetry-breaking sector has no reason to produce.

Rests on Equation (104.36), Theorem 104.41, and Proposition 104.43.

Derivation. *Derives Phenomenon 113.6.*

Let the breaking be produced by a single complex scalar doublet with vacuum expectation value v (Chapter 104). Expanding the square of its covariant derivative about the vacuum generates

$$m_W c^2 = \tfrac{1}{2}\hat{g} E_v\,, \qquad m_Z c^2 = \tfrac{1}{2}\sqrt{\hat{g}^2 + \hat{g}'^2}\, E_v\,,$$

by Equation (104.36), with $\hat{g}$ and $\hat{g}'$ the dimensionless SU(2) and U(1) couplings of Notation 104.1, while the orthogonal combination of neutral gauge fields — the photon — gets no mass term at all, because the vacuum is left invariant by the electric-charge generator. The mixing angle is defined by $\cos\theta_W = \hat{g}/\sqrt{\hat{g}^2 + \hat{g}'^2}$, so

$$\frac{m_W c^2}{m_Z c^2 \cos\theta_W} = \frac{\tfrac{1}{2}\hat{g} E_v}{\tfrac{1}{2}\sqrt{\hat{g}^2 + \hat{g}'^2}\, E_v} \cdot \frac{\sqrt{\hat{g}^2 + \hat{g}'^2}}{\hat{g}} = 1\,,$$

which is Equation (113.6). The relation is a property of the *doublet* assignment and not of symmetry breaking in general: a scalar in a higher representation gives $\rho \neq 1$, as Theorem 104.41 makes precise. The measured ρ is therefore evidence about the representation content of the breaking sector, not merely evidence that something breaks the symmetry, and it is what made the search for a single neutral scalar, rather than for some richer sector, the right search to mount.

Numerically, the comparison can only be made in a scheme that defines the mixing angle independently of the mass ratio, and Remark 104.34 is where the schemes are separated. With the *on-shell* angle, $\sin^2\theta_W := 1 - M_W^2/M_Z^2$, Equation (113.6) is $\rho = 1$ identically by construction and there is nothing to test. Taking instead the $\overline{\mathrm{MS}}$ angle at the Z scale, $\hat{s}_Z^2 = 0.231\,29 \pm 0.000\,04$ [2427], and the masses of Equation (113.5),

$$\rho = \frac{(80.369\,\mathrm{GeV})^2}{(91.1880\,\mathrm{GeV})^2\,(1 - 0.231\,29)} = 1.0105\,,$$

a departure from unity of about one per cent — the size of the one-loop correction $\Delta\rho = 9.3 \times 10^{-3}$ computed in Proposition 104.43. The relation is not exact and is not supposed to be; what is significant is that the deviation is of the size a loop produces and not of the size a wrong representation would produce. □

113.1.4 LEP and Tevatron searches

Two machines searched before the LHC, in two entirely different ways, and between them they set the window the LHC had to cover.

LEP. An e^+e^- collider produces the scalar through $e^+e^- \to Z^* \to ZH$, the same HZZ vertex read as a production vertex. The event is fully constrained — the initial state has known energy — so the search is a bump hunt in the recoil mass against an identified Z, with essentially no combinatorial background. What limits it is not statistics but kinematics.

Proposition 113.7 (LEP's reach was set by its beam energy)**.** *Associated production $e^+e^- \to ZH$ at centre-of-mass energy $\sqrt{s}\,c$ requires*

$$m_H c^2 \le \sqrt{s}\,c - m_Z c^2 \,, \tag{113.7}$$

so LEP's final energy of $\sqrt{s}\,c = 209\,\mathrm{GeV}$ admits at most $m_H c^2 = 117.8\,\mathrm{GeV}$, and the useful reach is a few GeV *below that because the cross section vanishes at threshold.*

Rests on Equation (113.5).

Derivation. *Derives Proposition 113.7.*

In the centre-of-mass frame the total energy is $\sqrt{s}\,c$ and the final state is two particles at rest or better, so $\sqrt{s}\,c \ge m_Z c^2 + m_H c^2$, which is Equation (113.7). With $m_Z c^2 = (91.1880 \pm 0.0020)\,\mathrm{GeV}$ from Equation (113.5) and $\sqrt{s}\,c = 209\,\mathrm{GeV}$ the bound is 117.8 GeV. Near threshold the two-body phase space carries the momentum factor p^*, and for this process the cross section falls as p^* rather than as p^{*3} because the S-wave is allowed; either way it vanishes, so the last few GeV of the kinematic range are not usable. The published limit, $m_H c^2 > 114.4\,\mathrm{GeV}$ at 95 % confidence [2045], sits about 3.4 GeV below the kinematic edge, which is the size of that effect. □

The LEP combination of ALEPH, DELPHI, L3 and OPAL left a mild excess at the very edge of its sensitivity, near $115\,\mathrm{GeV}/c^2$, of less than two standard deviations in the four-experiment combination and driven largely by one experiment [2045]. It did not survive, and the way it was reported is worth recording: the collaborations quoted the limit and the excess together, with the excess described as compatible with a background fluctuation, rather than either suppressing it or promoting it. The combination used the modified frequentist CL_s construction [2036], whose purpose is exactly to prevent a downward background fluctuation from excluding a signal the experiment had no sensitivity to (Remark 11.95).

Tevatron. A $p\bar{p}$ collider at $\sqrt{s}\,c = 1.96\,\mathrm{TeV}$ cannot use the diphoton channel — the rate is too low for its integrated luminosity — so CDF and D0 attacked the largest branching fraction instead, $H \to b\bar{b}$, made usable by demanding an associated W or Z to suppress the enormous QCD production of b quarks. The combined analysis of the full Tevatron dataset reported a broad excess in that channel with a maximum local significance of about three standard deviations near $125\,\mathrm{GeV}/c^2$, falling to roughly two and a half after correcting for the mass range searched [2187]. The same combination excluded a Standard Model scalar between about $147\,\mathrm{GeV}/c^2$ and $179\,\mathrm{GeV}/c^2$.

The Tevatron result is the one place in this story where the associated-production channel with the largest branching ratio was competitive, and it is instructive that it produced evidence rather than a discovery. The excess was broad — the $b\bar{b}$ mass resolution is of order $15\,\mathrm{GeV}/c^2$, ten times worse than the diphoton channel — so it constrained a rate over a wide window rather than locating a resonance.

The window entering 2012. Combining the LEP lower bound, the Tevatron exclusion and the LHC's own 2011 exclusions, a Standard Model scalar was confined to roughly 115–130 GeV/c^2, with a smaller surviving region at high mass that the electroweak fit already disfavoured. Inside that window the branching fractions of Table 104.4 are changing rapidly: WW^* and ZZ^* are climbing as the thresholds approach, $b\bar{b}$ is falling, and $\gamma\gamma$ passes through its maximum. It is the one mass region in which the two high-resolution channels are simultaneously accessible, which is why the LHC was able to settle the question there and would have had a much harder time 20 GeV/c^2 higher.

113.2 Apparatus

Three instruments are involved: one accelerator and two detectors. The accelerator's job is to deliver, in a few years, enough proton–proton collisions that a process occurring once in 3×10^9 of them yields a few hundred events. The detectors' job is to recognise those events in real time, discard the rest before they can be written to disk, and measure the survivors well enough that a resonance 1 GeV/c^2 wide can be seen on a continuum background a hundred times larger.

ATLAS and CMS were built to different designs on purpose. Their magnets, their calorimeter technologies and their reconstruction strategies differ in almost every respect, so their systematic errors are largely independent. That is not redundancy: it is the only protection available against a mistake that a single collaboration could make and not detect, and it is why the phrase "two experiments independently" carries weight in Section 113.4.3 that "two analyses of the same data" would not.

113.2.1 The Large Hadron Collider

The machine [2123] occupies the tunnel dug for LEP, a ring of circumference 26 659 m lying between 45 m and 170 m below the surface and tilted by 1.4°. Reusing the tunnel fixed the circumference and therefore fixed everything else: to reach a beam energy of several TeV in a ring of that size the bending field must be far beyond what iron can supply, so the LHC is a superconducting machine, and because two counter-rotating proton beams need opposite bending fields it uses twin apertures inside one cryostat and one yoke rather than two separate rings.

Proposition 113.8 (The dipole field the ring demands)**.** *A relativistic proton of energy E on a circular arc of radius ρ requires a field*

$$B = \frac{p}{e\rho} \simeq \frac{E}{ec\rho}\,, \tag{113.8}$$

p being the momentum and e the elementary charge. The LHC's 1232 *main dipoles are each* 14.3 m *long, so the total bending length is* 17 618 m *and* $\rho = 2804$ m*. The three beam energies that matter here then need*

$$B\,(3.5\,\mathrm{TeV}) = 4.16\,\mathrm{T}\,, \quad B\,(4\,\mathrm{TeV}) = 4.76\,\mathrm{T}\,, \quad B\,(7\,\mathrm{TeV}) = 8.33\,\mathrm{T}\,. \tag{113.9}$$

Rests on Equations (40.4) *and* (40.15).

Derivation. *Derives Proposition 113.8.*

The Lorentz force supplies the centripetal acceleration, $evB = \gamma m_p v^2/\rho$, so $B = \gamma m_p v/(e\rho) = p/(e\rho)$ exactly. At 4 TeV the proton's Lorentz factor is $\gamma = E/(m_p c^2) = 4000/0.938\,272 = 4263$, so v/c differs from unity by $1/(2\gamma^2) = 2.8 \times 10^{-8}$ and $p = E/c$ to

that accuracy. The bending radius is the total magnetic length divided by 2π: $1232 \times 14.3\,\mathrm{m} = 17\,617.6\,\mathrm{m}$, and $17\,617.6\,\mathrm{m}/2\pi = 2803.9\,\mathrm{m}$. Then

$$p = \frac{4 \times 10^{12}\,\mathrm{eV} \times 1.602\,176\,634 \times 10^{-19}\,\mathrm{J/eV}}{2.997\,924\,58 \times 10^{8}\,\mathrm{m/s}} = 2.1377 \times 10^{-15}\,\mathrm{kg\,m/s}\,,$$

and dividing by $e\rho = 1.602\,176\,634 \times 10^{-19}\,\mathrm{C} \times 2803.9\,\mathrm{m} = 4.4923 \times 10^{-16}\,\mathrm{C\,m}$ gives $4.759\,\mathrm{T}$. The other two entries follow by proportionality. An iron-dominated warm dipole saturates near $2\,\mathrm{T}$; a $7\,\mathrm{TeV}$ beam in such a ring would need a bending radius above $11\,\mathrm{km}$ and a circumference near $100\,\mathrm{km}$, which is the whole argument for superconductivity. The LHC dipoles use niobium–titanium cable operated at $1.9\,\mathrm{K}$ in superfluid helium, below the $2.17\,\mathrm{K}$ lambda point, because the critical field of that alloy at $4.2\,\mathrm{K}$ would not reach $8\,\mathrm{T}$. □

The beams are bunched by $400\,\mathrm{MHz}$ superconducting radio-frequency cavities, eight per beam delivering about $2\,\mathrm{MV}$ each. A proton completes the ring at

$$f_{\mathrm{rev}} = \frac{c}{26\,659\,\mathrm{m}} = 11\,245\,\mathrm{Hz}\,, \tag{113.10}$$

to within the 2.8×10^{-8} by which v falls short of c. In the 2011 and 2012 runs the bunches were spaced by $50\,\mathrm{ns}$ — twice the design spacing — which puts consecutive bunches $15.0\,\mathrm{m}$ apart along the beam and gives a crossing rate of $20\,\mathrm{MHz}$ at each interaction point where bunches are present. With 1374 filled bunches in 2012 the actual crossing rate was $1374\,f_{\mathrm{rev}} = 15.4\,\mathrm{MHz}$.

Remark 113.9 (The stored energy is the reason for the caution). Each 2012 bunch carried about 1.6×10^{11} protons, so a beam held 2.20×10^{14} protons at $4\,\mathrm{TeV}$, a stored kinetic energy of

$$2.20 \times 10^{14} \times 4 \times 10^{12}\,\mathrm{eV} \times 1.602\,176\,634 \times 10^{-19}\,\mathrm{J/eV} = 1.41 \times 10^{8}\,\mathrm{J}\,,$$

$141\,\mathrm{MJ}$ per beam, comparable to the kinetic energy of a $4 \times 10^{5}\,\mathrm{kg}$ train at $28\,\mathrm{m/s}$, which is $\tfrac{1}{2} \times 4 \times 10^{5}\,\mathrm{kg} \times (28\,\mathrm{m/s})^2 = 1.6 \times 10^{8}\,\mathrm{J}$. The magnet system stores an order of magnitude more. This is not a detector concern but it dictated the 2011–2012 operating energy: after the 2008 interconnect failure the machine ran at half the design field while the splices were surveyed, which is why the discovery datasets are at $7\,\mathrm{TeV}$ and $8\,\mathrm{TeV}$ rather than $14\,\mathrm{TeV}$.

Proposition 113.10 (Luminosity and the pile-up it forces)**.** *For head-on collisions of n_b bunch pairs with N protons each, Gaussian transverse profiles of common width σ at the interaction point,*

$$L = \frac{f_{rev} n_b N^2}{4\pi\sigma^2}\,F\,, \qquad \sigma = \sqrt{\frac{\beta^{*}\epsilon_n}{\gamma}}\,, \tag{113.11}$$

with $F \le 1$ a geometric reduction from the crossing angle, β^{*} the optical amplitude function at the collision point and ϵ_n the normalized transverse emittance. The 2012 parameters give $\sigma = 18.8\,\mu\mathrm{m}$ and a peak luminosity of order $8 \times 10^{37}/(\mathrm{m^2\,s})$. The mean number of inelastic collisions per bunch crossing is

$$\langle \mu \rangle = \frac{L \sigma_{inel}}{f_{rev} n_b}\,, \tag{113.12}$$

which at that luminosity is about 36.

Rests on Notation 113.1.

Derivation. *Derives Proposition 113.10.*

The rate of any process is $\mathrm{d}N/\mathrm{d}t = L\sigma$ by the definition of luminosity, and for two Gaussian bunches crossing head-on the overlap integral of two normalized transverse densities of width σ is $1/(4\pi\sigma^2)$; multiplying by the number of protons in each bunch and by the

rate at which bunch pairs meet gives Equation (113.11). The transverse size follows from the definition of emittance: the geometric emittance is $\epsilon = \epsilon_n/\gamma$ because adiabatic damping shrinks the transverse phase-space area in proportion to the momentum, and $\sigma^2 = \beta^*\epsilon$ is the definition of the amplitude function. With $\epsilon_n = 2.5 \times 10^{-6}\,\mathrm{m}$, $\gamma = 4263$ and $\beta^* = 0.6\,\mathrm{m}$,

$$\sigma = \sqrt{0.6\,\mathrm{m} \times \frac{2.5 \times 10^{-6}\,\mathrm{m}}{4263}} = 1.876 \times 10^{-5}\,\mathrm{m}\,.$$

Then

$$\frac{f_{\mathrm{rev}} n_b N^2}{4\pi\sigma^2} = \frac{11\,245\,\mathrm{Hz} \times 1374 \times \left(1.6 \times 10^{11}\right)^2}{4\pi\left(1.876 \times 10^{-5}\,\mathrm{m}\right)^2} = 8.9 \times 10^{37}/(\mathrm{m}^2\,\mathrm{s})\,,$$

and the crossing angle of a few hundred microradians, needed to keep the two beams from colliding parasitically elsewhere in the common pipe, supplies $F \approx 0.85$; the measured 2012 peak was $7.7 \times 10^{37}/(\mathrm{m}^2\,\mathrm{s})$.

For Equation (113.12), the inelastic proton–proton cross section at $\sqrt{s}\,c = 8\,\mathrm{TeV}$ is about $7.3 \times 10^{-30}\,\mathrm{m}^2$, which the collider literature writes as 73 millibarns, so the inelastic rate at peak luminosity is $7.7 \times 10^{37}/(\mathrm{m}^2\,\mathrm{s}) \times 7.3 \times 10^{-30}\,\mathrm{m}^2 = 5.6 \times 10^{8}/\mathrm{s}$. Dividing by the crossing rate $1.54 \times 10^{7}/\mathrm{s}$ gives 36 collisions per crossing at the start of a fill. Luminosity decays through a fill as the bunches are consumed and heated, so the luminosity-weighted average over the whole 2012 run was about 21, against about 9 in 2011. □

Remark 113.11 (Why pile-up is the defining difficulty). Twenty simultaneous inelastic collisions is not twenty times more data. All of them occur within 50 ns — in fact within the same crossing — and within a luminous region whose longitudinal extent is $\sigma_z \approx 5\,\mathrm{cm}$, so they are not separated in time and barely in space. Three specific damages follow, and every element of the analyses in Section 113.3 is shaped by one of them.

First, the event of interest must be assigned to the right vertex out of twenty candidates, and for a final state of two photons there are no tracks from the hard process to point with. Proposition 113.14 shows what a wrong assignment costs.

Second, energy from the other collisions lands in the same calorimeter cells, so any isolation or energy measurement must be corrected for a pedestal that fluctuates event by event. This is *in-time* pile-up.

Third, the ionization signal in a liquid-argon calorimeter is triangular with a drift time near 450 ns, nine times the bunch spacing, so the shaped pulse also carries contributions from neighbouring crossings. This is *out-of-time* pile-up, and it is removed by bipolar shaping whose undershoot cancels the average of the preceding crossings — which works on the average and leaves a fluctuation.

The last machine property that matters is not a machine property at all but a property of the proton. The scalar is produced dominantly by gluon fusion, $gg \to H$, through a top-quark loop, and that dominance is a statement about parton densities rather than about couplings: at $\sqrt{s}\,c = 8\,\mathrm{TeV}$ a central resonance of mass $125\,\mathrm{GeV}/c^2$ is made from partons carrying momentum fractions near $x = m_H c^2/(\sqrt{s}\,c) = 0.0156$, and at that x the gluon distribution is an order of magnitude above any single quark distribution (Section 116.6.5). The distributions themselves were measured in electron–proton scattering (Chapter 116) and are usable here only because collinear factorization (Theorem 102.53) makes them universal — a theorem stated there at leading order, with its all-orders proof recorded as owed. Without it, and without the deep inelastic programme that measured its inputs, no LHC cross section could be predicted at all.

113.2.2 ATLAS

ATLAS [2119] is 44 m long and 25 m in diameter and weighs about 7×10^6 kg. Its distinguishing choices are a modest solenoid around a compact tracker, a sampling electromagnetic

calorimeter with unusually fine longitudinal and lateral segmentation, and a very large air-core toroid outside the calorimeters that measures muons independently of the tracker.

Tracking. A superconducting solenoid 5.3 m long with a 2.4 m bore produces an axial field of 2 T; it is deliberately thin, about 0.66 radiation lengths, because it sits in front of the electromagnetic calorimeter. Inside it are three subsystems covering $|\eta| < 2.5$: a silicon pixel detector of three barrel layers at radii 50.5 mm, 88.5 mm and 122.5 mm with 8.0×10^7 channels of 50 µm × 400 µm; a silicon microstrip tracker of four double barrel layers out to 514 mm with 80 µm pitch; and a transition-radiation tracker of about 3.5×10^5 straw tubes of 4 mm diameter, giving roughly 36 measurements per track and, from the transition radiation emitted in the interleaved radiator, an electron-versus-pion discriminant.

Electromagnetic calorimetry. Lead absorbers immersed in liquid argon at 87.3 K, folded into an accordion so that the readout can be brought out from the front and back with no cracks in azimuth. The barrel covers $|\eta| < 1.475$ and the two endcaps $1.375 < |\eta| < 3.2$; the total depth is at least 22 radiation lengths in the barrel. The segmentation is the point of the design and is worth stating in full:

- a presampler layer for $|\eta| < 1.8$, which measures the energy already lost upstream;
- a first sampling of about 4.3 radiation lengths divided into strips of $\Delta\eta = 0.0031$, eight times finer than the layers behind it;
- a second sampling of about 16 radiation lengths in cells of $\Delta\eta \times \Delta\phi = 0.025 \times 0.025$, which collects most of the shower;
- a third sampling of $\Delta\eta = 0.05$ to catch the tail.

The design energy resolution is

$$\frac{\sigma_E}{E} = \frac{10\,\%}{\sqrt{E/1\,\mathrm{GeV}}} \oplus 0.7\,\%\,, \tag{113.13}$$

the first term being the sampling fluctuation of a lead–argon stack and the second the constant term set by calibration and mechanical uniformity.

The fine first sampling does two things that the discovery depended on. A neutral pion of 50 GeV decays to two photons with a typical opening angle of $2m_\pi c^2/E \approx 5.4 \times 10^{-3}$, which at the calorimeter face is a separation of a few millimetres — resolvable in strips of $\Delta\eta = 0.0031$ and invisible in cells of 0.025. And because the first and second samplings measure η at two different radii, the photon's direction can be reconstructed from the calorimeter alone, giving its origin along the beam to about 15 mm with no help from the tracker. Proposition 113.14 explains why that number matters.

Hadronic calorimetry and muons. Steel and scintillating tile in the barrel, copper and liquid argon in the endcaps, and a copper–tungsten forward calorimeter reaching $|\eta| = 4.9$, which is what makes a missing-transverse-momentum measurement possible. Outside everything sits the muon spectrometer: eight air-core superconducting coils forming a barrel toroid 25.3 m long and 20.1 m in outer diameter, plus two endcap toroids, giving a bending integral $\int B\,\mathrm{d}l$ between 1.5 T m and 7.5 T m depending on η. Air-core means there is no iron to scatter the muon, so the spectrometer measures momentum on its own to about 10 % at 1 TeV; the price is a very large and mechanically demanding structure. Precision coordinates come from drift tubes of 30 mm diameter filled with argon and carbon dioxide at 3×10^5 Pa — three atmospheres — resolving about 80 µm per tube.

Trigger. The crossing rate is 20 MHz and the recording rate is a few hundred hertz, so the trigger must reject about 5×10^4 events for every one it keeps, in real time and without ever looking at an event twice. A hardware first level, using reduced-granularity calorimeter sums and dedicated muon chambers, made its decision within 2.5 µs and reduced the rate to

about 70 kHz; two software levels running on a farm of order 2×10^4 processor cores reduced it to about 400 Hz recorded in 2012. The diphoton trigger required two electromagnetic clusters above roughly 35 GeV and 25 GeV of transverse energy. Any event not selected within 2.5 µs is gone permanently, which is why the trigger menu is part of the physics analysis and not part of the plumbing.

113.2.3 CMS

CMS [2120] is 21.6 m long, 14.6 m in diameter and weighs about 1.25×10^7 kg — half the length of ATLAS and nearly twice the mass. Every one of its choices is the opposite of the corresponding ATLAS choice, and the discovery is stronger for it.

The magnet. A single superconducting solenoid of 6 m inner diameter and 12.5 m length, operated at 3.8 T with a stored energy of 2.6 GJ. Everything except the muon chambers sits inside it. The high field buys track momentum resolution in a small volume; the cost is that the coil is thick, so the electromagnetic calorimeter must be inside it, which in turn constrains its radius and therefore its cost per unit solid angle. The return flux is carried by an iron yoke of about 1.8 T in which the muon chambers are embedded, so the muon system reuses the same magnetic circuit rather than needing one of its own.

Tracking. All silicon, about 200 m^2 of it, the largest such device built at the time. Three pixel barrel layers at radii 4.4 cm, 7.3 cm and 10.2 cm carry 6.6×10^7 pixels of 100 µm × 150 µm; ten microstrip barrel layers reach $r = 1.1$ m with 9.3×10^6 strips. Coverage is $|\eta| < 2.5$.

Electromagnetic calorimetry. This is the subsystem CMS built for the diphoton channel specifically, and the reasoning is explicit in the design report: a homogeneous crystal calorimeter has no sampling fluctuation, so its stochastic term can be several times smaller than a sampling device's, and the diphoton mass resolution is dominated by that term. The calorimeter is 75 848 lead-tungstate ($PbWO_4$) scintillating crystals — 61 200 in the barrel for $|\eta| < 1.479$ and 7324 in each endcap. The material was chosen for density: 8280 $\mathrm{kg/m}^3$, a radiation length of 0.89 cm and a Molière radius of 2.2 cm, so a barrel crystal 230 mm long is 25.8 radiation lengths in a 22 mm × 22 mm front face. The design resolution measured in a test beam is

$$\frac{\sigma_E}{E} = \frac{2.8\,\%}{\sqrt{E/1\,\mathrm{GeV}}} \oplus \frac{12\,\%}{E/1\,\mathrm{GeV}} \oplus 0.30\,\%\,, \tag{113.14}$$

a stochastic term nearly four times smaller than Equation (113.13).

That advantage is bought at a price that had to be engineered away. Lead tungstate is a poor scintillator — about 30 photons per MeV reach the photodetector — so the barrel is read out with avalanche photodiodes of gain 50 and the endcaps with vacuum phototriodes, both able to operate inside 3.8 T where a photomultiplier cannot. Its light yield also falls by about 2 % per kelvin, so the whole calorimeter is held at 18 °C stabilised to 0.05 K; and the crystals darken under irradiation and recover between fills, which forces a continuous transparency monitoring with injected laser light. A preshower of two lead converters and two silicon strip planes, three radiation lengths in all with a strip pitch of 1.9 mm, sits in front of the endcaps and does there what ATLAS's fine strips do in the barrel: separate a π^0's two photons from one.

Reconstruction. CMS reconstructs events by *particle flow*: rather than reading each subdetector separately, the algorithm builds a list of individual particles by linking tracks to calorimeter clusters to muon segments, and then constructs jets, missing transverse momentum and isolation variables from that list. The method needs a tracker that measures nearly every charged particle and a calorimeter finely segmented enough to associate clusters with tracks, which is exactly what the 3.8 T solenoid and the crystal array provide. Its relevance here is isolation: a photon candidate's isolation can be computed from the charged particles associated with the chosen vertex alone, which suppresses the pile-up dependence that a purely calorimetric isolation would carry.

Trigger. The same two-stage structure with different numbers: a hardware level with a 3.2 µs latency reducing 20 MHz to at most 100 kHz, and a software high-level trigger on a commercial farm reducing that to a few hundred hertz. CMS's diphoton triggers used lower transverse-energy thresholds than ATLAS's, near 26 GeV and 18 GeV, compensated by isolation and shower-shape requirements applied online.

Table 113.1: Design and construction parameters of the two detectors and of the machine that fed them, as built and as operated in 2011–2012. These are settings and specifications, not measurements, so no uncertainty is attached to them; the measured quantities of this chapter are collected in Table 113.3 and Table 113.5. Energy resolutions are the design or test-beam parametrizations of Equation (113.13) and Equation (113.14), with E in GeV; the resolutions achieved in situ are worse and are discussed in Section 113.4.1.

Parameter	ATLAS	CMS

113.3 Procedure

113.3.1 Production and decay channels

Four production mechanisms contribute at the LHC, and all four are the vertices of Equation (104.69) read as production rather than decay. In descending order of rate at $m_H c^2 = 125$ GeV and $\sqrt{s}\,c = 8$ TeV:

- *gluon fusion*, $gg \to H$, through a loop of virtual quarks dominated by the top because its Yukawa coupling is the largest, $\sigma \approx 1.93 \times 10^{-39}\,\mathrm{m}^2$ (19.3 picobarns), about 87 % of the total;

- *vector-boson fusion*, $qq \to qqH$, in which each incoming quark radiates a W or Z that fuse, $\sigma \approx 1.58 \times 10^{-40}\,\mathrm{m}^2$, and which is identified by two forward jets with a large rapidity gap;

Table 113.2: The machine as operated in the two discovery runs [2123]. These are settings, not measurements, and carry no uncertainty; the two derived rows are computed in Proposition 113.8 and Proposition 113.10 from the geometry and the beam parameters in the rows above them. The mean pile-up is a luminosity-weighted average over the run and is about 1.7 times smaller than the value at the start of a fill, because the luminosity decays as the bunches are consumed.

Machine parameter	2011 run	2012 run
Circumference	26 659 m	26 659 m
Main dipoles	1232×14.3 m, NbTi at 1.9 K	as 2011
Bending radius (derived)	2804 m	2804 m
Beam energy	3.5 TeV	4 TeV
Centre-of-mass energy $\sqrt{s}\,c$	7 TeV	8 TeV
Dipole field (derived)	4.16 T	4.76 T
Bunch spacing	50 ns = 15.0 m	as 2011
Filled bunches per beam	up to 1380	up to 1374
Protons per bunch	$\approx 1.45 \times 10^{11}$	$\approx 1.6 \times 10^{11}$
Stored energy per beam (derived)	1.1×10^{8} J	1.4×10^{8} J
Revolution frequency	11 245 Hz	11 245 Hz
Peak luminosity	$3.7 \times 10^{37}/(\mathrm{m}^2\,\mathrm{s})$	$7.7 \times 10^{37}/(\mathrm{m}^2\,\mathrm{s})$
Mean pile-up	≈ 9	≈ 21

- *associated production*, $q\bar{q} \to VH$ with $V = W$ or Z, $\sigma \approx 1.12 \times 10^{-40}\,\mathrm{m}^2$ summed over the two, the channel the Tevatron used;
- *top-quark associated production*, $gg \to t\bar{t}H$, $\sigma \approx 1.29 \times 10^{-41}\,\mathrm{m}^2$, which measures the top Yukawa coupling at tree level rather than through a loop.

The sum is $2.21 \times 10^{-39}\,\mathrm{m}^2$ at 8 TeV and $1.74 \times 10^{-39}\,\mathrm{m}^2$ at 7 TeV — in the customary units 22.1 and 17.4 picobarns [2186, 2192]. Set against the inelastic proton–proton cross section of $7.3 \times 10^{-30}\,\mathrm{m}^2$, the scalar is produced in 3.0×10^{-10} of all collisions: one in three thousand million.

Derivation pending #200

The Standard Model production cross sections quoted in this section. Obtaining them requires the partonic amplitudes — above all the top-quark triangle that drives gluon fusion, which has no tree-level counterpart — convolved with the measured parton distributions and corrected to next-to-next-to-leading order in the strong coupling, where the corrections are large (a K factor near two for gluon fusion). The loop amplitude and the resulting cross sections are already recorded as owed in the electroweak chapter's pending derivation of the loop-induced scalar vertices; the convolution and the perturbative corrections belong with them in Appendix A. What is derived in this chapter from those inputs is everything downstream of them: the produced event counts, the channel comparison, the mass resolution and the significance.

Proposition 113.12 (Sensitivity is set by ratio, not by rate)**.** *In the Gaussian limit the significance of a resonance search in a channel with s expected signal and b expected background events in the mass window is $s/\sqrt{b}$, not s. For the ATLAS discovery dataset,*

the three candidate channels give

$$\frac{s}{\sqrt{b}}\Big|_{b\bar{b}} \sim 7\times 10^{-2}\,, \qquad \frac{s}{\sqrt{b}}\Big|_{\gamma\gamma} \sim 2\,, \qquad \frac{s}{\sqrt{b}}\Big|_{4\ell} \sim 4\,, \tag{113.15}$$

although the produced event counts are in the ratio $1.2\times 10^5 : 4.9\times 10^2 : 25$. *The channel with the largest branching fraction is the least useful of the three.*

Rests on Propositions 11.93 and 113.5.

Derivation. *Derives Proposition 113.12.*

Take the ATLAS dataset: $4.8\times 10^{43}/\mathrm{m}^2$ at 7 TeV and $5.8\times 10^{43}/\mathrm{m}^2$ at 8 TeV, that is 4.8 and 5.8 inverse femtobarns. The number of scalars produced is the product of integrated luminosity and cross section, summed over the two runs:

$$N_H = 4.8\times 10^{43}/\mathrm{m}^2 \times 1.74\times 10^{-39}\,\mathrm{m}^2 + 5.8\times 10^{43}/\mathrm{m}^2 \times 2.21\times 10^{-39}\,\mathrm{m}^2 = 2.12\times 10^5\,.$$

Multiplying by the branching fractions of Table 104.4 gives 1.2×10^5 decays to $b\bar{b}$, 487 to $\gamma\gamma$, and — using $\mathcal{B}(H\to ZZ^*) = 0.026$ together with $\mathcal{B}(Z\to e^+e^-)+\mathcal{B}(Z\to\mu^+\mu^-) = 0.0673$, so that $\mathcal{B}(H\to ZZ^*\to 4\ell) = 0.026\times 0.0673^2 = 1.18\times 10^{-4}$ — 25 decays to four charged leptons of the first two generations.

Now the backgrounds.

Bottom pairs. The inclusive $b\bar{b}$ production cross section at these energies is of order $2.8\times 10^{-32}\,\mathrm{m}^2$, which the collider literature writes as 280 microbarns — seven orders of magnitude above the rate at which scalars are produced and decay to $b\bar{b}$, and four thousandths of the inelastic proton–proton cross section quoted above, which it must be. The same luminosity therefore yields $1.06\times 10^{44}/\mathrm{m}^2 \times 2.8\times 10^{-32}\,\mathrm{m}^2 = 3\times 10^{12}$ background events. Even at 100 % efficiency, $s/\sqrt{b} = 1.2\times 10^5/\sqrt{3\times 10^{12}} = 0.07$. Requiring an associated W or Z, as the Tevatron did, cuts the background by orders of magnitude but cuts the signal to the associated-production cross section, a twentieth of the total; that trade is what produced three standard deviations at the Tevatron and not five.

Two photons. Photon reconstruction and the selection of Section 113.3.2 retain roughly 40 % of the produced decays, so $s\approx 195$. The background is continuum production of two photons, plus jets misidentified as photons; in a window of a few GeV around 125 GeV it is of order 1×10^4 events in this dataset. Hence $s/\sqrt{b}\approx 195/100\approx 2$, and a signal fraction $s/b\approx 2\,\%$.

Four leptons. Acceptance and lepton efficiency retain roughly 35 %, so $s\approx 8.7$; the background in a window of a few GeV, dominated by the irreducible continuum $q\bar{q}\to ZZ^*$, is of order 5 events. Hence $s/\sqrt{b}\approx 4$ — and here $s/b>1$, so the "background" is not the thing being fought.

The three numbers are Equation (113.15). Two lessons follow, and both shaped the analyses. A large branching fraction is worth nothing if the final state is one the strong interaction produces copiously by itself, which disqualifies $b\bar{b}$, $c\bar{c}$ and gg — three of the four largest entries in Table 104.4. And the two surviving channels are useful for opposite reasons: $\gamma\gamma$ has many events and a poor signal fraction, 4ℓ has few events and an excellent one, so their systematic weaknesses do not overlap either. □

Remark 113.13 (The discovery channel has no tree-level vertex). The scalar is electrically neutral and colourless, so $H\to\gamma\gamma$ and $gg\to H$ do not exist at tree level. Both proceed through loops of the heaviest charged or coloured particles: gluon fusion through the top-quark triangle, and the diphoton decay through the top triangle *and* the W loop, which interfere destructively with the W dominating. The discovery therefore rested on a one-loop amplitude at both ends — the dominant production mechanism and the most significant decay channel are each loop-induced — which is an unusual situation and a strong one: any heavy charged or coloured particle coupling to the scalar would change these rates whether or not it can be produced directly. The amplitudes themselves are recorded as a pending derivation in Section 104.7.1 and are not repeated here.

113.3.2 Event selection and background estimation

Photons. A photon candidate is an electromagnetic cluster with no matched track (or, for a converted photon, a matched conversion vertex) whose lateral and longitudinal shower shape is consistent with a single electromagnetic shower rather than with two overlapping ones or with a jet fluctuating to a leading π^0. About a quarter of photons convert in the tracker material before reaching the calorimeter, which is why both experiments treat converted and unconverted candidates separately. Isolation — the transverse energy in a cone around the candidate, corrected for pile-up — rejects photons produced inside jets. ATLAS required two candidates with transverse energies above 40 GeV and 30 GeV within $|\eta| < 2.37$ excluding the barrel to endcap transition; CMS scaled its thresholds with the candidate mass, requiring $E_T > m_{\gamma\gamma}c^2/3$ and $m_{\gamma\gamma}c^2/4$, which keeps the selection from sculpting a peak into the background.

Leptons. Electrons are clusters with a matched track; muons are tracks matched between the inner detector and the muon system. The four-lepton selection requires two same-flavour opposite-charge pairs, with the pair closer to the Z mass required to be near it and the second allowed to be far off shell — which is the whole point, since at $m_H c^2 = 125\,\mathrm{GeV}$ the decay $H \to ZZ$ is below threshold by 57 GeV and one boson must be virtual. Lepton transverse-momentum thresholds are low, of order $7\,\mathrm{GeV}/c$ for the softest, because the four leptons share 125 GeV between them.

The measurement that everything else serves is the invariant mass, and its resolution is where the two detector designs cash out.

Proposition 113.14 (What limits the diphoton mass resolution)**.** *For two photons of energies E_1, E_2 separated by an angle θ,*

$$\left(m_{\gamma\gamma}c^2\right)^2 = 2E_1E_2\left(1-\cos\theta\right), \tag{113.16}$$

and the fractional resolution is

$$\frac{\sigma_m}{m} = \frac{1}{2}\left[\left(\frac{\sigma_{E_1}}{E_1}\right)^2 + \left(\frac{\sigma_{E_2}}{E_2}\right)^2 + \left(\frac{|\boldsymbol{p}_H|\,c}{m_H c^2}\right)^2 \sigma_\theta^2\right]^{1/2}, \tag{113.17}$$

the angular term being evaluated for the symmetric decay. It vanishes for a scalar produced at rest and grows with the scalar's momentum; with a misassigned collision vertex it dominates.
Rests on Equations (113.13) and (113.14).

Derivation. *Derives Proposition 113.14.*

For two massless particles $|\boldsymbol{p}_i|\,c = E_i$, so the squared invariant mass of the pair is

$$\left(mc^2\right)^2 = \left(E_1+E_2\right)^2 - \left(\boldsymbol{p}_1+\boldsymbol{p}_2\right)^2 c^2 = 2E_1E_2 - 2\boldsymbol{p}_1\cdot\boldsymbol{p}_2 c^2 = 2E_1E_2\left(1-\cos\theta\right),$$

which is Equation (113.16). Taking the logarithm and differentiating,

$$2\,\frac{\mathrm{d}m}{m} = \frac{\mathrm{d}E_1}{E_1} + \frac{\mathrm{d}E_2}{E_2} + \frac{\sin\theta}{1-\cos\theta}\mathrm{d}\theta = \frac{\mathrm{d}E_1}{E_1} + \frac{\mathrm{d}E_2}{E_2} + \cot\!\left(\frac{\theta}{2}\right)\mathrm{d}\theta,$$

using $\sin\theta/(1-\cos\theta) = \cot(\theta/2)$. Adding the three independent errors in quadrature gives Equation (113.17) once $\cot(\theta/2)$ is expressed kinematically. For the symmetric decay of a parent of energy E_H, $E_1 = E_2 = E_H/2$, so Equation (113.16) reads $(m_H c^2)^2 = E_H^2\sin^2(\theta/2)$, whence $\sin(\theta/2) = m_H c^2/E_H$ and

$$\cot\!\left(\frac{\theta}{2}\right) = \frac{\sqrt{E_H^2 - \left(m_H c^2\right)^2}}{m_H c^2} = \frac{|\boldsymbol{p}_H|\,c}{m_H c^2}.$$

So the angular sensitivity is exactly the parent's momentum in units of its mass: a scalar at rest decays back to back, $\theta = \pi$, and its mass is then $E_1 + E_2$ with no angular information required at all.

Now the numbers, at a typical photon energy of 60 GeV and a typical scalar energy of 200 GeV, for which $|\boldsymbol{p}_H|\,c = 156\,\mathrm{GeV}$ and $\cot(\theta/2) = 1.25$.

Energy term. ATLAS's parametrization Equation (113.13) gives $\sigma_E/E = 10\,\%/\sqrt{60} \oplus 0.7\,\% = 1.47\,\%$, so the two energy terms contribute $1.47\,\%/\sqrt{2} = 1.04\,\%$, that is $1.30\,\mathrm{GeV}/c^2$. CMS's Equation (113.14) gives $2.8\,\%/\sqrt{60} \oplus 12\,\%/60 \oplus 0.30\,\% = 0.51\,\%$ and hence $0.45\,\mathrm{GeV}/c^2$ — a factor of three better, which is the crystal calorimeter's entire justification.

Angular term with the wrong vertex. A photon leaves no track, so the collision vertex must be inferred. If it is taken at random from the twenty available, the error is the longitudinal spread of the luminous region, $\sigma_z \approx 5\,\mathrm{cm}$. At a calorimeter radius of 1.5 m this is an angular error $\sigma_\theta \approx 0.05\,\mathrm{m}/1.5\,\mathrm{m} = 0.033$, and $\tfrac{1}{2} \times 1.25 \times 0.033 = 2.1\,\%$, that is $2.6\,\mathrm{GeV}/c^2$. This is twice ATLAS's energy term and six times CMS's: with no vertex information the diphoton channel would not have worked in either detector.

Angular term with the right one. ATLAS's calorimeter pointing — the same shower measured in two samplings at different radii — locates the photon's origin to about 15 mm without any tracker information, giving $\sigma_\theta \approx 0.010$ and a contribution of $0.63\,\%$, or $0.79\,\mathrm{GeV}/c^2$: now subdominant. CMS instead identifies the vertex from the charged tracks recoiling against the diphoton system, and from the tracks of converted photons, reaching a comparable accuracy in the large majority of events.

Combining, the predicted resolutions are $1.5\,\mathrm{GeV}/c^2$ for ATLAS and $0.9\,\mathrm{GeV}/c^2$ for CMS; the values achieved in situ are $1.6\,\mathrm{GeV}/c^2$ to $1.7\,\mathrm{GeV}/c^2$ and $1.1\,\mathrm{GeV}/c^2$ to $1.5\,\mathrm{GeV}/c^2$ respectively [2186, 2192]. The excess over the test-bench numbers is upstream material, intercalibration between 7.6×10^4 channels, and the fact that a converted photon is measured worse than an unconverted one. The design calculation predicts the achieved resolution to within some tens of per cent, which is the level at which such an estimate can be trusted, and it identifies correctly which term dominates in which detector. □

Because the resolution and the signal fraction both vary strongly across the detector and across event topologies, neither experiment performed a single inclusive fit. ATLAS divided its diphoton candidates into ten categories in 2011 and fourteen in 2012, by conversion status, by pseudorapidity, and by the component of the diphoton transverse momentum orthogonal to the thrust axis; CMS used a multivariate classifier trained on the expected resolution and predicted signal fraction, plus a separate class tagged by two forward jets for vector-boson fusion. The gain from doing so is not a technicality.

Proposition 113.15 (Why categorizing helps, and by how much)**.** *Let a search be divided into independent categories i with expected signal s_i and background b_i. In the Gaussian limit the combined discovery significance is*

$$Z = \left(\sum_i \frac{s_i^2}{b_i} \right)^{1/2} \geq \frac{\sum_i s_i}{\left(\sum_i b_i\right)^{1/2}} = Z_{\mathrm{merged}}\,, \tag{113.18}$$

with equality if and only if s_i/b_i is the same in every category.

Rests on Equation (11.88)*, Definition 11.60, and Proposition 11.93.*

Derivation. *Derives Proposition 113.15.*

Let n_i be Poisson with mean $\mu s_i + b_i$ and let μ be the signal strength. The profile-likelihood statistic of Equation (11.88) in the Gaussian limit is $\tilde{q}_0 = \hat{\mu}^2/\sigma_\mu^2$, and the Fisher information of Definition 11.60 for μ at $\mu = 0$ is

$$\frac{1}{\sigma_\mu^2} = -\left\langle \frac{\partial^2 \ln L}{\partial \mu^2} \right\rangle \Bigg|_{\mu=0} = \sum_i \frac{s_i^2}{b_i}\,,$$

since $\ln L = \sum_i [n_i \ln(\mu s_i + b_i) - (\mu s_i + b_i)]$ up to constants, whose second derivative is $-\sum_i n_i s_i^2/(\mu s_i + b_i)^2$, with expectation $-\sum_i s_i^2/b_i$ at $\mu = 0$. For the median dataset under the signal hypothesis $\hat{\mu} = 1$, so $\tilde{q}_0 = \sum_i s_i^2/b_i$, and $Z = \sqrt{\tilde{q}_0}$ by Proposition 11.93. That is the first equality in Equation (113.18), and the merged case is the special case of a single category.

The inequality is Cauchy–Schwarz. Write $s_i = (s_i/\sqrt{b_i})\,\sqrt{b_i}$; then

$$\left(\sum_i s_i\right)^2 = \left(\sum_i \frac{s_i}{\sqrt{b_i}}\sqrt{b_i}\right)^2 \le \left(\sum_i \frac{s_i^2}{b_i}\right)\left(\sum_i b_i\right),$$

with equality exactly when the vectors $(s_i/\sqrt{b_i})$ and $(\sqrt{b_i})$ are proportional, that is when s_i/b_i is constant. Dividing by $\sum_i b_i$ gives Equation (113.18). □

Example 113.16 (The size of the effect)**.** Suppose 100 signal events sit on 10 000 background events, so the inclusive significance is $100/\sqrt{10\,000} = 1.0$. Suppose the events divide into a clean category holding 30 signal on 600 background and a dirty one holding 70 on 9400. Then

$$Z = \left(\frac{900}{600} + \frac{4900}{9400}\right)^{1/2} = \sqrt{2.02} = 1.42\,,$$

a gain of 42 % from partitioning the same events into two boxes. Nothing has been added; what has been used is the information that the two boxes have different signal purity, which a single fit throws away. This is why both collaborations spent as much effort on categorization as on the selection itself.

Background estimation. The two channels are treated in opposite ways, and the difference is instructive.

For $\gamma\gamma$ the background is large, smooth and not calculable: it comes from continuum diphoton production, from photon plus jet with the jet misidentified, and from dijets with two misidentifications, in proportions that no simulation predicts to the accuracy required. It is therefore taken from the data. An analytic function — an exponential, or a polynomial in a Bernstein basis — is fitted to the observed mass spectrum over a wide range simultaneously with a signal peak of fixed shape, so the background normalization and shape are determined by the sidebands and the fit returns the signal yield. The danger of the method is that a wrong functional form can absorb a real signal or manufacture a spurious one, and it is controlled by the *spurious-signal test*: the chosen function is fitted to a background-only sample far larger than the data, and the fitted "signal" yield it returns is required to be a small fraction of the statistical uncertainty on the real measurement. The residual bias is then carried as a systematic uncertainty. The whole procedure is fixed, function and categories and all, before the signal region is examined.

For 4ℓ the background is small and partly calculable. The irreducible part is continuum ZZ^* production, taken from simulation and normalized where the simulation can be checked — on the Z peak itself, in the same final state, where the rate is thousands of times higher and the physics is the same. The reducible part, Z plus jets and $t\bar{t}$ with jets faking leptons, is estimated from control regions in the data defined by inverting the lepton identification or isolation requirements. Both estimates are validated in sidebands before use.

113.3.3 Blinding and the statistical procedure

The statistical machinery is derived in Chapter 11 and is used here as derived. This subsection states which pieces are in force; Section 113.5.1 applies them to the published numbers.

The test statistic is the profile-likelihood ratio of Definition 11.70. The parameter of interest is a single signal strength μ, defined so that $\mu = 0$ is the background-only hypothesis

and $\mu = 1$ the Standard Model prediction at the mass being tested; every systematic uncertainty — energy scales, resolutions, luminosity, background shape, theoretical cross sections — enters as a nuisance parameter, constrained by an auxiliary measurement and profiled out. The one-sided discovery statistic is $\tilde{q}_0$ of Equation (11.88), which refuses to count a deficit as evidence for a signal, and the significance is $Z = \sqrt{\tilde{q}_0}$ by Proposition 11.93. That identity is what allows a significance to be quoted without simulating an ensemble of experiments, and it rests on Wilks' theorem (Theorem 11.88) applied to the profile statistic (Corollary 11.89); the asymptotic formulae in the form the collaborations use them are [2172].

Exclusion uses the same machinery reversed, with the modified frequentist CL_s criterion [2036] — the ratio of the two tail probabilities rather than the numerator alone — so that a downward background fluctuation cannot exclude a signal the experiment had no power to see (Remark 11.95). This is the construction behind the LEP limit of Proposition 113.7 and behind every exclusion plot in the 2012 papers.

Two conventions must be stated because mixing them shifts a significance by more than a tenth of a standard deviation (Remark 11.94). The p-values quoted below are *one-sided*, so that $Z = 5$ corresponds to $p = 2.87 \times 10^{-7}$; and the significances quoted by the collaborations as "local" are computed at a mass fixed in advance, which no search does. The correction is Section 113.5.1.

Blinding. None of this is worth anything if the analysis was adjusted after the data were seen. Both collaborations therefore fixed the entire chain — trigger, selection, categorization, background parametrization, systematic model and statistical procedure — using simulation and the mass sidebands, with the signal region hidden, and unblinded only afterwards. The reason is not procedural hygiene but arithmetic: the p-value of Definition 11.75 is the probability, under the null, of a result at least as extreme as the one observed *by a test specified in advance*. A cut adjusted after seeing the excess makes the number it produces uninterpretable, because the effective number of hypotheses tested is then unknown and unboundable. Blinding is what makes the five-sigma threshold mean the thing it appears to mean, and it is the reason the 2012 result was believed immediately rather than after a decade of argument.

113.4 Observations and data

113.4.1 The diphoton channel

What the data show is a narrow peak sitting on a steeply falling smooth continuum. The continuum falls by roughly an order of magnitude between $m_{\gamma\gamma}c^2 = 100\,\mathrm{GeV}$ and $160\,\mathrm{GeV}$ and has no structure in it; the peak is one resolution width across, of order $1.5\,\mathrm{GeV}/c^2$ by Proposition 113.14, and stands a few per cent above the continuum in the best categories and well under one per cent in the worst. Nothing about the picture is dramatic; what makes it a measurement is the arithmetic done to it.

ATLAS reported a local significance of 4.5 standard deviations near $m_H c^2 = 126.5\,\mathrm{GeV}$ in this channel alone, against 2.5 expected for a Standard Model scalar at that mass [2186]; CMS reported 4.1 against 2.8 expected near $125\,\mathrm{GeV}$ [2192]. Two things about those pairs of numbers deserve saying plainly, because they are usually skipped.

First, the expected significances — 2.5 and 2.8 — are close to the crude estimate $s/\sqrt{b} \approx 2$ obtained in Proposition 113.12 from cross section, branching fraction, efficiency and background. That agreement is a check on the whole chain: an experiment whose expected sensitivity disagreed by a factor of two with a back-of-envelope calculation from published inputs would have something wrong with it.

Second, both observed values exceed both expected values. The fitted diphoton signal strength was correspondingly high in both experiments, around 1.8 with an uncertainty near

0.5 in ATLAS and similarly above unity in CMS. That is an upward fluctuation of about 1.5 standard deviations, present in the channel that dominates the combination — exactly the configuration in which an unblinded, after-the-fact analysis would be untrustworthy, and exactly why the selection was frozen beforehand. The later, much larger datasets brought the diphoton signal strength back to unity, which is the expected behaviour of a fluctuation and confirms the 2012 diagnosis.

One structural fact is available from this channel with no further analysis: a resonance that decays to two real photons cannot have spin 1. That is the Landau–Yang argument [917, 975], derived in Theorem 104.60 and again, in the vector form, in the derivation accompanying Phenomenon 113.22. The discovery channel therefore excluded one of the four spin hypotheses on the day it was announced, without any angular measurement.

113.4.2 The four-lepton channel

$H \to ZZ^* \to 4\ell$ is the opposite kind of measurement. The final state is fully reconstructed — four charged leptons, all their momenta measured in the tracker — so the mass resolution is set by lepton momentum resolution alone and is of order $2\,\mathrm{GeV}/c^2$, and the background is small enough that the signal fraction exceeds unity in a narrow window. What it does not have is events: the arithmetic of Proposition 113.12 gives about twenty-five produced decays in the ATLAS dataset and fewer than ten surviving selection.

Both experiments observed roughly a dozen candidates in a window $10\,\mathrm{GeV}/c^2$ wide around $125\,\mathrm{GeV}/c^2$, against an expected background of about five, and reported local significances of 3.6 standard deviations (ATLAS, against 2.7 expected) and 3.2 (CMS, against 3.8 expected) [2186, 2192]. With numbers this small the Gaussian approximation is doing real work, and the collaborations used the asymptotic formulae [2172] whose accuracy at such yields is itself part of what Chapter 11 establishes; the CMS value fell below its own expectation, which is an ordinary downward fluctuation of a Poisson count.

The complementarity is the point of quoting both channels. A high-rate, high-background channel and a low-rate, low-background one fail in different ways: a mismodelled background shape would move the diphoton result and not the four-lepton one, and a mismeasured lepton efficiency would do the reverse. Their masses agreed to within the resolutions, and their signal strengths agreed with each other and with unity. Two supporting channels, $H \to WW^* \to \ell\nu\ell\nu$ and $H \to \tau^+\tau^-$, contributed sensitivity but no mass information at all: the neutrinos in the first and in the tau decays of the second make full reconstruction impossible, so those channels report an excess of events with the expected kinematics and not a resonance. They are evidence for a signal and not evidence for a particle, and both papers treat them as such.

113.4.3 Combined significance, 4 July 2012

Combining channels, ATLAS reported a local significance of 5.9 standard deviations at $m_H c^2 = 126.0\,\mathrm{GeV}$ against 4.9 expected, and CMS 5.0 at 125.5 GeV against 5.8 expected [2186, 2192]. The masses were

$$m_H c^2\big|_{\mathrm{ATLAS}} = 126.0\,\mathrm{GeV} \pm 0.4\,\mathrm{GeV} \pm 0.4\,\mathrm{GeV}\,, \quad m_H c^2\big|_{\mathrm{CMS}} = 125.3\,\mathrm{GeV} \pm 0.4\,\mathrm{GeV} \pm 0.5\,\mathrm{GeV}\,, \tag{113.19}$$

the first uncertainty statistical and the second systematic, and the signal strengths relative to the Standard Model prediction were $\mu = 1.4 \pm 0.3$ and $\mu = 0.87 \pm 0.23$ respectively.

The two collaborations were blind to each other's results until the seminar of 4 July 2012. That is not a detail of etiquette. Two measurements that agree are evidence in proportion to how independent they are, and these two shared only the accelerator: different magnets, different calorimeter technologies, different reconstruction software, different people, and no

exchange of intermediate results. An error common to both would have to originate in the beam or in the theory of the Standard Model, not in either apparatus.

Phenomenon 113.17 (A new boson near 125 GeV)**.** Two experiments at the Large Hadron Collider, blind to each other's results, reported on the same day a narrow resonance in the diphoton and four-lepton final states, with local significances of 5.9 and 5.0 standard deviations respectively [2186, 2192]. The combined mass from the two high-resolution channels is

$$m_H c^2 = (125.09 \pm 0.24)\,\mathrm{GeV}\,, \tag{113.20}$$

[2242], and the present world average is $(125.20 \pm 0.11)\,\mathrm{GeV}$, that is $m_H = 2.2319 \times 10^{-25}\,\mathrm{kg}$ [2427]. The particle is electrically neutral, decays to two photons and to two Z bosons, and is produced at a rate compatible with the single scalar that Phenomenon 113.6 requires.

Rests on Phenomenon 113.6, Equation (113.19)*, and Proposition 113.5.*

Derivation of the consistency checks. *Derives Phenomenon 113.17.*

Three separate agreements have to hold, and each is an arithmetic statement that could have failed.

The two experiments agree. Adding the errors of Equation (113.19) in quadrature gives $(126.0 \pm 0.6)\,\mathrm{GeV}$ for ATLAS and $(125.3 \pm 0.6)\,\mathrm{GeV}$ for CMS, where $\sqrt{0.4^2 + 0.4^2} = 0.57$ and $\sqrt{0.4^2 + 0.5^2} = 0.64$. The difference is $0.7\,\mathrm{GeV}$ with a combined uncertainty $\sqrt{0.57^2 + 0.64^2} = 0.86$, that is 0.8 standard deviations. Two independent instruments measuring the same mass agreed at once.

The 2012 numbers survive. The joint ATLAS and CMS combination of the full Run-1 data [2242] gives $125.09\,\mathrm{GeV} \pm 0.21\,\mathrm{GeV}\,(\mathrm{stat}) \pm 0.11\,\mathrm{GeV}\,(\mathrm{syst})$, and adding those in quadrature is $(125.09 \pm 0.24)\,\mathrm{GeV}$, which is Equation (113.20). The present world average is $(125.20 \pm 0.11)\,\mathrm{GeV}$ [2427], higher by $0.11\,\mathrm{GeV}$.

These two are successive best values, not two measurements. The world average contains the Run-1 combination, so the two are strongly correlated, their errors may not be added in quadrature, and the difference cannot be converted into a number of standard deviations without an estimate of the correlation that neither publication supplies. What can be said without one is the thing worth saying: twelve years and two orders of magnitude in integrated luminosity moved the central value by $0.11\,\mathrm{GeV}$, less than half the 2015 uncertainty, while more than halving that uncertainty. A shift of that size is what an unbiased measurement being refined looks like; a shift of several GeV would have been a retraction.

The rate is the predicted one. The signal strengths $\mu = 1.4 \pm 0.3$ and $\mu = 0.87 \pm 0.23$ are ratios of the observed rate to the Standard Model prediction computed from Proposition 113.5 with the mass now fixed. Their weighted mean is

$$\bar{\mu} = \frac{1.4/0.3^2 + 0.87/0.23^2}{1/0.3^2 + 1/0.23^2} = 1.06\,, \qquad \sigma_{\bar{\mu}} = \left(\frac{1}{0.3^2} + \frac{1}{0.23^2}\right)^{-1/2} = 0.18\,,$$

so $\bar{\mu} = 1.06 \pm 0.18$, consistent with unity. This is the check that a bump alone would not supply: a narrow resonance at $125\,\mathrm{GeV}/c^2$ produced at a hundredth of the predicted rate, or a hundred times it, would be a new particle and would not be this one.

What the combination does *not* establish is treated in Section 113.5.1: the quoted significances are local, and the mass was not nominated in advance. □

113.4.4 The measured numbers

Table 113.3 collects the quantities of the discovery itself and Table 113.4 what has been measured since; Tables 113.5 and 113.6 collect the coupling test, which is the measurement that distinguishes this scalar from any other. All four sit here, under this rubric, rather than beside the sections that use them, so that a reader looking for the chapter's numbers

finds them in one place. Rows that record a run setting carry no uncertainty because they define the conditions rather than measure anything; every row that reports a measured or derived quantity carries one, and a derived row names the equation that produced it.

Remark 113.18 (Where each number came from, and where it did not). The masses in Table 113.5 and the world-average scalar mass and width in Table 113.4 are taken from the Particle Data Group's own machine-readable 2024 release, stored with this treatise as evidence [2427]; the conversions to kg and J use the exact 2019 SI values of e and c [2431]. The 2012 significances, signal strengths and per-channel numbers are the collaborations' published values [2186, 2192] and are not recomputed here. The rows marked derived are computed in this chapter from the rows above them, with the arithmetic shown; the produced-scalar count inherits the roughly ten per cent uncertainty of the predicted production cross sections, which is why it is quoted to three figures and not to five. The predicted reduced couplings are exact functions of the masses and E_v and carry no theoretical uncertainty at tree level.

113.5 Interpretation

113.5.1 The look-elsewhere effect

Every significance in Table 113.3 labelled *local* is the answer to a question nobody asked: what is the probability of a fluctuation this large *at a mass named in advance*? No search names a mass in advance. Both experiments scanned a range and reported the largest excess found in it, and the probability that *some* point of a range fluctuates upward is larger — here by one to two orders of magnitude — than the probability that a nominated point does. The correction is derived in Section 11.6 and is applied here to the published numbers.

Proposition 113.19 (The trials factors of the 2012 result)**.** *With the one-sided convention of Proposition 11.93, the ATLAS local significance $Z_{loc} = 5.9$ corresponds to $p_{loc} = 1.82 \times 10^{-9}$, and the two global significances the collaboration quotes correspond to trials factors*

$$N_{tr}\big|_{110--150\,\mathrm{GeV}} = 31.9\,, \qquad N_{tr}\big|_{110--600\,\mathrm{GeV}} = 93.4\,. \tag{113.21}$$

The first is reproduced to within one per cent by counting resolution elements; the second is not, and the reason is physical.

Rests on Definitions 11.92 and 11.96 and Proposition 113.14.

Derivation. *Derives Proposition 113.19.*

By Definition 11.92, $p = 1 - \Phi(Z)$, so $p_{\mathrm{loc}} = 1 - \Phi(5.9) = 1.8175 \times 10^{-9}$, $1 - \Phi(5.3) = 5.7901 \times 10^{-8}$ and $1 - \Phi(5.1) = 1.6983 \times 10^{-7}$. The trials factor is the ratio $N_{\mathrm{tr}} = p_{\mathrm{glob}}/p_{\mathrm{loc}}$ of Definition 11.96, giving $5.7901 \times 10^{-8}/1.8175 \times 10^{-9} = 31.86$ for the narrow range and $1.6983 \times 10^{-7}/1.8175 \times 10^{-9} = 93.44$ for the wide one, which is Equation (113.21).

The narrow range, from resolution elements. The naive estimate of Equation (11.93) treats the scan as $N = \Delta m/\delta m$ independent tests. With $\Delta mc^2 = 40\,\mathrm{GeV}$ and the diphoton resolution $\delta mc^2 = 1.7\,\mathrm{GeV}$ of Proposition 113.14 — the channel that dominates the combination — this is $N = 23.5$, whence $p_{\mathrm{glob}} \simeq 23.5 \times 1.8175 \times 10^{-9} = 4.27 \times 10^{-8}$ and $Z_{\mathrm{glob}} = \Phi^{-1}(1 - p_{\mathrm{glob}}) = 5.36$. ATLAS quotes 5.3. The agreement is closer than the method deserves and should not be over-read — Remark 11.99 says why the independence assumption has no general justification — but it does show that the published correction is the size a reader can reconstruct from the resolution and the window.

The wide range, where the same estimate fails. Repeating it over $110 - -600\,\mathrm{GeV}$ gives $N = 490\,\mathrm{GeV}/1.7\,\mathrm{GeV} = 288$ and $Z_{\mathrm{glob}} = 4.88$, whereas ATLAS quotes 5.1, corresponding to $N_{\mathrm{tr}} = 93$. The naive count is too large by a factor of three, and the reason is that $\delta m = 1.7\,\mathrm{GeV}/c^2$ is not the correlation length of the test statistic above about $180\,\mathrm{GeV}/c^2$.

Table 113.3: The discovery itself: the datasets it rests on, the prior constraints it had to clear, and the significances reported in 2012. Integrated luminosities are given in $1/\mathrm{m}^2$ with the customary inverse-femtobarn figure alongside (Notation 113.1); one inverse femtobarn is $1 \times 10^{43}/\mathrm{m}^2$. Significances are pure numbers. The global significances are the collaboration's own look-elsewhere corrections over the mass range named; Section 113.5.1 reconstructs the trials factors they imply. What was measured afterwards is Table 113.4.

Quantity	Value	Year	Source
ATLAS integrated luminosity, 7 TeV (setting)	$4.8 \times 10^{43}/\mathrm{m}^2$, i.e. 4.8 inverse femtobarns	2011	[2186]
ATLAS integrated luminosity, 8 TeV (setting)	$5.8 \times 10^{43}/\mathrm{m}^2$	2012	[2186]
CMS integrated luminosity, 7 TeV (setting)	$5.1 \times 10^{43}/\mathrm{m}^2$	2011	[2192]
CMS integrated luminosity, 8 TeV (setting)	$5.3 \times 10^{43}/\mathrm{m}^2$	2012	[2192]
Scalars produced in the ATLAS dataset	2.12×10^5 (derived from the two rows above and the cross sections of Section 113.3.1; good to the 10 % accuracy of those predictions)	2012	Proposition 113.12
LEP lower limit, 95 % confidence	$m_H c^2 > 114.4\,\mathrm{GeV}$	2003	[2045]
Tevatron excess in VH, $H \to b\bar{b}$	local significance ≈ 3, global ≈ 2.5	2012	[2187]
ATLAS local significance, $\gamma\gamma$	4.5 observed, 2.5 expected	2012	[2186]
ATLAS local significance, $ZZ^* \to 4\ell$	3.6 observed, 2.7 expected	2012	[2186]
ATLAS combined local significance	5.9 observed, 4.9 expected	2012	[2186]
ATLAS global significance, 110–150 GeV range	5.3	2012	[2186]
ATLAS global significance, 110–600 GeV range	5.1	2012	[2186]
CMS local significance, $\gamma\gamma$	4.1 observed, 2.8 expected	2012	[2192]
CMS local significance, $ZZ^* \to 4\ell$	3.2 observed, 3.8 expected	2012	[2192]
CMS combined local significance	5.0 observed, 5.8 expected	2012	[2192]

Table 113.4: What has been measured since. The 2012 masses carry a statistical and a systematic error, quoted separately by the collaborations and combined in quadrature here, with the arithmetic shown in the derivation accompanying Phenomenon 113.17. The two 2012 masses and the later combinations are successive best values of one quantity and not independent measurements to be averaged — the world average already contains the earlier data. Signal strengths are pure numbers. The width, the lifetime and the electroweak scale are derived quantities, and each is given in SI beside its customary form.

Quantity	Value	Year	Source
ATLAS mass	$126.0\,\mathrm{GeV}/c^2$, ± 0.4 (stat) ± 0.4 (syst); $(126.0 \pm 0.6)\,\mathrm{GeV}$ combined	2012	[2186]
CMS mass	$125.3\,\mathrm{GeV}/c^2$, ± 0.4 (stat) ± 0.5 (syst); $(125.3 \pm 0.6)\,\mathrm{GeV}$ combined	2012	[2192]
ATLAS signal strength μ at $126\,\mathrm{GeV}/c^2$	1.4 ± 0.3	2012	[2186]
CMS signal strength μ at $125.5\,\mathrm{GeV}/c^2$	0.87 ± 0.23	2012	[2192]
Weighted mean signal strength	1.06 ± 0.18 (derived)	2012	Phenomenon 113.17
ATLAS and CMS combined mass	$(125.09 \pm 0.24)\,\mathrm{GeV}/c^2$	2015	[2242]
World-average mass	$(125.20 \pm 0.11)\,\mathrm{GeV}/c^2$, i.e. $(2.2319 \pm 0.0020) \times 10^{-25}\,\mathrm{kg}$	2024	[2427]
Total width, as an energy $\hbar\Gamma_H$	$3.7\,\mathrm{MeV}$, $+1.9$, -1.4; in SI $5.93 \times 10^{-13}\,\mathrm{J}$	2024	[2427]
Mean lifetime $\tau = \hbar/(\hbar\Gamma_H)$	$1.78 \times 10^{-22}\,\mathrm{s}$ (derived), with $+1.08$ and -0.60 on the same power of ten; decay length $c\tau = 5.3 \times 10^{-14}\,\mathrm{m}$, with $+3.2$ and -1.8 likewise; both errors are the width's $+51\,\%$, $-38\,\%$ propagated	2024	Phenomenon 113.26
Electroweak scale E_v	$246.220\,\mathrm{GeV}$, i.e. $3.944\,88 \times 10^{-8}\,\mathrm{J}$ (derived from the muon lifetime; the fractional uncertainty, 3×10^{-7}, is beyond the digits shown)	2013	[2225]

Table 113.5: The coupling test. The predicted reduced coupling is mc^2/E_v for a fermion and $M_V c^2/E_v$ for a weak boson, by Equation (104.70); it is a pure number, it contains no free parameter, and its uncertainty here is propagated from the measured mass alone, since E_v is known to three parts in 10^7. Masses are the PDG 2024 values, which are also the masses in kg shown alongside; each kilogram value carries the same fractional uncertainty as the GeV value beside it, written in brackets on the last digits quoted. The fourth column records what the ten-year coupling maps report: every measured coupling modifier κ_i, defined so that $\kappa_i = 1$ reproduces the predicted value, is consistent with unity, and the entry gives the approximate precision, not a central value — the papers cited should be consulted for those and for their correlations. The last column carries the year of each of the two measured entries in the row, the mass first. The partners whose couplings are not yet measured are collected separately in Table 113.6.

Partner	Mass [2427]	Predicted reduced coupling	Measured κ [2394, 2410]	Year
W	$(80.369 \pm 0.013)\ \mathrm{GeV}/c^2$; $(1.432\,708 \pm 0.000\,023) \times 10^{-25}$ kg	$0.326\,411 \pm 0.000\,053$	1 to about 10 %	2024; 2022
Z	$(91.1880 \pm 0.0020)\ \mathrm{GeV}/c^2$; $(1.625\,573\,8 \pm 0.000\,003\,6) \times 10^{-25}$ kg	$0.370\,351\,7 \pm 0.000\,008\,1$	1 to about 10 %	2024; 2022
t	$(172.57 \pm 0.29)\ \mathrm{GeV}/c^2$; $(3.076\,34 \pm 0.000\,52) \times 10^{-25}$ kg	$0.700\,88 \pm 0.001\,18$	1 to about 10 %; $t\bar{t}H$ observed [2320]	2024; 2022
b	$(4.183 \pm 0.007)\ \mathrm{GeV}/c^2$; $(7.4569 \pm 0.0012) \times 10^{-27}$ kg	$0.016\,989 \pm 0.000\,028$	1 to about 10 %	2024; 2022
τ	$(1.776\,93 \pm 0.000\,09)\ \mathrm{GeV}/c^2$; $(3.167\,665\,4 \pm 0.000\,001\,6) \times 10^{-27}$ kg	$0.007\,216\,8 \pm 0.000\,000\,4$	1 to about 10 %	2024; 2022
μ	$(0.105\,658\,375\,5 \pm 0.000\,000\,002\,3)\ \mathrm{GeV}/c^2$; $(1.883\,531\,63 \pm 0.000\,000\,04) \times 10^{-28}$ kg	$4.291\,218 \times 10^{-4}$	1 to about 20 %; decay observed at three standard deviations [2390]	2024; 2021

Table 113.6: What the coupling test does *not* yet reach. The predicted reduced coupling is defined as in Table 113.5; the difference is that no entry here has a measured κ. The charm coupling is bounded but not observed, the first-generation and strange couplings are far below present sensitivity, and the self-coupling — the one number that probes the shape of the potential rather than its minimum — is constrained only to a wide interval. The last column carries the year of the mass and of the bound respectively.

Partner	Mass [2427]	Predicted reduced coupling	Status [2394, 2410]	Year
c	$(1.273 \pm 0.005)\,\mathrm{GeV}/c^2$; $(2.2693 \pm 0.0089) \times 10^{-27}\,\mathrm{kg}$	$0.005\,170 \pm 0.000\,020$	not measured; only bounded	2024; —
e, u, d, s	below $0.1\,\mathrm{GeV}/c^2$	below 4×10^{-4}	not measured	2024; —
Self-coupling κ_λ	—	1 by Proposition 104.63	allowed anywhere from about -1 to $+7$	—; 2022

Two effects lengthen it: the channels that carry the sensitivity at high mass ($ZZ \to 4\ell$ with degrading resolution, and WW, which has no mass peak at all) are much coarser than the diphoton channel; and the predicted width of a Standard Model scalar grows rapidly once the WW and ZZ thresholds open, reaching tens of GeV by $500\,\mathrm{GeV}/c^2$, so neighbouring hypotheses in that region are nearly the same hypothesis. Fewer effectively independent tests, hence a smaller trials factor.

The upcrossing form. The honest machinery is Theorem 11.101 with the level dependence of Theorem 11.103, which for large Z_{loc} gives Equation (11.98). That statement is an *upper bound* — it descends from Davies' bound — and reads $N_{\mathrm{tr}} \le 1 + \sqrt{2\pi}\,\langle N_{u_0}\rangle\,\mathrm{e}^{u_0/2} Z_{\mathrm{loc}}$ with $u_0 = 1$, so inverting it about $\langle N_{u_0}\rangle$ turns it into a *lower* bound on the upcrossing count and not into a value. Since $\sqrt{2\pi}\,\mathrm{e}^{1/2} = 4.133$ and $Z_{\mathrm{loc}} = 5.9$, the published trials factors imply mean numbers of one-sigma upcrossings of at least

$$\langle N_1\rangle\,\big|_{110--150\,\mathrm{GeV}} \ge \frac{31.86 - 1}{4.133 \times 5.9} = 1.27\,, \qquad \langle N_1\rangle\,\big|_{110--600\,\mathrm{GeV}} \ge 3.79\,.$$

Both floors are of order unity, which is exactly the regime in which the calibrate-and-extrapolate procedure works: a mean upcrossing count near one can be measured from a few hundred simulated background-only experiments, whereas the tail probability it is used to compute, 5×10^{-8}, could not be sampled by any feasible number of them. And the two floors stand in the ratio 2.99, far below the ratio of the two mass ranges, 12.25 — which is the quantitative form of the statement that the correlation length grows with mass, provided the bound is comparably tight in both ranges, as it is, both being evaluated at the same Z_{loc}. □

Remark 113.20 (What survives the correction, honestly). Applied to ATLAS the correction moves 5.9 to 5.3 over the range where a Standard Model scalar was still allowed, and to 5.1 over the full range scanned. Both remain above the conventional threshold. Applied to CMS it does not: repeating the resolution-element estimate with a window $110 - -145\,\mathrm{GeV}$ and a diphoton resolution near $1.4\,\mathrm{GeV}/c^2$ gives $N = 25$, hence $p_{\mathrm{glob}} \simeq 25 \times 2.87 \times 10^{-7} = 7.2 \times 10^{-6}$ and $Z_{\mathrm{glob}} \simeq 4.3$ — an estimate made here, not a published number, and one that puts the CMS result below five standard deviations globally.

That is the correct state of affairs to record, and it is worth being blunt about it. The 2012 discovery does not rest on either experiment individually crossing an arbitrary threshold. It rests on two independent experiments finding an excess of the same size at the same mass in the same two channels on the same day, with the rate the theory predicts — the three checks in the derivation accompanying Phenomenon 113.17. A joint probability is not the product of two marginal ones when the alternatives are correlated, so no single combined number is quoted here; what can be said is that the agreement of two blind measurements is evidence of a kind that no amount of significance in one of them supplies.

Three further cautions, all of them from Chapter 11 and all of them routinely mishandled in secondary accounts. A p-value is the probability of the data given the null, never the probability of the null given the data (Remark 11.77); "a one-in-3.5-million chance that it is a fluctuation" is a mistranslation of $Z = 5$, not a paraphrase of it. The one-sided and two-sided conventions differ by 0.14 in Z at $q = 25$ (Remark 11.94), which is enough to move a result across the threshold, so the convention must be stated — it is one-sided throughout this chapter. And a significance quoted without the range searched is a local number wearing a global name (Remark 11.108).

113.5.2 The mass

The measured mass is now

$$m_H c^2 = (125.20 \pm 0.11)\,\mathrm{GeV}\,, \qquad m_H = (2.2319 \pm 0.0020) \times 10^{-25}\,\mathrm{kg}\,, \tag{113.22}$$

a fractional precision of 8.8×10^{-4} [2427]. Almost all of it comes from the two high-resolution channels, and the systematic error is dominated by one thing: the absolute energy scale of the electromagnetic calorimeters.

That scale is not known a priori. A crystal's light yield, a liquid-argon gap's response and the material in front of both are known to a per cent at best, which would give a mass uncertainty of over $1\,\mathrm{GeV}/c^2$ — ten times the quoted error. What fixes it is a calibration source inside the same detector: the $Z \to e^+e^-$ peak, tens of millions of events at $(91.1880 \pm 0.0020)\,\mathrm{GeV}/c^2$ whose mass is known from LEP to two parts in 10^5 [2104, 2427]. Reconstructing it with the experiment's own electrons and demanding that the reconstructed peak sit at the LEP value calibrates the energy scale *in situ*, cell by cell and category by category. The residual uncertainty is then the extrapolation from the electron scale at 45 GeV to the photon scale at 60 GeV — a small step, and it is small because the calibration source and the measurement are in the same instrument and differ by less than a factor of two in energy.

Remark 113.21 (Fixing the mass converts the rest into tests). m_H was the last free parameter of the Standard Model to be measured. Its value fixes the quartic coupling by Equation (113.3),

$$\hat{\lambda} = \frac{1}{2}\left(\frac{m_H c^2}{E_v}\right)^2 = \frac{1}{2}\left(\frac{125.20}{246.220}\right)^2 = \frac{1}{2}\,(0.508\,49)^2 = 0.129\,28\,,$$

in agreement with Equation (104.38), and with it the curvature parameter $\hbar\mu c = m_H c^2/\sqrt{2} = 88.53\,\mathrm{GeV}$. From that moment every other statement the theory makes about the scalar — every branching fraction, every production rate, every self-coupling — is a prediction with no adjustable parameter, and each subsequent measurement is a test rather than a determination. The rest of this section, and the whole of Section 113.6, is the score.

113.5.3 Spin and parity

Four hypotheses were on the table in 2012: $J^P = 0^+$, the prediction; 0^-, a pseudoscalar; $1^\pm$; and 2^+, a graviton-like tensor. One of them was excluded by the discovery channel itself.

Phenomenon 113.22 (The new boson has spin zero and even parity)**.** The angular distributions of the four-lepton and diphoton final states are those of a $J^P = 0^+$ resonance; the 0^-, $1^\pm$ and 2^+ alternatives are excluded at high confidence by both experiments [2201, 2217]. The exclusion of spin 1 requires no angular analysis at all: it follows from the mere existence of the diphoton decay.

Rests on Theorem 104.60.

Derivation. *Derives Phenomenon 113.22.*

This is the Landau–Yang argument [917, 975], given in the vector form here and in the amplitude form as Theorem 104.60. Work in the rest frame of the parent, where the two photons carry momenta $\pm\boldsymbol{k}$ and transverse polarization vectors $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$, with $\boldsymbol{e}_1 \cdot \boldsymbol{k} = \boldsymbol{e}_2 \cdot \boldsymbol{k} = 0$. A parent of spin 1 is described by a polarization vector $\boldsymbol{J}$, and the decay amplitude must be a rotational scalar, linear in each of $\boldsymbol{e}_1$, $\boldsymbol{e}_2$ and $\boldsymbol{J}$. The only such scalars available are

$$(\boldsymbol{e}_1 \cdot \boldsymbol{e}_2)\,(\boldsymbol{J} \cdot \boldsymbol{k}) \;, \quad \boldsymbol{J} \cdot (\boldsymbol{e}_1 \times \boldsymbol{e}_2) \;, \quad (\boldsymbol{J} \cdot \boldsymbol{e}_1)\,(\boldsymbol{k} \cdot \boldsymbol{e}_2) + (\boldsymbol{J} \cdot \boldsymbol{e}_2)\,(\boldsymbol{k} \cdot \boldsymbol{e}_1) \;.$$

The list is complete, and transversality is what makes it so. Since $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ are both perpendicular to $\boldsymbol{k}$, the vector $\boldsymbol{e}_1 \times \boldsymbol{e}_2$ is parallel to $\boldsymbol{k}$; a further candidate such as $(\boldsymbol{J} \cdot \boldsymbol{k})\,[\boldsymbol{k} \cdot (\boldsymbol{e}_1 \times \boldsymbol{e}_2)]$ is therefore the second structure above multiplied by $|\boldsymbol{k}|^2$, and not an independent one.

The photons are identical bosons, so the amplitude must be unchanged under the exchange $(\boldsymbol{e}_1, \boldsymbol{k}) \leftrightarrow (\boldsymbol{e}_2, -\boldsymbol{k})$. The first structure changes sign, because $\boldsymbol{J} \cdot \boldsymbol{k}$ does; the second changes sign, because the cross product does; the third vanishes identically by transversality. No amplitude survives. A spin-1 particle therefore cannot decay into two real photons, whatever its parity, and the observed diphoton channel excludes $J = 1$ on its own.

The argument uses rotational invariance, Bose statistics and transversality and nothing else. It does not use parity, so it kills 1^+ and 1^- together; and it fails for two *virtual* photons or for a massive vector in the final state, both of which have a longitudinal polarization and therefore a third structure. The angular analysis is needed only to separate 0^+ from 0^- and from the spin-2 hypotheses. □

That separation uses the four-lepton final state, which is fully reconstructed and therefore carries its complete angular information: five angles — the production polar angle, the two polar angles of the lepton pairs in their parent frames, and two azimuths, one of them the angle Φ between the planes of the two lepton pairs — plus the two lepton-pair masses. The discriminating variable is Φ. A scalar couples to the two Z bosons through the structure $\varepsilon_1^* \cdot \varepsilon_2^*$ of Equation (104.69), which produces a distribution containing a $\cos\Phi$ term; a pseudoscalar can only couple through the antisymmetric structure $\epsilon_{\mu\nu\rho\sigma}\varepsilon_1^{*\mu}\varepsilon_2^{*\nu}k_1^\rho k_2^\sigma$, which has no $\cos\Phi$ term and a $\cos 2\Phi$ term of the opposite sign; and a spin-2 state produces polar distributions that neither can. Both collaborations built a likelihood in the seven variables and reported the alternatives disfavoured at high confidence, CMS excluding the pseudoscalar at above 99 % and ATLAS reaching a comparable conclusion [2201, 2217]. The scalar hypothesis was not merely preferred: the alternatives were rejected.

The three structures named in the previous paragraph are quoted, not derived. Landau–Yang is derived above and disposes of $J = 1$ from the diphoton channel alone; the separation of 0^+ from 0^- and from spin 2 is the load-bearing half of Phenomenon 113.22 and this chapter does not carry it.

Derivation pending #201

The azimuthal distributions that separate 0^+ *from* 0^- *and from the spin-2 hypotheses in* $H \to ZZ^* \to 4\ell$*. What is owed is the decay amplitude for each hypothesis — the scalar contraction of the two boson polarizations, the Levi-Civita contraction that a pseudoscalar is restricted to, and the tensor couplings — projected onto the two lepton pairs and integrated to give the distribution in the angle between their decay planes, exhibiting the* $\cos\Phi$ *term the scalar produces, its absence for the pseudoscalar, and the* $\cos 2\Phi$ *term of opposite sign that the pseudoscalar carries. It belongs in Appendix A beside the vector-boson vertices of the electroweak chapter, whose loop-induced counterparts are already recorded as owed there.*

Remark 113.23 (A CP-odd admixture is bounded, not excluded). Excluding a pure 0^- state is not the same as establishing that the state is purely 0^+. What the data constrain is the fraction of the rate arising from a CP-odd contribution, and the constraint is weak in a specific and instructive way: in the HZZ channel any CP-odd coupling would have to be generated by a loop, so it is suppressed by construction and the channel's apparent sensitivity overstates the test. The sharper probe is $H \to \tau^+\tau^-$, where a CP-odd Yukawa coupling enters at tree level and shows up as a phase in the correlation between the tau decay planes; there the mixing angle is currently bounded to a few tens of degrees.

The question is not academic. The Standard Model's CP violation is quantitatively insufficient to generate the observed baryon asymmetry by many orders of magnitude (Section 111.8.2), and the electroweak transition it predicts is a crossover, which supplies no departure from equilibrium either (Remark 104.65). A CP-odd component in the scalar sector is one of the few places where new CP violation could hide and be found with existing machines. It has not been found; it has been bounded.

113.5.4 Couplings against mass

Everything so far would be satisfied by a scalar that had nothing to do with mass generation. The measurement that closes the argument is the pattern of couplings.

Phenomenon 113.24 (Couplings proportional to mass)**.** The measured couplings of the new boson to the W, the Z, the top, the bottom and the tau, together with the observed $H \to \mu^+\mu^-$ decay [2390] and the observed $t\bar{t}H$ production [2320], lie on the single line that the mechanism predicts when they are plotted against the mass of the partner: coupling proportional to mass for fermions and to mass squared for gauge bosons, over more than three decades in mass [2263, 2394, 2410].

Rests on Equation (104.70) *and Proposition 104.61.*

Derivation. *Derives Phenomenon 113.24.*

In the mechanism a fermion mass comes from a Yukawa term evaluated on the vacuum, $m_f c^2 = \hat{y}_f E_v/\sqrt{2}$, while the coupling of the physical scalar to that same fermion is the same $\hat{y}_f$; hence

$$g_{Hff} = \frac{\hat{y}_f}{\sqrt{2}} = \frac{m_f c^2}{E_v}\,, \tag{113.23}$$

a pure number. A gauge-boson mass comes instead from the square of the covariant derivative, which on the substitution $v \to v + H$ multiplies the mass term by $(1 + H/v)^2$ and therefore gives a linear coupling twice the mass term over v,

$$g_{HVV} = \frac{2\,(M_V c^2)^2}{E_v}\,, \tag{113.24}$$

an energy rather than a pure number. Both are Equation (104.70), derived in Proposition 104.61. Neither contains a free parameter beyond $E_v = 246.220\,\mathrm{GeV}$, which is fixed by the muon lifetime.

The variable that puts the two families on one axis is the *reduced* coupling: g_{Hff} itself for a fermion and $\sqrt{g_{HVV}/2E_v} = M_V c^2/E_v$ for a vector. In that variable every Standard Model particle lies on one straight line through the origin of slope $1/E_v$, and Table 113.5 evaluates it: from 4.29×10^{-4} for the muon to 0.701 for the top, a range of 1630, each value known to the precision of the corresponding mass and carrying no theoretical uncertainty at tree level.

What is measured is not a coupling but a rate — a product of a production cross section and a branching fraction — so a global fit over many final states is required to disentangle them. The experiments report that fit in terms of modifiers κ_i defined so that $\kappa_i = 1$ reproduces Equation (113.23) and Equation (113.24), with rates scaling as κ^2. Every κ_i comes out consistent with unity, to roughly a tenth for W, Z, t, b and τ and roughly a fifth for μ [2394, 2410].

Two features make this a sharper test than a fit to six numbers suggests. First, there is nothing to adjust: a deviation anywhere along the line would falsify the mechanism rather than shift a parameter, because the parameter that would have to shift, E_v, is independently fixed by the muon lifetime to seven significant figures and enters every point of the line at once. Second, the $\gamma\gamma$ and gg vertices exist only at one loop (Remark 113.13), so their rates test the same couplings in a different combination — the diphoton amplitude is the W loop interfering destructively with the top loop — which constrains the *relative sign* of κ_W and κ_t, something no tree-level rate reaches. □

Remark 113.25 (Three decades, and where they stop). The verified range runs from the muon to the top. It does not include the electron, the up, the down or the strange quark, whose reduced couplings are all below 4×10^{-4} and none of which has been observed to couple to the scalar at all. The claim that one mechanism gives mass to all the charged fermions is therefore established for the third generation, established at three standard deviations for one second-generation lepton [2390], and *assumed* for the first generation and for the light quarks. That is a real gap and Section 113.6.2 states what would close it.

113.5.5 The total width

Phenomenon 113.26 (The resonance is narrow)**.** The total decay width of the boson lies far below the mass resolution of either detector, so the width of the observed peak is entirely instrumental and no direct line-shape measurement is possible. Comparing ZZ production far above the resonance with production on it constrains the width to a value consistent with the predicted few megaelectronvolts [2411], and the world average is $\hbar\Gamma_H = 3.7\,\mathrm{MeV}$ with an asymmetric uncertainty of $+1.9$ and -1.4 [2427].

Rests on Proposition 113.14 and Equation (104.67)*.*

Derivation. *Derives Phenomenon 113.26.*

Two statements are needed: that the direct measurement is impossible, and that the indirect one works.

The direct measurement. The Standard Model prediction obtained by summing the partial widths of Table 104.4 is $\hbar\Gamma_H = 4.1\,\mathrm{MeV}$, that is $6.57 \times 10^{-13}\,\mathrm{J}$, a fraction 3.3×10^{-5} of the mass. The best mass resolution achieved is $1.1\,\mathrm{GeV}/c^2$ (Proposition 113.14), larger by a factor of 270. The observed peak is therefore a pure instrumental response function and carries no information about Γ_H beyond a bound of order 1 GeV. Equivalently, the mean lifetime is

$$\tau = \frac{\hbar}{\hbar\Gamma_H} = \frac{1.054\,572 \times 10^{-34}\,\mathrm{J\,s}}{5.93 \times 10^{-13}\,\mathrm{J}} = 1.78 \times 10^{-22}\,\mathrm{s}\,,$$

and the decay length $c\tau = 5.3 \times 10^{-14}\,\mathrm{m}$, a twentieth of a picometre: there is no displaced vertex to find either. Both inherit the width's asymmetric error, $+51\,\%$ and $-38\,\%$, inverted: the width's upper end 5.6 MeV gives $\tau = 1.18 \times 10^{-22}\,\mathrm{s}$ and its lower end 2.3 MeV gives $2.86 \times 10^{-22}\,\mathrm{s}$, so τ is known only to a factor of about two either way. Nothing in the argument depends on which end is taken.

The off-shell method. Let W be the invariant-mass energy of the ZZ system produced through the scalar in gluon fusion. The differential cross section carries a relativistic Breit–Wigner,

$$\frac{\mathrm{d}\sigma}{\mathrm{d}W^2} \propto \frac{\hbar\Gamma_{gg}\,\hbar\Gamma_{ZZ}}{\left[W^2 - (m_H c^2)^2\right]^2 + (m_H c^2)^2\,(\hbar\Gamma_H)^2}\,, \tag{113.25}$$

with $\hbar\Gamma_{gg}$ and $\hbar\Gamma_{ZZ}$ the partial widths into the initial and final states, written as energies like every other width in this chapter, so that numerator and denominator carry J^2 and J^4 respectively. Write each coupling as a modifier times its Standard Model value, so $\hbar\Gamma_{gg}\,\hbar\Gamma_{ZZ} = \kappa_g^2\kappa_Z^2\,\hbar\Gamma_{gg}^{\mathrm{SM}}\,\hbar\Gamma_{ZZ}^{\mathrm{SM}}$, and consider two regions.

On the peak, $\hbar\Gamma_H \ll m_H c^2$ lets the numerator be taken constant across the resonance, and

$$\int \frac{\mathrm{d}W^2}{\left[W^2 - (m_H c^2)^2\right]^2 + (m_H c^2)^2\,(\hbar\Gamma_H)^2} = \frac{\pi}{m_H c^2\,\hbar\Gamma_H}\,,$$

the standard Cauchy integral. Hence

$$\mu_{\mathrm{on}} := \frac{\sigma_{\mathrm{on}}}{\sigma_{\mathrm{on}}^{\mathrm{SM}}} = \frac{\kappa_g^2\kappa_Z^2}{\hbar\Gamma_H/\hbar\Gamma_H^{\mathrm{SM}}}\,. \tag{113.26}$$

Far above the peak, $W \gg 2m_Z c^2 \gg m_H c^2$, the denominator of Equation (113.25) is W^4 up to corrections of order $(m_H c^2/W)^2$ and $(\hbar\Gamma_H/W)^2$, both utterly negligible: the width has dropped out. Hence

$$\mu_{\mathrm{off}} := \frac{\sigma_{\mathrm{off}}}{\sigma_{\mathrm{off}}^{\mathrm{SM}}} = \kappa_g^2\kappa_Z^2\,, \tag{113.27}$$

and dividing Equation (113.27) by Equation (113.26),

$$\frac{\hbar\Gamma_H}{\hbar\Gamma_H^{\mathrm{SM}}} = \frac{\mu_{\mathrm{off}}}{\mu_{\mathrm{on}}}\,. \tag{113.28}$$

The couplings cancel and the width is measured by a ratio of two rates, neither of which resolves anything.

The method is usable only because the off-shell rate is not negligible: about a tenth of all $gg \to H^* \to ZZ$ production occurs above $W = 2m_Z c^2$, because the threshold opening enhances the rate and the top-quark loop amplitude keeps growing until $W = 2m_t c^2$. ATLAS reported evidence for that off-shell component and used Equation (113.28) to constrain the width to a value consistent with the prediction [2411]. □

Remark 113.27 (The assumptions the width bound rests on). Equation (113.28) is exact given Equation (113.25), and three of its inputs are assumptions rather than measurements. They are stated here because the resulting constraint is often quoted as if it were a direct measurement of a lifetime, and it is not.

First, κ_g and κ_Z are taken to be the same at $W = 125\,\mathrm{GeV}$ and at $W \gtrsim 400\,\mathrm{GeV}$. Any new particle in the gluon-fusion loop, or any new contribution to the high-mass ZZ amplitude, breaks that and the extracted width is wrong — and precisely such a particle is what an anomalous width would be evidence for, so the method assumes the absence of the thing it would be used to detect.

Second, the continuum $gg \to ZZ$ background proceeds through a box diagram with the same initial and final state and therefore *interferes* with the signal. The interference is

destructive and large, and it must be modelled; its higher-order strong corrections are not known to the order the signal's are, and are assumed to be the same.

Third, the narrow-width approximation used in Equation (113.26) is safe here only because $\hbar\Gamma_H/m_Hc^2 = 3.3\times10^{-5}$; that part of the derivation is not in doubt.

The honest summary is that the width is constrained, under stated model assumptions, to a value consistent with 4.1 MeV, and that no assumption-free measurement of it exists or is planned at a hadron collider.

113.5.6 What the discovery does and does not establish

It is worth separating the four claims, because they are established to very different degrees and are routinely run together.

A neutral scalar exists at $(125.20\pm0.11)\,\mathrm{GeV}/c^2$. Established, by two independent instruments, in two independent channels each, with the mass measured consistently and the rate as predicted. This is as secure as any result in particle physics.

Its quantum numbers are $J^P = 0^+$. Established: spin 1 by Landau–Yang from the existence of the diphoton decay, spin 0 over spin 2 and even over odd parity by the four-lepton angular analysis [2201, 2217]. A small CP-odd admixture is bounded, not excluded (Remark 113.23).

Its couplings are proportional to mass. Established over the range from the muon to the top — a factor of 1630 — to a precision of roughly ten per cent, with the first generation and the light quarks untested (Remark 113.25).

The potential is the quartic one of Equation (113.1). **Not established.** Everything above probes the theory at the minimum of the potential. Its shape away from the minimum enters only through the self-couplings, and those are bounded to within a factor of several of the predicted value and not measured (Section 113.6.1). The central postulate of the mechanism — that the vacuum sits at the minimum of a quartic — remains an assumption supported by the mass and the couplings, and not a measurement.

113.6 What is not yet measured

113.6.1 The self-coupling and the shape of the potential

Expanding Equation (113.1) in unitary gauge gives, by Proposition 104.63,

$$V(h) = \frac{1}{2}\left(\frac{m_Hc}{\hbar}\right)^2 h^2 + \frac{(m_Hc)^2}{2\hbar^2 v}h^3 + \frac{(m_Hc)^2}{8\hbar^2v^2}h^4\,, \tag{113.29}$$

so the trilinear and quartic self-couplings are fixed by m_H and E_v, both measured. Writing the trilinear coupling as κ_λ times its Standard Model value, the mechanism predicts $\kappa_\lambda = 1$ with nothing to adjust. Nobody has measured it.

The reason is the size of the only channel that carries it. Producing two scalars at once, $gg\to HH$, proceeds through two interfering amplitudes: a *triangle* in which a top loop makes one off-shell scalar that then splits, carrying κ_λ at the splitting vertex, and a *box* in which two scalars are emitted from the same top loop, carrying no self-coupling at all. The two interfere destructively — a low-energy theorem forces them to cancel at threshold in the limit of a heavy top — so the cross section is a quadratic in κ_λ with a minimum inside the range of interest rather than a monotone function of it. Three consequences follow, and all three are unhelpful.

First, the rate is tiny: some three orders of magnitude below single production, tens of femtobarns at LHC energies against the tens of picobarns of Section 113.3.1. Second, because the dependence is quadratic with a minimum inside the interesting range, a measured rate maps onto two values of κ_λ, so the constraint is naturally an interval with a possible second

solution rather than a value. Third, the destructive interference means the observable loses sensitivity in the neighbourhood of the predicted value rather than gaining it there.

The present constraints [2394, 2410] allow κ_λ over a range of order -1 to $+7$: consistent with the predicted 1, and far too loose to be called a test.

Derivation pending #202

The double-production cross section $\sigma(gg \to HH)$ as a function of κ_λ: the interference of the top-loop triangle carrying the trilinear vertex with the top-loop box that does not, giving the quadratic whose minimum locates the least sensitive value of κ_λ, and the normalization that puts the rate three orders of magnitude below single production. The location of the minimum and the absolute rate are stated in this subsection on the authority of the experimental compilations and are not derived here; the two loop amplitudes belong in Appendix A with the single-production ones already recorded as owed. The published constraint on κ_λ quoted below is a measurement and needs no derivation.

The high-luminosity programme is expected to reduce that to a band of order tens of per cent around the prediction, which would be the first real measurement of the shape of the potential; that is a projection, not a result, and it is recorded here as one.

Remark 113.28 (What is actually being assumed). It is worth being precise about what is unmeasured, because the phrase "the Higgs potential" is used for two different things. That the electroweak vacuum breaks the gauge symmetry and sits at some nonzero field value is established — it is what the boson masses of Phenomenon 113.6 measure, and what E_v is. That the function whose minimum it sits at is $-\mu^2 |\Phi|^2 + \lambda |\Phi|^4$, with the single coupling λ generating the mass and both self-interactions, is the minimal hypothesis and is unmeasured. Any potential with a minimum in the right place and the right curvature reproduces every result in Section 113.5; only the self-couplings distinguish them. Loop corrections make the point sharper: the object whose minimum determines the vacuum is not the tree-level potential but the effective potential of Coleman and Weinberg [1495], whose shape differs (Remark 104.64).

113.6.2 First-generation couplings and rare decays

The scalar has been seen to couple to the top, the bottom, the tau and — at three standard deviations — the muon [2390]. It has not been seen to couple to the electron, the up quark, the down quark or the strange quark, which between them account for essentially all the mass of ordinary matter that is not binding energy. The claim that one mechanism gives mass to all the fermions is therefore verified for the third generation, for one second-generation lepton, and nowhere else.

Proposition 113.29 (Why the electron coupling is out of reach)**.** *The Standard Model branching fraction to electrons is*

$$\mathcal{B}\left(H \to e^+e^-\right) = \mathcal{B}\left(H \to \mu^+\mu^-\right)\left(\frac{m_e}{m_\mu}\right)^2 = 2.2 \times 10^{-4} \times 2.34 \times 10^{-5} = 5.1 \times 10^{-9}\,, \tag{113.30}$$

so even the full high-luminosity dataset would contain of order one such decay, against a Drell–Yan background of order 10^9 events in the same mass window. The measurement is not difficult; it is impossible at this machine.

Rests on Equations (104.67) and (113.23).

Derivation. *Derives Proposition 113.29.*

By Equation (104.67) the partial width into a fermion pair is proportional to $\hat{y}_f^2$ times a phase-space factor which is unity to one part in 10^5 for both leptons, and $\hat{y}_f \propto m_f$ by Equation (113.23). Hence the ratio of branching fractions is $(m_e/m_\mu)^2$. With $m_e c^2 = 0.510\,998\,950\,69\,\mathrm{MeV}$ and $m_\mu c^2 = 105.658\,375\,5\,\mathrm{MeV}$ [2427, 2431] the ratio is $(4.8363 \times 10^{-3})^2 = 2.339 \times 10^{-5}$, and $2.2 \times 10^{-4} \times 2.339 \times 10^{-5} = 5.1 \times 10^{-9}$, which is Equation (113.30).

The high-luminosity programme aims at $3 \times 10^{46}/\mathrm{m}^2$, three thousand inverse femtobarns per experiment. At $\sqrt{s}\,c = 13\,\mathrm{TeV}$ the total production cross section is about $5.5 \times 10^{-39}\,\mathrm{m}^2$, so $N_H \approx 3 \times 10^{46}/\mathrm{m}^2 \times 5.5 \times 10^{-39}\,\mathrm{m}^2 = 1.7 \times 10^8$ scalars, of which $1.7 \times 10^8 \times 5.1 \times 10^{-9} = 0.87$ decay to an electron pair. One event, with an acceptance below unity, on a background of Drell–Yan electron pairs whose cross section in the same mass window exceeds the signal by nine orders of magnitude. No selection recovers that. The light quarks are worse still, because there is no way to tag a light-quark jet as up rather than down, so even the final state cannot be identified.

What is achievable is a *bound*. An enhanced electron Yukawa coupling, hundreds of times the Standard Model value, would produce a visible $H \to e^+e^-$ peak, and searches set limits at that level. A bound three orders of magnitude above the prediction is worth recording as a bound and is not a test of the prediction. □

Three other classes of measurement are open and are being pursued.

Loop-level rare decays. $H \to Z\gamma$ has a predicted branching fraction of 1.5×10^{-3} (Table 104.4) and, like $H \to \gamma\gamma$, no tree-level vertex: it proceeds through W and top loops in a combination different from the diphoton one, so measuring both constrains the loop content in two independent ways. Evidence for it has been reported by the two collaborations combined, at a significance near the evidence threshold; the treatise's bibliography does not currently hold that publication, and the claim is therefore stated here without a citation rather than attached to the wrong one.

Lepton-flavour-violating decays. $H \to \mu\tau$ and $H \to e\tau$ are forbidden in the Standard Model, where the Yukawa matrix and the mass matrix are diagonalized by the same transformation (Theorem 104.38) so that no flavour-changing neutral scalar current exists at tree level. Searches have found nothing and bound the branching fractions at the level of a part in a thousand. This is a null result and it is a meaningful one: it says the scalar's couplings are flavour-diagonal to that accuracy, which the mechanism requires and a general two-doublet sector would not.

Invisible decays. The Standard Model predicts $\mathcal{B}(H \to ZZ^* \to 4\nu) \approx 1.1 \times 10^{-3}$, which is one line of Table 104.4: the branching fraction to ZZ^* is 0.026 and each Z goes to neutrinos with probability 0.20, so $0.026 \times 0.20^2 = 1.04 \times 10^{-3}$, the small remainder coming from the off-shell boson's distorted phase space. Any additional invisible width would signal decays to particles the detector cannot see, so the bound on it — currently of order ten per cent of the total width — constrains a light unseen sector coupling to the scalar. Collecting those searches, together with the direct and indirect ones, belongs to Chapter 134, whose collider subsection is reserved for exactly this material and does not yet contain it.

113.6.3 Vacuum stability

The measured mass has one consequence that reaches far beyond the collider, and it is the most-quoted and least-secure statement in this chapter.

λ is a coupling, so it runs (Chapter 108). Its one-loop beta function Equation (104.72) is dominated by the top Yukawa through the term $-6\hat{y}_t^4$, negative because it descends from a closed fermion loop, and numerically fifty times larger than the bosonic terms. Proposition 104.66 evaluates it at a renormalization scale $\mu_R = m_t c^2$ — the scale of Notation 113.1, not the potential's mass parameter and not a signal strength — and finds $\mathrm{d}\hat{\lambda}/\mathrm{d}\ln\mu_R = -0.0206$: the quartic coupling falls with scale. Integrating the coupled system

upward, with the measured $m_H c^2 = (125.20 \pm 0.11)\,\mathrm{GeV}$ and $m_t c^2 = (172.57 \pm 0.29)\,\mathrm{GeV}$ as inputs, $\hat{\lambda}$ crosses zero somewhere near $1 \times 10^{10} - -1 \times 10^{11}\,\mathrm{GeV}$ [2193, 2215]. Above that scale the potential turns over and a deeper minimum exists at large field values: the electroweak vacuum is not the global minimum but a metastable one, with a computed tunnelling lifetime exceeding the age of the universe by hundreds of orders of magnitude.

This chapter records the result and, more importantly, records what it is worth. Remark 104.67 states the three caveats in full and none may be dropped: the conclusion sits on a knife edge in the top mass, where a shift of about 1 GeV moves the answer between absolute stability, metastability and instability, and the relation between what a hadron collider reconstructs and the short-distance mass entering the beta function carries a theoretical uncertainty of that size; the extrapolation assumes that nothing couples to the scalar anywhere between $10^3\,\mathrm{GeV}$ and the $10^{10}\,\mathrm{GeV}$ at which the quartic changes sign — seven decades of energy in which nothing has been looked at, and the extrapolation is only worth as much as that assumption; and the running is a statement about a coupling in a renormalization scheme, not about an observable.

That interval is seven decades wide and not sixteen: $\log_{10}(10^{10}/10^3) = 7$. Remark 104.67 names the same two endpoints and calls them sixteen, which is an arithmetic slip there; the count used here is the one the endpoints give.

The experimental content of this subsection is therefore narrow and should be stated as such: this chapter measured m_H, and Chapter 116 and its successors measured m_t and α_s, and those measurements are the inputs to a calculation whose output is interesting and whose error bar is dominated by an ambiguity in one of its inputs. It is a striking near-coincidence that the Standard Model, extrapolated with no new physics, lands so close to the boundary. It is not evidence for anything.

The related question — why $E_v = 246.220\,\mathrm{GeV}$ at all, when nothing in the theory protects a fundamental scalar's mass from corrections scaling with whatever completes it at high energy — is not a question this chapter can address, and it is recorded among the open problems in Section 133.2. The discovery made it sharper rather than softer: before 2012 one could hope the electroweak sector was not built from an elementary scalar; it is.

113.7 Primary references

The experiment is two papers, submitted on the same day to the same journal and published back to back. ATLAS [2186] and CMS [2192] each report the diphoton and four-lepton analyses in full, with the supporting WW^*, $\tau\tau$ and $b\bar{b}$ channels, the categorization, the background models and the statistical treatment. Both are readable end to end and both should be read in preference to any account of them, including this one; the numbers in Table 113.3 attributed to 2012 come from them and are not recomputed here.

The instruments have their own literature and it is where the apparatus section comes from. The ATLAS [2119] and CMS [2120] technical papers in the 2008 LHC machine special issue describe the detectors as built, subsystem by subsystem, with the design resolutions quoted in Equation (113.13) and Equation (113.14); Evans and Bryant [2123] in the same issue describe the accelerator, and it is the source for every machine parameter in Table 113.2 other than the two derived rows.

The statistical machinery has a small canonical literature and this chapter uses all of it. Cowan, Cranmer, Gross and Vitells [2172] fix the asymptotic formulae, the one-sided discovery statistic and the Asimov construction that the collaborations use to quote expected sensitivities; Read [2036] is the CL_s construction behind every exclusion limit quoted here, including LEP's; Wilks [825] is the theorem that makes $Z = \sqrt{q}$ possible and Gross and Vitells [2158] the trials-factor practice applied in Proposition 113.19, resting in turn on Davies' bound [1594, 1791] and on Rice's level-crossing formula [877]. All of it is derived in

Chapter 11 rather than quoted.

The theory the experiment tested was in print half a century before the data. Englert and Brout [1275], Higgs [1282, 1283, 1332] and Guralnik, Hagen and Kibble [1279] give the mechanism in 1964, with Kibble's non-abelian extension [1352] supplying the case the Standard Model needs and Anderson's plasmon argument [1245] the physical precedent; Goldstone [1207] and Nambu [1187] give the theorem that has to be evaded and the superconducting analogy that shows how. Glashow [1206], Weinberg [1362] and Salam [1381] assemble the electroweak theory around it, and Chapter 104 derives the whole of it; Weinberg's second volume [1933] is the standard reference treatment.

The searches that preceded the discovery are the LEP combination of ALEPH, DELPHI, L3 and OPAL [2045], which set the lower limit and reported the excess at the edge of its sensitivity, and the Tevatron combination of CDF and D0 [2187], which reported the associated-production excess in $b\bar{b}$. The indirect constraints are the LEP and SLD precision electroweak measurements [2104] and the global fits built on them [2228], together with Veltman's screening theorem [1612], which is why the constraint on the scalar mass was logarithmic and therefore weak.

The measurements made since 2012 divide by what they test. The spin-parity analyses are ATLAS [2201] and CMS [2217]; the first joint mass combination is [2242] and the first joint coupling fit [2263]; the ten-year coupling maps of the full Run-2 dataset are ATLAS [2394] and CMS [2410], which are the source for every κ statement in Tables 113.5 and 113.6 and for the self-coupling range in Section 113.6.1. Note that [2410] is the CMS ten-year portrait and not a discovery paper, and it is cited here only for couplings. Individual channel observations are $t\bar{t}H$ production [2320] and the $H \to \mu^+\mu^-$ evidence [2390]; the off-shell width constraint of Section 113.5.5 is [2411]. Vacuum stability is Degrassi *et al.* [2193] and its sequel [2215].

Two sources are used for numbers rather than for claims. The Particle Data Group's 2024 review [2427] supplies every world-average mass and width in this chapter, taken from its own machine-readable release and stored with the treatise; CODATA 2022 [2431] supplies the exact defining constants used in every conversion between electronvolts, joules and kilograms.

Finally, one gap should be named rather than papered over. The Standard Model production cross sections quoted in Section 113.3.1 are the compilations of the LHC Higgs Cross Section Working Group, which the collaborations cite and which this treatise's bibliography does not hold; they are attributed above to the two discovery papers, which quote and use them. The same applies to the ATLAS and CMS combination reporting evidence for $H \to Z\gamma$, referred to in Section 113.6.2 without a citation for the same reason.

Chapter 114

Experiment: Neutrino Oscillations

Tests Phenomenon 103.50.

Assuming Definition 103.46 and Theorems 103.54 and 103.57.

Neutrino oscillation is the only laboratory phenomenon that unambiguously falsifies the Standard Model as originally written: it requires neutrino masses, which the massless left-handed neutrino of Chapter 96 does not have. The evidence accumulated over thirty years, beginning as an anomaly rather than a discovery — the solar electron-neutrino deficit found at Homestake [1368, 1950] and confirmed by Kamiokande [1822] and the gallium detectors [1974, 2138] — and closing with two measurements that admit no astrophysical escape: the zenith-angle dependence of atmospheric muon neutrinos in Super-Kamiokande [1954] and the flavour-blind neutral-current flux measured at Sudbury [2021], which showed the missing solar neutrinos had changed flavour rather than gone away. The Nobel Prize of 2015 recognized those two. This chapter sits after the flavour and neutrino theory of Chapters 96 and 103 and supplies the parameters they use.

The prediction under test is that a neutrino changes flavour in flight. That is the single statement every instrument described below was built to confirm or to kill, and it is worth being exact about what a confirmation requires. It is not enough to find fewer neutrinos of a given flavour than expected: a deficit is what a wrong source model, a wrong cross-section or a wrong efficiency also produces. Three things, and only these three, distinguish flavour change from every mundane alternative, and the chapter is organized around them.

1. *The missing flux reappears in another flavour.* A detector that measures the electron-flavour rate and the flavour-summed rate in the same target, with the same exposure, can subtract one from the other; the difference is model-independent. This is the Sudbury measurement.

2. *The deficit depends on L/E and on nothing else.* Path length and energy enter the interference phase only in that combination. No absorption law, no decay law and no production spectrum reproduces a dependence on the ratio alone. This is the Super-Kamiokande zenith-angle measurement, and, in its sharpest form, the KamLAND spectrum.

3. *The deficit is not monotone in L/E but oscillates.* A normalization error can only scale a rate; only interference makes it come back. This is what a controlled terrestrial source, at a baseline chosen so that the phase is of order a radian across the detected spectrum, can show and an astrophysical source cannot.

The chapter is unusual among the experiment chapters in covering a family of instruments rather than one — radiochemical tanks, water Cherenkov detectors, heavy water, liquid scintillator, and long-baseline accelerator beams — because no single detector establishes the effect, and the argument is carried by the pattern across baselines and energies, sharpened

by the matter effect of Wolfenstein, Mikheyev and Smirnov [1631, 1779]. It closes on what is still unknown: the mass ordering, the CP phase, the absolute mass scale, and whether the neutrino is its own antiparticle.

Remark 114.1 (Units and the conventions of the experimental literature). Every experimental paper cited below writes its formulae with $\hbar = c = 1$, and this book does not: editorial rule 3 requires SI throughout, so $\hbar$ and c are carried explicitly in every equation and every intermediate step here. The bridge is Equation (103.1), $\hbar c = 1.973\,269\,8 \times 10^{-7}$ eV m, and the general dictionary is stated once in Remark 103.1. No derivation in this chapter is carried out inside this remark.

Four conventions of the experimental literature recur below and are translated here rather than in the running text.

Squared-mass splittings. A splitting is universally quoted as "Δm^2 in eV^2" when the quantity meant is $\Delta m^2 c^4$, an energy squared. This chapter writes the c^4.

The solar neutrino unit. A radiochemical capture rate is quoted in solar neutrino units, and one SNU is defined as 10^{-36} captures per target atom per second — in SI, 1×10^{-36}/s per target atom. It is a rate per nucleus, not a flux, and converting it to atoms per day requires the number of target atoms, which is why that number is given for every radiochemical detector below.

Fluxes. Solar neutrino fluxes are quoted in the literature per square centimetre per second. The SI value is larger by 10^4: a flux of 10^6 1/(cm^2 s) is 1×10^{10}/(m^2 s), and only the SI form appears below.

Source strengths. Calibration sources are quoted in curies. One curie is exactly 3.7×10^{10} Bq, so a 1.7×10^6 Bq source — the units in which this chapter writes it — is not what the papers call a megacurie; a 1.7-megacurie source is 6.3×10^{16} Bq, and that is the number written here.

114.1 Historical context and the prediction under test

114.1.1 Neutrinos: detection and flavour

The neutrino entered physics in 1930 as a bookkeeping device and became an object of experiment twenty-six years later. Cowan, Reines and their collaborators put a detector beside a fission reactor at Savannah River and looked for the inverse beta reaction Equation (101.3), $\bar{\nu}_e + p \to n + e^+$, whose threshold Equation (101.4) is 1.806 MeV, that is 2.894×10^{-13} J. Their target was two tanks each holding about 200 L of water loaded with cadmium chloride, sandwiched between three tanks of about 1400 L of liquid scintillator; the detector sat some 12 m below ground level and about 11 m from the reactor core. The signature was a delayed coincidence: two 511 keV annihilation photons from the positron, followed some microseconds later by the several megaelectronvolts of gamma rays released when the neutron, having thermalized, is captured on cadmium. The rate with the reactor on exceeded the rate with it off by about three counts an hour [1085, 1097], at a cross-section of order 10^{-47} m^2 — the number derived in Equation (101.5) and recorded as Phenomenon 101.5.

Everything in this chapter descends from that apparatus. The delayed-coincidence tag on a free-proton target is still the technique of KamLAND and Daya Bay sixty years later, scaled from a few hundred litres to a kilotonne; what changed is the radiopurity of the scintillator and the photocathode coverage, not the idea.

The second ingredient is flavour. Firing a beam of neutrinos from pion decay at a ten-tonne spark chamber behind 13.5 m of iron, Danby and collaborators at the Brookhaven alternating-gradient synchrotron found the charged particles produced to be muons and never electrons [1223]: thirty-four single-muon events and no electron showers, where the electron channel is kinematically the more open of the two. The null result establishes a

quantum number distinguishing the two families. The third family's neutrino was observed directly at Fermilab in 2000 by the DONUT collaboration, which found the short kinked track of a tau in nuclear emulsion exposed to a beam from 800 GeV protons on a tungsten target: four candidates on an expected background of 0.34 [2016].

The counting is closed from the other end by the invisible width of the Z boson, which fixes the number of light neutrino species that couple to it at

$$N_\nu = 2.9840 \pm 0.0082 \tag{114.1}$$

[2104]; this is Phenomenon 103.22, and its derivation from the measured widths is Equation (103.15). Three flavours, conserved separately in the Standard Model as written, and therefore three quantum numbers for an oscillation experiment to violate: that is the state of knowledge against which every measurement below is read.

114.1.2 Mixing and oscillation

Pontecorvo proposed in 1957 that a neutrino might transform into its antiparticle by analogy with the neutral kaon, whose strangeness oscillates because the states of definite strangeness are not the states of definite mass [1127], in the paper whose English translation is [1159]. Maki, Nakagawa and Sakata gave the idea its modern form in 1962: the states produced with definite flavour are superpositions of states of definite mass, and the mismatch is a unitary matrix [1237]. That matrix is defined in Definition 103.46 and its measured magnitudes are Equation (103.49).

The formalism is derived in Chapter 103 and is not rebuilt here. Three results from there are used throughout this chapter and are quoted now so that the experimental sections can refer to them without interruption. For two flavours with mixing angle θ and squared-mass splitting $\Delta m^2 := m_2^2 - m_1^2$, the probability that a neutrino born as ν_α is found as ν_β after a flight of length L at energy E is Equation (103.52),

$$P_{\alpha\to\beta} = \sin^2 2\theta \, \sin^2 \varphi \,, \qquad P_{\alpha\to\alpha} = 1 - \sin^2 2\theta \, \sin^2 \varphi \,, \qquad \varphi = \frac{\Delta m^2 c^3 L}{4\hbar E} \,. \tag{114.2}$$

Every symbol is SI: $\Delta m^2 c^4$ is an energy squared, $\hbar c E$ is an energy squared times a length, and φ is a pure number. The practical form of the phase, derived as Proposition 103.52, is

$$\varphi = \frac{(\Delta m^2 c^4)\, L}{4\hbar c\, E} = 1.26693 \, \frac{\left(\Delta m^2 c^4 / \mathrm{eV}^2\right) (L/\mathrm{km})}{(E/\mathrm{GeV})} \,, \tag{114.3}$$

and the oscillation length — the distance over which φ advances by π — is Equation (103.55),

$$L_{\mathrm{osc}} = \frac{4\pi\hbar c E}{\Delta m^2 c^4} = 2.4797\,1 \,\mathrm{km} \, \frac{(E/\mathrm{GeV})}{\left(\Delta m^2 c^4 / \mathrm{eV}^2\right)} \,. \tag{114.4}$$

The number 1.266 93 is the one every experimental paper writes as "1.27" and quotes rather than derives; it is $(4\hbar c)^{-1}$ expressed in the units the field happens to use, and nothing else.

Two consequences organize everything below. Oscillation is an interference between two mass components, so it measures a *difference* of squared masses and can never measure a mass; and it depends on L and E only through their ratio, so an experiment is characterized by L/E and not by either separately. A detector placed where $\varphi \ll 1$ sees nothing; one placed where $\varphi \gg 1$ sees a constant suppression by the averaged factor $1 - \frac{1}{2}\sin^2 2\theta$; only a detector placed where φ is of order one across the detected spectrum sees the oscillation itself. Equation (114.4) is therefore the design equation of every experiment in this chapter, and Table 114.1 is the resulting map.

Table 114.1: Why each experiment has the baseline it has. The phase φ is Equation (114.3) evaluated at the stated L and E with the splitting the experiment is sensitive to, $\Delta m^2_{21}c^4 = 7.53 \times 10^{-5}\,\mathrm{eV}^2$ or $\left|\Delta m^2_{32}\right| c^4 = 2.455 \times 10^{-3}\,\mathrm{eV}^2$ [2427]. An experiment is informative only where φ is of order unity; $\varphi \ll 1$ gives no effect and $\varphi \gg 1$ gives a constant averaged suppression that carries no information about the splitting.

Experiment	L	E	Splitting	φ
Daya Bay near	0.47 km	3.5 MeV	Δm^2_{32}	0.42
Daya Bay far	1.65 km	3.5 MeV	Δm^2_{32}	1.47
KamLAND	180 km	4 MeV	Δm^2_{21}	4.3
K2K	250 km	1.3 GeV	Δm^2_{32}	0.60
T2K	295 km	0.6 GeV	Δm^2_{32}	1.5
MINOS	735 km	3 GeV	Δm^2_{32}	0.76
NOvA	810 km	2 GeV	Δm^2_{32}	1.26
Atmospheric, downward	15 km	1 GeV	Δm^2_{32}	0.047
Atmospheric, upward	12 800 km	1 GeV	Δm^2_{32}	40
Sun to Earth	1.5×10^8 km	1 MeV	Δm^2_{21}	1.4×10^7

The last row is the reason the solar measurements are treated separately from all the others. At a phase of 10^7 radians the oscillating factor has averaged out completely long before the neutrino reaches the Earth, and a vacuum calculation would give a featureless suppression carrying no information; what the solar experiments actually measure is not vacuum oscillation at all but the matter-modified propagation of Theorem 103.57, whose signature is a dependence on *energy* rather than on baseline. That is taken up in Section 114.5.2.

114.1.3 The standard solar model prediction

The Sun burns hydrogen to helium by the pp chains, with a small contribution from the CNO cycle, and the net reaction of either is

$$4\,{}^1\mathrm{H} \longrightarrow {}^4\mathrm{He} + 2e^+ + 2\nu_e\,, \tag{114.5}$$

releasing $Q = 26.73\,\mathrm{MeV} = 4.283 \times 10^{-12}\,\mathrm{J}$ per helium nucleus and producing exactly two electron neutrinos. The chains themselves belong to Sections 52.2.2 and 52.2.3, and the detailed model that turns them into a predicted spectrum — opacities, equation of state, composition, calibrated against the observed luminosity and radius — is that of Bahcall, Serenelli and Basu [2072]. Its predictions are Table 114.2.

Two features of that table decided thirty years of argument. The first is that the total is not really a prediction at all. The luminosity constraint — derived in Equation (52.36) from nothing but the observed solar constant, the energy release of Equation (114.5) and the Earth–Sun distance — fixes

$$\Phi_\nu = \frac{2L_\odot}{Q\,4\pi d^2} \approx 6.4 \times 10^{14}/(\mathrm{m}^2\,\mathrm{s}) \tag{114.6}$$

independently of every uncertain input of the model, and the *pp* branch carries about 94 % of it. A deficit measured in the *pp* neutrinos therefore cannot be blamed on the model.

The second is that the ^{8}B flux is the least certain quantity in the table by a wide margin, because the reaction ${}^7\mathrm{Be} + p \to {}^8\mathrm{B} + \gamma$ sits far out on the Gamow peak and its rate varies as a very high power of the central temperature. For three decades that was the escape route: Homestake and Kamiokande measured only the ^{8}B branch, and a central temperature lower by a few per cent than the model's would have removed the discrepancy without any new

Table 114.2: Standard solar model neutrino fluxes at the Earth, from the BS05(OP) model of [2072], converted to SI: the source quotes them per square centimetre per second and the SI value is larger by 10^4. Endpoint energies are given in electronvolts and in joules. The ^{7}Be and *pep* neutrinos are lines rather than continua because the reaction is electron capture and the final state is two-body. The quoted uncertainty is the model's own, and its size is the point: the *pp* flux is fixed to one per cent by the luminosity constraint, while the ^{8}B flux — the one Homestake, Kamiokande and SNO are sensitive to — is uncertain by 16 %.

Branch	Flux $(1/(\mathrm{m}^2\,\mathrm{s}))$	Endpoint or line	Uncertainty
pp	5.99×10^{14}	420 keV, 6.73×10^{-14} J	1 %
^{7}Be	4.84×10^{13}	862 keV, 1.38×10^{-13} J	11.5 %
pep	1.42×10^{12}	1.44 MeV, 2.31×10^{-13} J	2 %
^{8}B	5.69×10^{10}	15 MeV, 2.40×10^{-12} J	16 %
^{13}N	3.07×10^{12}	1.20 MeV, 1.92×10^{-13} J	31 %
^{15}O	2.33×10^{12}	1.73 MeV, 2.77×10^{-13} J	34 %

physics. Closing that route — by measuring a branch the model cannot get wrong, and then by measuring the flavour content directly — is what the rest of this chapter is about.

That sensitivity is now derived where it belongs, in the stellar-structure chapter: the ^{8}B flux responds with the *sum* of the Gamow exponents of the reactions feeding and draining ^{7}Be, giving $\Phi(^8\mathrm{B}) \propto T_c^{\sim 29}$ at fixed density and composition — self-consistent solar-model perturbation studies soften the exponent toward the customary T^{24} without changing the argument — so a central temperature a few per cent low reproduces the whole measured deficit. The derivation, and the closing of that escape route by the luminosity-pinned *pp* flux and by helioseismology, are carried out under Phenomenon 52.22, with the exponents tabulated in Table 52.1.

114.1.4 The observable and what a measurement must deliver

An oscillation experiment reports one of four observables, and it is worth naming them before any apparatus is described, because the sources of error are different in each and the tables of Section 114.4 are organized by them.

A rate. The number of interactions of a given flavour per unit time in a known target, compared with a prediction. This is the weakest observable, because it inherits the full uncertainty of the source model, the cross-section and the detection efficiency. Homestake delivered a rate, and that is why its result was arguable for thirty years.

A ratio of rates in one detector. Two channels with different flavour sensitivity, measured in the same target during the same exposure. The source normalization cancels exactly. This is Sudbury's charged-current to neutral-current ratio, and it is the strongest observable in the chapter.

A ratio of rates in two detectors. Identical detectors at two baselines from one source. Source normalization, cross-section and efficiency all cancel to the extent that the detectors are identical. This is the Daya Bay and RENO design.

A shape. The dependence of the survival probability on L/E within one dataset. Nothing that scales a rate can produce a shape, so this is the observable that distinguishes oscillation from every rival hypothesis without appeal to any external prediction. Super-Kamiokande delivered it in the zenith angle, KamLAND in the reactor energy spectrum.

The chapter's argument is the accumulation of these four, in that order of strength, over thirty-five years.

114.2 Apparatus

Every instrument in this chapter solves the same two problems. A neutrino cross-section of order $10^{-47}\,\mathrm{m}^2$ (Phenomenon 101.5) means that a useful counting rate demands a target of 10^{30} nuclei or more, that is hundreds of tonnes; and a rate of a few events per day in such a target means that any background above a few events per day destroys the measurement. Mass and quiet are therefore the two axes along which these detectors are designed, and everything else — the choice of target nucleus, the depth, the purification chemistry, the photomultiplier coverage — follows from one or the other.

Table 114.3 collects the physical parameters. The subsections that follow give, for each class, the target, the reaction it exploits, the signal it produces and the background it must beat.

Table 114.3: The instruments of this chapter. Depth is given both as overburden of rock and, where the collaborations quote it, as the equivalent depth of water that would give the same muon attenuation, which is the comparable number because rock densities differ. Target mass is the sensitive mass, not the total mass of the installation: Super-Kamiokande holds 50 kt of water of which 22.5 kt is fiducial for atmospheric neutrinos, and Sudbury's 1 kt of heavy water sits inside 7 kt of ordinary water that is shielding and not target.

Detector	Target	Sensitive mass	Depth
Homestake	C_2Cl_4	615 t	1478 m, 4200 m w.e.
GALLEX/GNO	$GaCl_3$ solution	30.3 t Ga	3300 m w.e.
SAGE	metallic Ga	50 t	4700 m w.e.
Kamiokande-II	H_2O	680 t fid.	1000 m, 2700 m w.e.
Super-Kamiokande	H_2O	22.5 kt fid.	1000 m, 2700 m w.e.
SNO	D_2O	1 kt	2092 m, 6010 m w.e.
KamLAND	liquid scintillator	1 kt	1000 m, 2700 m w.e.
Borexino	liquid scintillator	278 t	3800 m w.e.
Daya Bay	Gd-loaded scintillator	20 t per module	250 m to 860 m w.e.

114.2.1 Radiochemical detectors

A radiochemical detector counts atoms, not events. The neutrino converts a stable nucleus into a radioactive one by inverse beta decay; the product is a different chemical element, so it can be separated from a target of hundreds of tonnes by ordinary chemistry and counted afterwards by its own decay. The method is uniquely insensitive to background *during* exposure — nothing that is not a neutrino makes the target element into the product element — and it pays for that with the total loss of every other piece of information. There is no energy, no direction, no time of arrival: only a number of atoms integrated over a run of weeks.

The two properties that matter are the threshold, fixed by the mass difference of the two nuclei, and the half-life of the product, which must be long enough to accumulate a countable population and short enough that counting does not take forever. Both detectors described here sit near the optimum: a product half-life of a few weeks against an exposure of a few weeks.

114.2.2 The Homestake chlorine tank

Davis's detector was a horizontal steel tank 6.1 m in diameter and 14.6 m long, holding 615 t — about 3.8×10^5 L — of tetrachloroethylene, C_2Cl_4, an ordinary dry-cleaning fluid chosen because it is cheap, dense in chlorine and chemically inert. It was installed 1478 m below the surface in the Homestake gold mine at Lead, South Dakota, an overburden of about 4200 m of water equivalent [1368, 1950].

The reaction is

$$\nu_e + {}^{37}\mathrm{Cl} \longrightarrow {}^{37}\mathrm{Ar} + e^- \,, \tag{114.7}$$

with a threshold of 814 keV, that is 1.304×10^{-13} J. The threshold is what makes the detector a ^{8}B instrument: by Table 114.2 it is above the *pp* endpoint of 420 keV altogether, so the branch carrying 94 % of the flux is invisible to it, and about three quarters of the predicted rate comes from ^{8}B with most of the remainder from ^{7}Be.

The number of target atoms is worth computing, because every rate in Section 114.4 is quoted per target atom and the conversion to atoms per day runs through it. Tetrachloroethylene has molar mass 165.83 g/mol, so 615 t is 3.71×10^6 moles, containing $4 \times 3.71 \times 10^6$ moles of chlorine and hence 8.93×10^{30} chlorine atoms; the isotopic abundance of ^{37}Cl is 24.23 %, giving

$$N\left({}^{37}\mathrm{Cl}\right) = 2.16 \times 10^{30} \,. \tag{114.8}$$

At the measured capture rate of 2.56×10^{-36}/s per atom (Section 114.4.1) this is a production rate of 5.54×10^{-6}/s, that is 0.48 atoms of argon per day in 615 t of liquid. The saturated population, reached when production balances decay of the 3.024×10^6 s half-life, is $5.54 \times 10^{-6}\ 1/\mathrm{s} / (\ln 2 / 3.024 \times 10^6\ \mathrm{s}) \approx 24$ atoms. Those two dozen atoms, in 2.2×10^{30} target nuclei, are the entire signal.

The product is counted by its own decay. ^{37}Ar decays by electron capture back to ^{37}Cl with a half-life of 3.024×10^6 s, that is 35.0 days, and the K-shell capture leaves an Auger cascade of 2.82 keV, that is 4.52×10^{-16} J, deposited in a few nanoseconds within a fraction of a millimetre. A gas proportional counter of about 0.5 cm^3 internal volume — deliberately tiny, because the background scales with the volume and the signal does not — registers this as a fast-rising pulse of characteristic energy. The counters were made of low-background materials, filled with the extracted argon mixed with tritium-free methane, and operated inside a well of sodium iodide within a lead castle.

The backgrounds that had to be excluded before the deficit could be believed were of two kinds. Cosmic-ray muons surviving to 4200 m of water equivalent produce ^{37}Ar by spallation on chlorine at an estimated 0.047 ± 0.013 atoms per day, some 10 % of the signal; this was measured by exposing the same target at shallower depths and extrapolating. Fast neutrons from the rock, and alpha emitters in the tank walls acting through $^{37}\mathrm{Cl}(\alpha, n)$-type reactions, contribute less. The counting background — a proportional counter firing when no argon atom decayed — was suppressed by rise-time discrimination, since a genuine 2.82 keV Auger cascade is far more localized than a Compton electron traversing the same gas, and by requiring the decay times of a run's candidate events to be consistent with a 3.024×10^6 s half-life.

114.2.3 The gallium detectors

The gallium experiments exist because of one number: the threshold of

$$\nu_e + {}^{71}\mathrm{Ga} \longrightarrow {}^{71}\mathrm{Ge} + e^- \tag{114.9}$$

is 233 keV, that is 3.74×10^{-14} J, comfortably below the *pp* endpoint of 420 keV. A gallium detector therefore sees the branch whose flux is fixed by Equation (114.6) to one per cent, and a deficit there cannot be attributed to the solar model. That is the whole argument

for spending a substantial fraction of the world's annual gallium production on a physics experiment.

GALLEX, and its successor GNO, operated at the Gran Sasso laboratory under about 3300 m of water equivalent, with 30.3 t of gallium held as about 101 t of gallium trichloride in concentrated hydrochloric acid, in a tank of some 54 m^3 [1974]. SAGE, at the Baksan Neutrino Observatory under about 4700 m of water equivalent, used 50 t of gallium in the metallic form — gallium melts at 29.8 °C, so the target is a liquid metal held in seven reactors of about 7 t each [2138].

The target counts are, by the same arithmetic as Equation (114.8) with a molar mass of 69.72 g/mol and an isotopic abundance of 39.89 % for ^{71}Ga,

$$N_{\mathrm{GALLEX}} = 1.04 \times 10^{29}\,, \qquad N_{\mathrm{SAGE}} = 1.72 \times 10^{29}\,. \tag{114.10}$$

At the measured rates of Table 114.4 these correspond to 0.63 and 0.97 atoms of ^{71}Ge per day, and to saturated populations of about ten and sixteen atoms respectively, the ^{71}Ge half-life being 9.875×10^5 s, that is 11.43 days.

The chemistry differs from Homestake's in one important respect: germanium tetrachloride is volatile from the acid solution, so extraction is again a gas purge, but the counting gas is germane, $\mathrm{GeH_4}$, synthesized from the extracted germanium. The decay is again electron capture, with K-shell and L-shell peaks at 10.37 keV and 1.17 keV, that is 1.66×10^{-15} J and 1.88×10^{-16} J. Having two peaks is a real advantage over the single Auger line of ^{37}Ar: a background source that mimics one rarely mimics both in the right ratio.

The gallium detectors are also the only ones in this chapter that were calibrated with an artificial neutrino source of known strength. A ^{51}Cr source of about 6.3×10^{16} Bq — 1.7 megacuries, produced by neutron irradiation of enriched ^{50}Cr in a reactor — emits electron neutrinos by electron capture at 750 keV, above the gallium threshold and below the chlorine one. Lowered into the tank, it turns the detector into an experiment with a known input. SAGE additionally used an ^{37}Ar source. What those calibrations returned is discussed in Section 114.6.4, because the answer was not quite one and the discrepancy has not gone away.

114.2.4 Water Cherenkov detectors

A water Cherenkov detector gives up the radiochemical method's freedom from background and buys, in exchange, everything the radiochemical method throws away: the time of each event to a few nanoseconds, its position to tens of centimetres, its energy, its direction, and — decisively for this chapter — its flavour.

The mechanism is the Cherenkov cone of Section 115.4.4. A charged particle faster than the phase velocity of light in the medium radiates on a cone of half-angle given by Equation (115.36),

$$\cos\theta_c = \frac{1}{n\beta}\,, \tag{114.11}$$

which for water, $n = 1.34$, and an ultrarelativistic particle gives $\theta_c = 41.7°$. The threshold follows from requiring $\beta > 1/n$: with $\gamma_{\mathrm{th}} = \left(1 - n^{-2}\right)^{-1/2} = 1.502$, a particle of rest mass m must have total energy above $1.502\,mc^2$, that is 768 keV for an electron and 159 MeV for a muon. The projection of the cone on the detector wall is a ring, and the number of photons per unit path length is given by Equation (115.38) — some 340 photons per centimetre in the visible band, of which a detector with 40 % photocathode coverage records a few per cent.

Kamiokande-II was the first instrument to detect solar neutrinos in real time. It was a cylindrical tank holding 3 kt of purified water 1000 m underground in the Kamioka mine, viewed by 948 photomultipliers of 50 cm diameter giving about 20 % photocathode coverage,

with a fiducial volume of 680 t for the solar analysis [1822]. It detected neutrino–electron elastic scattering,

$$\nu_x + e^- \longrightarrow \nu_x + e^- \,, \tag{114.12}$$

which has no threshold of its own but is limited from below by radioactive background: the analysis threshold was 9.3 MeV initially and 7.5 MeV later, so that Kamiokande, like Homestake, saw only the ^{8}B branch. Its decisive advantage was that the recoil electron remembers the neutrino direction to within about 25° at these energies, so the signal appears as a peak in the distribution of event directions relative to the Sun sitting on a flat background. The same detector recorded the neutrino burst from SN 1987A [1793].

Super-Kamiokande is the same idea built seventeen times larger. The tank is 39 m in diameter and 42 m high and holds 50 kt of water; the inner detector is viewed by 11 146 photomultipliers of 50 cm diameter for a photocathode coverage of 40 %, and is optically separated from an outer shell instrumented with 1885 smaller tubes that serves as an anticoincidence veto against entering cosmic-ray muons. The fiducial volume for atmospheric neutrinos is 22.5 kt. It sits under 1000 m of rock, about 2700 m of water equivalent, in the Mozumi mine at Kamioka, where the residual cosmic-ray muon rate through the detector is a few per second — a rate that would swamp everything were the outer veto not there [1954]. The water is continuously recirculated through filtration, reverse osmosis, ion exchange and ultraviolet sterilization, reaching a resistivity near $1.8 \times 10^{5}\,\Omega\,\mathrm{m}$ and a light attenuation length beyond 70 m; radon-reduced air is kept above the water surface, because ^{222}Rn dissolved in the water is the limiting background at low energy.

The property that makes Super-Kamiokande an oscillation instrument rather than merely a large one is flavour tagging by ring shape. A charged-current interaction of a ν_μ produces a muon, which is heavy, loses energy slowly and travels in a straight line: its Cherenkov ring has a sharp outer edge. A charged-current interaction of a ν_e produces an electron, which scatters and radiates, initiating an electromagnetic shower whose many low-energy tracks smear the ring into a fuzzy disc. The two are separated event-by-event with a misidentification probability of a few per cent. Nothing else in this chapter measures the two flavours of a single natural source side by side in one detector, and that is precisely why the atmospheric measurement is decisive.

114.2.5 Heavy water and the neutral-current channel

The Sudbury Neutrino Observatory was designed around one property of the deuteron: it is the lightest nucleus that a neutrino can break up by the neutral current, so a heavy-water target gives access, in one detector, to a reaction that counts electron neutrinos and a reaction that counts all three flavours equally.

The apparatus was 1 kt of heavy water of 99.92 % isotopic purity — on loan from the Canadian strategic reserve, the loan being the reason the experiment was possible at all — held in a spherical acrylic vessel 12 m in diameter with a wall about 5 cm thick. The vessel was surrounded by 7 kt of ultrapure ordinary water acting as shielding against radioactivity from the rock and the photomultipliers, and viewed by 9456 photomultipliers of 20 cm diameter mounted on a geodesic sphere of 17.8 m diameter. The whole assembly sat in a cavity 2092 m below the surface in the Creighton nickel mine near Sudbury, Ontario, an overburden of about 6010 m of water equivalent — the greatest of any detector in this chapter, and necessary because a cosmic-ray muon passing through the heavy water would produce spallation neutrons indistinguishable from the neutral-current signal. At that depth the muon rate through the detector is about three per hour [2008, 2021].

Three reactions were used.

$$\nu_e + d \longrightarrow p + p + e^- \qquad \text{(charged current, CC)}\,, \tag{114.13}$$

$$\nu_x + d \longrightarrow p + n + \nu_x \qquad \text{(neutral current, NC)}\,, \tag{114.14}$$

$$\nu_x + e^- \longrightarrow \nu_x + e^- \qquad \text{(elastic scattering, ES)}\,. \tag{114.15}$$

The charged-current reaction has a threshold of $1.442\,\mathrm{MeV}$ ($2.31 \times 10^{-13}\,\mathrm{J}$) and, because only the electron flavour has a charged-current partner light enough to be produced at solar energies, counts ν_e alone. The neutral-current reaction is the breakup of the deuteron, so its threshold is the deuteron binding energy, $2.224\,\mathrm{MeV}$ or $3.56 \times 10^{-13}\,\mathrm{J}$; the Z couples identically to all three flavours, so its rate is proportional to the total active flux with no flavour weighting whatever. Elastic scattering is sensitive to all three but not equally: ν_e can scatter through both the charged and the neutral current while ν_μ and ν_τ have only the neutral one, so the effective flux it measures is

$$\Phi_{\mathrm{ES}} = \Phi_e + 0.154\,\Phi_{\mu\tau}\,. \tag{114.16}$$

The weight is a ratio of cross-sections and is worth deriving, since it is used quantitatively twice below.

Derivation of the elastic-scattering weight. For $E_\nu \gg m_e c^2$ the differential cross-section for $\nu_x + e^- \to \nu_x + e^-$ in the recoil kinetic energy T is

$$\frac{\mathrm{d}\sigma}{\mathrm{d}T} = \frac{2 G_{\mathrm{F}}^2 m_e c^2}{\pi \hbar^4 c^4}\left[g_L^2 + g_R^2\left(1 - \frac{T}{E_\nu}\right)^2 - g_L g_R \frac{m_e c^2 T}{E_\nu^2}\right], \tag{114.17}$$

with $G_{\mathrm{F}}/(\hbar c)^3 = 1.1664 \times 10^{-5}/\mathrm{GeV}^2$, that is $G_{\mathrm{F}} = 1.4359 \times 10^{-62}\,\mathrm{J\,m^3}$ in SI. The prefactor is then an area per energy: $\mathrm{J^2\,m^6} \times \mathrm{J}$ divided by $\mathrm{J^4\,m^4}$ is $\mathrm{m^2/J}$. Evaluated for ν_e at $E_\nu = 10\,\mathrm{MeV}$ it gives a total cross-section of $9.5 \times 10^{-48}\,\mathrm{m^2}$, about a hundredth of the inverse beta decay cross-section at the same energy. The chiral couplings differ between the flavours only through the charged-current contribution, which the electron flavour alone has:

$$g_L^{(e)} = \tfrac{1}{2} + \sin^2\theta_{\mathrm{W}}\,, \qquad g_L^{(\mu,\tau)} = -\tfrac{1}{2} + \sin^2\theta_{\mathrm{W}}\,, \qquad g_R^{(e)} = g_R^{(\mu,\tau)} = \sin^2\theta_{\mathrm{W}}\,. \tag{114.18}$$

Integrating Equation (114.17) over all T and dropping the interference term, which is smaller by $m_e c^2/E_\nu$, gives $\sigma \propto g_L^2 + \tfrac{1}{3} g_R^2$. With $\sin^2\theta_{\mathrm{W}} = 0.2312$ [2427] this is 0.5525 for ν_e and 0.0901 for ν_μ and ν_τ, a ratio of 0.163. Imposing the analysis threshold lowers it: for $E_\nu = 10\,\mathrm{MeV}$ and $T > 5\,\mathrm{MeV}$ the same integral run from the threshold gives 0.142, because the flat g_L^2 term survives the cut in the same proportion for both flavours while the g_R^2 term, which is relatively far more important for ν_μ and ν_τ, is concentrated at low recoil. The coefficient in Equation (114.16) is this ratio averaged over the $^8\mathrm{B}$ spectrum and the detector acceptance and corrected radiatively, which the Sudbury analysis evaluates as 0.154 [2021]; the two bracketing estimates above show where that number comes from and how much of it is threshold-dependent. □

The experimental difficulty is entirely in the neutral-current channel, whose only observable is a free neutron. Three successive configurations were run, deliberately chosen so that the systematic errors of the neutron measurement would be unrelated.

Phase I, pure heavy water. The neutron captures on a deuteron, $n + d \to {}^3\mathrm{H} + \gamma$, emitting a single photon of $6.25\,\mathrm{MeV}$ ($1.00 \times 10^{-12}\,\mathrm{J}$) which Compton-scatters an electron above the Cherenkov threshold. The capture cross-section of deuterium is small, so the overall neutron detection efficiency was only about $14\,\%$, and the resulting Cherenkov light is similar in amount and in isotropy to a charged-current event: the separation between the two channels rests on a statistical fit to the distributions of energy, radius and direction.

Phase II, salt. Two tonnes of sodium chloride were dissolved in the heavy water. Neutrons then capture predominantly on ^{35}Cl, which has a far larger capture cross-section and de-excites through a cascade of photons totalling 8.6 MeV (1.38×10^{-12} J). Both the efficiency and the discrimination improve: efficiency rises to about 40 %, and a multi-photon cascade produces a markedly more isotropic pattern of hit tubes than the single electron of a charged-current event, so the two channels separate on event topology rather than on energy alone.

Phase III, discrete counters. The salt was removed and an array of ^{3}He proportional counters — some forty vertical strings, about 400 m of counter in total — was deployed in the heavy water. A neutron captured on ^{3}He gives $n + {}^{3}\mathrm{He} \to p + {}^{3}\mathrm{H}$ with 764 keV released, detected as an ionization pulse in the counter and *not* in the photomultipliers at all. The neutral-current measurement is then completely decoupled from the Cherenkov measurement of the charged current, so the statistical anticorrelation between the two channels that limited the first two phases disappears.

114.2.6 Liquid scintillator detectors

An organic liquid scintillator emits some ten thousand photons per megaelectronvolt of deposited energy, against the few hundred of a Cherenkov radiator, and it emits them isotropically and with no velocity threshold. The trade is exact: the scintillator sees far lower energies, and it loses all directional information. For a reactor experiment, where the source direction is known and the energies are a few megaelectronvolts, that is the right trade.

The reaction is the one Reines and Cowan used, inverse beta decay Equation (101.3) on the free protons of the hydrocarbon, with the threshold of Equation (101.4), 1.806 MeV. The signature is the delayed coincidence described in Section 101.1.3: a prompt pulse from the positron carrying $E_{\bar{\nu}} - 0.78$ MeV plus its two annihilation photons, followed by a delayed pulse when the neutron, having thermalized, is captured. That the reaction is charged-current on a proton means it detects $\bar{\nu}_e$ and nothing else, which is what makes a reactor experiment a pure disappearance measurement.

KamLAND placed 1 kt of liquid scintillator — about 80 % dodecane and 20 % pseudocumene by volume, with 1.5 g/L of the fluor PPO — inside a balloon of nylon and ethylene-vinyl-alcohol copolymer 13 m in diameter, itself suspended in 1800 t of non-scintillating mineral oil inside a steel sphere 18 m in diameter carrying 1879 photomultipliers, for a photocathode coverage of about 34 %. A water Cherenkov outer detector of 3.2 kt vetoes cosmic-ray muons. It occupies the cavern that held Kamiokande, under the same 2700 m of water equivalent [2049]. Neutrons capture on the free protons of the scintillator itself, giving a 2.22 MeV photon (3.56×10^{-13} J) after a mean capture time near 200 µs.

What makes KamLAND a solar-parameter experiment rather than a reactor experiment is its position. Japan's fifty-odd power reactors, some 70 GW of thermal power in total, are distributed at distances from 140 km to several hundred kilometres, with a flux-weighted mean baseline near 180 km. A thermal power P produces antineutrinos at a rate of about

$$\frac{\mathrm{d}N}{\mathrm{d}t} \approx \frac{6P}{200\,\mathrm{MeV}} = 1.9 \times 10^{20}/\mathrm{s} \times \frac{P}{1\,\mathrm{GW}}\,, \tag{114.19}$$

since fission releases about 200 MeV and the resulting fragments beta-decay about six times each on the way to stability, so the Japanese reactor complex is a source of order 1.3×10^{22}/s. At 180 km that is a flux of order $1 \times 10^{10}/(\mathrm{m}^2\,\mathrm{s})$ at the detector — and, above the prompt-energy threshold actually analysed, about three hundred detected events per year per kilotonne of scintillator. Only part of the kilotonne is usable: the analysis is restricted to a fiducial volume of 408 t, well inside the balloon, so that the radioactivity of

the balloon film and of the surrounding mineral oil cannot reach it. That is why the first result rested on 54 events.

Daya Bay and RENO use the same reaction at a hundredth of the baseline and with a completely different logic. Daya Bay observes six reactors of 2.9 GW thermal each, 17.4 GW in total, from three underground halls: two near halls at flux-weighted baselines of about 470 m and 576 m under 250 m and 265 m of water equivalent, and a far hall at about 1648 m under 860 m [2189]. Each hall holds one or more functionally identical antineutrino detector modules. A module is a nest of three volumes: an inner acrylic vessel 3 m in diameter holding 20 t of liquid scintillator doped with 0.1 % gadolinium by mass; an outer acrylic vessel holding a further 20 t of undoped scintillator, which catches photons escaping from the inner volume; and 40 t of mineral oil, optically transparent and non-scintillating, separating both from the 192 photomultipliers of 20 cm diameter that view the assembly. The whole module is immersed in a pool of purified water 2.5 m deep instrumented as a Cherenkov muon veto, itself covered by resistive plate chambers.

Gadolinium is the essential ingredient. Its thermal-neutron capture cross-section is some five orders of magnitude larger than hydrogen's, so at 0.1 % doping the great majority of neutrons capture on gadolinium rather than on protons; the capture releases a gamma cascade totalling about 8 MeV (1.28×10^{-12} J) after a mean time near 28 µs. A delayed pulse at 8 MeV is far above natural radioactivity, whereas the 2.22 MeV of capture on hydrogen sits in the middle of it; and the shorter capture time narrows the coincidence window, cutting accidental backgrounds by a further order of magnitude. RENO is built on the same plan with two identical detectors of 16 t of gadolinium-loaded scintillator at about 294 m and 1383 m from the centre of a six-reactor array of 16.5 GW thermal [2188].

Borexino is the extreme case of the same technology, optimized not for reactor antineutrinos but for the lowest-energy solar neutrinos. It holds 278 t of pseudocumene with 1.5 g/L of PPO in a nylon vessel of 8.5 m diameter, inside a stainless steel sphere of 13.7 m carrying 2212 photomultipliers, inside 2.1 kt of water serving as shield and muon veto, at Gran Sasso under about 3800 m of water equivalent [2229]. It detects elastic scattering Equation (114.12) on electrons, which has no threshold, so the limit is set entirely by radiopurity. The achieved contamination is the lowest ever reached in a bulk material: below 1×10^{-19} g/g for ^{238}U and below 6×10^{-19} g/g for ^{232}Th, with an isotopic ratio $^{14}\mathrm{C}/^{12}\mathrm{C}$ near 3×10^{-18}. The last of these is irreducible — ^{14}C is chemically identical to ^{12}C and cannot be purified away — and its beta spectrum, with endpoint 156 keV, is what sets the lower edge of the *pp* measurement.

114.2.7 Accelerator beams

An accelerator gives what no natural source can: a beam whose flavour, energy spectrum, direction, time structure and intensity are all under the experimenter's control, so that the same detector can be compared with itself with the beam on and off, and a near detector can measure the unoscillated flux directly.

The production chain is the same one that makes atmospheric neutrinos (Section 115.7.2), run deliberately. Protons of tens of gigaelectronvolts strike a thin target of graphite or beryllium; the secondary pions and kaons are focused by magnetic horns — pulsed conductors carrying currents of order 200 kA whose toroidal field sign-selects and collimates one charge — and are allowed to decay in an evacuated or helium-filled tunnel a few hundred metres long. Charged pion decay is two-body, $\pi^+ \to \mu^+ \nu_\mu$, so the beam is almost pure ν_μ; the residual ν_e contamination, from three-body kaon decay and from muon decay in the tunnel, is at the level of 1 % and is the irreducible background of every appearance measurement. A beam dump and hundreds of metres of rock absorb the surviving hadrons and muons.

K2K sent a beam from the 12 GeV proton synchrotron at KEK, with a mean neutrino energy of 1.3 GeV, over 250 km to Super-Kamiokande, using the same detector that had

made the atmospheric measurement [2089].

MINOS used the NuMI beam from Fermilab's 120 GeV main injector over 735 km to a detector in the Soudan mine: 5.4 kt of alternating steel and plastic scintillator planes, magnetized to about 1.3 T so that the muon charge, and hence whether the parent was a neutrino or an antineutrino, can be read from the track curvature. A functionally similar near detector of 1 kt sat 1 km from the target [2100].

T2K and NOvA introduced the off-axis technique, which is the main advance in beam design of the last two decades. Because pion decay is two-body, the neutrino energy in the pion rest frame is fixed by the two masses alone,

$$E_\nu^* = \frac{\left(m_\pi^2 - m_\mu^2\right) c^4}{2 m_\pi c^2} = 29.79\,\mathrm{MeV} = 4.773 \times 10^{-12}\,\mathrm{J}\,, \tag{114.20}$$

and the Lorentz transformation to the laboratory at a fixed angle θ to the pion direction gives

$$E_\nu = \frac{E_\nu^*}{\gamma_\pi \left(1 - \beta_\pi \cos\theta\right)} = \frac{\left(m_\pi^2 - m_\mu^2\right) c^4}{2\left(E_\pi - p_\pi c \cos\theta\right)}\,, \tag{114.21}$$

where the second form follows from $\gamma_\pi = E_\pi / m_\pi c^2$ and $\gamma_\pi \beta_\pi = p_\pi c / m_\pi c^2$, so that $\gamma_\pi \left(1 - \beta_\pi \cos\theta\right) = \left(E_\pi - p_\pi c \cos\theta\right) / m_\pi c^2$. On axis ($\theta = 0$) and for $E_\pi \gg m_\pi c^2$ the denominator is $m_\pi^2 c^4 / E_\pi$ and the result is $E_\nu \approx 0.427\, E_\pi$: the neutrino spectrum simply copies the pion spectrum, which is broad. Off axis it does not. At fixed θ the right-hand side rises with E_π, turns over at $E_\pi \approx m_\pi c^2 / \theta$ and falls again, so across a wide band of parent energies E_ν is almost independent of E_π. A detector placed slightly off the beam axis therefore sees a narrow band of energies rather than the broad spectrum on axis, which is exactly what an oscillation measurement wants: all the flux is concentrated where φ is near $\pi/2$, and the high-energy tail that would otherwise feed the ν_e background is suppressed. T2K sends a beam from the 30 GeV J-PARC main ring 295 km to Super-Kamiokande at 2.5° (43.6 mrad) off axis, peaking at 0.6 GeV [2168]; Equation (114.21) at that angle gives 0.61 GeV at $E_\pi = 2$ GeV, 0.68 GeV at the stationary point $E_\pi = 3.2$ GeV and 0.62 GeV at $E_\pi = 5$ GeV. NOvA sends the NuMI beam 810 km to a 14 kt segmented liquid scintillator detector at Ash River, 14.6 mrad off axis, peaking near 2 GeV [2398]; there the same expression gives 1.84 GeV, 2.04 GeV and 1.85 GeV at $E_\pi = 6$ GeV, 9.6 GeV and 15 GeV.

OPERA solved the hardest problem of the field: detecting the appearance of ν_τ, whose charged-current interaction produces a tau that decays after travelling of order a millimetre. Nothing with electronic readout resolves that. OPERA used 1.25 kt of target in the form of about 150 000 bricks, each a stack of fifty-seven lead plates 1 mm thick interleaved with nuclear emulsion films — lead to supply the mass, emulsion to supply a position resolution of under a micrometre. Electronic trackers identified which brick had been hit; the brick was then extracted, developed and scanned automatically. The CNGS beam from CERN, of mean energy 17 GeV, travelled 730 km through the Earth to Gran Sasso [2247].

114.2.8 What all of them have in common

Three requirements recur in every one of these instruments, and it is worth stating them once.

Depth. The rate of cosmic-ray muons falls roughly as the inverse cube of the water-equivalent overburden over the range covered by Table 114.3. The depth an experiment needs is set by its signal rate and by whether muons produce a background that mimics its signal. Homestake, with a signal of 0.5 atoms a day and a muon-induced spallation background in the same channel, needed 4200 m of water equivalent; SNO, whose neutral-current signature is a free neutron and for which every muon-induced spallation neutron is an irreducible

fake, needed 6010 m; Daya Bay, whose delayed-coincidence tag rejects almost everything and whose signal rate is hundreds of events a day, manages with 250 m.

Radiopurity. Every material within sight of the target contributes. The dominant chains are ^{238}U and ^{232}Th, whose daughters emit betas and gammas up to a few megaelectronvolts, and ^{40}K. Above about 5 MeV natural radioactivity essentially stops, which is why every Cherenkov measurement in this chapter has an analysis threshold in the range 5–9 MeV and why reaching below that — Borexino's achievement — requires purity at the level of 1×10^{-19} g/g.

Calibration with a known source. A rate measurement is only as good as the efficiency it is divided by. The instruments in this chapter are calibrated with deployed radioactive sources of known strength: gamma sources of a few megaelectronvolts to fix the energy scale, neutron sources such as ^{252}Cf or Am–Be to fix the neutron detection efficiency that the SNO and reactor measurements rest on, and, in the gallium case, an artificial neutrino source that calibrates the whole apparatus end to end.

114.3 Procedure

114.3.1 The radiochemical run cycle

A radiochemical run is a single measurement lasting weeks, and it proceeds in five steps that have not changed since 1968.

Reset. The tank is purged, removing all product atoms accumulated so far, and a measured quantity of a stable isotopic carrier is added: about 0.1 cm^3 at standard temperature and pressure of ^{36}Ar or ^{38}Ar for Homestake, a comparable trace of stable germanium for the gallium detectors. The carrier is the key to the whole procedure: it is chemically identical to the product, it is present in a quantity that can be measured by ordinary means, and whatever fraction of it is recovered at the end is the fraction of the signal atoms recovered too. Chemical efficiency is thereby measured in every run rather than estimated once.

Exposure. The tank stands undisturbed for a period comparable with the product half-life — some 3×10^6–9×10^6 s at Homestake, that is between one and three months, and about 1.8×10^6 s for the gallium runs. The number of product atoms present at time t after a reset obeys

$$\frac{\mathrm{d}N}{\mathrm{d}t} = R - \lambda N\,, \qquad N(t) = \frac{R}{\lambda}\left(1 - \mathrm{e}^{-\lambda t}\right)\,, \tag{114.22}$$

with R the production rate and $\lambda = \ln 2 / t_{1/2}$ the decay constant. Exposing for one half-life recovers half the saturated population; exposing for three recovers seven eighths. There is no gain beyond about two half-lives, which is why the exposure time is what it is.

Extraction. A large volume of carrier gas is circulated through the target. At Homestake, several hundred thousand litres of helium were bubbled through the 615 t of perchloroethylene, sweeping the dissolved argon — a noble gas, chemically bound to nothing — into a charcoal trap at liquid-nitrogen temperature. At GALLEX, nitrogen was swept through the acid solution, carrying volatile $\mathrm{GeCl_4}$ with it. The extraction is repeated and the recovered carrier measured, giving efficiencies of about 95 %.

Counting. The purified product is loaded into a proportional counter of about 0.5 cm^3 together with a counting gas, and the counter is observed for several months — long enough that the decay curve itself can be fitted. Each pulse is recorded with its energy and its rise time.

Analysis. A candidate event must satisfy three independent conditions: its energy must match the K- or L-capture peak, its rise time must be that of a localized Auger cascade rather than of an extended ionizing track, and — the decisive one — the times of the run's candidate events must be distributed as an exponential of the known half-life on a flat

background. A maximum-likelihood fit to the time distribution separates the product decays from the constant counter background, and it is this fit, not a raw count, that yields the number quoted. In practice, of order twenty candidate pulses per run.

The result of one run is a production rate in atoms per day, converted to a capture rate per target atom by dividing by the target count of Equation (114.8) or Equation (114.10). The published number is the average over more than a hundred such runs.

114.3.2 Reconstructing a Cherenkov event

A water Cherenkov detector records, for every photomultiplier, the arrival time of the first photon and the integrated charge. Everything else is inference, and the inference proceeds in a fixed order.

Vertex. Cherenkov light from a point of origin arrives at the tubes at times $t_i = t_0 + n\,|\boldsymbol{x}_i - \boldsymbol{x}_0|\,/c$, with n the refractive index. Minimizing the spread of the implied t_0 over all hit tubes locates the vertex. With a timing resolution of a few nanoseconds per tube and several thousand tubes hit, the vertex resolution is a few tens of centimetres. This is what defines the fiducial volume: events reconstructed within about 2 m of the wall are discarded, because the wall and the tubes themselves are the dominant source of radioactivity.

Direction and ring. With the vertex fixed, the pattern of hit tubes is fitted to a cone of half-angle θ_c from Equation (114.11). The cone axis is the particle direction; for a multi-GeV muon the angular resolution is a degree or two.

Flavour. The fitted ring is tested for sharpness. The figure of merit is essentially the goodness of fit of a sharp-edged cone against that of a diffuse disc, and the classification is calibrated on beams of electrons and muons of known momentum injected into the detector, and cross-checked on the sample of cosmic-ray muons that stop in the detector and decay, which supplies a muon and, microseconds later, an electron from the same vertex.

Energy. The total collected charge, corrected for water attenuation, tube-by-tube gain and geometrical acceptance, is proportional to the track length and hence to the energy. The proportionality constant is fixed by deployed sources and by the end-point of the electron spectrum from stopping-muon decay, which is a known 52.8 MeV.

Zenith angle to baseline. The step that makes the atmospheric measurement possible is the last one. The reconstructed direction of the outgoing lepton approximates the direction of the incoming neutrino, to within the scattering angle of the interaction — of order 15° to 20° at 1 GeV and better at higher energy. The zenith angle θ_z of the neutrino then fixes the distance it travelled from its production point at an altitude $h \approx 15\,\mathrm{km}$,

$$L\,(\theta_z) = \sqrt{(R_\oplus + h)^2 - R_\oplus^2 \sin^2\theta_z} - R_\oplus \cos\theta_z\,, \tag{114.23}$$

which runs from 15 km directly overhead ($\cos\theta_z = 1$) through 437 km at the horizon ($\theta_z = 90°$, where the expression reduces to $\sqrt{2R_\oplus h + h^2}$) to 12 800 km directly below. A single detector therefore scans three orders of magnitude in L at fixed E, with the same target, the same efficiency and the same analysis — the cleanest L/E scan available anywhere in physics, and it costs nothing but the angular resolution.

114.3.3 Separating the three Sudbury channels

SNO's three reactions all end as Cherenkov light in the same detector — Equations (114.13) to (114.15) — and separating them is the entire experimental problem. The separation is statistical, not event by event, and rests on three distributions.

Energy. The charged-current electron carries essentially the full neutrino energy less 1.442 MeV, so its spectrum follows the ^{8}B spectrum. The neutral-current signal is monoenergetic in the sense that every neutron capture gives the same photon energy — 6.25 MeV on deuterium, 8.6 MeV on chlorine — so it appears as a bump.

Radial distribution. Charged-current and elastic events occur uniformly in the heavy water, so their density in the cube of the radius is flat out to the acrylic vessel. Neutrons diffuse before capturing, so the neutral-current events are depleted near the vessel wall.

Direction. Elastic scattering is strongly forward-peaked, so its events cluster at $\cos\theta_\odot \to 1$ with respect to the direction from the Sun. Charged-current events on deuterium have a mild backward asymmetry, roughly $1 - \frac{1}{3}\cos\theta_\odot$. Neutron captures are isotropic, having lost all memory of the incident direction during thermalization.

An extended maximum-likelihood fit to the joint distribution in energy, radius and direction returns the three normalizations at once. The three are anticorrelated — the fit can trade charged-current events against neutral-current events to some extent — and it is that anticorrelation, not the statistics, which dominated the uncertainty in the first phase. Adding salt sharpens the separation by adding a fourth variable, the isotropy of the hit pattern, which distinguishes a multi-photon cascade from a single electron; and the ^{3}He counters of the third phase remove the correlation entirely by moving the neutral-current measurement into a separate instrument.

The neutron detection efficiency, which multiplies the whole neutral-current result, is measured by deploying a calibrated ^{252}Cf neutron source at many positions in the vessel and mapping the response.

114.3.4 The delayed coincidence and the reactor flux model

A reactor experiment selects an antineutrino by requiring two pulses in sequence.

The prompt pulse is the positron: its kinetic energy plus the two 511 keV annihilation photons, so that the visible energy is $E_{\bar\nu} - 0.78\,\mathrm{MeV}$. The prompt spectrum is therefore a shifted copy of the antineutrino spectrum, which is what makes a reactor experiment a spectral measurement and not merely a counting one.

The delayed pulse is the neutron capture: 2.22 MeV on hydrogen after about 200 µs, or about 8 MeV on gadolinium after about 28 µs.

The coincidence conditions are a time window a few capture times wide, a spatial separation below a metre or so, and energy windows on both pulses. Their product rejects everything uncorrelated. The residual backgrounds are of three kinds, and all three are measured rather than modelled: accidental coincidences of two uncorrelated radioactive decays, whose rate is obtained by opening an off-time window; correlated events from fast neutrons produced by cosmic-ray muons, which give a proton recoil followed by the same capture and are measured from the muon-tagged sample; and the (α, n) reactions of ^{210}Po on ^{13}C in the scintillator, which are estimated from the measured polonium activity.

The flux prediction is the one place where a reactor experiment depends on something it does not measure. The antineutrino emission of a reactor core is computed from four ingredients: the thermal power, known to a few tenths of a per cent from the coolant flow and temperature rise; the fission fractions of ^{235}U, ^{238}U, ^{239}Pu and ^{241}Pu, which drift over a fuel cycle and are tracked by the reactor operator's own core simulation; the energy released per fission of each isotope; and the antineutrino spectrum per fission of each. The last is the weak link, carrying an uncertainty of a few per cent in normalization and having twice been revised. For KamLAND, where the observable is the survival probability itself, that uncertainty enters the result directly and is the second-largest systematic. For Daya Bay it very nearly cancels, and the next subsection is why.

114.3.5 The near-to-far ratio

The design of Daya Bay and RENO is the reason θ_{13} could be measured at the per-cent level within months of turning on, and the argument is short enough to give in full.

Proposition 114.2 (What a near-to-far ratio cancels)**.** *Let a reactor emit $S(E)\,\mathrm{d}E$ antineutrinos per unit time in $\mathrm{d}E$, and let detector d, at baseline L_d, contain N_d free protons and detect an interaction with efficiency $\varepsilon_d(E)$. Its counting rate is*

$$R_d = \frac{N_d}{4\pi L_d^2} \int \mathrm{d}E\, S(E)\, \sigma(E)\, \varepsilon_d(E)\, P\left(E, L_d\right) \,, \tag{114.24}$$

with σ the inverse-beta cross-section Equation (101.5) and P the survival probability. If two detectors are built identically, so that $\varepsilon_n(E) = \varepsilon_f(E)$ for all E, then the geometrically corrected ratio

$$\mathcal{R} := \frac{R_f}{R_n} \cdot \frac{N_n L_f^2}{N_f L_n^2} = \frac{\int \mathrm{d}E\, S\sigma\varepsilon\, P\left(E, L_f\right)}{\int \mathrm{d}E\, S\sigma\varepsilon\, P\left(E, L_n\right)} \tag{114.25}$$

is independent of the absolute normalization of S, of the absolute normalization of σ, and of the absolute normalization of ε. It depends on their shapes *in E only through the difference between $P(E, L_f)$ and $P(E, L_n)$, and it equals unity identically if P does not depend on L.*
Rests on Equation (101.5).

Proof. *Derives Proposition 114.2.*
Multiply the numerator and denominator of R_f/R_n by $4\pi L_f^2/N_f$ and $4\pi L_n^2/N_n$ respectively, which is what the geometric factor in Equation (114.25) does; the prefactors of Equation (114.24) cancel exactly. Write $S = S_0 s(E)$, $\sigma = \sigma_0 \hat{\sigma}(E)$ and $\varepsilon = \varepsilon_0 \hat{\varepsilon}(E)$ with the hatted functions normalized however one likes. The constants $S_0\sigma_0\varepsilon_0$ multiply both integrals and cancel, which is the first statement. If P is independent of L it comes out of both integrals as the same function and the two integrals are equal, which is the second. What survives is the ratio of two weighted averages of P over the same weight $s\hat{\sigma}\hat{\varepsilon}$, so only the difference of P between the two baselines is observable. □

The proposition converts a hard absolute measurement into an easy relative one, and it explains every feature of the apparatus. The detector modules are built to the same drawings, filled from the same batch of scintillator so that the proton density is common, and their masses measured to better than a part in a thousand; at Daya Bay two modules were placed in the same near hall specifically so that their measured rates could be compared, giving a direct experimental bound of a few tenths of a per cent on the residual difference in efficiency. The far hall is placed where Equation (114.4) makes the phase near maximal, the near halls where it is small, so that the numerator of Equation (114.25) is suppressed and the denominator is not.

The one thing the ratio does not cancel is the relative contribution of the six reactors to each hall, since the halls are at different distances from each core; that is why the baselines quoted in Section 114.2.6 are flux-weighted, and why the reactors' individual thermal powers must still be tracked.

114.3.6 Calibration, blindness and the treatment of systematics

Two procedural points deserve recording because they are what makes the numbers in Section 114.4 usable.

Calibration is end-to-end where possible. The gallium experiments are the only ones that could be calibrated with a neutrino source of known activity, and they were: a ^{51}Cr source of 6.3×10^{16} Bq lowered into the target tests the capture cross-section, the extraction chemistry, the counter efficiency and the analysis in a single measurement. Every other instrument is calibrated in pieces — an optical calibration for the light transport, a gamma source for the energy scale, a neutron source for the capture efficiency — and the composition of those pieces is itself a systematic.

The analyses were blind. SNO, KamLAND, Daya Bay and T2K each fixed their selection cuts, their efficiency corrections and their background estimates on a subset of the data,

or on data with an unknown offset applied, before looking at the number the experiment was built to measure. This matters more here than in most fields because the expected answer was known in advance: an experiment looking for a factor of three that everyone expects to find will find it if the cuts are chosen after the fact. The published SNO result was unblinded once, and the value quoted is the value that appeared.

114.4 Observations and data

114.4.1 The solar neutrino deficit

Table 114.4 gives the radiochemical results. Every entry is a rate per target atom, in SI, together with the prediction of the standard solar model of Table 114.2 and the ratio of the two.

Table 114.4: Radiochemical solar neutrino capture rates. The literature quotes these in solar neutrino units, one SNU being 10^{-36} captures per target atom per second; the SI column is that number written as a rate. Statistical and systematic uncertainties are combined in quadrature where the source gives them separately. Target counts are Equation (114.8) and Equation (114.10). Predictions are the BS05(OP) model of [2072]. The last column is what mattered: chlorine, which sees only ^{8}B, and gallium, which sees the *pp* flux fixed by Equation (114.6), are both short, and by different amounts.

Detector	Years	Measured (1/s/atom)	Predicted	Ratio
Homestake	1970–1994	$(2.56 \pm 0.23) \times 10^{-36}$	$(8.1 \pm 1.2) \times 10^{-36}$	0.32 ± 0.05
GALLEX/GNO	1991–2003	$(6.93 \pm 0.55) \times 10^{-35}$	$(1.26 \pm 0.08) \times 10^{-34}$	0.55 ± 0.05
SAGE	1990–2007	$(6.54 \pm 0.41) \times 10^{-35}$	$(1.26 \pm 0.08) \times 10^{-34}$	0.52 ± 0.04

The Homestake number, $(2.56 \pm 0.23) \times 10^{-36}$ captures per target atom per second [1950], is the average over one hundred and eight extractions between 1970 and 1994. Multiplied by the 2.16×10^{30} target atoms of Equation (114.8) it is a production rate of

$$R = 2.16 \times 10^{30} \times 2.56 \times 10^{-36}/\mathrm{s} = 5.54 \times 10^{-6}/\mathrm{s} = 0.478 \text{ atoms per day}\,, \qquad (114.26)$$

against a cosmic-ray-induced background in the same channel of 0.047 ± 0.013 atoms per day and a predicted solar rate near 1.5 atoms per day. Twenty-five years of running, in a target of six hundred tonnes, to establish a shortfall of one atom of argon per day.

The gallium results [1974, 2138] are the ones that closed the astrophysical escape route, and the reason is arithmetic rather than statistical. Their threshold of 233 keV admits the *pp* neutrinos, whose flux is fixed by Equation (114.6) to about one per cent from the observed solar luminosity alone. Of the predicted 1.26×10^{-34} captures per second per atom, some 55 % comes from the *pp* branch; even setting the entire ^{8}B and ^{7}Be contribution to zero and moving the whole luminosity-constrained flux into *pp* — which no solar model allows, but which brackets the astrophysical uncertainty — leaves a predicted rate of 7.4×10^{-35} per second per atom, against a measured 6.5×10^{-35} to 6.9×10^{-35}. The deficit is reduced by that extreme assumption but not removed, and the assumption itself is contradicted by the direct measurements of the two branches it sets to zero.

Phenomenon 114.3 (The solar electron-neutrino deficit)**.** The rate at which solar neutrinos convert ^{37}Cl into ^{37}Ar is about one third of the rate predicted by the standard solar model, and the deficit persisted through twenty-five years of running [1368, 1950]. It reappears in the real-time, directional elastic-scattering measurement, which also confirms that the

neutrinos come from the Sun [1822], and — decisively — at the far lower threshold of the gallium detectors, which reach the *pp* neutrinos whose flux is fixed by the solar luminosity itself and is therefore almost independent of the uncertain inputs of the model [1974, 2138]. The predicted fluxes are those of [2072].

Rests on Equations (114.5), (114.6) *and* (114.9).

Derivation. *Derives Phenomenon 114.3.*

What has to be shown is that the deficit cannot be absorbed into the solar model, and the argument is a bound, not a fit. Write the predicted capture rate of a gallium detector as a sum over branches,

$$\mathcal{C} = \sum_{b} \Phi_b \, \langle \sigma \rangle_b \, ,$$

with $\langle \sigma \rangle_b$ the cross-section for Equation (114.9) averaged over branch b. The branch fluxes Φ_b are model outputs and carry the uncertainties of Table 114.2, but they are not independent: they satisfy the luminosity constraint Equation (114.6), which the model does not supply and cannot violate, since it follows from the observed solar constant and the energy release of Equation (114.5) alone. Because the *pp* branch produces two neutrinos per completion of Equation (114.5) and the higher branches produce them at a lower rate per unit energy released, maximizing the astrophysical freedom means transferring as much flux as possible *out* of the branches gallium sees best. The extreme case sets $\Phi(^8\mathrm{B}) = \Phi(^7\mathrm{Be}) = 0$ and puts everything in *pp*, which *raises* the total flux slightly while lowering the mean energy. Fix $\langle \sigma \rangle_{pp}$ from the model's own bookkeeping: the *pp* branch supplies 55 % of the predicted 1.26×10^{-34}, that is 6.93×10^{-35}, at the *pp* flux $5.99 \times 10^{14}/(\mathrm{m^2\,s})$ of Table 114.2, so $\langle \sigma \rangle_{pp} = 1.157 \times 10^{-49}\,\mathrm{m^2}$. Scaling that contribution up to the whole luminosity-constrained flux $6.4 \times 10^{14}/(\mathrm{m^2\,s})$ of Equation (114.6) gives

$$\mathcal{C} \geq 6.4 \times 10^{14}/(\mathrm{m^2\,s}) \times 1.157 \times 10^{-49}\,\mathrm{m^2} = 7.40 \times 10^{-35}/\mathrm{s\ per\ atom}\,. \tag{114.27}$$

The measurements are $(6.93 \pm 0.55) \times 10^{-35}$ and $(6.54 \pm 0.41) \times 10^{-35}$, whose inverse-variance combination is $(6.68 \pm 0.33) \times 10^{-35}$: below the bound Equation (114.27) by 2.2 standard deviations. The luminosity constraint alone therefore leaves a real but not decisive tension — and it is a bound obtained by assuming something now known to be false, since the two branches it zeroes have since been measured. Sudbury's flavour-blind channel gives the total ^{8}B production flux $(5.09 \pm 0.64) \times 10^{10}/(\mathrm{m^2\,s})$ with no oscillation input at all (Table 114.6), and Borexino gives the ^{7}Be production flux $(4.99 \pm 0.13) \times 10^{13}/(\mathrm{m^2\,s})$ (Table 114.11) — the latter obtained from a measured ν_e rate by dividing out the survival probability, so it presupposes oscillation and is quoted here only for the branch normalization, not as independent evidence for it. Both agree with Table 114.2. With the branch fluxes fixed by observation rather than left free, the prediction returns to 1.26×10^{-34} and the measured rate is 0.53 of it: a factor of two, far outside the uncertainty of either the measurement or the model. No redistribution of the solar fluxes consistent with the Sun's observed luminosity, and none consistent with the branch fluxes now measured directly, reproduces the gallium rate.

Two escapes remain and both were closed. Either the capture cross-section of Equation (114.9) is wrong, or the detector efficiency is; and the ^{51}Cr source calibrations of Section 114.3.6 test the product of the two directly against a known activity, returning a ratio consistent with unity to within about a tenth (Section 114.6.4 records the residual discrepancy honestly, and it is far too small to account for a factor of two). What is left is that fewer electron neutrinos arrive than leave, and the deficit is real. □

114.4.2 The directional and real-time solar measurements

Kamiokande-II was the first detector to see solar neutrinos in real time and the first to see that they come from the Sun. Its signal is the elastic scattering Equation (114.12), whose

recoil electron retains the neutrino direction well enough that the distribution of events in $\cos\theta_\odot$, the cosine of the angle between the reconstructed electron direction and the direction away from the Sun, shows a clear forward peak on a flat background [1822]. The measured ^{8}B flux was

$$\Phi\left(^8\mathrm{B}\right)_{\mathrm{ES}} = (2.7 \pm 0.5) \times 10^{10}/(\mathrm{m}^2\,\mathrm{s})\,, \tag{114.28}$$

for an analysis threshold of 7.5 MeV in recoil electron energy. Against the ^{8}B entry of Table 114.2, $(5.69 \pm 0.91) \times 10^{10}/(\mathrm{m}^2\,\mathrm{s})$, that is a ratio of 0.48 ± 0.12. The ratio quoted in the source itself is 0.46 ± 0.15 [1822], taken against the solar model current in 1989; the two are not the same comparison, and this chapter keeps them apart for the reason given in Section 114.8.

Two things follow that the radiochemical experiments could not establish. The neutrinos are solar, not terrestrial or cosmic — the angular distribution says so directly. And the deficit is about a factor of two rather than the factor of three seen in chlorine, at the same ^{8}B branch. That difference is not an inconsistency: elastic scattering retains sensitivity to the other flavours through the neutral current, with the weight of Equation (114.16), so a detector that measures $\Phi_e + 0.154\,\Phi_{\mu\tau}$ must report a smaller deficit than one measuring Φ_e alone — if and only if $\Phi_{\mu\tau}$ is not zero. The comparison of the two numbers was in fact the first quantitative hint of flavour change, well before SNO measured it in a single detector; but it required comparing two experiments with different targets, thresholds and systematics, and no one was prepared to draw the conclusion from it.

114.4.3 Atmospheric zenith-angle dependence

Super-Kamiokande's atmospheric measurement is the first in this chapter that needs no external prediction at all.

Two observables carry it. The first is the *double ratio*

$$R := \frac{(N_\mu/N_e)_{\mathrm{data}}}{(N_\mu/N_e)_{\mathrm{expected}}}\,, \tag{114.29}$$

in which the absolute atmospheric flux — uncertain by some 20 % — cancels, leaving only the flavour ratio, which by Equation (115.61) is fixed at two by the decay chain $\pi \to \mu\nu_\mu$, $\mu \to e\nu_e\bar{\nu}_\mu$ and is reliable to a few per cent. The second is the *up-down asymmetry*

$$A := \frac{U - D}{U + D}\,, \tag{114.30}$$

with U and D the numbers of events with $-1 < \cos\theta_z < -0.2$ and $0.2 < \cos\theta_z < 1$ respectively, in which the flux normalization, the cross-section and the detector efficiency all cancel, because the same detector counts both samples. The atmospheric flux is up-down symmetric above a few gigaelectronvolts to better than one per cent — the geomagnetic field distorts it at lower energies, which is why the asymmetry is quoted for the multi-GeV sample.

Phenomenon 114.4 (Zenith-angle dependence of atmospheric muon neutrinos)**.** Muon neutrinos produced in cosmic-ray air showers reach an underground detector from every direction. Those arriving from above have travelled some 15 km; those arriving from below have crossed the Earth, some 12 800 km. At the same energy the upward-going muon-neutrino rate is about half the downward-going one, while the electron-neutrino rates show no such deficit; and the size of the deficit is a function of the ratio L/E of path length to energy, not of L or E separately [1954, 2057].

Rests on Equations (114.2)*,* (114.3)*,* (114.23) *and* (114.30)*.*

Table 114.5: The Super-Kamiokande atmospheric neutrino result, from 33 kt yr of exposure — 535 days of the fiducial 22.5 kt [1954]. The first uncertainty is statistical, the second systematic. R is Equation (114.29) and A is Equation (114.30). A value $R = 1$ and $A = 0$ is what no oscillation would give. The electron-like asymmetry is consistent with zero and the muon-like asymmetry is not, which is the whole result in two numbers.

Sample	Quantity	Value
Sub-GeV	R	$0.63 \pm 0.03 \pm 0.05$
Multi-GeV	R	$0.65 \pm 0.05 \pm 0.08$
Multi-GeV, μ-like	A	$-0.296 \pm 0.048 \pm 0.01$
Multi-GeV, e-like	A	$-0.036 \pm 0.067 \pm 0.02$

Derivation. *Derives Phenomenon 114.4.*

The formalism is Equation (114.2), derived in Chapter 103; what is derived here is the number. Take the atmospheric splitting $|\Delta m^2_{32}|\,c^4 = 2.455 \times 10^{-3}\,\mathrm{eV}^2$ and $E = 1\,\mathrm{GeV}$, and evaluate the phase Equation (114.3) at the two extreme baselines of Equation (114.23):

$$\varphi_{\mathrm{down}} = 1.26693 \times 2.455 \times 10^{-3} \times \frac{15}{1} = 0.047\,, \tag{114.31}$$

$$\varphi_{\mathrm{up}} = 1.26693 \times 2.455 \times 10^{-3} \times \frac{12800}{1} = 40\,. \tag{114.32}$$

For the downward path, $\sin^2\varphi = 2.2 \times 10^{-3}$ and Equation (114.2) gives a survival probability of $1 - 2.2 \times 10^{-3} \sin^2 2\theta_{23}$: no observable deficit. For the upward path the phase is forty radians and sweeps rapidly across the finite spread of L within a zenith bin and of E within an energy bin, so the oscillating factor averages to $\frac{1}{2}$ and

$$\langle P \rangle = 1 - \tfrac{1}{2}\sin^2 2\theta_{23} = 1 - \tfrac{1}{2} \times 0.9915 = 0.504\,, \tag{114.33}$$

using $\sin^2\theta_{23} = 0.546$ from Table 103.3, whence $\sin^2 2\theta_{23} = 4\sin^2\theta_{23}\cos^2\theta_{23} = 0.9915$. The predicted up-down asymmetry Equation (114.30) follows immediately:

$$A = \frac{\langle P \rangle - 1}{\langle P \rangle + 1} = \frac{0.504 - 1}{0.504 + 1} = -0.330\,, \tag{114.34}$$

against the measured $-0.296 \pm 0.048 \pm 0.01$ of Table 114.5 — agreement to within seven tenths of a standard deviation, from a calculation containing no free parameter once θ_{23} and Δm^2_{32} are taken from the global fit. The electron-like asymmetry is predicted to vanish at this splitting because θ_{13} is small (Phenomenon 114.8), so the transition here is predominantly $\nu_\mu \to \nu_\tau$; the measured -0.036 ± 0.067 is consistent with zero.

That the two extreme baselines differ is not by itself decisive — an absorption law would also deplete the upward sample. What excludes absorption is that the depletion of the intermediate zenith bins follows $\sin^2$ of Equation (114.3) as a function of $L(\theta_z)/E$, and that the *electron* sample crossing the same rock shows no depletion at all. Matter cannot absorb one flavour and not another at these energies, because the neutral current is flavour-blind and the charged-current cross-sections differ by less than a per cent above a gigaelectronvolt. □

114.4.4 Sudbury and the flavour-blind flux

Phenomenon 114.5 (The missing solar neutrinos arrive as other flavours)**.** Heavy water gives access to reactions of different flavour sensitivity in one detector. The charged-current rate on deuterium, sensitive to ν_e alone, corresponds to a flux about one third of the

Table 114.6: The Sudbury fluxes, for an analysis threshold of 5 MeV in effective electron kinetic energy [2021]. The source quotes them per square centimetre per second; these are the SI values. Statistical and systematic uncertainties are combined. $\Phi_{\mu\tau}$ is the derived quantity Equation (114.35), and the model prediction is the ^{8}B entry of Table 114.2. The point of the table is the first two rows: a detector that counts only electron neutrinos and a detector that counts all three, in the same tonne of heavy water during the same exposure, disagree by a factor of three.

Channel	Flavour sensitivity	Flux $(1/(\mathrm{m}^2\,\mathrm{s}))$
Charged current	ν_e only	$(1.76 \pm 0.11) \times 10^{10}$
Elastic scattering	$\Phi_e + 0.154\,\Phi_{\mu\tau}$	$(2.39 \pm 0.27) \times 10^{10}$
Neutral current	all three equally	$(5.09 \pm 0.64) \times 10^{10}$
$\Phi_{\mu\tau}$ (derived)	—	$(3.41 \pm 0.66) \times 10^{10}$
Model ^{8}B	—	$(5.69 \pm 0.91) \times 10^{10}$

standard solar model prediction; the neutral-current deuteron breakup, equally sensitive to all three active flavours, gives a total flux of about $5.1 \times 10^{10}/(\mathrm{m}^2\,\mathrm{s})$, in agreement with that prediction [2008, 2021].

Rests on Equations (114.13) *and* (114.14).

Derivation. *Derives Phenomenon 114.5.*

Write ϕ_e for the solar ν_e flux above threshold and $\phi_{\mu\tau}$ for the combined ν_μ and ν_τ flux. The charged-current reaction measures ϕ_e; the neutral-current reaction has the same cross section for all three active flavours and therefore measures $\phi_e + \phi_{\mu\tau}$. Subtracting,

$$\phi_{\mu\tau} = \phi_{\mathrm{NC}} - \phi_{\mathrm{CC}} = 5.09 \times 10^{10}/(\mathrm{m}^2\,\mathrm{s}) - 1.76 \times 10^{10}/(\mathrm{m}^2\,\mathrm{s}) = 3.33 \times 10^{10}/(\mathrm{m}^2\,\mathrm{s})\,, \quad (114.35)$$

which the published likelihood fit, propagating the correlations between the two channels, gives as $(3.41 \pm 0.66) \times 10^{10}/(\mathrm{m}^2\,\mathrm{s})$ — positive by more than five standard deviations. No solar-model input enters Equation (114.35) at all: the conclusion that neutrinos leave the Sun as ν_e and arrive partly as ν_μ and ν_τ survives whatever the predicted flux, which the neutral-current number then independently confirms.

Three consequences follow in order.

First, the flavour changed in flight, so the flavour states are not stationary states of the free Hamiltonian, hence not states of definite mass.

Second, by Equation (114.2) a non-zero transition probability requires $\Delta m^2 \neq 0$, so at least one neutrino mass is non-zero. The strictly massless neutrino of Chapter 96 is thereby excluded, and with it the Standard Model as originally written.

Third — and this is the part the subtraction alone does not give — the ratio

$$\frac{\phi_{\mathrm{CC}}}{\phi_{\mathrm{NC}}} = \frac{1.76}{5.09} = 0.35 \pm 0.05 \quad (114.36)$$

is the electron-neutrino survival probability at ^{8}B energies, and it is a measurement of an oscillation parameter and not merely of a deficit. Vacuum oscillation over 1.5×10^{11} m at these energies averages to $1 - \frac{1}{2}\sin^2 2\theta_{12} = 0.57$, which Equation (114.36) excludes. The matter-modified value predicted by Example 103.58 is $\sin^2\theta_{12} = 0.31$, or 0.29 once the third angle is restored, and that is what is measured. The Sudbury result is therefore not only the proof that flavour changes but the first quantitative confirmation of the Mikheyev–Smirnov–Wolfenstein mechanism. □

The internal consistency of Table 114.6 is worth one more line, because it is a check the experiment supplies on itself. Given ϕ_e and $\phi_{\mu\tau}$ from the first and third rows, Equation (114.16) predicts an elastic-scattering flux of $1.76 + 0.154 \times 3.41 = 2.29$, in units of

$1 \times 10^{10}/(\mathrm{m}^2\,\mathrm{s})$, against the measured 2.39 ± 0.27. Three channels, two unknowns, one consistency condition satisfied.

114.4.5 KamLAND and reactor antineutrinos

Phenomenon 114.6 (Reactor antineutrinos disappear, and the deficit oscillates)**.** Electron antineutrinos from power reactors at an average baseline near 180 km arrive with a survival probability of about 0.6, and that probability, measured as a function of L/E, is not a monotone suppression but an oscillatory function of it [2049, 2071]. The parameters extracted from this terrestrial, controlled-source measurement agree with those extracted from the Sun.

Rests on Equations (114.2) *and* (114.3)*.*

The first KamLAND exposure was 162 t yr — 145.1 days of live time in a fiducial mass of 408 t inside the kilotonne target, 145.1 days being 0.397 of a year and $0.397 \times 408\,\mathrm{t} = 162\,\mathrm{t\,yr}$ — and it yielded 54 antineutrino candidates above a prompt-energy threshold of 2.6 MeV, against 86.8 ± 5.6 expected in the absence of oscillation from the reactor bookkeeping of Section 114.3.4, on an estimated background of 1.0 ± 1.0 events [2049]. The ratio is

$$\frac{N_{\mathrm{obs}} - N_{\mathrm{bg}}}{N_{\mathrm{exp}}} = 0.611 \pm 0.085 \pm 0.041\,, \tag{114.37}$$

the first uncertainty statistical, the second systematic. A ratio of one is excluded at better than 99.95 %.

Derivation. *Derives Phenomenon 114.6.*

The distinction that carries the argument is between a deficit and an oscillation: any error in the flux normalization produces the first, only interference produces the second. Evaluate the phase Equation (114.3) at the reactor scale, with $\Delta m^2_{21} c^4 = 7.53 \times 10^{-5}\,\mathrm{eV}^2$, $L = 180\,\mathrm{km}$ and the detected antineutrino energies E between 3.4 MeV and 8 MeV:

$$\varphi = 1.26693 \times 7.53 \times 10^{-5} \times \frac{180}{E/\mathrm{GeV}} = \frac{1.72 \times 10^{-2}}{E/\mathrm{GeV}}\,, \tag{114.38}$$

which runs from $\varphi = 5.05$ at the low end of the detected range to $\varphi = 2.15$ at the high end. That is nearly one complete oscillation *within a single detector's energy acceptance* — neither negligible, as at the reactor baselines of a few hundred metres, nor so large that it averages away, as for upward-going atmospheric neutrinos. In that regime two things are true at once. The survival probability averaged over the spectrum approaches the asymptotic value

$$\langle P \rangle \to 1 - \tfrac{1}{2}\sin^2 2\theta_{12} = 1 - \tfrac{1}{2} \times 0.851 = 0.57\,,$$

which Equation (114.37) matches within its uncertainty. And the *shape* of the variation across the prompt spectrum is measurable, because φ changes by 2.90 radians across it. The period of $\sin^2\varphi$ is π, so that swing is 0.92 of one full oscillation, and it straddles both a maximum of $\sin^2\varphi$ (at $\varphi = 3\pi/2 = 4.71$) and a minimum (at $\varphi = \pi$): the survival probability rises and falls again inside the accepted range rather than drifting monotonically. Observing the shape is what converts a missing flux into a determination of Δm^2_{21}: the position of the first minimum in φ fixes $\Delta m^2_{21} L/E$, and L and E are both known.

It is worth being explicit about why no rival hypothesis survives. Neutrino decay would give a survival probability falling monotonically as $\exp(-\alpha L/E)$; decoherence would give a monotone approach to a constant; an error in the reactor spectrum would scale the prediction smoothly. All three are monotone in L/E and none returns. The measured spectrum does return, and that is the signature of interference and of nothing else. □

Remark 114.7 (Why the coherence condition is not violated here). KamLAND is the one experiment in this chapter where the wave-packet caveats of Remark 103.51 could have mattered, since its baseline is long and its energy low. The coherence length Equation (103.53) at $E = 3\,\mathrm{MeV}$ and $\Delta m^2_{21}c^4 = 7.53 \times 10^{-5}\,\mathrm{eV}^2$ is $6.8 \times 10^3\,\mathrm{km}$ if the relevant localization is the atomic scale of the decaying fission fragment, against 180 km of baseline — a margin of thirty-eight — and 0.68 km if it were the nuclear scale, in which case coherence would be lost hundreds of times over and no oscillatory pattern could appear at all. KamLAND sees one. The observation is therefore also a measurement of the production localization, and it comes out atomic.

114.4.6 The third mixing angle

Table 114.7: The short-baseline reactor measurements of θ_{13}, both published in 2012. $\mathcal{R}$ is the geometrically corrected far-to-near ratio Equation (114.25); a value of one would mean no oscillation. Uncertainties are statistical then systematic. The two experiments use the same technique at different sites and reactor complexes, and their systematic errors are largely independent.

Experiment	Exposure	$\mathcal{R}$	$\sin^2 2\theta_{13}$
Daya Bay [2189]	55 days	$0.940 \pm 0.011 \pm 0.004$	$0.092 \pm 0.016 \pm 0.005$
RENO [2188]	229 days	$0.920 \pm 0.009 \pm 0.014$	$0.113 \pm 0.013 \pm 0.019$

Phenomenon 114.8 (The third mixing angle is small but not zero)**.** Comparing near and far identical detectors at reactor complexes reveals a deficit corresponding to $\sin^2 2\theta_{13}$ of order 0.09, measured independently and consistently by two experiments [2188, 2189]. It is the smallest of the three mixing angles, and many had expected it to vanish; that it does not is the precondition for any observation of leptonic CP violation.

Rests on Theorem 103.54, Equation (114.25)*, and Proposition 114.2.*

Derivation. *Derives Phenomenon 114.8.*

Two things have to be shown: that the three-flavour survival probability at a reactor baseline of a kilometre or two reduces to a two-flavour form governed by θ_{13} alone, and that the ratio Equation (114.25) then reproduces the measured number.

The survival probability. The exact three-flavour expression for $\bar{\nu}_e$ disappearance, obtained from Theorem 103.54 with the CP-odd term absent because the survival channel is CP-even, is

$$P_{\bar{e}\bar{e}} = 1 - \sin^2 2\theta_{13}\left(\cos^2\theta_{12}\sin^2\varphi_{31} + \sin^2\theta_{12}\sin^2\varphi_{32}\right) - \cos^4\theta_{13}\sin^2 2\theta_{12}\sin^2\varphi_{21}\,, \tag{114.39}$$

with φ_{jk} the phase Equation (114.3) built from Δm^2_{jk}. At $L = 1.65\,\mathrm{km}$ and $E = 3.5\,\mathrm{MeV}$ the solar phase is

$$\varphi_{21} = 1.26693 \times 7.53 \times 10^{-5} \times \frac{1.65}{3.5 \times 10^{-3}} = 0.0450\,,$$

so $\sin^2\varphi_{21} = 2.0 \times 10^{-3}$ and the last term of Equation (114.39), with $\cos^4\theta_{13}\sin^2 2\theta_{12} = 0.81$, contributes 1.6×10^{-3} — a sixth of a per cent, below the experimental resolution. Meanwhile Δm^2_{31} and Δm^2_{32} differ by three per cent, so φ_{31} and φ_{32} may be identified, and the bracket collapses to $\sin^2\varphi_{31}$ since $\cos^2\theta_{12} + \sin^2\theta_{12} = 1$. Hence

$$P_{\bar{e}\bar{e}} \approx 1 - \sin^2 2\theta_{13}\sin^2\left(\frac{(\Delta m^2_{31}c^4)\,L}{4\hbar c\,E}\right)\,, \tag{114.40}$$

a two-flavour form in which θ_{13} appears alone. This is the reason the experiment can be done at all: there is a window in L/E in which one, and only one, of the three angles is visible.

The ratio. Evaluate Equation (114.40) at the Daya Bay baselines with $\Delta m^2_{31} c^4 = 2.53 \times 10^{-3}\,\mathrm{eV}^2$, $E = 3.5\,\mathrm{MeV}$ and $\sin^2 2\theta_{13} = 4 \sin^2\theta_{13} \cos^2\theta_{13} = 0.086$ from Table 114.9. The phases are $\varphi_{\mathrm{far}} = 1.511$ and $\varphi_{\mathrm{near}} = 0.430$, giving $\sin^2\varphi_{\mathrm{far}} = 0.996$ and $\sin^2\varphi_{\mathrm{near}} = 0.174$, so

$$P_{\mathrm{far}} = 1 - 0.086 \times 0.996 = 0.914\,, \qquad P_{\mathrm{near}} = 1 - 0.086 \times 0.174 = 0.985\,,$$

and by Proposition 114.2

$$\mathcal{R} = \frac{P_{\mathrm{far}}}{P_{\mathrm{near}}} = 0.928\,, \tag{114.41}$$

against the measured $0.940 \pm 0.011 \pm 0.004$. The one per cent residual is what the full analysis recovers by averaging over the six reactor cores, the two near halls at different baselines and the whole prompt spectrum rather than evaluating at a single representative energy; the point of the estimate is that the effect is of the size measured and arises from θ_{13} alone.

Why the ratio is trustworthy. By Proposition 114.2 the reactor flux normalization, the inverse-beta cross-section and the absolute detector efficiency all cancel in $\mathcal{R}$; what remains is the relative efficiency of two detectors built to the same drawings and filled from the same batch of scintillator, bounded experimentally at Daya Bay by comparing two modules in the same hall. A measurement whose dominant systematic is the difference between two nominally identical objects is a very different thing from one whose dominant systematic is a predicted flux, and that is why an angle previously bounded only from above was resolved at five standard deviations in fifty-five days. □

114.4.7 Accelerator beams: disappearance and appearance

The accelerator programme does three things the natural sources cannot: it confirms the atmospheric parameters with a source whose spectrum and composition are known independently, it observes the *appearance* of a flavour rather than the disappearance of one, and it provides the only access to the CP phase.

Table 114.8: Long-baseline accelerator results. The disappearance experiments count ν_μ charged-current events at the far detector against the number predicted from the near detector; the appearance experiments count events of a flavour the beam did not contain. Uncertainties are as quoted by the sources, statistical and systematic combined where they are given separately.

Experiment	L	Observable	Result
K2K [2089]	250 km	ν_μ disappearance	112 events, 158 ± 9 expected
MINOS [2100]	735 km	ν_μ disappearance	215 events, 336 ± 14 expected
T2K [2168]	295 km	ν_e appearance	6 events, 1.5 ± 0.3 expected
NOvA [2398]	810 km	$\lvert\Delta m^2_{32}\rvert\, c^4$	$(2.41 \pm 0.07) \times 10^{-3}\,\mathrm{eV}^2$
OPERA [2247]	730 km	ν_τ appearance	5 events, background 0.25

K2K's deficit corresponds to $\lvert\Delta m^2_{32}\rvert\, c^4$ near $2.8 \times 10^{-3}\,\mathrm{eV}^2$ at maximal mixing, and excludes the no-oscillation hypothesis at about four standard deviations [2089]; MINOS, with ten times the statistics and a magnetized detector, gives $\lvert\Delta m^2_{32}\rvert\, c^4 = 2.74 \times 10^{-3}\,\mathrm{eV}^2$ with an uncertainty of about 15 % and $\sin^2 2\theta_{23} > 0.87$ [2100]. Both agree with the atmospheric determination from a completely different source, which is the point of doing them.

The appearance measurements are the harder and the more informative. T2K's six electron-neutrino candidates on an expected background of 1.5 ± 0.3 were a two-and-a-half standard deviation indication in 2011 [2168], published months before the reactor measurements of Table 114.7 and consistent with them: $\nu_\mu \to \nu_e$ appearance requires $\theta_{13} \neq 0$ by the same three-flavour expression that gives Equation (114.40), so the two are measurements of the same parameter in different channels. OPERA's five tau candidates on a background of 0.25 close the three-flavour picture from the other side [2247]: the flavour that the atmospheric and accelerator disappearance measurements infer must be there, because the muon neutrinos go somewhere, is observed directly.

114.4.8 The global fit

All of the above, together with the solar and reactor spectra in full, is combined into a fit for six parameters — two independent squared-mass splittings, three mixing angles and one phase. Table 114.9 is the result. It repeats Table 103.3 deliberately, because an experiment chapter must state the numbers its measurements produce, and because the third column here is different: it records which measurement dominates each parameter.

Table 114.9: The measured oscillation parameters, from the global fit of [2356, 2427], with the measurement that dominates each. The splittings are quoted as $\Delta m^2 c^4$, an energy squared, per Remark 114.1. The sign of Δm^2_{32} is not measured and the value listed assumes the normal ordering; the inverted ordering gives $(-2.529 \pm 0.029) \times 10^{-3}\,\mathrm{eV}^2$. The phase δ_{CP} is constrained, not measured, and is recorded as such.

Parameter	Value	Dominant measurement
$\Delta m^2_{21} c^4$	$(7.53 \pm 0.18) \times 10^{-5}\,\mathrm{eV}^2$	KamLAND reactor spectrum shape
$\lvert\Delta m^2_{32}\rvert\, c^4$	$(2.455 \pm 0.028) \times 10^{-3}\,\mathrm{eV}^2$	accelerator ν_μ disappearance; atmospheric
$\sin^2\theta_{12}$	0.307 ± 0.013	Sudbury charged-current to neutral-current ratio; Borexino
$\sin^2\theta_{23}$	0.546 ± 0.021	atmospheric and accelerator ν_μ disappearance
$\sin^2\theta_{13}$	0.0220 ± 0.0007	short-baseline reactor near-to-far ratio
δ_{CP}	$\approx 1.2\pi$, poorly bounded	$\nu_\mu \to \nu_e$ against $\bar\nu_\mu \to \bar\nu_e$

Two properties of that table are physics rather than bookkeeping. The two splittings differ by a factor of about thirty-three, which is why the solar and atmospheric sectors decouple and why each could be measured before the other was understood. And two of the three angles are large — $\sin^2 2\theta_{23} = 0.99$ and $\sin^2 2\theta_{12} = 0.85$ — in flat contradiction to the near-diagonal quark mixing matrix of Section 103.4.2, whose largest off-diagonal magnitude is about 0.22. Two mixing matrices generated by the same mechanism in the same theory, one nearly the identity and one nearly democratic: that is a fact with no explanation. It belongs to the flavour puzzle of Section 133.1, which catalogues the Yukawa couplings the Standard Model accommodates without predicting, though the contrast between the two matrices is not itemized there and is recorded here.

114.5 Interpretation

114.5.1 What the data force

The interpretation of Section 114.4 is a chain of four steps, and it is worth setting it out as a chain, because each link excludes something the previous one did not.

Step one: the deficit is real. Three radiochemical detectors with different thresholds and different chemistry, one water Cherenkov detector with direction, and one heavy-water detector all find fewer solar electron neutrinos than the model predicts (Tables 114.4 and 114.6). The gallium threshold reaches a branch whose flux is fixed by Equation (114.6) independently of the model, so the deficit is not an artefact of the astrophysics.

Step two: the missing neutrinos are still there. Sudbury's neutral-current channel measures the flavour-summed flux and finds it in agreement with the model, while the charged-current channel finds a third of it (Equation (114.35)). The subtraction is model-free. Whatever happened to the electron neutrinos, they were not absorbed and they did not decay into something invisible.

Step three: the change depends on L/E and oscillates. Super-Kamiokande's zenith-angle distribution is a scan in L at fixed E over three orders of magnitude with one detector (Equation (114.23)), and the depletion follows $\sin^2$ of Equation (114.3). KamLAND's prompt-energy spectrum is a scan in E at fixed L, and the survival probability returns rather than falling monotonically (Equation (114.38)). Absorption, decay and decoherence are all monotone in L/E; interference is not.

Step four: therefore the neutrino has mass. By Equation (114.2) the phase is proportional to $\Delta m^2 c^4$, so a non-zero oscillation amplitude requires $m_2^2 \neq m_1^2$ and hence at least one non-zero mass. The left-handed neutrino of Chapter 96 has none, and the Standard Model as originally written is therefore false. That is the only place where a laboratory measurement contradicts it.

Three technical points belong here rather than in the observational sections.

Plane waves. The derivation of Equation (114.2) gives the two mass components the same momentum and the same flight time, both of which are approximations. The conditions under which they are good — production and detection regions small compared with the oscillation length, and wave packets still overlapping on arrival — are stated and evaluated in Remark 103.51, and the tightest case in this chapter is KamLAND, examined in Remark 114.7.

Three flavours. The two-flavour formula is used throughout the observational sections because the two splittings differ by a factor of thirty-three and each experiment sits in a window where one dominates. The exact three-flavour expression is Theorem 103.54, and Equation (114.39) shows explicitly how it reduces at a short reactor baseline, with the neglected term quantified at 1.6×10^{-3}. Wherever the two-flavour statement is used here, the correction is of order $\cos^4 \theta_{13} = 0.957$ or smaller.

What oscillation does not measure. The probabilities depend on Δm^2, on the mixing angles and on one phase. They do not depend on the absolute masses, on whether the mass term is of Dirac or of Majorana type (Proposition 103.47), or on the mechanism that generates the masses. Everything in Table 114.9 is silent on all three.

114.5.2 Matter effects: the MSW mechanism

The solar measurements are not measurements of vacuum oscillation, and treating them as such gives the wrong answer by a factor of two. The theory is Theorem 103.57; what belongs here is the evidence for it.

The mechanism in one sentence: matter contains electrons and contains no muons or taus, so ν_e alone can forward-scatter coherently through the charged current and acquires

the extra potential energy Equation (103.57), $V_e = \sqrt{2} G_F n_e$, which at the centre of the Sun is 1.22×10^{-30} J, that is 7.6×10^{-12} eV. Because the shift is flavour-dependent it changes the mixing angle, and by Equation (103.61) the effective mixing becomes maximal at the energy Equation (103.62), $E_{\text{res}} = 1.9$ MeV. That single number splits the solar neutrino spectrum in two.

Table 114.10: The measured electron-neutrino survival probability of solar neutrinos as a function of energy, which is the observable signature of the matter effect. The Borexino values are from the comprehensive pp-chain measurement [2297]; the Sudbury value is Equation (114.36). The predictions are those of Example 103.58: below the resonance energy of 1.9 MeV the propagation is essentially vacuum-like and $P_{ee} \to 1 - \frac{1}{2}\sin^2 2\theta_{12}$, above it the neutrino leaves the Sun as the mass eigenstate ν_2 and $P_{ee} \to \sin^2\theta_{12}$, both multiplied by $\cos^4\theta_{13}$. There is no free parameter: θ_{12} and θ_{13} come from Table 114.9. The two asymptotes are sharp predictions; the ^{7}Be and *pep* entries lie in the transition region and are quoted as a smooth interpolation between them, which is where the prediction is least sharp and where the data are weakest.

Branch	Energy	Measured P_{ee}	Predicted
pp	0.1–0.4 MeV	0.57 ± 0.09	0.55
^{7}Be	0.862 MeV	0.53 ± 0.05	0.54
pep	1.44 MeV	0.43 ± 0.11	0.50
^{8}B	> 5 MeV	0.37 ± 0.08	0.29
^{8}B (SNO)	> 5 MeV	0.35 ± 0.05	0.29

Table 114.10 is the test, and it is worth saying exactly what makes it one. A survival probability that is *constant* in energy is what vacuum oscillation over an averaged phase gives; the measured values are not constant, and they fall with energy in the direction and by the amount the matter effect predicts. Two energy decades, one curve, no adjustable parameter. The intermediate points — *pep* at 1.44 MeV, sitting almost exactly at the resonance — are where the transition happens, and they are also where the measurement is weakest, which is an honest statement about what has and has not been established: the two asymptotes are solid, the shape of the transition between them is not yet resolved.

Two further consequences of Theorem 103.57 are the subject of current work, and Remark 103.60 names them both.

Day–night asymmetry. Solar neutrinos arriving at night have crossed the Earth, whose electron density partially regenerates the ν_e component, so the night-time rate should exceed the daytime rate by a few per cent with no free parameter beyond those already measured. The predicted asymmetry for the ^{8}B flux is a few per cent and the measurements sit at about the level of two standard deviations: an indication, not an observation, and this treatise records it as one. No source for the day–night measurement is cited in this treatise; the size of the effect is stated here without one, and nothing later in the chapter rests on it.

The sign of the splitting. This is the deepest consequence. Vacuum oscillation depends on Δm^2 only through $\sin^2\varphi$, which is even in Δm^2 and therefore blind to its sign; the matter term is not, because $V_e > 0$ for matter and $V_e < 0$ for antimatter, so the resonance condition Equation (103.61) can be satisfied for neutrinos or for antineutrinos but not both. The solar data therefore determine the sign of Δm^2_{21} — ν_2 is heavier than ν_1 — which no vacuum measurement could. The same argument applied to Δm^2_{32} with the Earth's density in place of the Sun's is the route to the mass ordering, and it is why the long-baseline experiments of Table 114.8 matter beyond their statistics.

114.5.3 The PMNS matrix and the measured parameters

Collecting Table 114.9 into the mixing matrix Definition 103.46 gives magnitudes Equation (103.49): every entry of the first two rows is of order one half, and only $|U_{e3}| = \sin\theta_{13} = 0.148$ is small. This is Phenomenon 103.48.

Three observations about the parameter set, each of which is a statement about the evidence rather than about the theory.

The measurements are over-determined and they agree. The solar splitting is fixed by KamLAND's terrestrial reactor spectrum and, independently, by the energy dependence of the solar survival probability in Table 114.10; the atmospheric splitting by Super-Kamiokande's zenith distribution and, independently, by MINOS and NOvA with a controlled beam; θ_{13} by two reactor experiments at different sites and, independently, by T2K's appearance channel. In each case the sources are astrophysical against terrestrial, or disappearance against appearance, with unrelated systematics. That is the strongest form of confirmation an experimental result can have.

The parameter count is the honest statement of ignorance. Three neutrino masses, three mixing angles and one phase — seven new numbers, and nine if the neutrino is of Majorana type — are added to the Standard Model by the results of this chapter, and not one of them is predicted by anything. The free-parameter bookkeeping is in the appendix on the fundamental parameters of physics, which sets out how the count changes according to the mass mechanism assumed.

The contrast with quark mixing is unexplained. The quark mixing matrix of Section 103.4.2 is nearly the identity, its largest off-diagonal magnitude being 0.22 and its smallest 0.0037; the lepton mixing matrix is nearly democratic. Both arise, in the Standard Model extended by neutrino masses, as the same kind of misalignment between two bases. There is at present no evidence-based account of why the two should look so different, and it belongs among the mass and mixing puzzles of Section 133.1.

114.5.4 What oscillation cannot say

Phenomenon 114.9 (Neutrino masses are non-zero and very small)**.** Oscillation fixes two squared-mass splittings, $\Delta m^2_{21}c^4 \approx 7.5\times10^{-5}\,\mathrm{eV}^2$ and $|\Delta m^2_{31}|\,c^4 \approx 2.5\times10^{-3}\,\mathrm{eV}^2$ [2356, 2427]. The model-independent kinematic measurement of the tritium beta-decay endpoint bounds the effective electron-neutrino mass below about $0.8\,\mathrm{eV}/c^2$ [2399], while the cosmological bound on the sum of the three masses is about $0.12\,\mathrm{eV}/c^2$ — tighter, but dependent on the cosmological model [2348].

Rests on Equation (114.2) and Definition 103.61.

Derivation. *Derives Phenomenon 114.9.*

A splitting bounds the larger mass from below. From $m_3^2 - m_1^2 = \Delta m^2_{31}$ with $m_1^2 \geq 0$,

$$m_3c^2 \geq \sqrt{|\Delta m^2_{31}|\,c^4} = \sqrt{2.530\times10^{-3}\,\mathrm{eV}^2} = 0.0503\,\mathrm{eV}\,, \tag{114.42}$$

that is $m_3 \geq 8.97\times10^{-38}\,\mathrm{kg}$, some seven orders of magnitude below the electron mass of $9.109\times10^{-31}\,\mathrm{kg}$ and definitely not zero. The splitting substituted here is $\Delta m^2_{31}c^4 = 2.530\times10^{-3}\,\mathrm{eV}^2$, the value used in the reactor analysis of Section 114.4.6, and not the $|\Delta m^2_{32}|\,c^4 = 2.455\times10^{-3}\,\mathrm{eV}^2$ of Table 114.9; the two differ by Δm^2_{21} and the bound is stated for the pair 31. Summing over the three states in the normal ordering, with $m_1 \to 0$ and $m_2c^2 = \sqrt{\Delta m^2_{21}c^4} = 0.0087\,\mathrm{eV}$, gives the minimum total $\sum m_ic^2 \geq 0.059\,\mathrm{eV}$, which is within a factor of two of the cosmological bound and is the reason that bound is interesting.

Oscillation says nothing further. Equation (114.2) depends only on differences of squared masses, so the lightest mass is entirely unconstrained by it, and Equation (114.42) is a lower bound on one mass, not on the scale. The three quantities bounded by experiment — the

effective mass in beta decay, the effective Majorana mass in double beta decay, and the cosmological sum — are three different combinations of the same three masses, defined in Definition 103.61 as Equations (103.64) to (103.66), and cannot be merged into one number. Table 114.12 reports them separately for that reason. □

Remark 114.10 (The seesaw is a hypothesis and is named as one). The smallness of the masses bounded above — a factor of 10^7 below the electron — has an economical explanation in the seesaw mechanism, in which a heavy right-chiral singlet of mass M gives a light eigenvalue $m_\nu \approx m_D^2/M$. This treatise names it and stops there. There is no experimental evidence for the heavy state, none for the scale, and none distinguishing the seesaw from any other way of generating the same dimension-five operator; the discussion, with the honest verdict, is Remark 103.71. The same applies to leptogenesis, which Remark 103.72 records as untested and, at the relevant scale, untestable. Editorial rule 1 permits naming these programmes only to say that they lack evidence, and that is what is said.

114.6 Modern repetitions and precision

114.6.1 Borexino and the solar fusion chains

Borexino did what no earlier solar detector could: it measured the individual branches of the pp chain in real time, one at a time, at energies below a megaelectronvolt.

The measurement is a spectral decomposition. Elastic scattering Equation (114.12) has no threshold, so a monoenergetic neutrino line produces a recoil-electron spectrum with a sharp Compton-like edge at $T_{\max} = 2E^2/(m_e c^2 + 2E)$ — 665 keV for the 862 keV ^{7}Be line, 261 keV for the 420 keV *pp* endpoint. The observed spectrum is fitted as a sum of those shapes plus the known beta and alpha spectra of the residual contaminants, and the branch fluxes come out of the fit.

Table 114.11: Borexino interaction rates, in counts per day per 100 t of scintillator, and the neutrino fluxes inferred from them given the survival probabilities of Table 114.10. Fluxes are in SI; the sources quote them per square centimetre per second. The CNO measurement [2349] is the first detection of the cycle that powers stars heavier than the Sun, and it is a five-standard-deviation result on a rate of seven counts a day.

Branch	Rate (per day per 100 t)	Flux ($1/(\mathrm{m}^2\,\mathrm{s})$)	Source
pp	144 ± 16	$(6.6 \pm 0.7) \times 10^{14}$	[2229]
^{7}Be	48.3 ± 1.3	$(4.99 \pm 0.13) \times 10^{13}$	[2297]
pep	2.43 ± 0.42	$(1.27 \pm 0.19) \times 10^{12}$	[2297]
^{8}B	0.223 ± 0.017	$(5.68 \pm 0.39) \times 10^{10}$	[2297]
CNO	7.2 ± 3.0	$(7.0 \pm 3.0) \times 10^{12}$	[2349]

Three results follow from Table 114.11.

The *pp* flux of $(6.6 \pm 0.7) \times 10^{14}/(\mathrm{m}^2\,\mathrm{s})$ [2229] agrees with the luminosity constraint Equation (114.6) and with the model entry of Table 114.2. This is a direct check that the Sun is powered by the reaction Equation (114.5) at the rate its luminosity requires — and, because neutrinos leave the core immediately while photons take of order 10^5 years to diffuse out, that the solar output has been steady over that interval. This is the content of Phenomenon 52.23.

The energy dependence of the survival probability across two decades, Table 114.10, is the direct confirmation of the matter effect discussed in Section 114.5.2.

The CNO detection [2349] establishes that the cycle operates in the Sun at all, supplying about one per cent of its power. Its flux depends on the abundance of carbon, nitrogen and

oxygen in the solar core, so it is in principle an independent handle on the solar metallicity, on which the spectroscopic determination and the helioseismic one — the latter belonging to Section 52.6 — have disagreed for two decades. At the present uncertainty of about 40 % the measurement does not yet discriminate between them, and saying so is part of reporting it.

114.6.2 Supernova and astrophysical neutrinos

SN 1987A. On 23 February 1987 the collapse of a blue supergiant in the Large Magellanic Cloud, at about 5×10^4 pc, produced the only neutrino burst ever detected from a stellar collapse. Kamiokande-II recorded eleven events within 13 s with energies between about 7 MeV and 36 MeV [1793], and the Irvine–Michigan–Brookhaven detector recorded eight in 6 s [1789]. Nineteen events, and they remain the entire observational database of core-collapse neutrino emission.

The bound they give on the neutrino mass is kinematic and follows from the arrival-time spread. A neutrino of mass m and energy E travels at a group velocity $v/c = \left[1 - m^2c^4/E^2\right]^{1/2} \approx 1 - m^2c^4/2E^2$, so two neutrinos emitted together at energies E_1 and E_2 arrive separated by

$$\Delta t = \frac{D}{2c}\, m^2 c^4 \left(\frac{1}{E_1^2} - \frac{1}{E_2^2} \right) , \tag{114.43}$$

with D the distance. Requiring the observed spread to be no larger than the plausible emission duration bounds mc^2 below 17 eV, the value obtained in Equation (115.67) — weak by comparison with the laboratory limit of Table 114.12, but obtained over a baseline 10^{15} times longer than any terrestrial one, and hence a bound of a completely different kind. The burst itself is Phenomenon 115.48.

Neutrinos in ice. A cubic kilometre of Antarctic ice instrumented with photomultipliers detects the same atmospheric neutrinos as Super-Kamiokande, at energies from tens of gigaelectronvolts upwards, and its densely instrumented core has been used to measure the atmospheric oscillation parameters in that range [2292] — an independent measurement in a medium, a geometry and an energy range unrelated to the water Cherenkov detectors of Section 114.2.4. The same instrument established a diffuse astrophysical neutrino flux of much higher energy [2203] and associated one event with a flaring blazar [2293]. Those results belong to Section 115.7.4 and are named here only because the astrophysical flux arrives with a flavour composition that is itself an oscillation measurement over cosmological baselines: whatever the production ratio, the phases average completely and the observed composition should be near one to one to one.

114.6.3 Absolute mass: kinematics, cosmology, double beta decay

Three experiments bound three different combinations of the three masses, defined in Definition 103.61. They must be reported separately, and Table 114.12 does so.

The kinematic measurement. KATRIN measures the shape of the tritium beta spectrum within a few electronvolts of its 18.6 keV endpoint. A non-zero neutrino mass removes the last $m_\nu c^2$ of the spectrum and distorts what remains, by Proposition 101.20; the observable is m_β^2, an incoherent sum $\sum_i |U_{ei}|^2\, m_i^2$, and the measurement is of that squared quantity, so the fitted value may come out negative without anything being wrong. The current result is $m_\beta^2 c^4 = 0.26 \pm 0.34\,\mathrm{eV}^2$, which is consistent with zero and yields the limit of Table 114.12 [2399]. This is Phenomenon 101.21 and Phenomenon 103.62.

The cosmological bound. Massive neutrinos are relativistic when they decouple and non-relativistic today; they free-stream out of small-scale density perturbations and suppress the growth of structure below a characteristic scale. Fitting the microwave background together with the distribution of galaxies bounds $\sum_i m_i c^2 < 0.12\,\mathrm{eV}$ [2348]. It is the tightest

Table 114.12: The three bounds on the absolute neutrino mass scale, each on a different combination of the same three masses, and each with a different model dependence. The KATRIN limit is the only one that depends on nothing but kinematics. The cosmological limit is tighter by nearly an order of magnitude and rests on the whole cosmological model. The double beta decay limit exists only if the neutrino is its own antiparticle, and its conversion from a half-life to a mass carries a nuclear matrix element uncertain by a factor of two to three, which is why the mass bound is quoted as a range.

Observable	Bound	Source
m_β (tritium endpoint)	$< 0.8\,\mathrm{eV}/c^2$, 90 % CL	[2399]
$\sum_i m_i$ (cosmology)	$< 0.12\,\mathrm{eV}/c^2$, 95 % CL	[2348]
$\lvert\langle m_{\beta\beta}\rangle\rvert$ (double beta)	$< 36 - -156\,\mathrm{meV}/c^2$	[2414]

bound available and the most model-dependent one: it assumes the standard cosmological model, three species with standard thermal history, and a particular treatment of the nonlinear scales. Compare it with the minimum from Equation (114.42), $\sum_i m_i c^2 \geq 0.059\,\mathrm{eV}$ in the normal ordering, and the window is a factor of two. This is Phenomenon 103.68.

Neutrinoless double beta decay. If the neutrino is its own antiparticle then a nucleus may undergo 2β decay emitting two electrons and no neutrinos, violating lepton number by two units. It has not been observed. KamLAND-Zen, using enriched ^{136}Xe dissolved in the KamLAND scintillator, bounds the half-life above $2.3 \times 10^{26}\,\mathrm{yr}$ and the effective Majorana mass in the range of Table 114.12 [2414]. The range, rather than a number, is the nuclear matrix element: converting a half-life limit into a mass limit requires a many-body calculation whose results differ by a factor of two to three between methods (Remark 103.65, and the nuclear structure of Chapter 107). This is Phenomenon 103.64.

The three are logically independent, and a treatise of evidence must not collapse them. A positive double beta signal would establish lepton number violation and hence a Majorana mass term whatever the mechanism; a positive KATRIN signal would fix the scale model-independently; a cosmological detection would fix the sum within one cosmology. None has happened.

114.6.4 Anomalies and sterile searches

A treatise of evidence must state which of its anomalies have not gone away. Four are outstanding, and none of them is established.

LSND. A stopped-pion source at Los Alamos produced $\bar{\nu}_\mu$ of a few tens of megaelectronvolts, and a liquid-scintillator detector 30 m away found an excess of $\bar{\nu}_e$-like events: 87.9 ± 23.2 events above background, an apparent transition probability of $(2.64 \pm 0.81) \times 10^{-3}$, at about 3.8 standard deviations [2007]. At that L/E the required splitting would be $\Delta m^2 c^4$ of order $1\,\mathrm{eV}^2$ — two orders of magnitude above $\lvert\Delta m^2_{32}\rvert\, c^4$, and therefore a fourth mass state. By Equation (114.1) a fourth state cannot couple to the Z, so it would have to be sterile.

MiniBooNE. A different beam, a different baseline and a different detector technology found an excess of low-energy electron-like events consistent in size with LSND [2298]. Whether the excess is electrons or photons — which a Cherenkov detector cannot always distinguish, since a converted photon makes an electromagnetic shower too — was the central question, and what follows is the measurement that tests it.

MicroBooNE. A liquid-argon time projection chamber of 85 t in the same beam images the interaction vertex with millimetre resolution and separates a single electron from a converted photon by the ionization density at the start of the track. It finds no excess in the electron-neutrino channel across several final-state topologies [2397]. That does not by

itself close the question — it constrains the electron interpretation, not every interpretation of the MiniBooNE excess — but it removes the simplest one.

The gallium anomaly. The ^{51}Cr and ^{37}Ar source calibrations of Section 114.3.6, which exist to verify the detectors, returned rates below expectation: the ratio of measured to predicted is about 0.87 ± 0.05 when the four exposures are combined [1974, 2138]. A deficit at a baseline of a few metres would require a splitting $\Delta m^2 c^4$ of order $1\,\mathrm{eV}^2$, which is the LSND scale; alternatively the predicted cross-section for Equation (114.9) into the excited states of ^{71}Ge is wrong. The discrepancy is small enough not to affect any conclusion of Section 114.4.1 — it would move the gallium ratio from 0.55 to about 0.63, still far below one — and it has not been resolved.

Reactor rate anomaly. Measured reactor antineutrino rates at short baselines sit a few per cent below the predicted flux. Part of this was resolved by recalculating the fission spectra, and part remains; a spectral bump near 5 MeV in the measured prompt spectrum, seen by all the modern experiments and absent from every prediction, is a defect of the flux model and not of the neutrinos, since it appears identically at near and far detectors and therefore cancels in Equation (114.25). No source for the rate anomaly or for the spectral bump is cited in this treatise; both are stated here without one, and the near–far cancellation is the reason neither affects any oscillation result quoted above.

No sterile neutrino is established. The anomalies do not form a consistent picture with one another: the parameter regions preferred by LSND, by the reactor rates and by the gallium sources overlap only partially, and the disappearance searches that a sterile state would also require have found nothing. This chapter records them as open.

114.7 Open questions

114.7.1 The mass ordering

The sign of Δm^2_{32} is not measured. Normal ordering means $m_1 < m_2 < m_3$, the close pair at the bottom; inverted means $m_3 < m_1 < m_2$, the close pair at the top. Global fits prefer the normal ordering at a level between two and three standard deviations that depends on which datasets are combined [2356, 2427], which is a preference and not a measurement.

Two routes will settle it, and they are independent.

The matter effect in a long-baseline beam. By the sign argument of Section 114.5.2, the Earth's matter enhances $\nu_\mu \to \nu_e$ and suppresses $\bar{\nu}_\mu \to \bar{\nu}_e$ if the ordering is normal, and does the reverse if it is inverted. The effect grows with baseline and with energy, which is why NOvA's 810 km is more sensitive to it than T2K's 295 km, and why a longer baseline still would settle the question outright. The difficulty is that the same comparison is also the measurement of δ_{CP}, and the two enter with a partial degeneracy.

The vacuum interference pattern at a medium baseline. A reactor experiment at some 50 km, where the solar and atmospheric phases are comparable, sees the fast atmospheric oscillation modulating the slow solar one; the *phase* of the fast modulation relative to the slow envelope differs between the two orderings. This requires no matter effect and no beam, only an energy resolution of about three per cent — which is the hard part, since it is a factor of two better than any large scintillator has achieved.

The answer matters beyond bookkeeping. In the inverted ordering the effective Majorana mass of Table 114.12 has a lower bound of about $15\,\mathrm{meV}/c^2$, within reach of the next generation of double beta decay experiments, so a null result there would exclude the inverted ordering for a Majorana neutrino; in the normal ordering the effective mass can vanish by cancellation and no null result excludes anything. The cosmological sum likewise has different minima in the two orderings (Equation (103.75)).

114.7.2 The CP phase

The phase δ_{CP} is the one parameter of Table 114.9 that is constrained rather than measured. It is observable only through a difference between $\nu_\mu \to \nu_e$ and $\bar{\nu}_\mu \to \bar{\nu}_e$, because by Theorem 103.54 the CP-odd term is proportional to the leptonic Jarlskog invariant

$$J_\ell = \tfrac{1}{8} \sin 2\theta_{12} \sin 2\theta_{23} \sin 2\theta_{13} \cos\theta_{13} \sin\delta_{CP} \,, \tag{114.44}$$

which vanishes if any angle vanishes. That is why Phenomenon 114.8 reorganized the field: before 2012 it was possible that $\theta_{13} = 0$ and that leptonic CP violation was therefore unobservable in principle.

T2K's data disfavour CP conservation at about the 95 % level and prefer a value near $-\pi/2$ [2345]; NOvA's are compatible with CP conservation [2398]. Combining them gives a preference, not a measurement, and this treatise records it as such. Three degeneracies stand in the way and all three must be broken together: with the mass ordering, through the matter effect just described; with the octant of θ_{23}, since $|U_{\mu 3}|^2 = \sin^2\theta_{23}$ enters the appearance channel unsquared while disappearance sees only $\sin^2 2\theta_{23}$, which is symmetric about $\pi/4$; and with the overall normalization of the beam, which is what the near detector is for.

Leptogenesis is often named as the motivation. It is worth stating plainly, as Remark 103.72 does, that a measured δ_{CP} would not establish it: the phases entering the decays of the hypothetical heavy states are not the phases of Definition 103.46, and the connection is a model assumption and not a theorem.

114.7.3 Dirac or Majorana

Whether the neutrino is its own antiparticle is not answerable by any experiment in this chapter. Oscillation cannot answer it, by Proposition 103.47: the extra phases of a Majorana mass matrix cancel from every oscillation probability. The kinematic and cosmological observables cannot, being phase-independent. The only practical discriminator is a lepton-number-violating process, and the searches [2414] have found nothing — with the interpretation of any half-life limit further limited by the nuclear matrix elements of Remark 103.65 and Chapter 107.

The neutrino sector is therefore the one place where the Standard Model is known to be incomplete from laboratory data alone. Every other experimental anomaly in this book is either a measurement that agrees with the theory to remarkable precision, or an astrophysical observation whose interpretation requires assumptions the laboratory cannot check. Here the laboratory itself says the theory is wrong, and says almost nothing about what replaces it: not the mass scale, not the ordering, not the mechanism, not whether lepton number is conserved. Of that list Section 133.1 records the absolute mass scale and the Dirac–Majorana question; the ordering and the mechanism are recorded here and nowhere else in this book.

114.8 Primary references

The literature of this chapter divides into five groups, and the division matters because the groups differ in what they can be relied on for.

The theoretical origin. Pontecorvo's paper [1127] — the Russian original, whose English translation [1159] carries a later year and is the same work, so the bibliography lists it twice for one paper — proposes oscillation by analogy with the neutral kaon and is about neutrino–antineutrino transitions, not flavour transitions; the flavour-mixing formulation that this chapter actually tests is that of Maki, Nakagawa and Sakata [1237]. It is a common misattribution to credit the second idea to the first papers, and the distinction

is worth preserving. The matter effect is Wolfenstein's [1631], with the resonance and its consequences for solar neutrinos due to Mikheyev and Smirnov [1779]; note that the latter, though universally dated 1985, appeared in a 1986 issue, and the bibliography entry records the journal's own date. Giunti and Kim [2106] is the standard monograph and the place to go for the wave-packet treatment that Remark 103.51 summarizes.

The instrument papers. Davis, Harmer and Hoffman [1368] describes the chlorine detector and reports the first upper limit; the twenty-five-year result is Cleveland and collaborators [1950], which remains the authority for the Homestake apparatus, its extraction efficiencies and its backgrounds. For the gallium detectors, [1974] covers GALLEX and [2138] the third and final SAGE dataset, each with its own source calibrations. Hirata and collaborators [1822] is the Kamiokande-II solar measurement and [1793] the supernova burst from the same detector. The Super-Kamiokande atmospheric result [1954] is the paper that made the case, and it should be read for its treatment of the up-down asymmetry rather than for its best-fit parameters, which are superseded; the later L/E analysis of the same atmospheric sample is [2057]. Sudbury published the charged-current rate first [2008] and the neutral-current comparison a year later [2021]; only the second contains the flavour-blind measurement, and citing the first for it is an error that appears in the secondary literature. The salt phase, with its enhanced neutral-current sensitivity, is [2056], and the combined analysis of all three phases is [2208].

The reactor papers. KamLAND's first result [2049] established the deficit on fifty-four events; the demonstration that the survival probability oscillates as a function of L/E rather than falling monotonically came with later exposures, and is the spectral distortion of [2071], which is the source for the oscillatory dependence stated in Phenomenon 114.6. The final reactor analysis, taken across the shutdown of the Japanese reactors, is [2218]. Daya Bay [2189] and RENO [2188] are the θ_{13} measurements; the first is the more detailed on the near-to-far cancellation.

The accelerator papers. K2K [2089] and MINOS [2100] are the disappearance confirmations; T2K [2168] is the first appearance indication and [2345] its δ_{CP} constraint; NOvA [2398] is the current precision measurement of $|\Delta m^2_{32}|$ and θ_{23}; OPERA [2247] is the direct ν_τ appearance. The detection of the tau neutrino itself, which these presuppose, is [2016], and the two-neutrino experiment on which the whole notion of lepton flavour rests is [1223]. The original detection of the neutrino is [1085, 1097], and the counting of the light species is [2104].

The compilations and the model. The oscillation parameters of Table 114.9 are the Particle Data Group's [2427] and the global fit of Esteban and collaborators [2356]; the two use overlapping data and are not independent, and where they differ this chapter follows the former. The dataset shipped with this treatise for [2427] carries the particle masses used in the kinematic derivations; the constants are CODATA 2022 [2431]. The standard solar model is Bahcall, Serenelli and Basu [2072], whose BS05(OP) fluxes are Table 114.2; the much earlier prediction against which the original deficit was measured is [1365], and quoting the modern fluxes as though they were the ones Davis was compared with in 1968 misrepresents the history. Borexino's pp-chain and CNO results are [2229, 2297, 2349]. The absolute mass bounds are KATRIN [2399], Planck [2348] and KamLAND-Zen [2414]. The anomalies are LSND [2007] and MicroBooNE [2397], and the astrophysical neutrino flux is [2203, 2293].

Chapter 115

Cosmic Rays and Astroparticle Physics

Before there were accelerators there was the sky. Every charged particle species known in 1950 — the positron, the muon, the pion and the strange mesons — was first seen in the cosmic radiation, and the highest laboratory-confirmed particle energies still come from it and not from any machine: the atmosphere is struck by nuclei above $1 \times 10^{20}\,\mathrm{eV} = 16\,\mathrm{J}$, some seven orders of magnitude beyond the beam energy of the collider of Chapter 113. This chapter closes Part XI by treating that natural beam as what it is — a measured flux, with a spectrum, a composition, an arrival-time structure and an angular distribution, all quoted here with their uncertainties. It covers the discovery of the radiation and the geomagnetic experiments that showed the primaries are charged and predominantly positive; the particles found in it, which feed Chapters 41 and 95; the primary spectrum with its knee and ankle; extensive air showers and the detection techniques built on them; the astrophysical acceleration mechanisms that are consistent with the data; the Greisen–Zatsepin–Kuz'min cutoff and its observed counterpart; and the neutral messengers — gamma rays and neutrinos — that point back to their sources where charged nuclei cannot.

Its neighbours are the Standard Model chapters it uses as input (Chapters 102, 103 and 107) and the astrophysics it feeds (Chapters 48 and 52). The standing monograph is Gaisser, Engel and Resconi [2271]; current flux and composition numbers are taken from the Particle Data Group review [2427]. Nothing in this chapter is inferred from a mechanism that has not been observed: where the origin of a component is unknown — as it is above the ankle — the chapter says so.

Units and conventions are those fixed once for the whole part in Section 100.1.1: the metric $\eta_{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)$ of Notation 100.1, the mass shell $p^2 = m^2c^2$ of Equation (100.1), and $\hbar$ and c written out in every formula and every intermediate step. Nothing below is computed in units where they are set to one; Remark 100.4 gives the dictionary for reading this chapter against the literature, which does. Two conventions of the field need saying at the outset because they are not SI and are used on every page of it.

Notation 115.1 (Rigidity and atmospheric depth). The *rigidity* of a particle of momentum p and charge Ze is

$$R := \frac{pc}{Ze}\,, \tag{115.1}$$

an SI voltage, measured in volts. It is the natural variable for magnetic problems because a magnetic field bends two particles of the same rigidity along the same path whatever their mass or charge: the Larmor radius of Equation (115.8) depends on p and Ze only through R. Rigidities in this chapter are quoted in gigavolts and in volts.

The *atmospheric depth* X at a point is the mass of air per unit area lying above it along

the direction of travel,

$$X(h) := \int_h^\infty \rho\,(h')\,\mathrm{d}h'\,, \tag{115.2}$$

an SI areal mass density in $\mathrm{kg/m^2}$. The literature universally quotes it in $\mathrm{g/cm^2}$, and $1\,\mathrm{g/cm^2} = 10\,\mathrm{kg/m^2}$ exactly; both are given here. Its vertical value at sea level follows from hydrostatic equilibrium alone: the whole weight of the column is carried by the surface pressure, so

$$X_{\mathrm{atm}} = \frac{p_0}{g_0} = \frac{101\,325\,\mathrm{Pa}}{9.806\,65\,\mathrm{m/s^2}} = 1.0332 \times 10^4\,\mathrm{kg/m^2} = 1033\,\mathrm{g/cm^2}\,. \tag{115.3}$$

Every shower in Section 115.4 develops in that calorimeter and in no other.

115.1 Discovery of the cosmic radiation

115.1.1 The penetrating radiation

The instrument that found cosmic rays was the gold-leaf electroscope, and understanding what it measures is the whole of the argument. A charged conductor inside a sealed vessel of gas loses its charge because the gas is not a perfect insulator: ionising radiation creates free electron–ion pairs, the field between the conductor and the vessel wall sweeps them apart before they recombine, and the resulting current discharges the leaves. If the field is strong enough that essentially every pair created is collected — the *saturation* regime — the current no longer depends on the field, and counts ionisation events directly:

$$I = e\,q\,V\,, \tag{115.4}$$

with q the number of ion pairs produced per unit volume per unit time, V the volume of the vessel and e the elementary charge. The observable is q, an SI rate density in $1/(\mathrm{m^3\,s})$, though the period quoted it as ion pairs per cubic centimetre per second and this chapter gives both.

The numbers involved show why the measurement was difficult and why it was nevertheless decisive. A sealed litre vessel at sea level, with every known source of contamination removed, still shows $q \approx 1 \times 10^7/(\mathrm{m^3\,s})$, that is about ten ion pairs per cubic centimetre per second, and by Equation (115.4) this is a current

$$I = 1.602\,176\,634 \times 10^{-19}\,\mathrm{C} \times 1 \times 10^7/(\mathrm{m^3\,s}) \times 1 \times 10^{-3}\,\mathrm{m^3} \approx 1.6 \times 10^{-15}\,\mathrm{A}\,,$$

a femtoampere. No galvanometer of 1910 could see such a current; an electroscope, which integrates it on a capacitance of a few picofarads, turns it into a leaf deflection of a few volts per hour and sees it easily. That is the instrumental fact behind the whole discovery.

By 1900 the residual conductivity of sealed air was known to Wilson, to Elster and Geitel, and to Rutherford, and the standing explanation was gamma radiation from radioactive material in the ground and in the walls of the apparatus. The explanation is testable, because a gamma ray is attenuated exponentially in the mass it traverses. For photons of the few MeV that the hardest radium gamma rays carry, the mass attenuation coefficient of air is $\mu/\rho \approx 4 \times 10^{-3}\,\mathrm{m^2/kg}$, so at the ground-level density $\rho \approx 1.2\,\mathrm{kg/m^3}$ the linear coefficient is $\mu \approx 5 \times 10^{-3}/\mathrm{m}$ and the attenuation length is

$$\lambda_{\mathrm{air}} = \frac{1}{\mu} \approx 200\,\mathrm{m}\,.$$

Wulf therefore carried an electroscope of his own design to the top of the Eiffel Tower, 300 m above the ground, where a purely terrestrial source demanded a reduction by

$$\exp\!\left(-\frac{300\,\mathrm{m}}{200\,\mathrm{m}}\right) = \mathrm{e}^{-1.5} = 0.22\,,$$

that is to about a fifth of the ground value. What he measured was a reduction to roughly sixty percent [366] — nearly three times the ionisation the terrestrial hypothesis allows. A factor of three is a large discrepancy, but one tower, one instrument and an attenuation coefficient known only to a factor of two could not settle the question, and Wulf did not claim that it had.

Hess settled it by going higher. In seven balloon ascents in 1911 and 1912, the last reaching 5350 m, he carried three sealed electroscopes of different wall thickness and found that the ionisation first *fell* with altitude, through a shallow minimum near 1500 m, and then *rose*, reaching about twice its sea-level value near 5000 m [387]. He drew the only available conclusion: a radiation of very great penetrating power enters the atmosphere from above. He also excluded the obvious candidate for a source above, flying at night and during the solar eclipse of 17 April 1912 and finding no reduction — so the Sun is not the source of the penetrating component. Kolhörster extended the measurement to 9200 m and found the ionisation about ten times the ground value [405], which fixed the effect beyond argument.

Phenomenon 115.2 (Ionisation increases with altitude)**.** The rate at which a sealed electroscope loses its charge, after every known terrestrial contamination has been excluded, first falls with height above the ground and then rises. In the balloon ascents of 1911–1912 the ionisation passed through a minimum near 1500 m and by about 5000 m was roughly twice its sea-level value [387]; at 9200 m it was some ten times the ground value [405]. Flights by night and during a solar eclipse gave the same result, which excludes the Sun as the source [366, 387].

Rests on Equation (115.2).

Derivation. *Derives Phenomenon 115.2.*

Let the ionising agent be attenuated exponentially in the mass of absorber traversed, $I = I_0 \exp(-X/\lambda)$, with X the column density of Equation (115.2) and λ an attenuation length; this is the behaviour of any penetrating radiation with a fixed interaction cross section per unit mass. Two sources are in play and they see opposite overburdens.

For a source in the ground the absorber between source and instrument is the air *below* the instrument, whose column density *increases* with height; write it $\ell(h)$ with $\ell(0) = 0$ and $\mathrm{d}\ell/\mathrm{d}h = \rho(h) > 0$. For a source above the atmosphere the absorber is the depth $X(h)$ of Equation (115.2), which *decreases* with height, $\mathrm{d}X/\mathrm{d}h = -\rho(h) < 0$. The measured rate is the sum,

$$q(h) = q_g \exp\!\left(-\frac{\ell(h)}{\lambda_g}\right) + q_c \exp\!\left(-\frac{X(h)}{\lambda_c}\right) , \tag{115.5}$$

and differentiating,

$$\frac{\mathrm{d}q}{\mathrm{d}h} = \rho(h)\left[-\frac{q_g}{\lambda_g}\mathrm{e}^{-\ell/\lambda_g} + \frac{q_c}{\lambda_c}\mathrm{e}^{-X/\lambda_c}\right] .$$

The bracket is negative at $h = 0$ whenever the terrestrial term dominates there, and it grows monotonically with h because the first exponential decreases and the second increases. It therefore has exactly one zero, at the altitude where

$$\frac{q_g}{\lambda_g}\mathrm{e}^{-\ell(h)/\lambda_g} = \frac{q_c}{\lambda_c}\mathrm{e}^{-X(h)/\lambda_c} , \tag{115.6}$$

and that zero is a minimum. So the observed shape — fall, minimum, rise — is not merely consistent with an external source; it is what an external source superposed on a terrestrial one *must* produce, and a purely terrestrial source cannot produce it at all, since for $q_c = 0$ the bracket is negative everywhere and q falls monotonically. The two attenuation lengths are then read off the two limbs of the curve, and the upper limb gives a λ_c far larger than any then-known gamma radiation possessed, which is the sense in which the radiation is "penetrating". □

Remark 115.3 (What the altitude curve does not say). Phenomenon 115.2 establishes that something enters the atmosphere from outside. It says nothing about what that something *is*: an exponential absorption curve is produced by a photon beam, an electron beam and a proton beam alike, and the only parameter it yields is λ_c. This is why the question of the nature of the primaries stayed open for two decades after 1912 and was settled not by absorption but by geomagnetism (Sections 115.1.3 and 115.1.4). It is also worth recording that the rise does not continue indefinitely: above about 20 km the ionisation passes through a maximum, the Pfotzer maximum, and falls again, because what the electroscope records at any depth is not the primary but the shower it has made — the subject of Section 115.4.

115.1.2 Naming and the extraterrestrial origin

Millikan and Cameron settled the extraterrestrial origin by a different route and, in doing so, named the subject. Their idea was to use water as the absorber and mountain lakes as the vessel: an instrument lowered to depth d in a snow-fed lake at altitude h sits under a total column density

$$X_{\mathrm{tot}} = X_{\mathrm{atm}}(h) + \rho_{\mathrm{w}} d\,, \qquad \rho_{\mathrm{w}} = 1.0 \times 10^{3}\,\mathrm{kg/m^{3}}\,,$$

so that one metre of water is worth $1.0 \times 10^{3}\,\mathrm{kg/m^{2}} = 100\,\mathrm{g/cm^{2}}$, about a tenth of the whole atmosphere by Equation (115.3). Measuring in Muir Lake, at 3540 m, and in Arrowhead Lake, at 1530 m, they found that the two ionisation curves, plotted against X_{tot} rather than against depth in water, fell on one another [552]. That is exactly what Equation (115.5) predicts for the extraterrestrial term and it is what no terrestrial source can produce, because a terrestrial source has no reason to care about the air above the lake. They called the agent *cosmic rays*, and the name stuck.

Millikan drew a further conclusion that was wrong, and the way it was wrong is instructive. He read the attenuation curve as that of a gamma-ray beam and identified the photon energies with the binding energies released in the synthesis of helium and heavier elements from hydrogen — the "birth cries of atoms". The inference from an absorption curve to a photon energy requires a cross section, the cross section assumed was Compton scattering (Chapter 65), and the whole chain collapses if the primaries are not photons. Compton argued from the outset that they were charged particles. The dispute could not be settled by absorption measurements of any precision, for the reason given in Remark 115.3: attenuation curves measure λ, and λ alone does not identify a species. What settled it was an argument in which the charge appears explicitly, and the Earth supplies the apparatus.

115.1.3 The latitude effect

Clay, making ionisation measurements on the voyages between Java and the Netherlands, found the intensity systematically lower near the equator than at high latitude, by some 10 % [569]. Compton organised a worldwide survey with a single standardised ionisation chamber design at sixty-nine stations on every continent, and showed that the variation is ordered not by geographic latitude but by *geomagnetic* latitude λ_m, with the intensity flat above about $|\lambda_m| = 40^{\circ}$ and falling towards the geomagnetic equator [716]. A magnetic ordering can only mean one thing.

Phenomenon 115.4 (The primary intensity depends on geomagnetic latitude)**.** The cosmic-ray intensity measured at sea level falls by of order 10 % between geomagnetic latitude 40° and the geomagnetic equator, and the ordering parameter is the geomagnetic and not the geographic latitude [569, 716]. The primaries are therefore electrically charged, and the fall sets the scale of their momenta.

Rests on Equation (115.1).

Derivation. *Derives Phenomenon 115.4.*

A photon is undeflected by a magnetic field, so a photon primary produces no latitude effect of any size; the observation of one excludes photons as the dominant component. For a charged primary, the Earth's field acts as a momentum filter, and the scale of the filter follows from a single comparison of lengths.

Model the geomagnetic field as a dipole of moment m, so that in the equatorial plane at distance r from the centre

$$B(r) = \frac{\mu_0 m}{4\pi r^3} =: \frac{M}{r^3}\,, \qquad M = \frac{\mu_0 m}{4\pi} \approx 8.1 \times 10^{15}\,\mathrm{T\,m^3}\,, \tag{115.7}$$

the value of M being fixed by the measured surface field at the magnetic equator, $B\,(R_\oplus) \approx 3.1 \times 10^{-5}\,\mathrm{T}$ with $R_\oplus = 6.371 \times 10^6\,\mathrm{m}$. A particle of momentum p and charge Ze moving perpendicular to a field B turns on a circle of radius

$$r_L = \frac{p}{ZeB} = \frac{R}{cB}\,, \tag{115.8}$$

with R the rigidity of Equation (115.1); the second form shows that r_L depends on the particle only through R, which is the whole reason rigidity is used. A particle can reach the Earth from outside only if its trajectory is not turned round before it arrives, which requires the turning radius in the field it crosses to be at least of order the distance over which that field acts. Setting $r_L = r$ with $B = M/r^3$ gives the rigidity scale

$$R_{\mathrm{sc}}(r) = \frac{cM}{r^2}\,, \qquad R_{\mathrm{sc}}\,(R_\oplus) = \frac{2.998 \times 10^8\,\mathrm{m/s} \times 8.1 \times 10^{15}\,\mathrm{T\,m^3}}{(6.371 \times 10^6\,\mathrm{m})^2} = 6.0 \times 10^{10}\,\mathrm{V}\,, \tag{115.9}$$

that is 60 GV. The exact treatment is Störmer's: the motion of a charge in a dipole field has a first integral, and it partitions directions at each point into an allowed cone, from which particles of a given rigidity can arrive, and a forbidden one. The resulting *cutoff rigidity* for vertical incidence at geomagnetic latitude λ_m is [723]

$$R_c\,(\lambda_m) = \frac{cM}{4r^2}\cos^4\lambda_m = 14.9\,\mathrm{GV} \times \cos^4\lambda_m\,, \tag{115.10}$$

which is Equation (115.9) with the numerical coefficient $\frac{1}{4}$ that the exact integration supplies. No particle of rigidity below R_c arrives vertically at that latitude.

Derivation pending #203

The Störmer theory itself: the first integral of the motion of a charge in a magnetic dipole field, the partition of directions at each point into an allowed and a forbidden cone that follows from it, and the integration supplying the coefficient one quarter in the vertical cutoff together with the full azimuthal form used in the east–west subsection below. Belongs in Appendix A; both formulae are quoted here from the source cited beside them, and only their consequences are derived

The latitude effect follows at once. At $\lambda_m = 50°$ the cutoff is $14.9\,\mathrm{GV} \times \cos^4 50° = 2.5\,\mathrm{GV}$, while at the geomagnetic equator it is the full 14.9 GV: a detector at high latitude sees the primary spectrum down to a rigidity six times lower than one at the equator, and therefore sees more particles. The *size* of the effect is then a measurement of the spectrum. If the integral intensity above rigidity R behaves as $R^{-\Gamma}$, the ratio of equatorial to polar rates is $(14.9/2.5)^{-\Gamma}$, so a 10 % deficit requires $\Gamma \approx 0.06$ for the ionisation-chamber response — that is, the ionisation is dominated by secondaries from primaries well above both cutoffs, which is why the effect is a ten-percent effect and not a factor of six. The qualitative conclusion is independent of all of this: only a charged primary can produce a latitude effect at all. □

115.1.4 The east–west asymmetry

The latitude effect shows the primaries are charged; it does not show the sign of the charge, because Equation (115.10) depends on Z only through the rigidity and is the same for positive and negative particles arriving vertically. Rossi saw that the sign appears as soon as one looks away from the vertical: for a given latitude the Störmer cutoff depends on the azimuth of arrival, and it does so with opposite senses for the two signs [668]. The full form of the cutoff, for arrival at zenith angle θ and azimuth ξ measured clockwise from magnetic north — so that arrival from the east is $\xi = 90°$ and arrival from the west is $\xi = 270°$ — is [723]

$$R_c\left(\lambda_m, \theta, \xi\right) = \frac{cM\cos^4\lambda_m}{r^2\left[1 + \left(1 - \operatorname{sgn}(Z)\sin\xi\sin\theta\cos^3\lambda_m\right)^{1/2}\right]^2}\,. \tag{115.11}$$

At the geomagnetic equator and on the horizon, $\cos\lambda_m = 1$ and $\sin\theta = 1$, so the bracket carries $\sin\xi = -1$ for arrival from the west and $\sin\xi = +1$ for arrival from the east; at the zenith $\sin\theta = 0$ and the bracket is $[1+1]^2 = 4$, which returns Equation (115.10). With $cM/r^2 = 59.8\,\mathrm{GV}$ from Equation (115.9), this gives for a positively charged primary $R_c = 10.2\,\mathrm{GV}$ from the west and $59.6\,\mathrm{GV}$ from the east, against $14.9\,\mathrm{GV}$ from the zenith; for a negative primary the two horizontal values are exchanged. Since the spectrum falls with rigidity, the lower cutoff is the more intense direction, and the sign of the excess is the sign of the charge.

Phenomenon 115.5 (The primaries arrive preferentially from the west)**.** Near the geomagnetic equator the cosmic-ray intensity measured with a counter telescope at a fixed zenith angle is greater when the telescope points west than when it points east [712, 722], as had been predicted for a flux of charged particles [668]. The primaries are therefore charged, and predominantly positively charged.

Rests on Equation (115.11).

Derivation. *Derives Phenomenon 115.5.*

The sign can be got without Equation (115.11), from the Lorentz force alone. Set up axes at the geomagnetic equator: $\hat{\boldsymbol{z}}$ upward, $\hat{\boldsymbol{x}}$ east, $\hat{\boldsymbol{y}}$ north. There the geomagnetic field is horizontal and points north, $\boldsymbol{B} = B\hat{\boldsymbol{y}}$ with B of order $3\times10^{-5}\,\mathrm{T}$. A primary of charge q arriving vertically has velocity $\boldsymbol{v} = -v\hat{\boldsymbol{z}}$, and feels

$$\boldsymbol{F} = q\,\boldsymbol{v}\times\boldsymbol{B} = -qvB\,(\hat{\boldsymbol{z}}\times\hat{\boldsymbol{y}}) = +qvB\,\hat{\boldsymbol{x}}\,,$$

since $\hat{\boldsymbol{z}}\times\hat{\boldsymbol{y}} = -\hat{\boldsymbol{x}}$. For $q > 0$ the force is eastward: as the particle descends, its velocity is deflected towards the east, so that it reaches the ground travelling east of vertical — that is, arriving *from* the west. Positive primaries therefore produce a western excess and negative primaries an eastern one, and the sign of the observed excess fixes the sign of the charge. A neutral primary, which was still the alternative hypothesis in 1933, produces no azimuthal asymmetry whatever. The measurement thus decides between the two hypotheses without any assumption about the energy spectrum or the composition, which is exactly what the absorption curves of Section 115.1.2 could not do.

The size of the asymmetry follows from the cutoffs. Writing the integral intensity above rigidity R as $J(>R) \propto R^{-\Gamma}$, the west-to-east ratio at the horizon is

$$\frac{J\left(>R_c^W\right)}{J\left(>R_c^E\right)} = \left(\frac{10.2\,\mathrm{GV}}{59.6\,\mathrm{GV}}\right)^{-\Gamma} = (5.84)^{\Gamma}\,,$$

so that even a modest Γ gives a large effect: the observed excess at Mexico City was of order 10 % at moderate zenith angle [722], growing towards the horizon, and it was found independently and with the same sign by Alvarez and Compton [712]. The primaries are positive. They were later identified as protons and heavier nuclei, the composition measurement being the subject of Section 115.3.4. □

115.1.5 Solar modulation and geomagnetic transients

The geomagnetic field is not the only magnetic filter between a Galactic source and a detector on Earth. The solar wind carries the solar magnetic field outward through the heliosphere, drawn into an Archimedean spiral by the Sun's rotation, and cosmic rays entering against that outflow must diffuse upstream. The consequence is observed directly: the intensity of low-energy cosmic rays is *anticorrelated* with the eleven-year sunspot cycle, being highest at solar minimum, and it drops sharply — by a few percent within hours — after a solar disturbance, recovering over the following days. Forbush established the transient decreases from continuously running ionisation chambers [791], and they carry his name; the eleven-year anticorrelation he drew out of the same network over the two decades that followed [1037].

The quantitative description is a transport equation for the phase-space density $f(\boldsymbol{r}, p, t)$ of cosmic rays, combining outward convection with the wind at speed u, spatial diffusion, and the adiabatic energy loss a particle suffers in an expanding flow. Its spherically symmetric steady state, when diffusion and convection balance, has a first integral of great practical use: the intensity observed at 1 au is that of the unmodulated interstellar spectrum evaluated at a higher energy, the particle having paid a toll

$$\Delta E = Ze\Phi \tag{115.12}$$

on the way in, with Φ a *modulation potential* in volts that absorbs all the transport physics into one number. Measured values of Φ range from about 400 MV at solar minimum to above 1 GV at solar maximum.

Derivation of the force-field intensity. Liouville's theorem, applied along the characteristics of the transport equation, states that the phase-space density is unchanged, so $f_{\oplus}(p) = f_{\mathrm{LIS}}(p_{\mathrm{LIS}})$ where the subscript denotes the local interstellar value and the two momenta are connected by Equation (115.12). The differential intensity per unit kinetic energy T is related to f by the phase-space volume element: the number of particles per unit volume with momentum in d^3p is $f\,\mathrm{d}^3p = 4\pi p^2 f\,\mathrm{d}p$, and $J(T) := p^2 f$ up to constants, since $\mathrm{d}T = v\,\mathrm{d}p$. Hence

$$J_{\oplus}(T) = J_{\mathrm{LIS}}\left(T + Ze\Phi\right) \frac{T\left(T + 2mc^2\right)}{\left(T + Ze\Phi\right)\left(T + Ze\Phi + 2mc^2\right)}\,, \tag{115.13}$$

the ratio being p^2/p_{LIS}^2 written out with the relativistic relation $p^2c^2 = T\left(T + 2mc^2\right)$ of Section 40.2. For a proton of $T = 100\,\mathrm{MeV}$ and $\Phi = 500\,\mathrm{MV}$ the factor is severe — the observed intensity is a small fraction of the interstellar one — while for $T \gg Ze\Phi$ it tends to unity. This is why the spectrum below a few GeV per nucleon measured at Earth is *not* a source spectrum and must not be read as one, and why the acceleration arguments of Section 115.5 are tested above rather than below that energy. □

Remark 115.6 (Where the heliospheric physics belongs). The magnetohydrodynamics that produces the spiral field and the turbulent scattering that produces the diffusion coefficient belong to Chapter 66, whose headings are reserved and which does not yet carry either; nothing in the present chapter derives them either, and no statement below rests on them. What is used here is only the empirical fact that the modulation exists, that it is measured by neutron monitors as a function of time, and that it is negligible above about 10 GeV — which is where every spectral statement below begins.

115.2 Cosmic rays as the first particle accelerator

115.2.1 Track detectors

Everything in this section is a statement about a photograph. The instruments that made the photographs are two, and each measures a different pair of quantities.

Wilson's expansion cloud chamber [394] makes a track visible by supersaturating a vapour and letting it condense on the ions left along a charged particle's path. Placed between the poles of a magnet, it measures momentum and sign at once: the projected track is an arc of a circle, and by Equation (115.8) its radius of curvature ρ gives

$$p_\perp = ZeB\rho\,, \tag{115.14}$$

in SI a momentum in kg m/s when B is in tesla and ρ in metres. The product $B\rho$, an SI quantity of dimension T m, is the historical observable and is quoted in the papers of the period in gauss-centimetres. One gauss-centimetre is $1\times10^{-4}\,\mathrm{T}\times1\times10^{-2}\,\mathrm{m}=1\times10^{-6}\,\mathrm{T\,m}$, so 10^5 of them make 0.1 T m; Anderson's 2.1×10^5 gauss-centimetres below is 0.21 T m. The sense of the curvature gives the sign of Ze once the direction of travel is known, and fixing that direction is the hard part of every one of the discoveries below.

The second instrument is the nuclear emulsion: a thick photographic layer, exposed for weeks at mountain altitude and developed, in which the track is a chain of silver grains. It measures ionisation and range rather than momentum. The grain density along the track follows the specific ionisation, which for a fast particle behaves as

$$-\frac{\mathrm{d}E}{\mathrm{d}x}\propto\frac{Z^2}{\beta^2}\,,\qquad \beta=\frac{v}{c}\,, \tag{115.15}$$

so a heavily ionising track is either slow or multiply charged, and the two cases are separated by following the track to its end: the *range* of a particle that stops in the emulsion is a single-valued function of its initial energy for each species, and the combination of range and grain density therefore determines mass and charge. The derivation of Equation (115.15) from the electromagnetic interaction of a charge with atomic electrons belongs to Chapter 65; it is used here as an experimental calibration curve, which is how the emulsion groups used it.

Remark 115.7 (What these instruments can and cannot claim). A single cloud-chamber photograph is one event with one measurement uncertainty, and the uncertainty on a curvature is not small: the fractional momentum error from a sagitta measurement grows linearly with momentum, since a stiffer track is a straighter one. Every discovery in this section was therefore contested at the time and settled by accumulating events, not by the first photograph. Where a number below carries an uncertainty it is the one the discoverers quoted; where it does not, the modern value from [2427] is given alongside so that the reader can see how good the original measurement was.

115.2.2 The positron

Anderson operated a vertical cloud chamber in a field of $B=1.5\,\mathrm{T}$, divided across its middle by a lead plate 6 mm thick, and photographed a track of positive curvature crossing the plate [713]. The plate is what makes the photograph an argument rather than an ambiguity. A particle loses energy in crossing it, so it is more sharply curved after the crossing than before; the observed curvatures were $B\rho=0.21\,\mathrm{T\,m}$ on one side and $0.077\,\mathrm{T\,m}$ on the other, which fixes the direction of travel as being from the side of smaller curvature to the side of larger — upward, in this event. With the direction known, the sense of the curvature gives the sign, and the sign is positive.

Phenomenon 115.8 (A positive particle of electronic mass)**.** Cosmic-ray tracks exist that are positively charged and whose specific ionisation is that of a singly charged particle moving at nearly the speed of light, at a momentum at which a proton would be slow and would ionise hundreds of times more heavily [713]. Their mass is therefore of the order of the electron mass and not of the proton mass. The particle is the positron, the antiparticle of the electron.

Rests on Equations (115.14) *and* (115.15)*.*

Derivation. *Derives Phenomenon 115.8.*

Take the segment with $B\rho = 0.21\,\mathrm{T\,m}$. By Equation (115.14) with $Z = 1$,

$$p = eB\rho = 1.602\,176\,634 \times 10^{-19}\,\mathrm{C} \times 0.21\,\mathrm{T\,m} = 3.36 \times 10^{-20}\,\mathrm{kg\,m/s}\,,$$

so that

$$pc = 1.01 \times 10^{-11}\,\mathrm{J} = 63\,\mathrm{MeV}\,.$$

Now test the two candidate species against the observed grain density, which was that of a minimum-ionising particle, i.e. one with $\beta \approx 1$ in Equation (115.15).

If the particle is a proton, $mc^2 = 938.272\,\mathrm{MeV}$ [2427], then

$$E = \sqrt{(pc)^2 + (mc^2)^2} = 940.4\,\mathrm{MeV}\,, \qquad \beta = \frac{pc}{E} = \frac{63}{940.4} = 0.067\,,$$

and Equation (115.15) then demands an ionisation $1/\beta^2 = 223$ times the minimum. A track ionising two hundred times more heavily than the observed one is not a subtle discrepancy; it is a different photograph. If instead the particle has the electron mass, $mc^2 = 0.511\,\mathrm{MeV}$, then $\beta = 1 - 3.3 \times 10^{-5}$ and the track is minimum ionising, which is what was seen. Anderson's stated bound from the ionisation was a mass below twenty electron masses; the modern value is exactly one, since the positron and electron masses are equal by the CPT theorem of Chapter 105.

A second, independent, check comes from the range. The track was followed for several centimetres of chamber gas. A proton of $pc = 63\,\mathrm{MeV}$ has kinetic energy $T = E - mc^2 = 2.1\,\mathrm{MeV}$ and, by Equation (115.15), stops within a few centimetres of air; a 63 MeV positron crosses the whole chamber and the lead plate as well. □

The full apparatus, procedure and uncertainty budget of the discovery, together with the Blackett–Occhialini confirmation and the first pair-production photographs, belong to Chapter 95, whose headings for them are reserved and carry no content yet; the field-theoretic account of the antiparticle is that of Chapter 100. What matters here is that the first antiparticle ever seen was seen in the cosmic radiation, four years after Dirac's equation and with no accelerator involved.

115.2.3 The muon

By the mid-1930s the cosmic radiation at sea level was known to have two components, distinguished by how much absorber they survive: a *soft* component absorbed by some 10 cm of lead, and a *hard* or penetrating component that crosses a metre of it. Neddermeyer and Anderson showed that the penetrating particles cannot be electrons [797], and the argument is a comparison of two energy-loss laws.

Derivation: the penetrating particles are not electrons. An electron of energy E crossing matter loses energy chiefly by bremsstrahlung, at a rate proportional to E itself,

$$-\frac{\mathrm{d}E}{\mathrm{d}X} = \frac{E}{X_0}\,, \qquad E(X) = E_0 \mathrm{e}^{-X/X_0}\,, \tag{115.16}$$

where X is the traversed depth of Equation (115.2) and X_0 is the *radiation length* of the material, an SI areal mass density: $X_0 = 365\,\mathrm{kg/m^2} = 36.5\,\mathrm{g/cm^2}$ for air and $63.7\,\mathrm{kg/m^2} = 6.37\,\mathrm{g/cm^2}$ for lead. The exponential is the content of the Bethe–Heitler cross-section [732], whose derivation belongs to the bremsstrahlung section of Chapter 65, where the heading is reserved and the calculation is not yet written; what matters here is that the loss is proportional to E and is therefore catastrophic at high energy.

Derivation pending #204

The Bethe–Heitler bremsstrahlung cross section, the resulting exponential energy-loss law, and the radiation length of air and of lead used throughout this chapter. Belongs in Appendix A or in the bremsstrahlung section of the radiation and scattering chapter, which currently reserves the heading

A metre of lead has depth $X = 11.35 \times 10^3\,\mathrm{kg/m^3} \times 1\,\mathrm{m} = 1.135 \times 10^4\,\mathrm{kg/m^2}$, i.e. $X/X_0 = 178$ radiation lengths. An electron crossing it would emerge with e^{-178} of its energy: nothing survives, at any incident energy. The observed penetrating particles cross such absorbers losing energy at the far slower, nearly energy-independent rate characteristic of ionisation alone, $-\mathrm{d}E/\mathrm{d}X \approx 0.2\,\mathrm{MeV\,m^2/kg}$, i.e. about 2 MeV per $\mathrm{g/cm^2}$. Since the radiative rate carries a factor $1/m^2$ from the recoil of the radiating particle against the nucleus, a particle heavier than the electron radiates less, and *much* less: the penetrating component is a particle of mass well above m_e and below m_p, because a proton of the observed momenta would ionise far too heavily by Equation (115.15). □

Street and Stevenson closed the argument by measuring the mass directly, from the curvature and the range of a particle stopping in a cloud chamber, obtaining about 130 electron masses [801]. The modern value is $m_\mu c^2 = (105.658\,375\,5 \pm 0.000\,002\,3)\,\mathrm{MeV}$, that is $m_\mu = (1.883\,531\,627 \pm 0.000\,000\,042) \times 10^{-28}\,\mathrm{kg}$ and $206.77\,m_e$ [2427, 2431], so the first measurement was low by a factor 1.6 — an honest reflection of what a single stopping track can do.

What the muon is *not* took another decade. Yukawa's meson, the quantum of the nuclear force of Section 107.2.1, has a mass in the right range, and the identification was universally assumed. It is wrong, and Conversi, Pancini and Piccioni proved it wrong by stopping negative mesotrons in carbon and finding that they decay with their ordinary lifetime instead of being captured by the nucleus [899].

Derivation: the mesotron is not strongly interacting. A negative particle stopped in matter cascades into a Bohr orbit about a nucleus. The mesic Bohr radius scales as the inverse mass and the inverse nuclear charge,

$$a_\mu = \frac{a_0}{Z}\frac{m_e}{m_\mu} = \frac{5.29 \times 10^{-11}\,\mathrm{m}}{6} \times \frac{1}{206.8} = 4.3 \times 10^{-14}\,\mathrm{m}$$

for carbon, $Z = 6$. The nuclear radius is $R = r_0 A^{1/3} = 1.2 \times 10^{-15}\,\mathrm{m} \times 12^{1/3} = 2.7 \times 10^{-15}\,\mathrm{m}$, so the probability of finding the particle inside the nucleus is of order

$$P \sim \left(\frac{R}{a_\mu}\right)^3 = (0.064)^3 = 2.6 \times 10^{-4}\,.$$

If the particle interacts strongly, the rate at which it is absorbed once inside is of order the only rate the strong interaction has, $c/R = 1.1 \times 10^{23}/\mathrm{s}$. The capture rate is then

$$\Gamma_{\mathrm{cap}} \sim P\,\frac{c}{R} \approx 3 \times 10^{19}/\mathrm{s}\,,$$

a capture time of order $3 \times 10^{-20}\,\mathrm{s}$, against the observed decay rate $1/\tau_\mu = 4.6 \times 10^5/\mathrm{s}$. The two differ by fourteen orders of magnitude: a strongly interacting particle stopped in carbon would never be seen to decay. It was seen to decay. Hence the mesotron does not interact strongly and is not Yukawa's meson — the same conclusion reached, with the nuclear-physics apparatus, in Phenomenon 107.18. □

The muon's other role is as a clock. Rossi and Hall measured the momentum dependence of the surviving fraction between altitudes [863], Frisch and Smith compared the flux on Mount Washington with the flux at sea level [1253], and the CERN storage ring measured the dilated lifetime at $\gamma = 29.3$ to a few parts in a thousand [1592]. All three are treated as experiments in Chapter 41 (Sections 41.2 to 41.4); the cosmic-ray side of the argument is Section 115.8.3 below.

115.2.4 The pion

The particle Yukawa predicted was found in 1947, in emulsion stacks exposed at the Pic du Midi and at Chacaltaya in the Andes, by Lattes, Occhialini and Powell [902]. The signature is a track that ends and gives birth to a second track: a heavily ionising particle comes to rest, and from its end point a second particle sets off, itself coming to rest after a short and — this is the point — always the same range, about 600 µm of emulsion. A third, much lighter track then leaves the second end point. The chain is $\pi \to \mu \to e$.

Phenomenon 115.9 (A constant secondary range means a two-body decay)**.** In emulsion the secondary of a stopping cosmic-ray meson has a fixed range, corresponding to a kinetic energy of about 4 MeV, whatever the history of the primary [902]. The parent therefore decays into exactly two bodies, one of which is unseen, and the parent and the charged secondary are two *different* particles of different mass.

Rests on Equation (40.11).

Derivation. *Derives Phenomenon 115.9.*

Let a particle of mass m_π decay at rest into a charged particle of mass m_μ and n unseen particles. Conservation of four-momentum, Equation (40.11), gives for the charged secondary

$$m_\pi c^2 = E_\mu + E_X\,, \qquad \boldsymbol{p}_\mu + \boldsymbol{p}_X = \boldsymbol{0}\,,$$

with X the unseen system. Squaring the four-momentum of X,

$$m_X^2 c^4 = \left(m_\pi c^2 - E_\mu\right)^2 - p_\mu^2 c^2\,,$$

so that

$$E_\mu = \frac{\left(m_\pi^2 + m_\mu^2 - m_X^2\right)c^2}{2m_\pi}\,, \qquad p_\mu c = \frac{c^2}{2m_\pi}\left[\left(m_\pi^2 - (m_\mu + m_X)^2\right)\left(m_\pi^2 - (m_\mu - m_X)^2\right)\right]^{1/2}. \tag{115.17}$$

If $n = 1$ then m_X is a fixed mass and E_μ is a single number: the secondary is monoenergetic and its range is constant. If $n \geq 2$ then m_X ranges continuously from $\sum m_i$ upwards, E_μ is spread over a continuum, and no fixed range can occur. A constant range therefore establishes a two-body decay — which is the same logic that identifies the beta spectrum as three-body in Section 101.1.1, read in the opposite direction.

Putting $m_X = 0$ and the modern masses $m_{\pi^+}c^2 = 139.570\,39\,\mathrm{MeV}$, $m_\mu c^2 = 105.658\,375\,5\,\mathrm{MeV}$ [2427] into Equation (115.17),

$$p_\mu c = \frac{\left(m_\pi^2 - m_\mu^2\right)c^4}{2m_\pi c^2} = 29.79\,\mathrm{MeV}\,, \qquad T_\mu = \sqrt{(p_\mu c)^2 + (m_\mu c^2)^2} - m_\mu c^2 = 4.12\,\mathrm{MeV}\,,$$

in SI $T_\mu = 6.60 \times 10^{-13}\,\mathrm{J}$, and the range of a 4.12 MeV muon in emulsion is indeed about 600 µm. The unseen partner is the muon neutrino, whose own story is Chapter 103. □

The pion is the strongly interacting particle the nuclear force demands, and its role as the lightest quantum of that force is developed in Section 107.2.2; that it is light for a reason — being the pseudo-Goldstone boson of the broken chiral symmetry of Section 102.8 — is the QCD side of the same fact. For the present chapter its importance is different and entirely practical: pion production is the dominant channel by which a primary nucleus converts its energy into a shower, and Section 115.4.2 is built on the branching ratios of pion decay and nothing else.

115.2.5 Strange particles

Rochester and Butler, operating a counter-controlled cloud chamber, photographed tracks that fork in mid-flight with no incoming track at the vertex [903]. A neutral particle had decayed into two charged ones. The mass of the parent follows from the two secondaries by the invariant-mass construction of Equation (40.12),

$$M^2c^4 = (E_1 + E_2)^2 - (\boldsymbol{p}_1 + \boldsymbol{p}_2)^2\, c^2 \,, \tag{115.18}$$

each E_i and $\boldsymbol{p}_i$ coming from the curvature and ionisation of one track, and it came out near $5 \times 10^8\,\mathrm{eV}/c^2$ — about half the proton mass, and a particle nobody had ordered. The modern value for the neutral kaon is $m_{K^0}c^2 = (497.611 \pm 0.013)\,\mathrm{MeV}$ [2427].

What made these particles "strange" is a rate, not a mass.

Phenomenon 115.10 (Copious production, slow decay)**.** The V particles are produced with cross sections characteristic of the strong interaction, and yet they live of order $1 \times 10^{-10}\,\mathrm{s}$ before decaying into ordinary hadrons [903] — some thirteen orders of magnitude longer than the strong-interaction time scale. A quantum number conserved in production and violated in decay is therefore required.

Derivation. *Derives Phenomenon 115.10.*

The only time scale the strong interaction possesses is the light transit time of a hadron. With a hadronic radius $r_h \approx 1 \times 10^{-15}\,\mathrm{m}$,

$$\tau_{\mathrm{strong}} \sim \frac{r_h}{c} = \frac{1 \times 10^{-15}\,\mathrm{m}}{2.998 \times 10^8\,\mathrm{m/s}} = 3 \times 10^{-24}\,\mathrm{s}\,,$$

and any decay proceeding through the strong interaction into kinematically allowed hadronic channels must take a time of that order. The observed lifetime is $1 \times 10^{-10}\,\mathrm{s}$, larger by 3×10^{13}. Since the production is strong — the cross sections are millibarns, not microbarns — the initial and final states are connected by the strong interaction in one direction and not in the other, which is impossible for a single interaction. The resolution is an additive quantum number S, conserved by the strong interaction and violated by the weak one: strange particles are then produced only in pairs of opposite S, so that production conserves S, and each must then wait for a weak decay, whose rate is smaller by the square of the Fermi constant. The classification of the resulting spectrum by SU(3) is Section 102.1.1, and the identification of S as a quark flavour is Section 102.1.3; the weak decay itself is quark mixing, Chapter 101. □

After 1953 this physics moved to accelerators, where a controlled beam and a known incident energy do in an afternoon what a mountain laboratory did in a year. What cosmic rays retained is what no accelerator can supply: energies above the beam energy of any machine, which is Section 115.8, and an isotropic natural flux over the whole sky, which is what makes them astronomy.

115.3 The primary spectrum and composition

115.3.1 The all-particle spectrum

The primary observable is the *differential intensity* $J(E)$: the number of particles per unit area, per unit time, per unit solid angle and per unit energy crossing a surface normal to their arrival direction. Its SI unit is $1/(\mathrm{m^2\,s\,sr\,J})$; the literature quotes it per GeV, and $1\,\mathrm{GeV} = 1.602\,176\,634 \times 10^{-10}\,\mathrm{J}$ converts between them.

Over the range in which direct measurement above the atmosphere is possible, the primary nucleon intensity is described by a single power law [2427],

$$J_N(E) \approx 1.8 \times 10^{4} \left(\frac{E}{1\,\mathrm{GeV}}\right)^{-2.7} 1/(\mathrm{m^2\,s\,sr\,GeV}) = 1.12 \times 10^{14} \left(\frac{E}{1\,\mathrm{GeV}}\right)^{-2.7} 1/(\mathrm{m^2\,s\,sr\,J})\,, \tag{115.19}$$

valid from a few GeV — below which the solar modulation of Equation (115.13) takes over — up to about $1 \times 10^{14}\,\mathrm{eV}$. Above that the flux is too small for a satellite and is measured through air showers, and the power law continues, with two changes of index, to the highest energies observed.

Phenomenon 115.11 (A power-law spectrum over eleven decades)**.** The differential intensity of primary cosmic rays is, to a good approximation, a featureless power law

$$\frac{\mathrm{d}N}{\mathrm{d}E} \propto E^{-\gamma}\,, \qquad \gamma \approx 2.7\,, \tag{115.20}$$

from about 1 GeV to above $1 \times 10^{20}\,\mathrm{eV}$, across which the flux falls by some thirty-two orders of magnitude. Three integral rates fix the scale: about one particle per square centimetre per second per steradian above 1 GeV, about four per square metre per second per steradian above 100 GeV, and of order one per square kilometre per year above $1 \times 10^{19}\,\mathrm{eV}$ [2271, 2427]. No terrestrial accelerator produces anything remotely like this range.

Rests on Equation (115.19).

Derivation of the integral rates. *Derives Phenomenon 115.11.*

For a power law $J(E) = J_0\,(E/E_0)^{-\gamma}$ with $\gamma > 1$ the integral intensity above E converges and is

$$J(>E) = \int_E^{\infty} J\,(E')\,\mathrm{d}E' = \frac{J_0 E_0}{\gamma - 1}\left(\frac{E}{E_0}\right)^{-(\gamma-1)}\,. \tag{115.21}$$

Inserting Equation (115.19) with $E_0 = 1\,\mathrm{GeV}$, $J_0 = 1.8 \times 10^{4}/(\mathrm{m^2\,s\,sr\,GeV})$ and $\gamma = 2.7$,

$$J\,(>1\,\mathrm{GeV}) = \frac{1.8 \times 10^{4}}{1.7} = 1.06 \times 10^{4}/(\mathrm{m^2\,s\,sr}) = 1.06/(\mathrm{cm^2\,s\,sr})\,,$$

which is the first anchor, and

$$J\,(>100\,\mathrm{GeV}) = 1.06 \times 10^{4} \times 100^{-1.7} = 4.2/(\mathrm{m^2\,s\,sr})\,,$$

which is the second. For the third the index must be changed at the knee of Section 115.3.2. Matching a second power law $\gamma_2 = 3.1$ continuously at $E_k = 3 \times 10^{15}\,\mathrm{eV}$ gives, for $E > E_k$,

$$J(>E) = \frac{J_0 E_0}{\gamma_2 - 1}\left(\frac{E_k}{E_0}\right)^{\gamma_2-\gamma_1}\left(\frac{E}{E_0}\right)^{-(\gamma_2-1)}\,,$$

and at $E = 1 \times 10^{19}\,\mathrm{eV} = 1 \times 10^{10}\,\mathrm{GeV}$ this evaluates to $3.3 \times 10^{-15}/(\mathrm{m^2\,s\,sr})$. Multiplying by $1 \times 10^{6}\,\mathrm{m^2/km^2}$ and by $3.156 \times 10^{7}\,\mathrm{s/yr}$,

$$J\left(>1 \times 10^{19}\,\mathrm{eV}\right) \approx 0.1/(\mathrm{km^2\,yr\,sr})\,,$$

so that an array accepting some π steradians records of order one event per square kilometre per year — the third anchor, and the reason the observatories of Section 115.4.3 are the size of a small country. The total dynamic range follows in the same way: $J\left(1\times10^{20}\,\mathrm{eV}\right)/J\left(1\,\mathrm{GeV}\right)=3.1\times10^{-32}$, thirty-one and a half orders of magnitude. □

Remark 115.12 (Why the spectrum is plotted multiplied by E^3). A quantity falling over thirty-two decades cannot be examined on a linear scale, and even on a logarithmic one a change of index from 2.7 to 3.1 is invisible to the eye. Every published spectrum is therefore plotted as $E^3J(E)$, or as $E^{2.7}J(E)$, which turns a pure power law of that index into a horizontal line and turns the knee and ankle into visible kinks. The multiplication is cosmetic and carries a trap: the vertical scale then has SI units $\mathrm{J}^2/(\mathrm{m}^2\,\mathrm{s}\,\mathrm{sr})$, and a systematic shift of the energy scale by a factor $1+\epsilon$ moves every plotted point diagonally — right by ϵ and up by 2ϵ, since the abscissa carries one power of the energy and the ordinate the remaining two. What that displacement does to the *curve* is what matters, and at a fixed abscissa the plotted ordinate is then in error by $(\gamma-1)\,\epsilon$: the common factor E^3 cancels between the true and the reconstructed curve, leaving exactly the error Equation (115.40) derives for the integral intensity. Section 115.4.6 treats that effect quantitatively, because it is the dominant uncertainty in every spectral measurement above $1\times10^{18}\,\mathrm{eV}$.

A featureless power law over eleven decades is the strongest single constraint on the acceleration mechanism. No process with a characteristic energy can produce one: a thermal source produces a Maxwellian with a temperature, a resonance produces a line, and a mechanism with a preferred scale produces a break at that scale. What produces a power law is a process in which the fractional energy gain per step and the escape probability per step are both independent of energy, and Section 115.5.3 shows that a strong shock is exactly such a process.

115.3.2 The knee

Phenomenon 115.13 (The knee)**.** Near $3\times10^{15}\,\mathrm{eV}$ the spectrum of Equation (115.20) steepens, the index changing from about 2.7 to about 3.1. The break was first seen in the shower-size spectrum [1171], and was later resolved into successive rigidity-ordered cutoffs of the individual elemental groups, the light component breaking first [2070]. Which of the two standing readings — a limit of the Galactic accelerators, or a change in Galactic confinement — is correct is not settled by the data.

Rests on Equation (115.20).

Kulikov and Khristiansen found the break not in the energy spectrum but in the *shower-size* spectrum: the number of showers containing more than N particles at the ground falls as a power of N, and the power changes near $N\approx1\times10^6$ [1171]. Since $N\propto E$ for an electromagnetic cascade (Equation (115.29)), a break in N is a break in E, and the calibration puts it at $3\times10^{15}\,\mathrm{eV}=4.8\times10^{-4}\,\mathrm{J}$.

Derivation: any magnetic origin of the knee is ordered by rigidity. *Derives Phenomenon 115.13.*

Suppose the break is produced by a magnetic process, either at the accelerator (a maximum energy the source can reach) or in transport (a maximum energy the Galaxy can retain). Both are governed by the equation of motion of a charge in a magnetic field, and that equation, written for the momentum,

$$\frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t}=Ze\,\boldsymbol{v}\times\boldsymbol{B}\,,$$

depends on the species only through Ze. Dividing by Ze and using Equation (115.1),

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\boldsymbol{p}c}{Ze}\right)=c\,\boldsymbol{v}\times\boldsymbol{B}\quad\Longrightarrow\quad\frac{\mathrm{d}\boldsymbol{R}}{\mathrm{d}t}=c\,\boldsymbol{v}\times\boldsymbol{B}\,,$$

so two particles of the same rigidity and the same velocity follow identical trajectories in any magnetic field whatever, regardless of their charge and mass. Any limit imposed by magnetic fields is therefore a limit on rigidity, $R \le R_{\max}$, and for an ultrarelativistic nucleus of charge Z this is a limit on energy

$$E_{\max}(Z) = ZeR_{\max} = Z\,E_{\max}(1)\,. \tag{115.22}$$

The prediction is sharp: the knee of the proton component sits at E_k, that of helium at $2E_k$, and that of iron at $26E_k$, so that the all-particle spectrum steepens gradually as one species after another drops out, and the composition becomes progressively heavier across the knee region. With $E_k = 3 \times 10^{15}\,\mathrm{eV}$ the iron knee is predicted at $7.8 \times 10^{16}\,\mathrm{eV}$. This is what KASCADE found by unfolding the measured shower-size and muon-number distributions into elemental groups: the light component breaks first, the heavy components later, in the rigidity-ordered sequence Equation (115.22) demands [2070]. □

Remark 115.14 (What the rigidity ordering does not decide). The derivation above is the reason the knee is *not* yet understood. Both candidate explanations are magnetic and both therefore predict the same rigidity ordering, so the observation that confirmed the ordering cannot discriminate between them. An acceleration limit predicts that the sources stop supplying particles above $ZeR_{\max}$; a confinement limit predicts that the Galaxy stops retaining them. Distinguishing the two requires an observable that is not a spectrum: the anisotropy expected from a leaking population, or a direct measurement of a source spectrum in gamma rays extending past the knee — which is what the LHAASO sources of Section 115.7.1 begin to supply. It is reported here as open because it is open.

115.3.3 The ankle and the highest energies

Linsley, operating the Volcano Ranch array in New Mexico, recorded in 1962 a shower whose reconstructed primary energy was about $1 \times 10^{20}\,\mathrm{eV} = 16\,\mathrm{J}$ — the kinetic energy of a well-struck tennis ball, carried by a single nucleus [1261]. It remains, sixty years later, within a factor of a few of the highest energy ever measured.

Between the knee and that regime the spectrum steepens once more and then *flattens* again, near $4 \times 10^{18}\,\mathrm{eV}$, the index falling from about 3.3 back to about 2.6. The feature is called the ankle and was measured with high statistics at the Pierre Auger Observatory [2116]. The standard reading is that it marks the crossing of two populations: a Galactic component dying out and an extragalactic component taking over. The argument that the highest-energy particles cannot be Galactic is a comparison of two lengths and is worth doing in SI.

Phenomenon 115.15 (The highest-energy primaries are not confined by the Galaxy)**.** A proton of $1 \times 10^{19}\,\mathrm{eV}$ in the Galactic magnetic field has a gyroradius of several kiloparsecs, larger than the thickness of the Galactic disc by more than an order of magnitude and comparable to the distance from the Sun to the Galactic centre. Such particles cannot be stored in the Galaxy, and a Galactic source population cannot supply an isotropic flux of them.

Rests on Equation (115.8).

Derivation. *Derives Phenomenon 115.15.*

The Galactic magnetic field measured through Faraday rotation and synchrotron polarisation has a regular component of order $B = 3 \times 10^{-10}\,\mathrm{T}$, that is 0.3 nT or three microgauss in the older literature. An ultrarelativistic proton of energy E has $p = E/c$, so Equation (115.8) gives

$$r_L = \frac{p}{ZeB} = \frac{E}{ZecB}\,. \tag{115.23}$$

For $E = 1 \times 10^{19}\,\mathrm{eV} = 1.602\,\mathrm{J}$ and $Z = 1$,

$$r_L = \frac{1.602\,\mathrm{J}}{1.602\,176\,634 \times 10^{-19}\,\mathrm{C} \times 2.998 \times 10^{8}\,\mathrm{m/s} \times 3 \times 10^{-10}\,\mathrm{T}} = 1.11 \times 10^{20}\,\mathrm{m} = 3.6\,\mathrm{kpc}\,,$$

using $1\,\mathrm{pc} = 3.0857 \times 10^{16}\,\mathrm{m}$. The half-thickness of the Galactic disc is about 0.15 kpc and the distance to the Galactic centre about 8 kpc, so the orbit is twenty-four times the disc thickness and about half the size of the whole Galaxy. At $1 \times 10^{20}\,\mathrm{eV}$ the same formula gives $r_L = 36\,\mathrm{kpc}$, larger than the Galaxy itself: such a particle crosses the disc essentially in a straight line. A population confined by the Galactic field therefore cannot extend to these energies, and conversely a Galactic *source* of them would produce a strong anisotropy towards the Galactic plane, which Section 115.6.3 shows is not observed. The particles are extragalactic. □

115.3.4 Elemental and leptonic composition

Above the modulation region and below the knee the primaries are measured species by species with magnetic spectrometers and calorimeters above the atmosphere. By number they are roughly 90 % protons, 9 % helium and 1 % heavier nuclei, with an electron component of order 1 % of the protons at the same energy. The elemental pattern tracks solar-system abundances closely — with two conspicuous exceptions, and the exceptions are the measurement.

Phenomenon 115.16 (Light secondary nuclei are enormously overabundant)**.** Lithium, beryllium and boron are present in the cosmic radiation at a level of order 25 % of the carbon–nitrogen–oxygen group, whereas in solar-system material their abundance relative to that group is of order 10^{-6}. The same holds, less dramatically, for scandium through manganese relative to iron. These nuclei are not made in stars in such quantities; they are made in flight, by the fragmentation of heavier cosmic-ray nuclei on interstellar gas, and their abundance measures the amount of matter traversed.

Rests on Equation (115.2).

Derivation of the traversed grammage. *Derives Phenomenon 115.16.*

Let N_C be the number of carbon nuclei in a beam and N_B the number of boron nuclei produced from them by spallation, and let X be the traversed grammage of Equation (115.2), now measured through interstellar gas rather than air. Over a path element the number of fragmentations is the number of target nuclei per unit area times the cross section,

$$\mathrm{d}N_B = N_C\,\frac{\sigma_{C\to B}}{\bar{m}}\,\mathrm{d}X\,,$$

with $\bar{m}$ the mean target mass, essentially the proton mass $1.673 \times 10^{-27}\,\mathrm{kg}$ for interstellar hydrogen. As long as the secondary fraction stays small this integrates to

$$\frac{N_B}{N_C} \approx \frac{\sigma_{C\to B}}{\bar{m}}\,X\,, \qquad \text{so} \qquad X \approx \frac{\bar{m}}{\sigma_{C\to B}}\,\frac{N_B}{N_C}\,. \tag{115.24}$$

The measured boron-to-carbon ratio at a few GeV per nucleon is $N_B/N_C \approx 0.3$, and the fragmentation cross section is $\sigma_{C\to B} \approx 6 \times 10^{-30}\,\mathrm{m}^2$, which is 60 millibarn in the customary non-SI unit (one barn is $1 \times 10^{-28}\,\mathrm{m}^2$ exactly), whence

$$X \approx \frac{1.673 \times 10^{-27}\,\mathrm{kg}}{6 \times 10^{-30}\,\mathrm{m}^2} \times 0.3 = 84\,\mathrm{kg/m^2} = 8.4\,\mathrm{g/cm^2}\,.$$

That is the whole of the matter a cosmic ray meets between its source and the Earth. It is a small quantity — less than one percent of the atmosphere of Equation (115.3) — and it is

nevertheless enough to make the secondary nuclei, because their solar-system abundance is essentially zero. The corresponding path length in an interstellar medium of number density $n \approx 3 \times 10^5/\mathrm{m}^3$ is $L = X/(n\bar{m}) = 1.7 \times 10^{23}\,\mathrm{m}$, some 5 Mpc of path — folded, of course, into a volume a few kiloparsecs across, since the trajectory is a random walk and not a straight line. Since X is by Equations (115.2) and (115.24) the matter traversed *along* the path, $L/c = 5.6 \times 10^{14}\,\mathrm{s}$, that is $1.8 \times 10^7\,\mathrm{yr}$, is already the residence time; it is recomputed directly as Equation (115.53) and confirmed there by the independent radioactive clock of Section 115.5.5. □

The ratio is not constant: AMS-02 measured the boron-to-carbon ratio above a rigidity of 65 GV and found it to follow a single power law in rigidity,

$$\frac{N_B}{N_C} \propto R^{-\delta}\,, \qquad \delta = 0.333 \pm 0.014_{\mathrm{fit}} \pm 0.005_{\mathrm{syst}}\,, \tag{115.25}$$

with no break [2266]. By Equation (115.24) this says the grammage — and hence the residence time — falls as $R^{-1/3}$: faster particles leave sooner. That single exponent is the input to every propagation calculation in Section 115.5.5, and the value 1/3 is what Kolmogorov turbulence in the Galactic magnetic field would give.

The leptonic composition carries an anomaly that is still unresolved. Secondary positrons are made in the same collisions that make boron — $p + \mathrm{gas} \to \pi^+ + \ldots$, $\pi^+ \to \mu^+ \to e^+$ — so their intensity is that of a secondary and must fall relative to the primary electrons as $R^{-\delta}$, exactly as the boron does. The positron *fraction* $e^+/(e^+ + e^-)$ must therefore decrease monotonically with energy. PAMELA found it *rising* above about 10 GeV [2139], and AMS-02 measured the rise precisely over the band 0.5 GeV to 350 GeV, finding a fraction that increases with energy while its slope decreases [2207]. Later AMS-02 data extend the measurement to 1 TeV and show the rise flattening and turning over [2327].

Remark 115.17 (The positron excess is unexplained). A rising positron fraction requires a source of primary positrons. Three classes of candidate are discussed: nearby pulsar wind nebulae, which produce electron–positron pairs and are known to exist; a nearby supernova remnant with an unusually hard secondary production; and the annihilation of a dark-matter particle, which is the subject of Chapter 134. The measurement does not distinguish them. The spectral shape alone cannot: a turnover is produced by a nearby source of finite age and by an annihilation cutoff equally well. What would distinguish them is a measured anisotropy towards a nearby pulsar, and none has been detected at the sensitivity so far reached. The honest statement is that a primary positron source exists and is unidentified; asserting a dark-matter interpretation would be asserting a mechanism that has not been observed, which Chapter 134 declines to do and so does this chapter.

115.4 Extensive air showers

115.4.1 Auger's coincidence experiment

Above about $1 \times 10^{14}\,\mathrm{eV}$ the primary flux is too small for any detector that can be flown, and the atmosphere must be used as the detector. That this is possible at all was discovered by Auger and collaborators, who placed Geiger counters at increasing separations on the roof of a laboratory, at the Jungfraujoch and at the Pic du Midi, and recorded coincidences [827]. Coincidences persisted at separations of 300 m.

Phenomenon 115.18 (A single primary makes a wide particle front)**.** Counters separated by distances up to 300 m fire simultaneously far more often than uncorrelated counting can produce, and the coincidence rate falls smoothly with separation instead of being independent of it [827]. A single primary particle therefore produces a coherent front of

secondaries tens of thousands strong spread over a large area at the ground, and the primary energies required are of order $1 \times 10^{15}\,\mathrm{eV}$ — six orders of magnitude above anything then measured.

Derivation. *Derives Phenomenon 115.18.*

Two counters with singles rates r_1 and r_2 and a coincidence resolving time τ register accidental coincidences at the rate

$$r_{\mathrm{ch}} = 2\tau r_1 r_2\,, \tag{115.26}$$

since counter 2 must fire within $\pm\tau$ of counter 1. For counters of area $100\,\mathrm{cm}^2$ at sea level, where the vertical muon intensity is about $70/(\mathrm{m}^2\,\mathrm{s\,sr})$, the singles rate is $r \approx 1.7/\mathrm{s}$; with the $\tau \approx 10\,\mu\mathrm{s}$ of the period, Equation (115.26) gives $r_{\mathrm{ch}} = 5.8 \times 10^{-5}/\mathrm{s}$, about five accidental coincidences a day.

The decisive point is not the size of this number but its *independence of the separation*: Equation (115.26) contains no distance at all. The measured coincidence rate, by contrast, falls steeply and smoothly as the counters are drawn apart, and remains above the accidental rate out to 300 m. A distance-dependent excess over a distance-independent background can only be a correlation, and a correlation over 300 m at the speed of light means a single common ancestor.

The energy follows from the particle number. If the front contains N particles at the ground and each was produced by dividing the primary energy down to the point where production stops — the critical energy $E_c \approx 85\,\mathrm{MeV}$ of Section 115.4.2 — then $E_0 \gtrsim N E_c$. Auger's estimate of $N \approx 10^6$ particles gives $E_0 \gtrsim 8.5 \times 10^{13}\,\mathrm{eV}$, and correcting for the fact that the ground lies well past the shower maximum, where most of the particles have already been absorbed, raises this to of order $1 \times 10^{15}\,\mathrm{eV} = 1.6 \times 10^{-4}\,\mathrm{J}$. □

The shower is thus an amplifier: one particle arriving once per square metre per century is converted by the atmosphere into a signal spread over square kilometres, which a sparse array of detectors covering a 10^{-5} fraction of that area can still sample. Every measurement above $1 \times 10^{15}\,\mathrm{eV}$ in this chapter rests on it.

115.4.2 Cascade development

Take the electromagnetic part of the cascade first, since the hadronic part feeds it and cannot be described without it.

A high-energy photon in matter converts to an e^+e^- pair; a high-energy electron radiates a bremsstrahlung photon. Both processes have the same characteristic depth, the radiation length X_0 of Equation (115.16), which for air is

$$X_0 = 365\,\mathrm{kg/m}^2 = 36.5\,\mathrm{g/cm}^2\,, \tag{115.27}$$

so that the vertical atmosphere of Equation (115.3) is $1.0332 \times 10^4\,\mathrm{kg/m}^2 / 365\,\mathrm{kg/m}^2 = 28$ radiation lengths deep — a calorimeter as thick as any built. Below a *critical energy* E_c the electron loses energy faster by ionisation than by radiation and the multiplication stops; for air $E_c \approx 85\,\mathrm{MeV} = 1.36 \times 10^{-11}\,\mathrm{J}$ [2080]. Heitler's model replaces the two processes by one [1043]: every particle splits into two, each carrying half the energy, after a fixed *splitting length* $d = X_0 \ln 2$.

Theorem 115.19 (Heitler's cascade)**.** *In the splitting model the number of particles at depth X and the energy per particle are*

$$N(X) = 2^{X/d}\,, \qquad E(X) = \frac{E_0}{N(X)} = E_0 2^{-X/d}\,, \qquad d = X_0 \ln 2\,, \tag{115.28}$$

the cascade stops at the depth where $E(X) = E_c$, and therefore

$$N_{\max} = \frac{E_0}{E_c}\,, \qquad X_{\max} = X_0 \ln\!\left(\frac{E_0}{E_c}\right). \tag{115.29}$$

Two consequences follow, and both are what is actually measured: the particle number at maximum is linear *in the primary energy, and the depth of maximum grows only* logarithmically *with it, at the rate*

$$D_{10} := \frac{\mathrm{d}X_{\max}}{\mathrm{d}\log_{10} E_0} = X_0 \ln 10 = 84\,\mathrm{g/cm^2} \tag{115.30}$$

per decade of primary energy.

Rests on Equations (115.2) *and* (115.16).

Proof. *Derives Theorem 115.19.*

After n splittings the depth is $X = nd$ and the number of particles is 2^n, which is Equation (115.28) with $n = X/d$. Energy is conserved and shared equally, so $E(X)N(X) = E_0$. Multiplication continues while $E(X) > E_c$ and stops when equality is reached; at that depth $N = E_0/E_c$, which is the first of Equation (115.29), and $2^{X_{\max}/d} = E_0/E_c$ gives

$$X_{\max} = d\,\frac{\ln\left(E_0/E_c\right)}{\ln 2} = X_0 \ln\!\left(\frac{E_0}{E_c}\right),$$

which is the second. Differentiating with respect to $\log_{10} E_0 = \ln E_0 / \ln 10$ gives Equation (115.30). □

The numbers are informative. For $E_0 = 1 \times 10^{15}\,\mathrm{eV}$, Equation (115.29) gives $N_{\max} = 1.2 \times 10^7$ particles and $X_{\max} = 594\,\mathrm{g/cm^2}$; for $E_0 = 1 \times 10^{20}\,\mathrm{eV}$, $N_{\max} = 1.2 \times 10^{12}$ and $X_{\max} = 1014\,\mathrm{g/cm^2}$, which is just about the depth of the whole vertical atmosphere — so the highest-energy showers reach maximum near the ground and a detector on a high plateau sees them close to their peak. That is why the observatories of Section 115.4.3 sit at altitude.

Remark 115.20 (What the toy model gets wrong, and why it is still used). Heitler's model is not a calculation of a cascade; it is a book-keeping device that gets the two scaling laws right and the absolute numbers wrong by a fixed factor. Real cascades do not split in two: an electron radiates a photon of any energy fraction with the Bethe–Heitler spectrum, so the particle number at maximum is smaller than E_0/E_c by a factor of order 10, and the sub-threshold particles are not immediately absorbed. The full treatment is the coupled pair of integro-differential cascade equations, solved by Mellin transform in the depth variable — the technique of Chapter 17, applied to a physically different problem from the one it is introduced for. What survives unchanged from Theorem 115.19 is $N_{\max} \propto E_0$ and $X_{\max} \propto \ln E_0$, and those two are the entire basis of air-shower energy and composition measurement.

A primary nucleus does not start an electromagnetic cascade; it starts a hadronic one, and the electromagnetic component is a by-product. The interaction length follows from the cross section as $\lambda_I = \bar{m}_{\mathrm{air}}/\sigma_{p\text{-air}}$ with $\bar{m}_{\mathrm{air}} = 14.5 \times 1.6605 \times 10^{-27}\,\mathrm{kg} = 2.41 \times 10^{-26}\,\mathrm{kg}$ the mean mass of an air nucleus; the inelastic proton–air cross section grows slowly with energy, and near $1 \times 10^{15}\,\mathrm{eV}$ it is about $4.5 \times 10^{-29}\,\mathrm{m^2}$, that is 450 millibarn in the customary unit of Equation (115.24), so

$$\lambda_I = \frac{2.41 \times 10^{-26}\,\mathrm{kg}}{4.5 \times 10^{-29}\,\mathrm{m^2}} \approx 550\,\mathrm{kg/m^2} = 55\,\mathrm{g/cm^2}\,, \tag{115.31}$$

so that by Equation (115.3) the atmosphere is about nineteen interaction lengths deep and a primary interacts near the top with certainty [2271]. Each interaction produces of order

N_{ch} charged pions and $N_{\mathrm{ch}}/2$ neutral ones, the isospin content of Chapter 102 making the three charge states roughly equally populated. The neutral pions decay to two photons in $8.4 \times 10^{-17}\,\mathrm{s}$, far faster than they can interact, and feed the electromagnetic channel; the charged pions either interact again or decay to muons.

Derivation of the pion critical energy. A charged pion of Lorentz factor γ travels a mean distance $\gamma c\tau_\pi$ before decaying, with $\tau_\pi = 2.6033 \times 10^{-8}\,\mathrm{s}$ and $c\tau_\pi = 7.80\,\mathrm{m}$. It travels λ_I/ρ before interacting. At an altitude of 10 km, where most of the shower develops, the air density is $\rho \approx 0.41\,\mathrm{kg/m^3}$ and the interaction length is

$$\frac{\lambda_I}{\rho} = \frac{550\,\mathrm{kg/m^2}}{0.41\,\mathrm{kg/m^3}} = 1.34 \times 10^3\,\mathrm{m}\,.$$

Equating the two lengths gives the Lorentz factor at which the two fates are equally likely,

$$\gamma_c = \frac{1.34 \times 10^3\,\mathrm{m}}{7.80\,\mathrm{m}} = 172\,, \qquad E_c^\pi = \gamma_c m_\pi c^2 = 172 \times 139.57\,\mathrm{MeV} = 24\,\mathrm{GeV}\,,$$

in SI $3.8 \times 10^{-9}\,\mathrm{J}$. Pions above this energy interact and keep the hadronic cascade going; pions below it decay and become muons. The value depends on altitude through ρ and on energy through λ_I, and is conventionally taken as $E_c^\pi \approx 20\,\mathrm{GeV}$ for the shower as a whole [2080]; the derivation above shows where that number comes from and how much it can be trusted. Note how sensitive it is to the cross section: the older tabulated interaction length for air, $90\,\mathrm{g/cm^2}$, which is a few-GeV value, would give 39 GeV instead and turn a twenty-percent agreement into a factor-of-two puzzle. □

Theorem 115.21 (Muon number and its scaling)**.** *In the hadronic extension of Theorem 115.19, after n generations the energy remaining in the hadronic channel is $E_0\,(2/3)^n$, shared among N_{ch}^n charged pions; the cascade ends when the pion energy falls to E_c^π, and every surviving charged pion becomes a muon. Hence*

$$N_\mu = \left(\frac{E_0}{E_c^\pi}\right)^{\beta}\,, \qquad \beta = \frac{\ln N_{\mathrm{ch}}}{\ln\left(\frac{3}{2}N_{\mathrm{ch}}\right)} \approx 0.85\,, \tag{115.32}$$

so the muon number grows more slowly than linearly with primary energy, while the electromagnetic particle number grows linearly. The ratio of the two is therefore an energy-independent handle on the primary mass.

Rests on Theorem 115.19.

Proof. *Derives Theorem 115.21.*

Of the $\frac{3}{2}N_{\mathrm{ch}}$ pions made in one interaction, N_{ch} are charged and carry 2/3 of the energy onward; after n generations the hadronic energy is $E_0\,(2/3)^n$ spread over N_{ch}^n pions, so the energy per pion is $E_0\left(\frac{3}{2}N_{\mathrm{ch}}\right)^{-n}$. Setting this equal to E_c^π determines the number of generations,

$$n = \frac{\ln\left(E_0/E_c^\pi\right)}{\ln\left(\frac{3}{2}N_{\mathrm{ch}}\right)}\,,$$

and $N_\mu = N_{\mathrm{ch}}^n = \exp\left(n \ln N_{\mathrm{ch}}\right)$, which is Equation (115.32). With $N_{\mathrm{ch}} = 10$, $\beta = \ln 10/\ln 15 = 0.850$; the exponent is insensitive to N_{ch}, moving only from 0.80 to 0.88 as N_{ch} runs from 5 to 20, which is why it is quoted as a number rather than as a function. □

Corollary 115.22 (Superposition: more muons, shallower maximum)**.** *A nucleus of mass number A and total energy E_0 behaves, to a first approximation, as A independent nucleons each of energy E_0/A. Then*

$$N_\mu^A = A\left(\frac{E_0/A}{E_c^\pi}\right)^\beta = A^{1-\beta}N_\mu^p\,, \qquad \langle X_{\max}\rangle^A = \langle X_{\max}\rangle^p - D_{10}\log_{10}A\,. \tag{115.33}$$

An iron primary ($A=56$) therefore produces $56^{0.15}=1.83$ times as many muons as a proton of the same total energy, and its shower maximum lies about $D_{10}\log_{10}56 \approx 100\,\mathrm{g/cm^2}$ higher in the atmosphere, using the measured hadronic elongation rate $D_{10}\approx 58\,\mathrm{g/cm^2}$ per decade rather than the purely electromagnetic Equation (115.30)*.*

Rests on Equations (115.30) *and* (115.32)*.*

Proof. *Derives Corollary 115.22.*

Each of the A nucleons initiates a sub-shower of energy E_0/A; the muon numbers add, giving the first of Equation (115.33) directly from Equation (115.32), and $1-\beta=0.15$. The depths of maximum do not add: the shower maximum of the superposition is that of a single sub-shower, so $\langle X_{\max}\rangle$ is evaluated at E_0/A instead of at E_0, and by the definition Equation (115.30) of the elongation rate this shifts it by $-D_{10}\log_{10}A$. □

Remark 115.23 (The muon puzzle). Equation (115.32) is the point at which air-shower physics depends on hadronic interaction models extrapolated an order of magnitude in centre-of-mass energy beyond any collider measurement, and it is where the extrapolation currently fails. Measured muon numbers in showers above $1\times10^{19}\,\mathrm{eV}$ exceed the predictions of every hadronic model, by a factor of order 1.3 to 1.6, with the primary mass constrained independently by $X_{\max}$. The discrepancy is reported here as an unresolved defect of the modelling rather than absorbed into a fitted parameter, and it is one of the reasons a composition inference from muon number alone is not currently trustworthy; Section 115.8.1 returns to it.

115.4.3 Detection techniques

Two techniques dominate, and they measure different things.

A *surface array* samples the particle density of the shower front where it meets the ground, using either plastic scintillators or sealed tanks of water read by photomultipliers, the latter responding to Cherenkov light (Section 115.4.4) from the traversing particles and so being sensitive to the muonic as well as the electromagnetic component. From the sampled densities a lateral distribution function is fitted, and its value at a fixed distance from the axis — 1000 m for a kilometre-spaced array — is used as the energy estimator, because at that distance the fitted density is least sensitive to the shape assumed. The arrival direction comes from the relative timing.

Derivation of the angular resolution of an array. Treat the shower front as a plane advancing at speed c along the unit vector $\hat{\boldsymbol{n}}$. Two detectors separated by the baseline $\boldsymbol{d}$ are struck at times differing by

$$\Delta t = -\frac{\boldsymbol{d}\cdot\hat{\boldsymbol{n}}}{c} = \frac{d\sin\theta}{c}\,, \tag{115.34}$$

for a baseline in the plane of incidence, so that measuring Δt measures θ. Differentiating, $\sigma_\theta = c\,\sigma_t/\left(d\cos\theta\right)$. With a timing precision $\sigma_t = 10\,\mathrm{ns}$, achievable with photomultipliers and satellite time transfer, and a baseline $d=1500\,\mathrm{m}$,

$$\sigma_\theta = \frac{2.998\times10^{8}\,\mathrm{m/s}\times 1\times10^{-8}\,\mathrm{s}}{1500\,\mathrm{m}} = 2.0\times10^{-3}\,\mathrm{rad} = 0.11^\circ$$

at the zenith. The realised resolution of a large array is about 1°, an order of magnitude worse, because the front is not a plane but a curved and thick shell whose sampled thickness is tens of nanoseconds; Equation (115.34) sets the floor, not the answer. □

An *air-fluorescence detector* does something different: it photographs the shower in the dark. Nitrogen molecules excited by the shower's charged particles fluoresce isotropically in the near ultraviolet, at a yield of a few photons per metre per charged particle, and the light is proportional to the energy deposited. A telescope watching a dark sky therefore records the shower's longitudinal profile $N(X)$ directly, and the primary energy follows by integration,

$$E_{\mathrm{cal}} = \int \left(\frac{\mathrm{d}E}{\mathrm{d}X}\right)_{\mathrm{ion}} N(X)\,\mathrm{d}X\,, \tag{115.35}$$

which is calorimetry with no hadronic model in it at all. That is the technique's great advantage. It has two costs: the light must traverse kilometres of atmosphere whose transmission must be measured continuously, and Equation (115.35) misses the energy carried into the ground by muons and neutrinos, some 10 % to 15 %, which must be added back with a model-dependent correction. The technique was realised in the Fly's Eye detector [1748].

Their weaknesses are complementary. Fluorescence works only on clear moonless nights, a duty cycle of order 13 %; an array runs continuously. An array's energy scale depends on shower simulations; a fluorescence detector's does not. The Pierre Auger Observatory therefore does both, covering 3000 km^2 of Argentine plateau with 1600 water-Cherenkov tanks on a 1500 m triangular grid, overlooked by fluorescence telescopes at four sites, and using the subset of events seen by both — the *hybrid* events — to calibrate the array's estimator against the calorimetric energy [2241]. The energy scale of the whole observatory is then that of the fluorescence measurement, with a systematic uncertainty of about 14 %, and Section 115.4.6 shows what that costs.

115.4.4 The Cherenkov technique

A charged particle moving through a medium faster than the phase velocity of light in that medium radiates, at a fixed angle to its track. The phenomenon and the cone condition are established in Phenomenon 65.7: with n the refractive index and $\beta = v/c$,

$$\cos\theta_c = \frac{1}{n\beta}\,, \tag{115.36}$$

which has a solution only if $\beta > 1/n$ [789]. The intensity is Frank and Tamm's [792]; in SI, for a particle of charge Ze,

$$\frac{\mathrm{d}^2E}{\mathrm{d}x\,\mathrm{d}\omega} = \frac{(Ze)^2}{4\pi\varepsilon_0 c^2}\,\omega\left(1 - \frac{1}{\beta^2 n^2(\omega)}\right)\,, \tag{115.37}$$

an energy per unit path length per unit angular frequency, of SI dimension J s/m. Dividing by $\hbar\omega$ converts it to a photon count, and the factor of ω cancels:

$$\frac{\mathrm{d}^2N}{\mathrm{d}x\,\mathrm{d}\omega} = \frac{(Ze)^2}{4\pi\varepsilon_0\hbar c^2}\left(1 - \frac{1}{\beta^2 n^2}\right) = \frac{\alpha Z^2}{c}\left(1 - \frac{1}{\beta^2 n^2}\right)\,, \tag{115.38}$$

with $\alpha = e^2/(4\pi\varepsilon_0\hbar c)$ the dimensionless fine-structure constant of Section 100.1.1. The photon number per unit path is thus *flat in frequency*, which is why Cherenkov light looks blue: equal numbers per unit ω means many more per unit wavelength at the short end. The cone condition Equation (115.36) is derived, by the wavelet construction, in Phenomenon 65.7; the intensity Equation (115.37) is not derived anywhere in this book yet.

Derivation pending #205

The Frank–Tamm intensity formula in SI, obtained from the retarded fields of a uniformly moving charge in a dispersive medium by Fourier transform in space and time. Belongs in Appendix A; this chapter quotes the result and uses only its numerical consequences

Example 115.24 (Numbers for the three media that matter)**.** Rewriting Equation (115.38) per unit wavelength using $\omega = 2\pi c/\lambda$,

$$\frac{\mathrm{d}^2 N}{\mathrm{d}x\,\mathrm{d}\lambda} = \frac{2\pi\alpha Z^2}{\lambda^2}\left(1 - \frac{1}{\beta^2 n^2}\right),$$

and integrating over the photomultiplier band 300 nm to 600 nm for $\beta = 1$, $Z = 1$:

- *Water*, $n = 1.333$: $\theta_c = 41.4°$, and $\mathrm{d}N/\mathrm{d}x = 3.34 \times 10^4/\mathrm{m}$, that is 334 photons per centimetre of track. This is the tank of a surface array and the volume of Chapter 114.
- *Ice*, $n = 1.32$: $\theta_c = 40.7°$ and $\mathrm{d}N/\mathrm{d}x = 3.26 \times 10^4/\mathrm{m}$, essentially the same. This is IceCube (Section 115.7.4).
- *Air* at sea level, $n = 1.000293$: the cone collapses to $\theta_c = 1.39°$ and the yield to 45/m, but the track lengths are kilometres. The threshold is severe: $\beta > 1/n$ requires

  $$\gamma > \gamma_{\mathrm{th}} = \frac{1}{\sqrt{1 - n^{-2}}} = 41.3\,,$$

  so an electron needs 21 MeV and a muon 4.4 GeV. A shower's Cherenkov light is therefore emitted almost entirely by its electromagnetic component and is beamed into a narrow forward cone that illuminates a pool some 125 m in radius at the ground.

That narrow cone is the basis of gamma-ray astronomy from the ground. An *imaging atmospheric Cherenkov telescope* focuses the pool of light onto a camera of photomultipliers and forms an image of the shower; the image of a shower initiated by a gamma ray is a compact, regular ellipse pointing at the source position in the field, while a hadronic shower, which contains many sub-showers with large transverse momenta, gives a broad and irregular image. Hillas showed that a few moments of the light distribution — the ellipse's length, width, orientation and total intensity — separate the two classes with a rejection of better than 99 percent [1754]. The Whipple telescope used exactly this to detect TeV gamma rays from the Crab Nebula at 9σ, the first source ever found this way [1827], and every ground-based gamma-ray instrument since is a development of it.

115.4.5 Depth of maximum and mass composition

The observable that carries composition information with the least model dependence is $X_{\max}$, together with its shower-to-shower fluctuation. Both are predicted by Corollary 115.22 and both are measured directly by a fluorescence detector.

Phenomenon 115.25 (Composition inferred from the depth of maximum)**.** The mean depth of shower maximum increases logarithmically with primary energy, and at fixed energy is about $100\,\mathrm{g/cm^2} = 1000\,\mathrm{kg/m^2}$ smaller for an iron primary than for a proton. Its shower-to-shower spread is likewise smaller for heavy primaries. Auger measurements show $\langle X_{\max}\rangle$ and its spread consistent with a light, largely protonic composition near the ankle, becoming progressively heavier with increasing energy above it [2226].

Rests on Equation (115.31) and Corollary 115.22.

Derivation of the fluctuation scaling. *Derives Phenomenon 115.25.*

Two independent sources of fluctuation enter. The first is the depth of the first interaction, which is exponentially distributed with mean λ_I, so it contributes a standard deviation λ_I to $X_{\max}$. The relevant λ_I is the one at the energy of the measurement, and by Equation (115.31) it shrinks as the cross section grows: near $1 \times 10^{19}\,\mathrm{eV}$ the inelastic proton–air cross section is about $5.0 \times 10^{-29}\,\mathrm{m}^2$, that is 500 millibarn, so

$$\lambda_I = \frac{2.41 \times 10^{-26}\,\mathrm{kg}}{5.0 \times 10^{-29}\,\mathrm{m}^2} \approx 480\,\mathrm{kg/m^2} = 48\,\mathrm{g/cm^2}\,.$$

The second source is the fluctuation in the subsequent cascade, of comparable size; the two add in quadrature, and $\left(48^2 + 36^2\right)^{1/2} = 60$ reproduces the measured proton width of some $60\,\mathrm{g/cm^2}$.

For a nucleus of mass A, superposition (Corollary 115.22) replaces one shower by A sub-showers of energy E_0/A, each with its own first-interaction depth. The shower maximum of the sum is essentially the average of the A sub-maxima, and the variance of an average of A independent variables is $1/A$ of the individual variance:

$$\sigma\left(X_{\max}\right)\Big|_A \approx \frac{\sigma\left(X_{\max}\right)\Big|_p}{\sqrt{A}}\,. \tag{115.39}$$

For iron $\sqrt{56} = 7.5$, so the rule predicts a collapse from the proton value of some $60\,\mathrm{g/cm^2}$ to $8\,\mathrm{g/cm^2}$. The measured iron width is about $20\,\mathrm{g/cm^2}$: the superposition rule gets the direction and the order of the effect right and underpredicts the width by a factor of about two and a half, which is the same crudeness Remark 115.20 concedes for the model it rests on. The qualitative conclusion — heavy primaries fluctuate much less than light ones — is robust; the number is not. *Mean* and *width* are thus two independent composition observables, and they must agree: a mean lying between the proton and iron expectations can be produced either by an intermediate species, which would have a narrow distribution, or by a mixture of protons and iron, which would have a very wide one. Auger sees the mean move heavier above the ankle *and* the width narrow, which favours a genuinely intermediate composition over a mixture [2226]. □

The consequence for Section 115.6.2 is direct and uncomfortable. If the highest-energy primaries are not protons, the suppression at the end of the spectrum cannot be read straightforwardly as photopion production on the microwave background, because Equation (115.22) allows the same break to be the maximum rigidity of the sources. That objection is stated where it belongs, in the derivation of Phenomenon 115.42.

115.4.6 Energy reconstruction and its uncertainty

Every spectrum in this chapter is a histogram of reconstructed energies, and two distinct errors act on it. Neither is small, and the statistical machinery for both is that of Chapter 11.

Counting. In an energy bin containing N events the estimator of the rate is the maximum-likelihood estimator of a Poisson mean, which by Example 11.58 is N itself with standard deviation $\sqrt{N}$. At the highest energies N is single digits: a bin with four events carries a 50 % statistical uncertainty, and no amount of care in the reconstruction improves it. This is why the exposure — area times time times solid angle, in $\mathrm{km^2\,yr\,sr}$ — is the figure of merit quoted for every observatory.

Energy scale and resolution. These act in opposite directions and must not be confused.

Proposition 115.26 (A steep spectrum converts an energy error into a flux error)**.** *Let the true differential intensity be* $J(E) = AE^{-\gamma}$.

1. *If the energy scale carries a systematic multiplicative bias, $E_{\mathrm{rec}} = (1+\epsilon)\,E$, the reconstructed integral intensity above a fixed energy is in error by the fraction*

$$\frac{\Delta J}{J} = (\gamma - 1)\,\epsilon\,, \tag{115.40}$$

   to first order in ϵ.

2. *If instead the energy is unbiased but smeared, with $\ln E_{\mathrm{rec}} = \ln E + u$ and u Gaussian of zero mean and standard deviation σ, the reconstructed differential intensity is the true one multiplied by*

$$\frac{J_{\mathrm{rec}}(E)}{J(E)} = \exp\left[\frac{(\gamma-1)^2\,\sigma^2}{2}\right] > 1\,, \tag{115.41}$$

   the same power law with an inflated normalisation. Resolution alone therefore raises *a measured flux; it never lowers it.*

Rests on Equation (115.21).

Proof. *Derives Proposition 115.26.*

For (i), $J(>E) = AE^{-(\gamma-1)}/(\gamma-1)$ by Equation (115.21). A scale bias means the flux reported at E is the true flux at $E/(1+\epsilon)$, so

$$\frac{J_{\mathrm{rec}}(>E)}{J(>E)} = (1+\epsilon)^{\gamma-1} = 1 + (\gamma-1)\,\epsilon + O\left(\epsilon^2\right)\,.$$

For (ii), change variable to $x = \ln E$. The number of events per unit x is $J(E)E = Ae^{-(\gamma-1)x}$, and smearing convolves this with a Gaussian of width σ:

$$f_{\mathrm{rec}}(x_r) = \int A\mathrm{e}^{-(\gamma-1)x}\frac{\mathrm{e}^{-(x_r-x)^2/2\sigma^2}}{\sqrt{2\pi}\sigma}\mathrm{d}x = A\mathrm{e}^{-(\gamma-1)x_r}\mathrm{e}^{(\gamma-1)^2\sigma^2/2}\,,$$

by completing the square — this is the moment generating function of a Gaussian evaluated at $\gamma - 1$. Dividing by E_r to return to a differential intensity gives Equation (115.41). The result is exact, not perturbative, and holds for any σ. □

Example 115.27 (What this costs at the end of the spectrum)**.** Above the suppression the local index is $\gamma \approx 4.5$. An energy-scale uncertainty of $\epsilon = 14\,\%$ — the Auger systematic [2241] — gives by Equation (115.40) a flux uncertainty of $3.5 \times 0.14 = 49\,\%$: a half-order-of-magnitude band on the vertical axis of every published spectrum, and much larger than the statistical error in the same bins. An energy resolution of $\sigma = 0.20$ in the logarithm gives by Equation (115.41) a flux inflation of $\exp\left(3.5^2 \times 0.04/2\right) = 1.28$, a $28\,\%$ overestimate that must be unfolded away before the spectrum is quoted. Both effects grow with γ, which is precisely why they matter most where the spectrum is steepest and the physics is most interesting.

Remark 115.28 (Stating a break honestly). The significance quoted for a spectral break — the 5σ and 6σ of Phenomenon 115.42 — is a likelihood-ratio statistic: the maximised likelihood of a broken power law against that of a single one, converted to a significance by Wilks's theorem (Theorem 11.88) and Proposition 11.93. Two cautions apply and are respected in the published analyses. First, the break energy is a free parameter that is *not* identified under the null hypothesis, which is the failure mode of Wilks's theorem discussed in Remark 11.91; the correct calibration is by simulation, and it lowers the significance. Second, the systematic of Equation (115.40) is common to all bins and so shifts the whole spectrum rather than scattering it, which means it cannot create a break — a genuinely useful fact, and the reason the suppression survives a $14\,\%$ scale uncertainty intact.

115.5 Acceleration and origin

115.5.1 The supernova-remnant hypothesis

Baade and Zwicky, in the short paper in which they proposed the neutron star, suggested that supernovae are the source of the cosmic radiation [730]; the term *super-nova* itself was introduced in the companion paper printed immediately before it in the same volume. The proposal was made before any acceleration mechanism was known, on energetic grounds alone, and the energetics remain the strongest argument for it.

Phenomenon 115.29 (Supernovae can supply the Galactic cosmic-ray power)**.** The energy density of cosmic rays in the Galaxy is about $1\,\mathrm{eV/cm^3} = 1.60 \times 10^{-13}\,\mathrm{J/m^3}$, and they escape on a time scale of about $1 \times 10^7\,\mathrm{yr}$. Sustaining that density requires a power of order $6 \times 10^{33}\,\mathrm{W}$, which is about 10 % of the kinetic power of Galactic supernovae. No other Galactic population comes within an order of magnitude of supplying it.

Rests on Equation (115.24).

Derivation. *Derives Phenomenon 115.29.*

Take the confinement volume to be a disc of radius $R = 15\,\mathrm{kpc} = 4.63 \times 10^{20}\,\mathrm{m}$ and half-thickness $h = 300\,\mathrm{pc} = 9.26 \times 10^{18}\,\mathrm{m}$:

$$V = \pi R^2\,(2h) = 1.25 \times 10^{61}\,\mathrm{m^3}\,,$$

so the stored energy is

$$U = u_{\mathrm{CR}} V = 1.602 \times 10^{-13}\,\mathrm{J/m^3} \times 1.25 \times 10^{61}\,\mathrm{m^3} = 2.0 \times 10^{48}\,\mathrm{J}\,.$$

In a steady state the injected power equals the stored energy divided by the residence time $\tau_{\mathrm{esc}} \approx 1 \times 10^7\,\mathrm{yr} = 3.16 \times 10^{14}\,\mathrm{s}$ of Section 115.5.5:

$$P_{\mathrm{CR}} = \frac{U}{\tau_{\mathrm{esc}}} = \frac{2.0 \times 10^{48}\,\mathrm{J}}{3.16 \times 10^{14}\,\mathrm{s}} = 6.3 \times 10^{33}\,\mathrm{W}\,. \tag{115.42}$$

The available power is that of the supernovae. A core-collapse supernova delivers of order $1 \times 10^{44}\,\mathrm{J}$ to the kinetic energy of its ejecta — three tenths of one percent of the $3 \times 10^{46}\,\mathrm{J}$ of gravitational binding energy released, the remaining ninety-nine and more percent leaving as the neutrino burst of Section 115.7.3 — and the Galactic rate is about two per century:

$$P_{\mathrm{SN}} = 1 \times 10^{44}\,\mathrm{J} \times \frac{2}{100\,\mathrm{yr}} = 1 \times 10^{44}\,\mathrm{J} \times 6.34 \times 10^{-10}/\mathrm{s} = 6.3 \times 10^{34}\,\mathrm{W}\,.$$

The required efficiency is therefore

$$\eta = \frac{P_{\mathrm{CR}}}{P_{\mathrm{SN}}} = \frac{6.3 \times 10^{33}\,\mathrm{W}}{6.3 \times 10^{34}\,\mathrm{W}} \approx 0.10\,, \tag{115.43}$$

ten percent of the mechanical energy of the blast wave. That is demanding but not absurd, and it is exactly what the shock acceleration of Section 115.5.3 predicts when the accelerated particles are dynamically important. Every alternative Galactic reservoir — stellar winds, pulsar rotational energy, the interstellar magnetic field — falls short of P_{CR} by an order of magnitude or more, which is why the supernova hypothesis has survived ninety years without a rival. □

An energy budget is not a detection, and for most of that ninety years the argument stopped there: supernova remnants were known to be bright in radio synchrotron emission, which proves they accelerate *electrons*, but the cosmic radiation is overwhelmingly protons and nuclei, and an electron accelerator is not evidence of a proton accelerator. The proof arrived in 2013.

Phenomenon 115.30 (Protons are accelerated in supernova remnants)**.** The gamma-ray spectra of the remnants IC 443 and W44, measured between 60 MeV and 2 GeV, show a characteristic break and low-energy turnover that is the kinematic signature of neutral-pion decay, and that no electron process reproduces [2205]. Protons and nuclei are therefore accelerated in these objects, not only electrons.

Rests on Phenomenon 115.29.

Derivation of the pion-decay signature. Derives Phenomenon 115.30.

A neutral pion at rest decays to two photons each of energy $m_{\pi^0}c^2/2 = 67.5\,\mathrm{MeV}$. Boost it to Lorentz factor γ_π: by the transformation of a null four-momentum, the photon energy in the laboratory is

$$E_\gamma = \gamma_\pi \frac{m_\pi c^2}{2}\left(1 + \beta_\pi \cos\theta^*\right) ,$$

with θ^* the emission angle in the pion frame. Because the decay is isotropic in that frame, $\cos\theta^*$ is uniform on $[-1, 1]$, so E_γ is uniformly distributed between $\gamma_\pi\left(1-\beta_\pi\right)m_\pi c^2/2$ and $\gamma_\pi\left(1+\beta_\pi\right)m_\pi c^2/2$. The distribution is flat, and in $\log E_\gamma$ it is *symmetric about* $\log\left(m_\pi c^2/2\right)$, since the two limits multiply to $\left(m_\pi c^2/2\right)^2$ whatever γ_π is. Summing over any pion spectrum preserves that symmetry point. The resulting photon spectrum therefore rises to a maximum at $E_\gamma = 67.5\,\mathrm{MeV}$ and falls below it, whatever the parent proton spectrum — the "pion bump".

No leptonic process produces such a feature. Bremsstrahlung from electrons follows the electron spectrum with no scale in it; inverse-Compton scattering likewise. The observed turnover below 200 MeV in IC 443 and W44 is thus a direct measurement of a hadronic population, and it is the observation that converts Phenomenon 115.29 from a budget into evidence [2205]. □

115.5.2 Fermi acceleration

Fermi proposed that cosmic rays gain energy by scattering repeatedly off moving magnetised clouds in the interstellar medium [929]. A magnetic field does no work, so all the energy comes from the motion of the scattering centre, and the sign of the exchange depends on whether the encounter is head-on or overtaking.

Theorem 115.31 (Second-order Fermi acceleration)**.** *A relativistic particle scattering elastically off a randomly moving cloud of speed $V \ll c$, isotropised in the cloud frame, gains on average the fraction*

$$\left\langle \frac{\Delta E}{E} \right\rangle = \frac{4}{3}\left(\frac{V}{c}\right)^2 \tag{115.44}$$

of its energy per encounter. The gain is second *order in V/c, because head-on and overtaking encounters cancel at first order and only the excess of head-on encounters survives.*

Rests on Definition 40.1 and Equation (40.3).

Proof. Derives Theorem 115.31.

Write $\beta_V = V/c$ and $\gamma_V = \left(1-\beta_V^2\right)^{-1/2}$, and let θ be the angle in the laboratory between the particle's direction and the cloud's velocity. Transforming the particle's energy into the cloud frame (a boost, as in Section 40.1),

$$E' = \gamma_V E\left(1 - \beta_V \cos\theta\right) ,$$

for an ultrarelativistic particle, $pc = E$. The scattering is elastic in the cloud frame — the field does no work there — so $E'' = E'$ with a new direction θ'', and transforming back,

$$E_f = \gamma_V E''\left(1 + \beta_V \cos\theta''\right) = \gamma_V^2 E\left(1 - \beta_V\cos\theta\right)\left(1 + \beta_V\cos\theta''\right) .$$

Isotropisation in the cloud frame gives $\langle \cos\theta'' \rangle = 0$, so

$$\left\langle \frac{\Delta E}{E} \right\rangle = \gamma_V^2 \left(1 - \beta_V \langle \cos\theta \rangle\right) - 1 \,.$$

The laboratory angles are not uniformly sampled: the rate of encounters with a cloud approaching at angle θ is proportional to the relative closing speed, $\propto (1 - \beta_V \cos\theta)$, so

$$\langle \cos\theta \rangle = \frac{\int_{-1}^{1} \mu \,(1 - \beta_V \mu)\, \mathrm{d}\mu}{\int_{-1}^{1} (1 - \beta_V \mu)\, \mathrm{d}\mu} = \frac{-\frac{2}{3}\beta_V}{2} = -\frac{\beta_V}{3} \,.$$

Head-on encounters, which gain energy, are commoner than overtaking ones, which lose it. Hence

$$\left\langle \frac{\Delta E}{E} \right\rangle = \frac{1 + \frac{1}{3}\beta_V^2}{1 - \beta_V^2} - 1 = \frac{4}{3}\beta_V^2 + O\left(\beta_V^4\right) \,,$$

which is Equation (115.44). □

Remark 115.32 (Why the second-order mechanism is not the answer). Interstellar clouds move at $V \approx 30\,\mathrm{km/s}$, so $\beta_V = 1 \times 10^{-4}$ and Equation (115.44) gives 1.3×10^{-8} per encounter. With a scattering mean free path of order a parsec the encounter interval is $1\,\mathrm{pc}/c = 3.3\,\mathrm{yr}$, so the energy e-folding time is

$$t_{\mathrm{acc}} \approx \frac{3.3\,\mathrm{yr}}{1.3 \times 10^{-8}} = 2.4 \times 10^{8}\,\mathrm{yr} \,,$$

some twenty-five times longer than the residence time $\tau_{\mathrm{esc}} \approx 1 \times 10^{7}\,\mathrm{yr}$ of Section 115.5.5. The particles leave the Galaxy long before they are accelerated. Worse, the predicted spectral index depends on the ratio $t_{\mathrm{acc}}/\tau_{\mathrm{esc}}$, which is a free parameter with no reason to take the same value in different regions, so the mechanism does not explain why the spectrum is a power law of one universal index. Both objections are removed at a stroke if the scattering centres approach the particle systematically rather than randomly, which is what a shock provides.

115.5.3 Diffusive shock acceleration

A supernova blast wave is a strong shock: a discontinuity across which the fluid speed drops and the density rises, propagating into the interstellar medium at $u_1 \approx 1 \times 10^{7}\,\mathrm{m/s}$. Magnetic irregularities are frozen into the fluid on both sides, so a particle crossing the shock finds the scattering centres on the far side approaching it — *whichever way it crosses.* Every crossing is head-on, and the first-order cancellation of Theorem 115.31 is gone.

Theorem 115.33 (The spectrum from a strong shock)**.** *Let a shock have upstream speed u_1 and downstream speed u_2 in the shock frame, with compression ratio $r = u_1/u_2$. A particle that repeatedly crosses and recrosses gains, per complete cycle,*

$$\xi := \left\langle \frac{\Delta E}{E} \right\rangle = \frac{4}{3}\,\frac{u_1 - u_2}{c} \,, \tag{115.45}$$

first order in the speeds, and escapes downstream with probability

$$P_{\mathrm{esc}} = \frac{4u_2}{c} \tag{115.46}$$

per cycle. The resulting integral spectrum is a power law

$$N(>E) \propto E^{-3/(r-1)} \,, \qquad \frac{\mathrm{d}N}{\mathrm{d}E} \propto E^{-\gamma_s} \,, \qquad \gamma_s = 1 + \frac{3}{r-1} = \frac{r+2}{r-1} \,, \tag{115.47}$$

and for a strong shock in a monatomic gas, $r = 4$ and $\gamma_s = 2$ — independently of the shock speed, the magnetic field and every other detail.

Rests on Theorem 115.31.

Proof. *Derives Theorem 115.33.*

The gain. Transform to the frame of the upstream fluid. The downstream fluid approaches it at speed $u_1 - u_2$, so a particle that crosses into the downstream region and is isotropised there undergoes exactly the calculation of Theorem 115.31 with $\beta_V = (u_1 - u_2)/c$, but with one difference: the crossing is always head-on, so the average over $\cos\theta$ is taken over the *flux* of particles crossing a plane, whose distribution is $\propto \mu\,\mathrm{d}\mu$ on $[0,1]$, giving $\langle\mu\rangle = \frac{2}{3}$. Each of the two crossings that make a cycle contributes $\beta_V\langle\mu\rangle = \frac{2}{3}\beta_V$, so $\xi = \frac{4}{3}\beta_V$, which is Equation (115.45). The result is first order because the approach is systematic: there are no overtaking encounters to cancel it.

The escape. Downstream the particles are isotropic in the fluid frame and their flux onto the shock from behind is $nc/4$, the standard one-sided flux of an isotropic gas. They are simultaneously carried away from the shock by the downstream flow at the rate nu_2. The fraction lost per cycle is the ratio,

$$P_{\mathrm{esc}} = \frac{nu_2}{nc/4} = \frac{4u_2}{c}\,,$$

which is Equation (115.46). Note that neither ξ nor P_{esc} depends on the particle's energy. That is the whole reason the spectrum is a power law.

The spectrum. After k cycles a particle has energy $E_k = E_0(1+\xi)^k$ and the number surviving is $N_k = N_0(1-P_{\mathrm{esc}})^k$. Eliminating k,

$$\frac{\ln(N_k/N_0)}{\ln(E_k/E_0)} = \frac{\ln(1-P_{\mathrm{esc}})}{\ln(1+\xi)} \approx -\frac{P_{\mathrm{esc}}}{\xi}\,,$$

so $N(>E) \propto E^{-P_{\mathrm{esc}}/\xi}$ with

$$\frac{P_{\mathrm{esc}}}{\xi} = \frac{4u_2/c}{\frac{4}{3}(u_1-u_2)/c} = \frac{3u_2}{u_1-u_2} = \frac{3}{r-1}\,,$$

which is Equation (115.47); the differential index is one greater.

The compression ratio. Work in the shock frame, where the flow is steady, and impose conservation of mass, momentum and energy across the discontinuity — the Rankine–Hugoniot conditions, which belong to the fluid mechanics of Section 31.10.2:

$$\rho_1 u_1 = \rho_2 u_2 =: j\,, \qquad P_1 + \rho_1 u_1^2 = P_2 + \rho_2 u_2^2\,, \qquad h_1 + \tfrac{1}{2}u_1^2 = h_2 + \tfrac{1}{2}u_2^2\,,$$

with the specific enthalpy of an ideal gas $h = \gamma_{\mathrm{ad}}P/[(\gamma_{\mathrm{ad}}-1)\rho]$. A *strong* shock is one whose upstream pressure is negligible, $P_1 \to 0$ and hence $h_1 \to 0$; the momentum condition then gives $P_2 = j(u_1-u_2)$, and substituting this and $\rho_2 = j/u_2$ into the energy condition,

$$\frac{u_1^2 - u_2^2}{2} = \frac{\gamma_{\mathrm{ad}}P_2u_2}{(\gamma_{\mathrm{ad}}-1)j} = \frac{\gamma_{\mathrm{ad}}(u_1-u_2)u_2}{\gamma_{\mathrm{ad}}-1}\,.$$

Cancelling the common factor $u_1 - u_2$, which is non-zero for a genuine shock, leaves $u_1 + u_2 = 2\gamma_{\mathrm{ad}}u_2/(\gamma_{\mathrm{ad}}-1)$ and therefore

$$r = \frac{u_1}{u_2} = \frac{\gamma_{\mathrm{ad}}+1}{\gamma_{\mathrm{ad}}-1} = \frac{5/3+1}{5/3-1} = 4 \tag{115.48}$$

for a monatomic ionised gas, whence $\gamma_s = 2$. □

The independence of Equation (115.47) from every parameter except r is what makes the mechanism credible, and it is why the result was found independently and almost simultaneously by several groups [1614, 1616]. It also answers Phenomenon 115.11: a featureless power law over eleven decades requires an energy-independent gain and an energy-independent escape, and a strong shock supplies both.

Proposition 115.34 (Propagation steepens the source spectrum)**.** *If sources inject a spectrum $Q(E) \propto E^{-\gamma_s}$ into a Galaxy from which particles escape on a rigidity-dependent time scale $\tau_{\rm esc} \propto R^{-\delta}$, the steady-state spectrum observed is*

$$J(E) \propto Q(E)\tau_{\rm esc}(E) \propto E^{-(\gamma_s+\delta)}\,. \tag{115.49}$$

Rests on Equations (115.1) *and* (115.25)*.*

Proof. *Derives Proposition 115.34.*

In a steady state the number density at energy E satisfies injection equals escape: $Q(E) = n(E)/\tau_{\rm esc}(E)$, so $n(E) = Q(E)\tau_{\rm esc}(E)$, and the intensity is $J = nc/4\pi$ for an isotropic distribution. Since the particles are ultrarelativistic, $R = E/(Ze)$ and the rigidity dependence is an energy dependence at fixed Z. □

Remark 115.35 (The arithmetic does not close, and saying so is the point). Put the two results together. Theorem 115.33 gives $\gamma_s = 2$; the boron-to-carbon measurement Equation (115.25) gives $\delta = 0.333 \pm 0.014$ [2266]; Equation (115.49) therefore predicts an observed index of 2.33 ± 0.02. The measured index below the knee is 2.7. The discrepancy is 0.37 in the exponent, which over the four decades between 10 GeV and 1×10^{14} eV is a factor of $10^{4\times 0.37} = 30$ in flux — far outside any uncertainty in either input.

Something in the chain is wrong, and the candidates are known: the test-particle assumption behind Theorem 115.33 fails when the accelerated particles carry a tenth of the shock's energy, as Equation (115.43) requires them to, and their pressure modifies the shock structure so that r and hence γ_s become energy dependent; and the escape time inferred from secondary nuclei is an average over the Galaxy that need not describe the region where the sources are. This chapter does not adjudicate between them. It records that diffusive shock acceleration explains the *existence* and the *universality* of the power law, and does not yet explain its *index*.

Derivation of the maximum energy. *Derives Equation* (115.51)*.*

The mechanism has a limit, and it is the reason the knee exists in the first reading of Remark 115.14. The time to complete one cycle is set by how far the particle diffuses from the shock before returning. Consider the upstream side. The flow sweeps the particles onto the shock at speed u_1 while diffusion carries them away from it, and the balance $u_1 n = D_1\,{\rm d}n/{\rm d}x$ gives a precursor of scale length D_1/u_1, hence a column nD_1/u_1 of particles per unit area waiting to recross. They recross at the one-sided isotropic flux $nc/4$ already used in Equation (115.46), so the mean time spent upstream per crossing is $(nD_1/u_1)\,/\,(nc/4) = 4D_1/(u_1 c)$, and the same argument downstream gives $4D_2/(u_2 c)$. One complete cycle therefore takes

$$t_{\rm cyc} = \frac{4}{c}\left(\frac{D_1}{u_1} + \frac{D_2}{u_2}\right),$$

and since each cycle multiplies the energy by $1+\xi$ with the ξ of Equation (115.45), the time to raise the energy by one e-folding is $t_{\rm acc} = t_{\rm cyc}/\xi$, that is

$$t_{\rm acc} = \frac{3}{u_1 - u_2}\left(\frac{D_1}{u_1} + \frac{D_2}{u_2}\right).$$

Taking the same diffusion coefficient D on both sides and $r = 4$, so that $u_2 = u_1/4$ and $u_1 - u_2 = 3u_1/4$, the bracket is $5D/u_1$ and

$$t_{\rm acc} = \frac{20\,D}{u_1^2}\,, \qquad D = \frac{r_L c}{3} = \frac{E}{3ZeB}\,, \tag{115.50}$$

the second expression being the smallest diffusion coefficient a magnetic field permits, the Bohm value, obtained when the scattering mean free path equals the gyroradius of Equation (115.8). Setting t_{acc} equal to the lifetime T of the shock,

$$E_{\max} = \frac{3ZeB\,u_1^2 T}{20}\,. \tag{115.51}$$

With $Z = 1$, $u_1 = 1 \times 10^7\,\mathrm{m/s}$, $T = 1000\,\mathrm{yr} = 3.16 \times 10^{10}\,\mathrm{s}$ and the ambient interstellar field $B = 3 \times 10^{-10}\,\mathrm{T}$,

$$E_{\max} = 2.3 \times 10^{-5}\,\mathrm{J} = 1.4 \times 10^{14}\,\mathrm{eV}\,,$$

a factor of twenty below the knee at $3 \times 10^{15}\,\mathrm{eV}$. The mechanism as stated therefore fails to reach the knee. It succeeds if the field at the shock is amplified above the ambient value by a factor of order 30: with $B = 1 \times 10^{-8}\,\mathrm{T}$, Equation (115.51) gives $E_{\max} = 4.7 \times 10^{15}\,\mathrm{eV}$, which does reach it. Such amplification is observed — the X-ray synchrotron filaments at young remnant shocks are thin, and their thinness measures a downstream field of order $1 \times 10^{-8}\,\mathrm{T}$ — and the physical mechanism proposed for it is a streaming instability driven by the accelerated particles themselves. □

Derivation pending #206

The non-resonant streaming instability by which the accelerated particles amplify the magnetic field at the shock, and the saturation level that fixes $[B]$ in the maximum-energy estimate. Belongs in Appendix A; the estimate in this chapter takes the amplified field from the X-ray filament observations instead of deriving it

115.5.4 The Hillas criterion and candidate sources

Whatever the mechanism, an accelerator cannot confine a particle whose gyroradius exceeds its own size. That single observation, due to Hillas [1741], excludes most of the astrophysical zoo at the highest energies and it does so with no assumption about how the acceleration works.

Theorem 115.36 (The Hillas criterion)**.** *An accelerator of characteristic size L containing a magnetic field B, whose scattering centres move with speed βc, cannot accelerate a nucleus of charge Ze beyond*

$$E_{\max} = Ze\,\beta\,B\,L\,c\,, \tag{115.52}$$

an SI energy in joules when B is in tesla and L in metres. Equivalently the maximum rigidity of Equation (115.1) is $R_{\max} = \beta BLc$, in volts.

Rests on Equations (115.1), (115.8) and (115.45).

Proof. *Derives Theorem 115.36.*

By Equation (115.8) a particle of rigidity R has a gyroradius $r_L = R/(cB)$. It remains in the accelerating region only while $r_L \le L$, i.e. while $R \le BLc$; beyond that it leaves in less than one gyration and cannot be turned back. The factor β enters because the energy gain per crossing is first order in the speed of the scattering centres (Equation (115.45)), so a slow shock requires many crossings and loses a corresponding factor. Converting rigidity to energy with $E = ZeR$ gives Equation (115.52). Dimensionally, $[Ze]\,[B]\,[L]\,[c] = \mathrm{C \cdot T \cdot m \cdot m/s} = \mathrm{J}$, as required. □

Example 115.37 (The criterion applied)**.** Evaluating Equation (115.52) for $Z = 1$:

Object	B (T)	L (m)	β	$E_{\max}$ (eV)
Neutron star	1×10^{8}	1×10^{4}	1	3×10^{20}
Supernova remnant shock	1×10^{-8}	3.1×10^{17}	0.03	2.8×10^{16}
Active-galaxy jet (parsec scale)	1×10^{-7}	3.1×10^{16}	1	9×10^{17}
Radio-galaxy lobe	1×10^{-9}	3.1×10^{21}	1	9×10^{20}
Cluster accretion shock	1×10^{-10}	3.1×10^{22}	0.003	2.8×10^{18}
Galactic disc (for comparison)	3×10^{-10}	4.6×10^{20}	1	4×10^{19}

Only two entries reach 1×10^{20} eV for a proton, and each has a difficulty. The neutron-star value assumes the whole magnetospheric potential is available to one particle, which radiative losses in that field forbid. The radio-galaxy lobe is a plausible site but the nearest such object is tens of megaparsecs away, which the horizon of Section 115.6.1 makes marginal. Note also that Equation (115.52) scales with Z, so an iron nucleus reaches 26 times the plotted energy, which is why the composition result of Phenomenon 115.25 changes the shortlist.

Remark 115.38 (No source of the highest-energy rays is identified). This is the honest state of the subject. The Hillas criterion tells us which objects are *not* excluded; it identifies nothing. The anisotropy of Section 115.6.3 establishes that the highest-energy particles come from outside the Galaxy and no more. Correlations of arrival directions with catalogues of nearby active galaxies and starburst galaxies have been reported at significances between 3σ and 4σ and have neither strengthened decisively nor gone away with additional exposure. This chapter therefore names candidates and states that none is established.

115.5.5 Galactic propagation and confinement

Between the source and the detector the particles diffuse through the Galactic magnetic field. The simplest description that fits the data is the *leaky box*: the Galaxy is treated as a container of uniform density from which particles escape with a constant probability per unit time, $1/\tau_{\mathrm{esc}}$. It has one free function, $\tau_{\mathrm{esc}}(R)$, and two independent measurements of it.

The first is the grammage of Equation (115.24): the traversed matter is $X = \bar{m} n \, c \, \tau_{\mathrm{esc}}$ for a particle moving at essentially c through gas of number density n, so

$$\tau_{\mathrm{esc}} = \frac{X}{\bar{m} n c} = \frac{84\,\mathrm{kg/m^2}}{1.673 \times 10^{-27}\,\mathrm{kg} \times 3 \times 10^{5}/\mathrm{m^3} \times 2.998 \times 10^{8}\,\mathrm{m/s}} = 5.6{\times}10^{14}\,\mathrm{s} = 1.8{\times}10^{7}\,\mathrm{yr}\,, \tag{115.53}$$

where the effective density $n \approx 3 \times 10^{5}/\mathrm{m^3}$ (that is $0.3/\mathrm{cm^3}$) is the disc density averaged over a trajectory that spends most of its time in the low-density halo. That average is the weak point of the estimate, and it is why a second, independent measurement matters.

The second is a clock. Beryllium-10 is produced by the same spallation that produces boron, and it is radioactive with a half-life of 1.39×10^{6} yr, that is a mean life $\tau_{1/2}/\ln 2 = 2.0 \times 10^{6}$ yr. If the residence time were much shorter than this, all the ^{10}Be produced would still be present and the measured $^{10}\mathrm{Be}/^{9}\mathrm{Be}$ ratio would equal the production ratio; if it were much longer, essentially none would survive. The observed ratio is suppressed by a factor of several relative to production, which requires

$$\tau_{\mathrm{esc}} \approx 1.5 \times 10^{7}\,\mathrm{yr} = 4.7 \times 10^{14}\,\mathrm{s}\,,$$

in agreement with Equation (115.53) and independent of the assumed gas density — which is what makes the agreement informative rather than circular. The corresponding diffusion

coefficient, for a halo of half-height $H \approx 3\,\mathrm{kpc} = 9.3 \times 10^{19}\,\mathrm{m}$, is

$$D \approx \frac{H^2}{2\tau_{\mathrm{esc}}} = \frac{(9.3 \times 10^{19}\,\mathrm{m})^2}{2 \times 4.7 \times 10^{14}\,\mathrm{s}} \approx 1 \times 10^{25}\,\mathrm{m^2/s}\,, \tag{115.54}$$

some thirty orders of magnitude above the self-diffusion coefficient of a gas at room temperature and atmospheric pressure, which is of order $2 \times 10^{-5}\,\mathrm{m^2/s}$, and rising as R^{δ} with the $\delta = 0.333 \pm 0.014$ of Equation (115.25) [2266]. Standard treatments of the whole transport problem, of which the leaky box is the crudest useful limit, are in [2271].

Remark 115.39 (Why charged cosmic rays are not astronomy). Equation (115.54) is also the end of any hope of pointing with them. A particle that diffuses for $1.5 \times 10^{7}\,\mathrm{yr}$ before leaving the Galaxy has had its direction randomised completely: by Equation (115.23) a $1 \times 10^{15}\,\mathrm{eV}$ proton in $3 \times 10^{-10}\,\mathrm{T}$ has a gyroradius of 0.36 pc, utterly negligible against the kiloparsec scales of the Galaxy, so its arrival direction retains no memory whatever of its source. Only above $1 \times 10^{19}\,\mathrm{eV}$, where Phenomenon 115.15 gives gyroradii of kiloparsecs, does any directional information survive — and there the sources are extragalactic and the intervening extragalactic fields are poorly known. This is the reason the subject needs neutral messengers, and Section 115.7 is about them.

115.6 The end of the spectrum

115.6.1 The Greisen–Zatsepin–Kuz'min prediction

Within two years of the discovery of the cosmic microwave background, Greisen [1330] and, independently, Zatsepin and Kuz'min [1339] pointed out that it makes intergalactic space opaque to protons above a definite energy. The argument is pure relativistic kinematics applied to a measured photon bath, and it is one of the sharpest predictions in astrophysics: it uses no unknown source, no unknown field, and no free parameter.

Phenomenon 115.40 (Intergalactic space is opaque to the highest-energy protons)**.** A proton propagating through the 2.725 48 K microwave background of Phenomenon 51.3 loses energy by photopion production, $p + \gamma \to \Delta^{+} \to p + \pi^{0}$ or $n + \pi^{+}$, once its energy exceeds a threshold of order $1 \times 10^{20}\,\mathrm{eV}$ against a typical background photon and a few times $1 \times 10^{19}\,\mathrm{eV}$ against the high-energy tail of the bath. The energy-loss length above the threshold is of order tens of megaparsecs, far smaller than the Hubble radius, so the sources of any observed particle above the threshold must lie within that distance [1330, 1339, 1385].

Rests on Phenomenon 51.3 and Equation (40.12).

Derivation of the threshold. *Derives Phenomenon 115.40.*

Let a proton of energy E and momentum $p = \sqrt{E^2/c^2 - m_p^2 c^2}$ meet a photon of energy E_γ head-on. The invariant mass of the pair is given by Equation (40.12):

$$s = (p_p + p_\gamma)^2\, c^2 = m_p^2 c^4 + 2\,(E E_\gamma + p c E_\gamma) \longrightarrow m_p^2 c^4 + 4 E E_\gamma\,, \tag{115.55}$$

the limit being the ultrarelativistic one, $pc \to E$; for a general collision angle θ the last term is $2EE_\gamma\,(1 - \cos\theta)$, maximal head-on. Photopion production $p + \gamma \to N + \pi$ is kinematically possible once $\sqrt{s} \geq (m_N + m_\pi)\,c^2$, and the lowest such threshold is the $p\pi^0$ channel. Solving Equation (115.55),

$$E \geq E_{\mathrm{th}} = \frac{m_\pi c^2\,(2 m_p c^2 + m_\pi c^2)}{4 E_\gamma}\,. \tag{115.56}$$

The photon bath is measured, not assumed. Its temperature is $T_0 = (2.725\,48 \pm 0.000\,57)\,\mathrm{K}$ [2144], so

$$k_B T_0 = 1.380\,649 \times 10^{-23}\,\mathrm{J/K} \times 2.725\,48\,\mathrm{K} = 3.7629 \times 10^{-23}\,\mathrm{J} = 2.348\,69 \times 10^{-4}\,\mathrm{eV}\,,$$

and the mean energy of a Planck photon is

$$\langle E_\gamma \rangle = \frac{\pi^4}{30\zeta(3)} k_B T_0 = 2.70118\, k_B T_0 = 6.344 \times 10^{-4}\,\mathrm{eV} = 1.0164 \times 10^{-22}\,\mathrm{J}\,, \tag{115.57}$$

while their number density is

$$n_\gamma = 16\pi\zeta(3) \left(\frac{k_B T_0}{hc}\right)^3 = 4.107 \times 10^8/\mathrm{m}^3 = 411/\mathrm{cm}^3\,. \tag{115.58}$$

With $m_p c^2 = 938.272\,\mathrm{MeV}$ and $m_{\pi^0} c^2 = 134.977\,\mathrm{MeV}$ [2427], Equation (115.56) gives

$$E_{\mathrm{th}} = \frac{1.349\,77 \times 10^8\,\mathrm{eV} \times 2.011\,52 \times 10^9\,\mathrm{eV}}{4 \times 6.344 \times 10^{-4}\,\mathrm{eV}} = 1.07 \times 10^{20}\,\mathrm{eV} = 17.1\,\mathrm{J}\,,$$

and the same calculation with the $\Delta(1232)$ mass in place of $(m_p + m_\pi)$ puts the resonance *peak* at $2.5 \times 10^{20}\,\mathrm{eV}$. □

Derivation of the onset against the Planck tail. A threshold computed with the mean photon energy is not the energy at which the effect begins, because the Planck distribution has a tail. At proton energy E the reaction proceeds on any photon with $E_\gamma \geq \varepsilon_{\mathrm{th}}(E)$, where by Equation (115.56) $\varepsilon_{\mathrm{th}} = m_\pi c^2 \left(2 m_p c^2 + m_\pi c^2\right)/(4E)$. Writing $x = \varepsilon_{\mathrm{th}}/\left(k_B T_0\right)$, the fraction of the bath above that energy is

$$\frac{n_\gamma(>x)}{n_\gamma} = \frac{1}{2\zeta(3)} \int_x^\infty \frac{u^2\,\mathrm{d}u}{\mathrm{e}^u - 1} \approx \frac{\mathrm{e}^{-x}\left(x^2 + 2x + 2\right)}{2\zeta(3)}\,, \tag{115.59}$$

the approximation being the leading term of the expansion of $(\mathrm{e}^u - 1)^{-1}$, excellent for $x \gtrsim 3$. At $E = 5 \times 10^{19}\,\mathrm{eV}$, $\varepsilon_{\mathrm{th}} = 1.36 \times 10^{-3}\,\mathrm{eV}$ and $x = 5.78$, so Equation (115.59) gives 6.0 %: six percent of the bath, that is $2.5 \times 10^7/\mathrm{m}^3$ photons, are already above threshold. At $E = 1 \times 10^{20}\,\mathrm{eV}$, $x = 2.89$ and the fraction is 37 %. The onset of the suppression is therefore expected in the range $4 \times 10^{19}\,\mathrm{eV}$ to $1 \times 10^{20}\,\mathrm{eV}$, and not at the nominal $1.07 \times 10^{20}\,\mathrm{eV}$ — which is where the observed break in Phenomenon 115.42 lies. □

Order-of-magnitude derivation of the horizon. The mean free path is $\ell = 1/\left(n_{\mathrm{eff}}\sigma\right)$ with n_{eff} the density of above-threshold photons and σ the photopion cross section, which near the Δ peak is about $5 \times 10^{-32}\,\mathrm{m}^2$, that is 500 microbarn. At $E = 1 \times 10^{20}\,\mathrm{eV}$ the fraction above threshold is 37 %, so $n_{\mathrm{eff}} = 1.5 \times 10^8/\mathrm{m}^3$ and

$$\ell = \frac{1}{1.5 \times 10^8/\mathrm{m}^3 \times 5 \times 10^{-32}\,\mathrm{m}^2} = 1.3 \times 10^{23}\,\mathrm{m} = 4\,\mathrm{Mpc}\,.$$

Each interaction removes only the fraction $\kappa \approx 0.2$ of the proton's energy — the inelasticity, fixed by the kinematics of Equation (115.17) applied to the Δ decay — so the *energy-loss* length is $\ell/\kappa \approx 20\,\mathrm{Mpc}$. This estimate is crude in two ways that both push it upward: it uses the resonance-peak cross section for every above-threshold photon, and it treats every collision as head-on rather than averaging over angle. The proper calculation, integrating the measured cross section over the Planck spectrum and over angle, gives an energy-loss length of order 100 Mpc at $1 \times 10^{20}\,\mathrm{eV}$, falling to a few tens of megaparsecs above it [1385].

Either number is small in the only comparison that matters. The Hubble radius is

$$\frac{c}{H_0} = \frac{2.998 \times 10^5\,\mathrm{km/s}}{67.4\,\mathrm{km/s/Mpc}} = 4.4 \times 10^3\,\mathrm{Mpc}\,,$$

with H_0 from [2348]. A particle above the threshold therefore reaches us from at most one or two percent of the radius of the observable universe: the sky at these energies is a local sky, and if a source is identified it will be a nearby one. □

Derivation pending #207

The photopion energy-loss length as a proper integral of the measured $p\gamma$ cross section over the Planck spectrum and over collision angle, replacing the order-of-magnitude estimate given here. Belongs in Appendix A

Remark 115.41 (Nuclei are attenuated too, but differently). For a nucleus the relevant process is not photopion production but photodisintegration through the giant dipole resonance, which sits at a photon energy of about 20 MeV *in the nucleus rest frame*. A photon of laboratory energy E_γ appears in that frame boosted by up to 2γ, so the threshold is

$$\gamma \gtrsim \frac{20\,\mathrm{MeV}}{2 \times 6.34 \times 10^{-4}\,\mathrm{eV}} = 1.6 \times 10^{10}\,,$$

that is 1.5×10^{19} eV per nucleon, and hence 8×10^{20} eV for an iron nucleus of $A = 56$. A heavy primary therefore survives to a *higher total energy* than a proton, and its attenuation, when it sets in, proceeds by shedding nucleons rather than by losing a fifth of its energy at a stroke. The shape of the predicted suppression consequently depends on the composition, which is exactly the loophole Section 115.4.5 opened and Phenomenon 115.42 must respect.

115.6.2 The observed suppression

Phenomenon 115.42 (Suppression at the highest energies)**.** The flux falls below the extrapolation of Equation (115.20) above a few times 1×10^{19} eV: a break at about 5.6×10^{19} eV with a significance near 5σ [2115], and a suppression above about 4×10^{19} eV at more than 6σ [2116], measured by two observatories with different techniques. Individual events well above the break exist, including one of $(3.2 \pm 0.9) \times 10^{20}$ eV [1895].

Rests on Equations (115.20) *and* (115.59) *and Phenomenon 115.40.*

Derivation and its limits. *Derives Phenomenon 115.42.*

The predicted position is Equation (115.56) softened by the Planck tail, Equation (115.59): an onset between 4×10^{19} eV and 1×10^{20} eV. The two measurements bracket that range. The HiRes fluorescence detectors found the spectrum to break at 5.6×10^{19} eV $= 9.0$ J, the break being significant at about five standard deviations against a continued power law [2115]; the Pierre Auger Observatory, with a larger exposure and the hybrid calibration of Section 115.4.3, found the flux above 4×10^{19} eV $= 6.4$ J to be suppressed relative to the extrapolation at more than six standard deviations [2116]. The two techniques share no systematic, which is why the joint statement is stronger than either.

That events exist above the break is not a contradiction; it is required. Attenuation is exponential in distance, not a wall, so a source within 20 Mpc can deliver a particle of any energy its accelerator reaches. The Fly's Eye event of $(3.2 \pm 0.9) \times 10^{20}$ eV $= (51 \pm 14)$ J [1895] is such a particle, and its existence constrains its own source to lie within the horizon of Phenomenon 115.40 — which is a strong statement, since no candidate accelerator is known within that distance.

The inference is nevertheless not closed, and the reason is Remark 115.41 together with Phenomenon 115.25. If the primaries at these energies are nuclei rather than protons, the same break is produced, equally well, by the maximum rigidity of the sources through Equation (115.22): an accelerator limited to $R_{\max} \approx 5 \times 10^{18}$ V delivers protons to 5×10^{18} eV and iron to 1.3×10^{20} eV, and the superposition of the elemental cutoffs mimics a propagation suppression. The measurement therefore establishes that the spectrum is suppressed; it does not by itself establish that the mechanism is the one Greisen, Zatsepin and Kuz'min predicted. Distinguishing them requires the composition above the break, which is where the current data are weakest, and the appearance of the cosmogenic neutrinos that photopion production must also produce, which have not been detected. □

Remark 115.43 (The AGASA disagreement, and what settled it). For a decade the field held two incompatible measurements: AGASA, a scintillator array in Japan, reported a spectrum *continuing* unbroken past 1×10^{20} eV with eleven events there, while HiRes reported the break. Both could not be right. The disagreement was resolved not by a new argument but by the energy-scale analysis of Proposition 115.26: a scintillator array infers energy from a simulation of the shower's particle content at the ground, a fluorescence detector measures it calorimetrically by Equation (115.35), and the two scales differed by some 20 %. By Equation (115.40) with $\gamma \approx 4.5$, a 20 % scale difference moves the flux by 70 % and moves events across a threshold; the Auger hybrid design, which measures both ways on the same showers, was built to remove exactly this ambiguity, and it did.

115.6.3 Anisotropy at the highest energies

Phenomenon 115.44 (A large-scale dipole above 8×10^{18} electronvolts)**.** The arrival directions of cosmic rays above 8×10^{18} eV are not isotropic: they carry a dipole of amplitude about 6.5 % whose direction lies some 125° away from the Galactic centre, with a chance probability below 10^{-6} [2276]. A dipole pointing away from the Galactic centre is not what a Galactic source population produces; the origin of these particles is extragalactic.

Rests on Theorem 11.46 and Definition 11.80.

Derivation: why a few percent is a detection. *Derives Phenomenon 115.44.*

Let N events arrive with right ascensions φ_i, and form the first-harmonic amplitudes

$$a = \frac{2}{N}\sum_{i=1}^{N}\cos\varphi_i\,, \qquad b = \frac{2}{N}\sum_{i=1}^{N}\sin\varphi_i\,, \qquad r = \sqrt{a^2+b^2}\,.$$

Under isotropy each φ_i is uniform, so $\sum\cos\varphi_i$ and $\sum\sin\varphi_i$ are sums of N independent zero-mean terms of variance $\frac{1}{2}$ each; by the central limit theorem (Theorem 11.46) they are Gaussian of variance $N/2$, and independent. Then $Na^2/2$ and $Nb^2/2$ are independent χ^2 variables of one degree of freedom (Definition 11.80), so $Nr^2/2$ is χ^2 with two, i.e. exponential, and

$$P\,(>r) = \exp\!\left(-\frac{Nr^2}{4}\right)\,. \tag{115.60}$$

This is the Rayleigh probability. With the $N \approx 3.2 \times 10^4$ events recorded above 8×10^{18} eV and $r = 0.065$, Equation (115.60) gives $\exp(-33.8)$, a number so small that it is not the quoted result: the published chance probability is far more conservative, because a three-dimensional dipole must be reconstructed from an exposure that does not cover the whole sky, and the declination component is measured much less well than the right-ascension component. Equation (115.60) shows *why* a percent-level anisotropy is measurable at all with tens of thousands of events — the sensitivity goes as $N^{-1/2}$, so 3×10^4 events probe amplitudes near 1 % — and the published 10^{-6} is the honest number after the exposure is accounted for [2276]. □

Remark 115.45 (What survives magnetic deflection). It is not an accident that a dipole and not a set of point sources is what is seen. By Equation (115.23) a proton of 8×10^{18} eV crossing the Galaxy in a 3×10^{-10} T field has a gyroradius of 2.9 kpc, and the deflection over a path of a few kiloparsecs is therefore tens of degrees; for an iron nucleus, $Z = 26$, it is larger by that factor and the direction is lost entirely. The extragalactic fields add more, and are less well known. The result is that a genuinely anisotropic extragalactic source distribution is smeared into precisely the lowest multipole that survives — a dipole. The absence of a confirmed point source is therefore expected, not anomalous, and no honest reading of the present data identifies one (Remark 115.38).

115.7 Neutral messengers

115.7.1 Gamma-ray astronomy

A photon travels in a straight line. Above the atmosphere, a gamma ray is detected by letting it convert to an e^+e^- pair in a thin foil, tracking the pair to reconstruct the incoming direction, and stopping it in a calorimeter to measure the energy. That is the Large Area Telescope on the Fermi observatory: a tungsten-and-silicon pair-conversion tracker over a caesium-iodide calorimeter, covering 20 MeV to above 300 GeV with a field of view of 2.4 sr, so that it surveys the entire sky every two orbits [2141]. Above about 100 GeV the flux is too small for any instrument that can be flown, and the ground-based Cherenkov technique of Section 115.4.4 takes over, using the atmosphere as the converter and the calorimeter both.

Two results define the current reach. The MAGIC telescopes detected teraelectronvolt emission from the gamma-ray burst GRB 190114C, establishing that the most violent transients accelerate particles to those energies [2326]. And LHAASO, a kilometre-scale array on the Tibetan plateau, detected photons up to $1.4\,\mathrm{PeV} = 2.24 \times 10^{-4}\,\mathrm{J}$ from twelve sources within the Galaxy [2376].

Phenomenon 115.46 (PeV accelerators exist in the Galaxy)**.** Photons of energy up to 1.4 PeV arrive from twelve identified Galactic sources [2376]. Whatever population produces them accelerates parent particles to at least that energy, and in the hadronic case to more than ten times it — which places accelerators reaching the knee of Phenomenon 115.13 inside the Galaxy.

Rests on Phenomenon 115.13 and Equation (115.57).

Derivation of the parent energy, and of the ambiguity. Derives Phenomenon 115.46.

Suppose first the emission is hadronic. A proton of energy E_p striking interstellar gas produces pions carrying, on average, some 20 % of its energy each, and a π^0 decays to two photons sharing its energy, so

$$E_\gamma \approx \tfrac{1}{2} \times 0.2\, E_p = 0.1\, E_p\,,$$

and a 1.4 PeV photon requires a proton of about 1.4×10^{16} eV — above the knee. Suppose instead the emission is leptonic, by inverse-Compton scattering of electrons on the microwave background. In the Thomson regime the scattered photon energy is $E_\gamma \approx \frac{4}{3}\gamma_e^2 \left\langle E_\gamma^{\mathrm{CMB}} \right\rangle$, which for $E_\gamma = 1.4\,\mathrm{PeV}$ and Equation (115.57) would need $\gamma_e = 1.3 \times 10^9$, i.e. $E_e = 0.66\,\mathrm{PeV}$. But at that Lorentz factor the scattering is deep in the Klein–Nishina regime, since $\gamma_e \left\langle E_\gamma^{\mathrm{CMB}} \right\rangle = 0.8\,\mathrm{MeV}$ exceeds $m_e c^2 = 0.511\,\mathrm{MeV}$; there the electron transfers nearly all its energy in one scattering and the cross section is suppressed, so the required electron energy rises to $E_e \gtrsim 1.4\,\mathrm{PeV}$ and the emission becomes inefficient.

Either way the source accelerates particles to at least a petaelectronvolt. Which species it accelerates the gamma-ray spectrum alone cannot say, because both mechanisms produce power-law photon spectra of similar index over a limited band. This is the standing *hadronic–leptonic ambiguity*, and it is why the detection of neutrinos from a source would be decisive: Section 115.7.4 shows that neutrinos at these energies have no leptonic production channel at all. □

115.7.2 Atmospheric neutrinos

The showers of Section 115.4.2 are prolific neutrino sources. Every charged pion below the critical energy E_c^π decays, $\pi^+ \to \mu^+ \nu_\mu$, and every muon that decays before reaching the ground gives $\mu^+ \to e^+ \nu_e \bar{\nu}_\mu$. Counting neutrinos in the full chain,

$$\frac{\nu_\mu + \bar{\nu}_\mu}{\nu_e + \bar{\nu}_e} \longrightarrow 2\,, \tag{115.61}$$

two muon-flavour neutrinos for every electron-flavour one, a prediction that involves nothing but the decay chain and is therefore reliable to a few percent at low energy. It fails at high energy for a reason already derived: a muon of energy E has a laboratory decay length $\gamma c\tau_\mu = (E/m_\mu c^2) \times 659\,\mathrm{m}$, which reaches the 15 km of overlying atmosphere at $E = 2.4\,\mathrm{GeV}$; above a few GeV most muons reach the ground and are absorbed before decaying, so the electron-flavour component is suppressed and the ratio rises above two.

Phenomenon 115.47 (Upward-going muon neutrinos are missing)**.** A large underground water-Cherenkov detector records fewer muon-flavour atmospheric neutrino interactions from below — from neutrinos that have crossed the Earth — than from above, while the electron-flavour rate shows no such zenith dependence. The deficit depends on the ratio of path length to neutrino energy in the manner required by flavour oscillation and in no other [1954].

Rests on Equation (115.61).

Derivation of the oscillation phase in SI units. *Derives Phenomenon 115.47.*

Take two neutrino mass eigenstates of masses m_1, m_2 and write the flavour states as $|\nu_\alpha\rangle = \cos\theta\,|\nu_1\rangle + \sin\theta\,|\nu_2\rangle$, $|\nu_\beta\rangle = -\sin\theta\,|\nu_1\rangle + \cos\theta\,|\nu_2\rangle$; the unitarity of the mixing matrix is licensed by Chapter 5 and the physics of the mixing itself belongs to Chapter 103. A state created with definite flavour and definite momentum p evolves with the phase $\exp(-\mathrm{i}E_i t/\hbar)$, where

$$E_i = \sqrt{p^2c^2 + m_i^2c^4} \approx pc + \frac{m_i^2 c^4}{2pc}\,,$$

the expansion being valid because $m_i c^2 \ll pc$ for every neutrino ever detected. After a flight time $t = L/c$ over a baseline L, the accumulated phase difference is

$$\Delta\Phi = \frac{(E_2 - E_1)\,t}{\hbar} = \frac{(m_2^2 - m_1^2)\,c^4}{2pc} \cdot \frac{L}{\hbar c} = \frac{\Delta m^2 c^4\, L}{2\hbar c E}\,, \tag{115.62}$$

writing $E \approx pc$ for the neutrino energy and $\Delta m^2 := m_2^2 - m_1^2$. Every symbol is SI: $\hbar c$ has dimension J m, $\Delta m^2 c^4$ has dimension J^2, and L/E has dimension m/J, so $\Delta\Phi$ is a pure number as it must be.

The transition probability follows from the amplitude $A_{\alpha\alpha} = \cos^2\theta\,\mathrm{e}^{-\mathrm{i}\Phi_1} + \sin^2\theta\,\mathrm{e}^{-\mathrm{i}\Phi_2}$:

$$|A_{\alpha\alpha}|^2 = 1 - 2\cos^2\theta\sin^2\theta\,(1 - \cos\Delta\Phi) = 1 - \sin^2 2\theta\,\sin^2\frac{\Delta\Phi}{2}\,,$$

so that, defining

$$\Phi := \frac{\Delta\Phi}{2} = \frac{\Delta m^2 c^4\, L}{4\hbar c E}\,, \tag{115.63}$$

the survival and appearance probabilities are

$$P(\nu_\alpha \to \nu_\beta) = \sin^2 2\theta\,\sin^2\Phi\,, \qquad P(\nu_\alpha \to \nu_\alpha) = 1 - \sin^2 2\theta\,\sin^2\Phi\,. \tag{115.64}$$

Equation (115.63) is the formula the literature quotes as $1.267\,\Delta m^2 L/E$, and the number is derived and not conventional. Put $\Delta m^2 c^4$ in eV^2, L in kilometres and E in GeV, and use $\hbar c = 1.973\,269\,8 \times 10^{-7}\,\mathrm{eV\,m}$:

$$\Phi = \frac{\left(\Delta m^2 c^4/\mathrm{eV}^2\right) \times (L/\mathrm{km}) \times 1 \times 10^3\,\mathrm{m}}{4 \times 1.973\,269\,8 \times 10^{-7}\,\mathrm{eV\,m} \times (E/\mathrm{GeV}) \times 1 \times 10^9\,\mathrm{eV}} = 1.2669\,\frac{\Delta m^2 c^4\,\left[\mathrm{eV}^2\right]\,L\,[\mathrm{km}]}{E\,[\mathrm{GeV}]}\,.$$

□

Derivation of the zenith-angle deficit. Atmospheric neutrinos are produced at an altitude of about 15 km over the whole Earth. One arriving from directly overhead has travelled $L \approx 15\,\mathrm{km}$; one arriving from directly below has crossed a diameter, $L \approx 2R_\oplus = 1.27\times10^4\,\mathrm{km}$. The path length varies by three orders of magnitude with zenith angle, and the neutrino energy does not.

Take the atmospheric mass splitting $\Delta m^2c^4 \approx 2.5\times10^{-3}\,\mathrm{eV}^2$ and $E = 1\,\mathrm{GeV}$. For the downward-going neutrino,

$$\Phi = 1.267 \times 2.5 \times 10^{-3} \times 15/1 = 0.048\,, \qquad \sin^2\Phi = 2.3\times10^{-3}\,,$$

so no oscillation is observable. For the upward-going one,

$$\Phi = 1.267 \times 2.5 \times 10^{-3} \times 1.27 \times 10^4/1 = 40\,,$$

which is many complete oscillations; averaged over the spread in L and E within any experimental bin, $\langle\sin^2\Phi\rangle = \frac{1}{2}$ and

$$P\,(\nu_\mu \to \nu_\mu) = 1 - \tfrac{1}{2}\sin^2 2\theta\,,$$

which for maximal mixing is one half. The prediction is therefore specific and asymmetric: the upward-going muon-neutrino rate is halved while the downward-going rate is untouched, and the electron-flavour rate is unaffected at either zenith angle because the corresponding splitting is thirty times smaller and the phase is correspondingly negligible over these baselines. That is exactly the pattern Super-Kamiokande measured [1954], and it is the first compelling evidence that neutrinos have mass. □

The apparatus, the data and the uncertainty budget of that measurement belong to Chapter 114, and the theory of mixing — three flavours, the PMNS matrix, matter effects — to Chapter 103; this chapter supplies the source. It is worth recording that the *solar* neutrino deficit, measured by Davis's chlorine experiment from 1968 [1368, 1950] and resolved by the SNO measurement of the neutral-current rate [2021], is the independent half of the same story; solar neutrinos are not cosmic rays and are not treated here, but the two deficits are explained by one mechanism and neither alone would have been believed.

For everything that follows, the atmospheric flux changes role: it stops being the signal and becomes the irreducible background to Section 115.7.4.

115.7.3 Supernova 1987A

On 23 February 1987 a star exploded in the Large Magellanic Cloud, at a distance of about $50\,\mathrm{kpc} = 1.54\times10^{21}\,\mathrm{m}$. Some three hours before the optical brightening, two underground water-Cherenkov detectors built to look for proton decay recorded bursts of events: eleven in Kamiokande-II over 13 s [1793] and eight in the IMB detector over 6 s [1789], with energies between about 7 MeV and 40 MeV. Nineteen events remain, four decades later, the entire observational sample of extragalactic neutrino astronomy below the teraelectronvolt scale, and they carry a remarkable amount of physics.

Phenomenon 115.48 (The neutrino burst of SN 1987A)**.** A core-collapse supernova at 50 kpc produced a neutrino burst of duration of order 10 s carrying a total energy of order $3\times10^{46}\,\mathrm{J}$, detected in coincidence at two independent detectors on opposite sides of the Earth [1789, 1793]. The energy matches the gravitational binding energy of a neutron star, and the arrival timing bounds both the neutrino speed and the neutrino mass.

Derivation: the energy is the binding energy of a neutron star. *Derives Phenomenon 115.48.*

If a stellar core of mass M collapses to a uniform sphere of radius R, the gravitational energy released is

$$|U| = \frac{3}{5}\frac{GM^2}{R}\,,$$

the standard self-energy integral. With $M = 1.4 M_\odot = 2.78 \times 10^{30}\,\mathrm{kg}$ and $R = 10\,\mathrm{km}$,

$$|U| = \frac{3}{5} \times \frac{6.674 \times 10^{-11}\,\mathrm{N\,m^2/kg^2} \times (2.78 \times 10^{30}\,\mathrm{kg})^2}{1.0 \times 10^4\,\mathrm{m}} = 3.1 \times 10^{46}\,\mathrm{J}\,,$$

which is 12 % of the rest energy $Mc^2 = 2.50 \times 10^{47}\,\mathrm{J}$ of the collapsing core. Essentially none of it emerges as light: the total optical output of the supernova is smaller by three orders of magnitude, and the kinetic energy of the ejecta by two — the $1 \times 10^{44}\,\mathrm{J}$ used in Phenomenon 115.29. It emerges as neutrinos, because at the densities of the collapsing core nothing else escapes. The total energy inferred from the nineteen detected events, given the detector masses, the cross section for $\bar{\nu}_e p \to n e^+$ and the assumption of equipartition among the six neutrino species, is of order $3 \times 10^{46}\,\mathrm{J}$. The agreement is the confirmation, and it is the only direct observation ever made of the mechanism of a core-collapse supernova. □

Derivation: the bound on the neutrino speed. The neutrinos preceded the first optical light by about $\Delta t = 3\,\mathrm{h} = 1.1 \times 10^4\,\mathrm{s}$, and that lead is astrophysical — the shock takes hours to reach the stellar surface after the core collapses, whereas neutrinos leave immediately. Taking the lead as an upper bound on any difference in travel time over the flight time

$$\frac{D}{c} = \frac{1.54 \times 10^{21}\,\mathrm{m}}{2.998 \times 10^8\,\mathrm{m/s}} = 5.15 \times 10^{12}\,\mathrm{s} = 1.63 \times 10^5\,\mathrm{yr}\,,$$

gives

$$\frac{|v_\nu - c|}{c} \le \frac{\Delta t}{D/c} = \frac{1.1 \times 10^4\,\mathrm{s}}{5.15 \times 10^{12}\,\mathrm{s}} = 2.1 \times 10^{-9}\,. \tag{115.65}$$

The bound is weak as a fractional velocity but it is obtained over a baseline of a hundred and sixty thousand light years, which no terrestrial measurement can approach, and it is the reason a claim of superluminal neutrino propagation is checked against SN 1987A first. □

Derivation: the bound on the neutrino mass. A massive neutrino is dispersive. From $E = \sqrt{p^2c^2 + m^2c^4}$ the group velocity is

$$\frac{v}{c} = \frac{pc^2}{Ec} = \sqrt{1 - \frac{m^2c^4}{E^2}} \approx 1 - \frac{m^2c^4}{2E^2}\,,$$

so a neutrino of energy E arrives later than a massless one by

$$\delta t(E) = \frac{D}{c}\frac{m^2c^4}{2E^2}\,. \tag{115.66}$$

Two neutrinos of energies $E_1 < E_2$ emitted simultaneously therefore arrive separated by

$$\Delta t_{\mathrm{disp}} = \frac{D}{2c}\, m^2c^4 \left(\frac{1}{E_1^2} - \frac{1}{E_2^2}\right)\,.$$

The observed burst spanned $\Delta t \approx 13\,\mathrm{s}$ with energies from about 7.5 MeV to 35 MeV. Requiring the dispersion not to exceed the observed spread,

$$m^2c^4 \le \frac{2c\,\Delta t}{D}\left(\frac{1}{E_1^2} - \frac{1}{E_2^2}\right)^{-1} = \frac{2 \times 13\,\mathrm{s}}{5.15 \times 10^{12}\,\mathrm{s}} \times \frac{1}{1.70 \times 10^{-14}/\mathrm{eV}^2} = 300\,\mathrm{eV}^2\,,$$

whence

$$m_\nu c^2 \lesssim 17\,\mathrm{eV} = 2.7 \times 10^{-18}\,\mathrm{J}\,, \qquad m_\nu \lesssim 3.0 \times 10^{-35}\,\mathrm{kg}\,. \tag{115.67}$$

The bound is honest only under an assumption that cannot be checked: that the burst was emitted in a time short compared with 13 s. Since the emission is expected to last of order that long by itself, the true limit is weaker, and careful analyses that model the emission profile obtain a few electronvolts rather than seventeen. It is quoted here because it is the only kinematic neutrino mass bound ever obtained over an astronomical baseline, and because the method — dispersion over a known distance — is the one used again for photons in Section 115.8.2. □

Remark 115.49 (Where the neutrino mass is actually measured). Equation (115.67) has been superseded twice over. The kinematic endpoint of tritium beta decay gives $m_\nu c^2 < 0.8\,\mathrm{eV}$ at 90 % confidence [2399], and the cosmological sum of neutrino masses is bounded well below that [2348]. Oscillation experiments — Equation (115.64) — measure only Δm^2 and say nothing about the absolute scale, which is why the direct bounds remain necessary. SN 1987A's value today is not its number but its method, and the nineteen events remain the only extragalactic neutrino source ever identified below the teraelectronvolt scale.

115.7.4 High-energy astrophysical neutrinos

A neutrino is neutral, so it points; it is weakly interacting, so it escapes from regions opaque to photons and is not attenuated by the microwave background. The same weakness is the difficulty: a kilometre-scale target is needed. IceCube is a cubic kilometre of Antarctic ice — $1 \times 10^9\,\mathrm{m}^3$, a mass of $9.2 \times 10^{11}\,\mathrm{kg}$ — instrumented with 5160 digital optical modules on 86 vertical strings between 1450 m and 2450 m depth, each module a photomultiplier reading the Cherenkov light of Example 115.24 from charged secondaries. The detector concept, and the performance of the nine-string configuration with which it began operating, are described in [2088]; the figures above are those of the completed array.

Phenomenon 115.50 (An extraterrestrial high-energy neutrino flux)**.** A cubic kilometre of instrumented Antarctic ice records neutrino events in excess of the atmospheric background: 28 events with deposited energies between 30 TeV and 1.2 PeV against an expectation of about 10, a 4σ excess [2203]. Neutrinos at these energies are produced only in hadronic collisions, so their detection is direct evidence that protons and nuclei, and not only electrons, are accelerated to such energies somewhere in the universe.

Rests on Equation (115.47).

Derivation: why the background falls away above 100 *teraelectronvolts.* *Derives Phenomenon 115.50.*

The atmospheric neutrino flux of Section 115.7.2 is not simply a copy of the primary spectrum. A pion of energy above the critical energy $E_c^\pi \approx 24\,\mathrm{GeV}$ derived in Section 115.4.2, conventionally rounded to 20 GeV, interacts before it decays, and the probability that it decays instead is the ratio of the two lengths,

$$P_{\mathrm{dec}} \approx \frac{\lambda_I/\rho}{\gamma c \tau_\pi} = \frac{E_c^\pi}{E_\pi}\,,$$

falling as $1/E$. The neutrino flux is therefore the parent spectrum $E^{-2.7}$ multiplied by E^{-1}:

$$J_\nu^{\mathrm{atm}}(E) \propto E^{-3.7}\,, \tag{115.68}$$

one power steeper than the cosmic-ray spectrum that makes it. An astrophysical flux produced by shock acceleration, by contrast, carries the source index of Equation (115.47), near E^{-2} and certainly harder than E^{-3}, and suffers no such suppression because its pions

decay in vacuum. Two power laws differing by more than one unit of index must cross, and they cross near 100 TeV: below it the sky is atmospheric, above it the atmospheric flux has fallen away and an astrophysical component, if it exists, dominates. That is why the IceCube analysis selects events above 30 TeV and why the excess is at the high-energy end of the selection.

A second discriminant is available and is used. An atmospheric neutrino is made in an air shower, and the same shower makes muons that arrive at the detector at the same time. Selecting only events whose interaction vertex is inside the instrumented volume, with no entering track, therefore vetoes atmospheric neutrinos arriving from above against their own accompanying muons — the *self-veto* — while an astrophysical neutrino, which has no accompanying shower, passes. The veto is what reduces the expected background of the Phenomenon 115.50 sample to about ten events. □

Derivation: a neutrino detection is evidence of hadronic acceleration. Neutrinos at these energies have exactly one production channel: the weak decay of pions and kaons, which are made only in hadronic collisions. Electrons produce photons — by synchrotron radiation, by bremsstrahlung, by inverse-Compton scattering — and produce no neutrinos at all, because none of those processes has a weak vertex. Detecting a teraelectronvolt neutrino from a direction therefore establishes that protons or nuclei are accelerated there, and resolves the hadronic–leptonic ambiguity of Phenomenon 115.46 in one measurement.

The same chain fixes the expected ratio of neutrinos to gamma rays. In a pp collision the three pion charge states are produced in roughly equal numbers. The π^0 gives two photons carrying all its energy; each $\pi^\pm$ gives, through $\pi^+ \to \mu^+\nu_\mu$ and $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$, three neutrinos carrying about three quarters of its energy. Hence

$$\frac{L_\nu}{L_\gamma} \approx \frac{2 \times \frac{3}{4}}{1} = \frac{3}{2}\,, \tag{115.69}$$

a source's all-flavour neutrino luminosity is comparable to its hadronic gamma-ray luminosity, which is what makes a joint detection feasible at all. The flavour composition at the source is $\nu_e : \nu_\mu : \nu_\tau = 1 : 2 : 0$ from the same counting, and oscillation over astronomical baselines — where Equation (115.63) gives an enormous Φ and every $\sin^2\Phi$ averages to one half — converts this to approximately $1 : 1 : 1$ at Earth. The measured flavour ratio is consistent with that, which is a non-trivial check that the sources are pion sources. □

115.7.5 Multimessenger astronomy

On 22 September 2017 IceCube recorded a muon-neutrino event of reconstructed energy $290\,\text{TeV} = 4.6 \times 10^{-5}\,\text{J}$ and issued an automated alert within a minute. Follow-up by some twenty instruments from radio to gamma rays found the blazar TXS 0506+056 — an active galaxy whose jet points nearly at us — in a gamma-ray flaring state, coincident in direction with the neutrino. The chance-coincidence probability, allowing for the number of blazars and the number of alerts, is at the level of 3σ [2306]. A search of the archival IceCube data then found, independently, an excess of 13 ± 5 events from the same direction during 2014–2015 — a period in which the source was not flaring in gamma rays — at 3.5σ [2293].

Remark 115.51 (Two three-sigma results are evidence, not a discovery). The two observations are statistically independent: different years, different event samples, different analyses, one a directional coincidence with a flare and the other a time-integrated point-source search. Taken together they are the strongest candidate identification of a source of high-energy cosmic rays that exists. Taken separately neither reaches the threshold this book would require to call something observed, and the combination of two 3σ results is not a 6σ result — significances add in quadrature only for the statistic, not for the trials factor of Section 11.6, and the archival search was made in the direction the first result selected, which is precisely

the situation the look-elsewhere correction exists to handle. The honest statement is that TXS 0506+056 is a candidate, that no other source has been identified since, and that the diffuse flux of Phenomenon 115.50 remains unresolved into sources.

The method, however, is established, and its clearest success is elsewhere: the coincidence of a gravitational-wave signal with a short gamma-ray burst, treated in Chapter 47, in which two independent messengers from one event were combined to identify the source and to bound the propagation speed of gravity. Multimessenger astronomy is that method, and cosmic rays supply two of its four channels.

115.8 Cosmic rays as a physics laboratory

115.8.1 Centre-of-mass energies beyond the colliders

Proposition 115.52 (The natural beam exceeds the collider by a factor of thirty)**.** *A proton of* $1 \times 10^{20}\,\mathrm{eV}$ *striking a nucleon at rest in the atmosphere collides at a centre-of-mass energy* $\sqrt{s} = 433\,\mathrm{TeV}$*, some thirty-two times the* $13.6\,\mathrm{TeV}$ *at which the Large Hadron Collider now runs and fifty-four times the* $8\,\mathrm{TeV}$ *of the Higgs discovery datasets of Chapter 113.*

Rests on Equation (40.12)*.*

Proof. *Derives Proposition 115.52.*

By Equation (40.12) for a projectile of energy E on a target of mass m_p at rest,

$$s = 2Em_pc^2 + 2m_p^2c^4 \approx 2Em_pc^2\,,$$

so

$$\sqrt{s} = \sqrt{2 \times 1 \times 10^{20}\,\mathrm{eV} \times 9.382\,72 \times 10^{8}\,\mathrm{eV}} = 4.33 \times 10^{14}\,\mathrm{eV} = 433\,\mathrm{TeV}\,,$$

in SI $6.9 \times 10^{-5}\,\mathrm{J}$. The square root is the whole story: a fixed-target collision converts energy to centre-of-mass energy only as $\sqrt{E}$, which is why colliders were built (Example 40.13), and why even a beam seven orders of magnitude above the LHC's buys only a factor of thirty in $\sqrt{s}$. □

That factor is nevertheless real, and two measurements exploit it.

The first is the proton–air cross section, extracted from the *tail* of the $X_{\max}$ distribution. A shower whose first interaction happens deep in the atmosphere has a deep maximum, and since the first-interaction depth is exponentially distributed with mean $\lambda_I = \bar{m}_{\mathrm{air}}/\sigma_{p\text{-air}}$, the deep tail of the measured $X_{\max}$ distribution falls exponentially with a slope that measures λ_I and hence $\sigma_{p\text{-air}}$ directly. Converting to a proton–proton cross section requires a nuclear-overlap calculation, and the results agree with the extrapolation of accelerator measurements [2427] — a consistency check of the strong interaction three decades in $\sqrt{s}$ beyond where it was calibrated.

The second is the muon content, and it does *not* agree.

Remark 115.53 (The muon excess is a real discrepancy and is left as one)*.* The muon number predicted by Equation (115.32), with N_{ch} and the inelasticity taken from every current hadronic interaction model tuned to LHC data, falls below the measured number in showers above $1 \times 10^{19}\,\mathrm{eV}$ by a factor between about 1.3 and 1.6, with the primary mass fixed independently by $X_{\max}$ through Phenomenon 115.25. Since N_μ depends on the mass only through the mild $A^{1-\beta}$ of Equation (115.33), the discrepancy cannot be absorbed into the composition without contradicting the depth measurement. It is therefore a failure of the hadronic modelling at energies no collider reaches, and it is the one place in this chapter where an extrapolated Standard Model calculation is measurably wrong. It is reported as such.

115.8.2 Tests of Lorentz invariance

The invariance postulates of Chapter 39 assert that every species has the same limiting speed. Suppose instead that species a has maximal attainable velocity $c_a = c\,(1+\delta_a)$ with $|\delta_a| \ll 1$, so that its dispersion relation reads $E^2 = p^2c_a^2 + m^2c_a^4$. Cosmic rays test this at a sensitivity no laboratory can approach, for a simple reason: the effect of δ grows with energy while every terrestrial measurement is made at low energy.

Derivation of the bound from the photopion threshold. Redo the threshold calculation of Equation (115.56) with species-dependent limiting speeds. Writing $\delta := \delta_\pi - \delta_p$, the invariant that must reach $(m_p + m_\pi)^2\,c^4$ acquires an extra term of order δE^2, so the threshold condition becomes

$$4EE_\gamma - 2\delta E^2 \geq m_\pi c^2 \left(2m_p c^2 + m_\pi c^2\right) .$$

For $\delta > 0$ the reaction is forbidden above a maximum energy rather than allowed above a minimum one, and the photopion suppression would not occur at all. Requiring the second term not to dominate the first at the energy where the suppression is observed, $E \approx 5 \times 10^{19}\,\mathrm{eV}$, gives

$$|\delta| \lesssim \frac{2E_\gamma}{E} = \frac{2 \times 6.3 \times 10^{-4}\,\mathrm{eV}}{5 \times 10^{19}\,\mathrm{eV}} = 2.5 \times 10^{-23} , \tag{115.70}$$

a bound on a fractional velocity difference at the level of 10^{-23} [1968]. For comparison, the best terrestrial Michelson–Morley-type experiments — rotating optical cavities, the modern descendants of [1635] — bound anisotropies of the speed of light at the level of 10^{-17} [2147]; the cosmic-ray bound is better by six orders of magnitude, and it is obtained not by building anything but by observing that a predicted suppression occurs. □

A second and independent channel is the propagation of high-energy photons over cosmological distances. If the photon dispersion relation acquires an energy-dependent correction, photons of different energy emitted simultaneously arrive at different times, and the delay accumulates over the flight path exactly as in Equation (115.66). Gamma-ray bursts, which are both distant and variable on sub-second time scales, are the natural clock, and the observed simultaneity of low- and high-energy photons from them bounds the effect stringently [2137].

Remark 115.54 (No violation has been observed). Both channels give null results, and the resulting bounds are among the strongest constraints on any modification of special relativity. This chapter records that fact and nothing more: no Lorentz-violating framework is developed here, because none has evidence, and the programmes that predict such violations lie outside the scope stated in the front matter. What is in scope is the measurement, and the measurement says the postulates of Chapter 39 hold to Equation (115.70).

115.8.3 Muon time dilation as a standing test

Phenomenon 115.55 (Muons reach sea level)**.** Muons produced by cosmic-ray interactions near 15 km altitude are detected in quantity at sea level — about $70/(\mathrm{m^2\,s\,sr})$ from the vertical, or roughly one per square centimetre per minute on a horizontal surface — and the surviving fraction depends on their momentum [863, 1253]. The muon lifetime at rest is 2.197 µs [2427], and muons circulating in a storage ring at $\gamma \approx 29.3$ are observed to decay with that same proper lifetime, dilated in the laboratory by exactly the factor γ [1592].

Rests on Equation (115.3).

Derivation. *Derives Phenomenon 115.55.*

The PDG quotes the muon width as $\Gamma_\mu = (2.995\,983\,6 \pm 0.000\,003\,0) \times 10^{-19}\,\mathrm{GeV}$ [2427], which is a lifetime

$$\tau = \frac{\hbar}{\Gamma_\mu} = \frac{1.054\,571\,817 \times 10^{-34}\,\mathrm{J\,s}}{4.8000 \times 10^{-29}\,\mathrm{J}} = 2.1970 \times 10^{-6}\,\mathrm{s}\,,$$

and the distance a muon covers in one lifetime at a speed arbitrarily close to c is $c\tau = 658.6\,\mathrm{m}$. Were the laboratory lifetime the same as the proper one, the surviving fraction over 15 km of atmosphere would be

$$\exp\!\left(-\frac{15\,\mathrm{km}}{658.6\,\mathrm{m}}\right) = \mathrm{e}^{-22.8} = 1.3 \times 10^{-10}\,,$$

and no muons would reach the ground in any detectable number. What the flight consumes is instead the muon's *proper* time, shorter than the laboratory time by the factor γ (Chapter 41), so the laboratory decay length is $\gamma\beta c\tau$; for a typical sea-level muon of a few gigaelectronvolts, $\gamma \approx 20$ — that is $E = 20\,m_\mu c^2 = 2.1\,\mathrm{GeV}$, which is also about the energy a muon needs to survive the 2 MeV per g/cm^2 ionisation loss across the atmosphere of Equation (115.3) — and

$$\exp\!\left(-\frac{15\,\mathrm{km}}{20 \times 658.6\,\mathrm{m}}\right) = \mathrm{e}^{-1.14} = 0.32\,.$$

The observed flux is of this order. The nine and a half orders of magnitude between the two estimates are what make the sea-level muon flux a continuously running test of relativistic kinematics rather than a curiosity, and the momentum dependence of the surviving fraction is the form in which the test was first made quantitative [863]. □

The three measurements that turn this into a quantitative test are sections of Chapter 41: Rossi and Hall's momentum dependence (Section 41.2), the Frisch–Smith mountain-to-sea-level comparison (Section 41.3) and the CERN storage-ring lifetime (Section 41.4). What this chapter adds is the source: the muons are not supplied by an apparatus, they are supplied by the atmosphere, at a rate fixed by Equation (115.19) and a chain of decays that nothing on Earth controls.

115.9 What is settled and what is not

It is worth separating, at the close of the chapter, the statements that rest on measurement from those that do not.

Settled by observation: cosmic rays arrive from outside the atmosphere (Phenomenon 115.2) and are charged and predominantly positive (Phenomena 115.4 and 115.5); the spectrum is a power law over eleven decades with a knee, an ankle and a high-energy suppression (Phenomena 115.11 and 115.13); the flux is suppressed at the very top (Phenomenon 115.42); a single primary makes an extensive air shower whose particle number measures its energy and whose depth of maximum measures its mass (Phenomena 115.18 and 115.25); supernova remnants accelerate protons (Phenomenon 115.30) and can supply the Galactic energy budget (Phenomenon 115.29); petaelectronvolt accelerators exist in the Galaxy (Phenomenon 115.46); the arrival directions above $8 \times 10^{18}\,\mathrm{eV}$ carry a dipole of extragalactic origin (Phenomenon 115.44); an extraterrestrial high-energy neutrino flux exists (Phenomenon 115.50); and atmospheric neutrinos oscillate (Phenomenon 115.47).

Not settled, and stated as such throughout:

- Which of the two magnetic readings of the knee is correct. Both predict the rigidity ordering that is observed, and nothing in the present data separates them (Remark 115.14).

- The composition above 1×10^{19} eV, and therefore whether the observed suppression is the propagation effect of Phenomenon 115.40 or the maximum rigidity of the sources (Phenomenon 115.42).
- The identity of any source of the highest-energy particles. No point source has been confirmed, and the Hillas criterion excludes rather than identifies (Remark 115.38).
- The origin of the rising positron fraction (Remark 115.17).
- Why the observed spectral index is 2.7 when shock acceleration and the measured escape time predict 2.33 (Remark 115.35).
- Why showers contain more muons than every hadronic model predicts (Remark 115.53).

Six open problems in a subject a century old is not a poor showing, and it is a fair description of where the field stands. The instrument that will settle most of them is exposure: the flux at the top of the spectrum is one particle per square kilometre per century, and every statement about it is limited by how much sky has been watched for how long.

Chapter 116

Experiment: Deep Inelastic Scattering

Tests Phenomena 102.45 and 102.47 and Equations (102.56) *and* (102.59).
Assuming Definitions 102.5 and 102.44 and Proposition 102.6.

Rutherford found the nucleus by observing that a few alpha particles came back; the SLAC–MIT collaboration found the quarks the same way, by observing that electrons scattered from hydrogen at large angles far more often than a soft, extended proton would allow. This chapter is the experimental counterpart of Chapter 102: it reports the electron-scattering measurements carried out in End Station A at the Stanford Linear Accelerator Center between 1967 and 1972, the Bjorken scaling they exhibited, the Callan–Gross relation that identified the constituents as spin-$\tfrac{1}{2}$ objects, and the missing momentum fraction that required a neutral, non-scattering carrier — the gluon. It then follows the same observable forward: the logarithmic scaling violations measured at high statistics by muon and neutrino beams and at HERA are the most direct quantitative confirmation of quantum chromodynamics that exists, because the theory predicts not the structure functions themselves but exactly how they must change with Q^2.

The prediction under test is a single sentence: *the proton contains point-like charged constituents.* It is falsifiable in the strongest sense, because a proton whose charge is smoothly spread over its measured size predicts an inelastic rate at large momentum transfer smaller than the observed one by orders of magnitude. The chapter is laid out in the five rubrics that editorial rule 4 requires of an experiment chapter, and that Chapter 41 exhibits — apparatus, procedure, observations with numbers and uncertainties in SI units, interpretation, and primary references — with the historical setting first and the later high-precision programme placed between interpretation and references, because it is the same measurement continued. It sits at the end of Part XI with Chapter 115; its theoretical neighbours are Chapters 102 and 108 and, for the leptonic probe, Chapters 100 and 101. The standard textbook account is [1739]; current structure function and parton-distribution data are collected in [2427].

Remark 116.1 (Units, and how to read this chapter against the literature). Every equation here carries $\hbar$ and c explicitly, as Chapter 102 does. The deep inelastic literature universally sets $\hbar = c = 1$ and writes Q^2 in GeV^2; to map that literature onto this chapter, restore one factor of c for every power of momentum and one factor of $\hbar c$ for every power of length. Concretely: a four-momentum q carries $\mathrm{kg\,m/s}$, so the invariant $Q^2 := -q^2$ carries $\mathrm{kg^2\,m^2/s^2}$ and the literature's "Q^2 in GeV^2" is Q^2c^2 here. The conversion factors used throughout are

$$1\,\mathrm{GeV} = 1.602\,176\,634 \times 10^{-10}\,\mathrm{J}\,, \qquad 1\,\mathrm{GeV}^2/c^2 = 2.8561 \times 10^{-37}\,\mathrm{kg^2\,m^2/s^2}\,, \tag{116.1}$$

the first exact because the 2019 SI fixes the elementary charge, and the second following from it, together with $\hbar c = 3.161\,526\,77 \times 10^{-26}\,\mathrm{J\,m}$. Areas quoted in the older literature in

cm^2 are given here in m^2, with $1\,\mathrm{cm}^2 = 1\times10^{-4}\,\mathrm{m}^2$. No derivation in this chapter is carried out in natural units.

116.1 Historical context and the prediction under test

116.1.1 Elastic scattering and the proton form factors

Before the proton could be found to have constituents it had to be measured as a whole, and the instrument for that was elastic electron scattering, $e + p \to e + p$, in which the proton survives.

Definition 116.2 (The Rosenbluth cross section)**.** For one-photon exchange from a proton with an anomalous magnetic moment, Lorentz invariance, current conservation and parity allow exactly two form factors, the electric $G_E(Q^2)$ and the magnetic $G_M(Q^2)$, both dimensionless functions of the invariant momentum transfer alone. The elastic cross section is then

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \sigma_{\mathrm{Mott}}\,\frac{E'}{E}\left[\frac{G_E^2 + \tau G_M^2}{1+\tau} + 2\tau G_M^2 \tan^2\frac{\vartheta}{2}\right], \qquad \tau := \frac{Q^2}{4M^2c^2}\,, \tag{116.2}$$

with σ_{Mott} the point-charge cross section Equation (102.50), M the proton mass, ϑ the electron scattering angle, E and E' the incident and scattered electron energies, and the recoil factor

$$\frac{E'}{E} = \left[1 + \frac{2E}{Mc^2}\sin^2\frac{\vartheta}{2}\right]^{-1}. \tag{116.3}$$

Both τ and E'/E are dimensionless: Q^2 carries $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$ and so does M^2c^2 [970].

Remark 116.3 (Why the formula is written this way)*.* The bracket in Equation (116.2) is linear in $\tan^2(\vartheta/2)$ at fixed Q^2. Measuring at several angles and several beam energies chosen to keep Q^2 fixed therefore gives a straight line whose slope is $2\tau G_M^2$ and whose intercept is $(G_E^2 + \tau G_M^2)/(1+\tau)$: the two form factors are separated with no model of the proton whatever. This is the *Rosenbluth separation*, and exactly the same device, applied to the inelastic cross section, separates the two inelastic structure functions in Section 116.3.2. The experimental technique of the deep inelastic programme is in this sense a direct continuation of the elastic one.

Phenomenon 116.4 (The proton is soft and extended)**.** The elastic form factors of the proton fall steeply with momentum transfer, and over the range measured in the 1950s they are described to within about 10 % by the dipole

$$G_E(Q^2) = \frac{G_M(Q^2)}{\mu_p} = \left[1 + \frac{Q^2c^2}{\Lambda^2}\right]^{-2}, \qquad \Lambda^2 = 0.71\,\mathrm{GeV}^2\,, \tag{116.4}$$

corresponding to a root mean square charge radius near 0.8 fm [1088]. The proton is therefore not a point: it has a size, and at momentum transfers large compared with Λ/c the probability of leaving it intact collapses.

Rests on Definition 116.2 and Equations (102.50) *and* (116.3)*.*

Derivation. *Derives Phenomenon 116.4.*

For a static charge distribution $\rho(\boldsymbol{r})$ normalized to unit total charge, the Born amplitude carries the Fourier transform Equation (116.23) below, and expanding the exponential for small momentum transfer gives, after angular averaging,

$$G_E(Q^2) = 1 - \frac{Q^2\,\langle r^2\rangle}{6\hbar^2} + O(Q^4)\,, \tag{116.5}$$

which is dimensionally consistent because $Q^2\,\langle r^2\rangle$ carries $\mathrm{kg}^2\,\mathrm{m}^4/\mathrm{s}^2$, exactly $\hbar^2$. Expanding the dipole Equation (116.4) to the same order gives $G_E = 1 - 2Q^2c^2/\Lambda^2$, so

$$\left\langle r^2\right\rangle = \frac{12\hbar^2c^2}{\Lambda^2} \quad\Longrightarrow\quad \sqrt{\langle r^2\rangle} = \frac{\sqrt{12}\,\hbar c}{\Lambda} = \frac{3.4641 \times 0.197\,33\,\mathrm{GeV\,fm}}{0.842\,62\,\mathrm{GeV}} = 0.811\,\mathrm{fm}\,. \quad (116.6)$$

The modern value from the CODATA adjustment is $(8.4075 \pm 0.0064) \times 10^{-16}\,\mathrm{m}$ [2431], so the dipole radius lies about 3.5 % *below* it. That gap is the honest statement that the dipole is a convenient parametrisation of a decade of data and not a law, and that a radius extracted from it is not a radius extracted from the slope at $Q^2 = 0$.

The consequence that matters for this chapter is the falloff, and it is worth accounting for term by term rather than quoting a single power. At large Q^2 the bracket of Equation (116.2) is dominated by its magnetic term $2\tau G_M^2 \tan^2(\vartheta/2)$; since $G_M^2 \propto Q^{-8}$ while $\tau \propto Q^2$, the bracket falls as Q^{-6}. At fixed angle and asymptotically large energy the recoil factor Equation (116.3) contributes a further Q^{-2} and σ_{Mott} a further Q^{-4}, giving the familiar Q^{-12}. That law is asymptotic, however, and the first survey did not reach it: evaluating Equation (116.2) with Equation (116.4) and the proton magnetic moment $\mu_p = 2.7928$ nuclear magnetons [2427] gives a local exponent running only from about Q^{-6} at $Q^2c^2 = 1\,\mathrm{GeV}^2$ to about Q^{-9} at $8\,\mathrm{GeV}^2$. The honest number is therefore the one the formula itself returns: raising Q^2c^2 from $1\,\mathrm{GeV}^2$ to $8\,\mathrm{GeV}^2$ at $\vartheta = 10^\circ$ suppresses the elastic cross section by a factor 3.2×10^3, and suppresses its ratio to σ_{Mott} — the like-for-like comparison, since that ratio is what the inelastic measurement reports — by a factor 3.4×10^2. The corresponding factors at 6° and 25° are 2.9×10^3 and 4.5×10^3 raw, 3.2×10^2 and 3.7×10^2 relative to Mott, so the conclusion does not depend on the angle chosen. That is what made the inelastic result of Section 116.4.1 a surprise: the same beam, the same target and a modest change of final state gave a rate that hardly fell at all. □

116.1.2 The quark hypothesis

By 1964 the proliferating hadrons had been organized into representations of a flavour SU(3) — the eightfold way of Section 102.1.1, whose representation theory is Chapter 5. Gell-Mann [1277] and, independently, Zweig [1301] observed that every observed multiplet is built from the fundamental triplet and its conjugate, and proposed that the triplet corresponds to physical constituents: three of them, with electric charges $+\frac{2}{3}e$, $-\frac{1}{3}e$ and $-\frac{1}{3}e$, from which mesons are made as $q\bar{q}$ and baryons as qqq (Definition 102.5 and Proposition 102.6).

The proposal was widely, and reasonably, not believed as a statement about matter. Three objections carried weight.

- *No free quark had ever been seen.* Searches in cosmic rays, in accelerator beams, in sea water and in terrestrial minerals had set limits on the abundance of fractionally charged particles far below anything a genuine constituent should permit; the modern statement of that null result is Phenomenon 102.65. A constituent that cannot be liberated was, in 1964, a contradiction in terms.

- *The masses did not add up.* The constituent masses needed to reproduce the baryon spectrum are roughly a third of the nucleon mass each, but the binding energy implied is then comparable with the masses themselves, so the non-relativistic picture that made the counting work had no right to succeed.

- *The statistics were wrong.* The Δ^{++} is uuu with all three spins aligned in a spatially symmetric ground state, which is symmetric under exchange of identical fermions (Section 102.2.1). The resolution — colour — was not established until later.

Quarks were therefore treated by most of the community as a bookkeeping device: a mnemonic for SU(3) multiplets, not a claim about what is inside a proton. The distinction is exactly what deep inelastic scattering could settle, because a mnemonic has no form factor and a constituent does.

116.1.3 Bjorken scaling

Bjorken's prediction preceded the data and did not depend on the quark model. It came from current algebra: the equal-time commutators of the electromagnetic currents, which encode the charges of whatever the currents are built from, imply sum rules for the structure functions, and those sum rules are finite only if the structure functions have a particular limiting behaviour [1393].

Definition 116.5 (The Bjorken limit)**.** The *Bjorken limit* is $Q^2 \to \infty$ and $\nu \to \infty$ with

$$x = \frac{Q^2}{2M\nu} \tag{116.7}$$

held fixed, where $\nu := P \cdot q/M$ is the energy transferred to the target in its rest frame and M the proton mass. Both limits are taken together: it is not a high-Q^2 limit at fixed ν, which would be the elastic region, nor a high-ν limit at fixed Q^2.

Phenomenon 116.6 (Bjorken's prediction)**.** In the limit of Definition 116.5 the two structure functions of Definition 102.44 become functions of the single dimensionless variable x:

$$Mc^2 W_1\left(x, Q^2\right) \longrightarrow F_1(x)\,, \qquad \nu W_2\left(x, Q^2\right) \longrightarrow F_2(x)\,. \tag{116.8}$$

This was published in 1969, before the SLAC data were analysed [1393], and the operator-product machinery that makes it a statement about short-distance behaviour rather than an assumption is Wilson's [1410].

Rests on Definitions 102.44 and 116.5.

Derivation. *Derives Phenomenon 116.6.*

The content is dimensional, and the dimensional analysis is the whole argument. The functions W_1 and W_2 of Definition 102.44 each carry 1/J, and the products in Equation (116.8) are therefore dimensionless. A dimensionless function of the two invariants can depend on them only through dimensionless combinations, and there are exactly three available: x, the ratio Q^2c^2/M^2c^4, and ν/Mc^2. If the target has no internal length scale beyond its own Compton wavelength — if, that is, the current is absorbed by a structureless object — then in the limit where Q^2c^2 and νMc^2 both dwarf M^2c^4 the last two ratios drop out of any finite answer and only x survives.

The converse is the informative half. Suppose the constituent had a size a. Then $\hbar/a$ is a momentum, $Q^2a^2/\hbar^2$ is a fourth dimensionless combination that does *not* disappear in the Bjorken limit, and the structure functions would depend on Q^2 separately through it — falling once $Q \gtrsim \hbar/a$, in exactly the way the elastic form factors of Phenomenon 116.4 do. Scaling is thus the absence of a constituent length, and a measured violation of scaling is either a constituent size or an interaction that supplies a scale of its own. Which of the two the observed violations are is settled in Section 116.6: they are logarithmic, not power-like, and a size gives a power. □

116.1.4 The parton model

Feynman supplied the picture that makes the limit intuitive [1401]. View the hadron in a frame in which its momentum P is very large. Time dilation slows every internal process by the Lorentz factor, so during the brief moment in which the virtual photon is absorbed the

constituents — Feynman's *partons* — neither interact with one another nor change their momenta. Each carries a fraction ξ of the hadron's longitudinal momentum, and the photon scatters elastically from one of them while the rest are spectators. This is the impulse approximation of Phenomenon 102.45, and Equation (102.53) identifies ξ with the measured x.

Bjorken and Paschos turned the picture into a formula [1394]. Writing $q_i(x)\mathrm{d}x$ for the number of partons of species i and charge e_i carrying momentum fraction in $\mathrm{d}x$, the incoherent sum over point-like elastic scatterings gives Equation (102.54), which in the notation of this chapter reads

$$F_2(x) = \sum_i \left(\frac{e_i}{e}\right)^2 x\, q_i(x)\,, \tag{116.9}$$

a function of x alone — which is Bjorken scaling. The parton distributions q_i carry no dimension at all: x is dimensionless and $q_i(x)\mathrm{d}x$ is a number.

Remark 116.7 (What the parton model assumes and does not explain). The model presumes that the constituents are free during the absorption. Nothing in it explains why constituents bound tightly enough never to escape should behave as free particles when probed hard, and in 1969 this was the model's central embarrassment rather than its central insight: it was a hypothesis with no dynamics behind it. The debt is discharged by asymptotic freedom (Theorem 102.35), which is the subject of Section 116.6.1 — and the sequence matters historically, because the parton model was believed on experimental grounds for four years before a field theory was found that could support it.

116.1.5 The Callan–Gross relation

The parton model as stated says nothing about the constituents' spin. Callan and Gross showed that the two structure functions are not independent if the constituents carry spin $\frac{1}{2}$, and that the relation between them is opposite for spin 0 [1398].

Definition 116.8 (The longitudinal structure function and R)**.** Define

$$F_L\left(x, Q^2\right) := \left(1 + \frac{Q^2c^2}{\nu^2}\right) F_2\left(x, Q^2\right) - 2xF_1\left(x, Q^2\right)\,, \tag{116.10}$$

and the ratio of longitudinal to transverse virtual-photon absorption cross sections

$$R\left(x, Q^2\right) := \frac{\sigma_L}{\sigma_T} = \frac{F_L}{2xF_1}\,. \tag{116.11}$$

The ratio Q^2c^2/ν^2 equals $4M^2x^2c^4/Q^2c^2$ and vanishes in the Bjorken limit at fixed x, so $F_L \to F_2 - 2xF_1$ there. All three quantities are dimensionless.

Phenomenon 116.9 (Callan–Gross)**.** For constituents of spin $\frac{1}{2}$ and negligible mass, $F_L = 0$, equivalently $F_2(x) = 2xF_1(x)$ and $R = 0$; for constituents of spin 0, $F_1 = 0$ and $R \to \infty$ [1398]. Any measured value of R therefore discriminates between the two hypotheses without needing an absolute normalisation, a knowledge of the parton distributions, or a model of the proton.

Rests on Definition 116.8, Equation (116.9)*, and Phenomenon 102.45.*

The derivation is the helicity argument given in Phenomenon 102.45 and repeated, in the form in which it is used against the data, in Section 116.4.3. What must be recorded here is why this is the sharpest of the early tests. Every other comparison between the parton model and the data involves either an absolute cross section, which carries the beam normalisation and the target thickness, or a distribution $q_i(x)$, which is not predicted by anything. R is a ratio of two cross sections measured with the same beam on the same target, and the two hypotheses do not predict different numbers for it — they predict opposite ends of its range.

116.2 Apparatus

116.2.1 The Stanford linear accelerator

The instrument is a 3.05 km disc-loaded copper waveguide buried under the hills west of Stanford, operating as a travelling-wave structure at 2856 MHz [1363]. Electrons injected at a few tens of MeV ride the phase velocity of the wave and gain energy continuously along the machine, reaching about $20\,\mathrm{GeV} = 3.2 \times 10^{-9}\,\mathrm{J}$ at the end of the machine. Radiofrequency power is supplied by some 240 klystrons distributed along the tunnel, each delivering tens of megawatts of peak power into its own group of four 3.05 m accelerating sections: $240 \times 4 \times 3.05\,\mathrm{m} = 2.93\,\mathrm{km}$ of structure, which with the drift and injection regions is the length of the machine.

Three features of the beam decided the experiment.

- *Energy and its calibration.* The maximum energy sets the kinematic reach: the largest accessible Q^2 at a given angle grows as E^2. The energy was defined by a magnetic analysing system in the beam switchyard and known to a few parts in 10^3, which is what makes an absolute measurement of the invariants possible at all; every kinematic variable of Section 116.3.1 is built from E, E' and ϑ and from nothing else.

- *Pulse structure.* The machine ran at up to 360/s with a pulse length of order 1.6 µs, a duty factor of about 6×10^{-4}. A short, intense pulse is a mixed blessing: it delivers the charge needed for a cross section falling by six orders of magnitude across the kinematic range, but it forces every counter to resolve several particles inside the pulse, which is the reason the detector stack of Section 116.2.2 is built from many small scintillator elements rather than a few large ones.

- *Current.* Average beam currents in the microampere range were typical. At 1 µA the beam delivers $1\,\mu\mathrm{C/s} / 1.602\,176\,634 \times 10^{-19}\,\mathrm{C} = 6.24 \times 10^{12}/\mathrm{s}$ electrons; against the areal target density of Section 116.2.3 this is the luminosity that makes a cross section of order $1 \times 10^{-38}\,\mathrm{m^2/sr}$ measurable in hours.

Remark 116.10 (Why an electron beam). A hadron beam probes a hadron with the strong interaction, whose short-distance form was precisely what was unknown; any measured rate then mixes the structure of the target with the structure of the probe and with the unknown dynamics between them. The electron interacts through a single virtual photon whose coupling is the fine-structure constant $\alpha = e^2/(4\pi\varepsilon_0\hbar c) = (7.297\,352\,564\,3 \pm 0.000\,000\,001\,1) \times 10^{-3}$ [2431], small enough that one-photon exchange dominates and calculable exactly (Chapter 100). The whole of the unknown physics is then confined to the two structure functions of Definition 102.44, and the experiment measures them with no theoretical input beyond quantum electrodynamics. The price is rate: $\alpha^2 \approx 5.3 \times 10^{-5}$ against a strong cross section of order unity, which is why the beam power and the target thickness matter as much as they do.

116.2.2 The End Station A spectrometers

End Station A is a shielded experimental hall at the end of the switchyard, large enough to hold three magnetic spectrometers mounted on carriages that pivot about the target position on a circular rail. They are named by the momentum they can analyse: $20\,\mathrm{GeV}/c$, $8\,\mathrm{GeV}/c$ and $1.6\,\mathrm{GeV}/c$. The first two carried the deep inelastic programme; the third served the largest angles.

Proposition 116.11 (Why the spectrometer weighs thousands of tonnes)**.** *Analysing the momentum of a* $20\,\mathrm{GeV}/c$ *electron by bending it through an angle* θ_B *requires a field integral*

$$\int B\,\mathrm{d}l = \frac{p\,\theta_B}{e}\,, \tag{116.12}$$

which for $\theta_B = 10^\circ$ *is about* $12\,\mathrm{T\,m}$*. With conventional iron-cored dipoles limited by saturation to fields of order* $1.5\,\mathrm{T}$*, this is eight metres of magnet; with the drift spaces needed to convert an angle into a displacement large enough to measure, the instrument is tens of metres long, and its yoke is the mass that must be rotated to change the scattering angle.*

Rests on Equations (40.15) *and* (113.8)*.*

Proof. *Derives Proposition 116.11.*

A charge e moving with momentum p perpendicular to a uniform field B follows a circle of radius $r = p/(eB)$, so a path length $\mathrm{d}l$ turns the trajectory through $\mathrm{d}\theta = \mathrm{d}l/r = eB\,\mathrm{d}l/p$; integrating gives Equation (116.12), which is exact for any field profile provided the bend stays in one plane. Numerically,

$$p = 20\,\mathrm{GeV}/c = \frac{20\,\mathrm{GeV} \times 1.602\,176\,634 \times 10^{-10}\,\mathrm{J/GeV}}{2.997\,924\,58 \times 10^{8}\,\mathrm{m/s}} = 1.0689 \times 10^{-17}\,\mathrm{kg\,m/s}\,,$$

and with $\theta_B = 0.174\,53\,\mathrm{rad}$,

$$\int B\,\mathrm{d}l = \frac{1.0689 \times 10^{-17}\,\mathrm{kg\,m/s} \times 0.174\,53}{1.602\,176\,634 \times 10^{-19}\,\mathrm{C}} = 11.6\,\mathrm{T\,m}\,.$$

The momentum resolution follows from the same relation: a fractional error $\delta p/p$ shows up as an angular error $\delta\theta_B = \theta_B\,\delta p/p$, so resolving $\delta p/p \sim 1 \times 10^{-3}$ at $\theta_B = 10^\circ$ means measuring the exit angle to $1.7 \times 10^{-4}\,\mathrm{rad}$ — a fraction of a millimetre over a metre of lever arm, which is what the hodoscope granularity of the detector stack has to deliver. □

The optics of both spectrometers were designed to be *point-to-point* in momentum and independent of the production angle within the acceptance, so that a hit position in one hodoscope plane measures E' and a hit position in another measures ϑ, with the two decoupled. The acceptances are small: of order a tenth of a millisteradian in solid angle and a few percent in momentum for the $20\,\mathrm{GeV}/c$ instrument, roughly an order of magnitude more solid angle for the $8\,\mathrm{GeV}/c$ one, which is why the latter, reaching larger angles where the cross section is smaller, was the instrument for the Rosenbluth separations. The $20\,\mathrm{GeV}/c$ spectrometer covered angles from a few degrees to about 25°; the $8\,\mathrm{GeV}/c$ one reached 90°.

The detector stack behind the magnets had one job: identify an electron of measured momentum inside a burst that also contains pions from hadronic final states, at a pion-to-electron ratio that can reach 10^3 or more at small E'. It did so redundantly.

- *Scintillation hodoscopes.* Planes of narrow plastic scintillator strips, read by photomultipliers, giving the position in the dispersive and non-dispersive directions and hence E' and ϑ, together with the fast coincidence that forms the trigger.

- *A threshold gas Cherenkov counter.* A tank of gas at about atmospheric pressure — carbon dioxide or nitrogen, refractive index $n - 1 \approx 4.5 \times 10^{-4}$ — in which a particle radiates only if $\beta > 1/n$. The threshold Lorentz factor is $\gamma_{\mathrm{th}} = (1 - n^{-2})^{-1/2} \approx [2(n-1)]^{-1/2} = 33$, so the threshold momenta are

  $$p_{\mathrm{th}}(e) \approx \gamma_{\mathrm{th}} m_e c = 17\,\mathrm{MeV}/c\,, \qquad p_{\mathrm{th}}(\pi) \approx \gamma_{\mathrm{th}} m_\pi c = 4.7\,\mathrm{GeV}/c\,,$$

  using $m_e c^2 = (0.510\,998\,950\,00 \pm 0.000\,000\,000\,15)\,\mathrm{MeV}$ and $m_{\pi^\pm} c^2 = (139.570\,39 \pm 0.000\,18)\,\mathrm{MeV}$ [2427]. Every electron in the acceptance radiates; no pion below $4.7\,\mathrm{GeV}/c$ does.

- *A total-absorption shower counter.* Lead glass, some fifteen radiation lengths deep, in which an electron deposits its entire energy in an electromagnetic cascade while a pion deposits, on average, the small energy of a minimum-ionizing track plus whatever a nuclear interaction happens to give. Requiring the deposited energy to match the momentum measured magnetically is an independent rejection.

Together the two particle-identification devices suppress pions by three to four orders of magnitude with an electron efficiency near unity, and — because they are independent — each can be used to measure the other's efficiency directly from the data. First-hand accounts of the instrument and its use are the Nobel lectures of Taylor [1849] and Kendall [1848].

116.2.3 Targets, monitoring and normalisation

The target was liquid hydrogen, and for the neutron structure function liquid deuterium, held in thin-walled cells in a cryostat on the pivot axis.

Example 116.12 (The target as a number of scattering centres)**.** Liquid hydrogen at its boiling point, 20.3 K at atmospheric pressure, has density $\rho = 70.8\,\mathrm{kg/m^3}$. A cell of length $L = 0.30\,\mathrm{m}$ therefore presents an areal number density of protons

$$n_A = \frac{\rho L N_A}{M_{\mathrm{H}}} = \frac{70.8\,\mathrm{kg/m^3} \times 0.30\,\mathrm{m} \times 6.022\,140\,76 \times 10^{23}/\mathrm{mol}}{1.008 \times 10^{-3}\,\mathrm{kg/mol}} = 1.27 \times 10^{28}/\mathrm{m^2}\,, \tag{116.13}$$

with N_A the Avogadro constant, exact by the 2019 SI [2431]. Combined with the $6.24 \times 10^{12}/\mathrm{s}$ electrons of a 1 µA beam, the luminosity is $7.9 \times 10^{40}/(\mathrm{m^2\,s})$, so a differential cross section of $1 \times 10^{-38}\,\mathrm{m^2/sr}$ into the $1 \times 10^{-4}\,\mathrm{sr}$ acceptance of Section 116.2.2 yields $7.9 \times 10^{40}/(\mathrm{m^2\,s}) \times 1 \times 10^{-38}\,\mathrm{m^2/sr} \times 1 \times 10^{-4}\,\mathrm{sr} = 0.079/\mathrm{s}$, that is 285 counts an hour, which is the scale of the experiment.

Three systematic problems follow directly from the target and are dealt with in the design.

- *Boiling.* The beam deposits energy in the liquid and produces vapour bubbles, so the density in the beam path is lower than the static density and depends on the beam current. The cells were therefore built with forced circulation, and the density correction was measured *in situ* by comparing rates at different currents and extrapolating to zero.

- *Walls.* The cell windows scatter too. An identical empty cell was measured under identical conditions and subtracted; the subtraction is largest at small E', where the wall material's own inelastic yield is comparable with the hydrogen signal.

- *Radiation length.* The hydrogen itself is a radiator. With $X_0 = 630.4\,\mathrm{kg/m^2}$ for hydrogen, the 0.30 m cell is $\rho L/X_0 = 21.2\,\mathrm{kg/m^2}/630.4\,\mathrm{kg/m^2} = 0.034$ radiation lengths, and a 0.07 m cell about 0.008. That number enters the external radiative correction of Section 116.3.3 directly, and is the reason the short cell was used wherever the rate allowed.

The incident charge was measured by toroidal current monitors surrounding the beam pipe — non-intercepting, reading the pulse's own magnetic field — and by secondary-emission monitors, the two cross-calibrated against a Faraday cup that collects the beam absolutely. The absolute scale of the cross sections was in addition tied to elastic electron–proton scattering measured with the same apparatus, where Equation (116.2) and the

known form factors supply the answer: any error in luminosity, acceptance or efficiency shows up as a discrepancy in a cross section that is independently known. The residual normalisation uncertainty quoted for the programme is a few percent. The whole apparatus, the calibrations and the analysis are reviewed by Friedman and Kendall [1472].

116.3 Procedure

116.3.1 Kinematics of the measurement

The reaction is inclusive: $e + p \to e' + X$, with only the scattered electron detected and the hadronic system X left unobserved. That is not a limitation but the point — summing over every final state is what makes the cross section an object with a short-distance interpretation, and it is why a single-arm spectrometer suffices.

Notation 116.13 (The measured quantities and the invariants). Three numbers are measured for each event: the incident energy E, the scattered energy E' and the scattering angle ϑ. From them, neglecting the electron mass against the energies,

$$\nu = E - E' \,, \tag{116.14}$$

$$Q^2 = \frac{4EE'}{c^2} \sin^2 \frac{\vartheta}{2} \,, \tag{116.15}$$

$$x = \frac{Q^2}{2M\nu} = \frac{2EE' \sin^2(\vartheta/2)}{Mc^2\,(E - E')} \,, \tag{116.16}$$

$$y = \frac{\nu}{E} \,, \tag{116.17}$$

$$W^2 c^4 = M^2 c^4 + 2Mc^2 \nu - Q^2 c^2 \,, \tag{116.18}$$

where M is the proton mass, $Mc^2 = (0.938\,272\,088\,16 \pm 0.000\,000\,000\,29)\,\mathrm{GeV}$ [2427], and W is the invariant mass of the unobserved hadronic system. The variables x and y are dimensionless and lie in $[0, 1]$; ν is an energy; Q^2 carries $\mathrm{kg^2\,m^2/s^2}$; W is a mass. Elastic scattering is $W = M$, that is $x = 1$. This is Notation 102.43 written in laboratory variables.

Derivation of Equation (116.15). *Derives Equation* (116.15).

With $k = (E/c, \boldsymbol{k})$ and $k' = (E'/c, \boldsymbol{k}')$ the incident and scattered electron four-momenta and $q = k - k'$,

$$Q^2 = -q^2 = -\left(k - k'\right)^2 = -k^2 - k'^2 + 2k \cdot k' = 2\left(\frac{EE'}{c^2} - |\boldsymbol{k}|\,|\boldsymbol{k}'| \cos\vartheta\right)$$

using $k^2 = k'^2 = m_e^2 c^2 \approx 0$ at these energies. With $|\boldsymbol{k}| = E/c$ and $|\boldsymbol{k}'| = E'/c$ to the same accuracy,

$$Q^2 = \frac{2EE'}{c^2}\,(1 - \cos\vartheta) = \frac{4EE'}{c^2} \sin^2 \frac{\vartheta}{2} \,.$$

The neglect of m_e is quantitatively safe: at $E = 10\,\mathrm{GeV}$ the ratio $m_e^2 c^4 / E^2$ is 2.6×10^{-9}. □

The (E', ϑ) plane at fixed E divides into three regions, and the experiment is the traverse across them.

- *The elastic peak*, $W = M$, a line in the plane given by $E' = E/[1 + 2E \sin^2(\vartheta/2)/Mc^2]$. Its cross section is Equation (116.2) and it falls steeply, asymptotically as Q^{-12} and by a factor of a few thousand across the range of this survey (Phenomenon 116.4).
- *The resonance region*, W between M and about $2\,\mathrm{GeV}/c^2$, where the $\Delta(1232)$ and the higher nucleon resonances appear as bumps. Each resonance has its own transition form factor and each falls steeply with Q^2.

- *The deep inelastic region*, W above about $2\,\mathrm{GeV}/c^2$, where no individual state can be resolved and the cross section is smooth. This is where scaling is tested, and the $W > 2\,\mathrm{GeV}/c^2$ cut is the operational definition of "deep" used throughout the SLAC analysis.

The double-differential cross section in the measured variables is Equation (102.49),

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}E'} = \sigma_{\mathrm{Mott}}\left[W_2\left(x,Q^2\right) + 2W_1\left(x,Q^2\right)\tan^2\frac{\vartheta}{2}\right], \tag{116.19}$$

with σ_{Mott} given by Equation (102.50) and carrying m^2, so that the left-hand side carries $\mathrm{m}^2/(\mathrm{sr\,J})$ and W_1, W_2 each carry $1/\mathrm{J}$, as Definition 102.44 states.

116.3.2 The measurement programme

- *1967.* Commissioning runs with the $20\,\mathrm{GeV}/c$ spectrometer, elastic scattering measured first because it is the absolute calibration.
- *1968.* The inelastic survey at $\vartheta = 6^\circ$ and 10°, with incident energies from about $4.5\,\mathrm{GeV}$ to $17.7\,\mathrm{GeV}$, covering Q^2c^2 from roughly $0.7\,\mathrm{GeV}^2$ to $8\,\mathrm{GeV}^2$ and W up to about $5\,\mathrm{GeV}/c^2$. The results were reported at the Vienna conference in September 1968 [1379] and published as [1395].
- *1969.* The scaling analysis, in which νW_2 measured at different E, E' and ϑ is plotted against a single variable and found to collapse [1397].
- *1970–1972.* Extension to larger angles with the $8\,\mathrm{GeV}/c$ spectrometer, which is what makes the separation of W_1 from W_2 — and hence the measurement of R — possible; and deuterium running, which gives the neutron structure function by subtraction and hence the ratio F_2^{en}/F_2^{ep} of Section 116.4.4. Reviewed in [1472].

Proposition 116.14 (How two angles separate the two structure functions)**.** *Write the measured cross section Equation* (116.19) *in terms of the virtual-photon polarisation parameter*

$$\varepsilon = \left[1 + 2\left(1 + \frac{\nu^2}{Q^2c^2}\right)\tan^2\frac{\vartheta}{2}\right]^{-1}, \tag{116.20}$$

which is dimensionless and runs over $(0,1]$*. Then*

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}E'} = \Gamma_T\left[\sigma_T + \varepsilon\,\sigma_L\right], \tag{116.21}$$

with Γ_T *a purely kinematic flux factor. At fixed* (x,Q^2)*, plotting the measured cross section divided by* Γ_T *against* ε *gives a straight line whose intercept is* σ_T *and whose slope is* σ_L*; their ratio is* R *of Equation* (116.11)*.*

Rests on Equations (116.11) *and* (116.19) *and Notation 116.13.*

Proof. *Derives Proposition 116.14.*

Both ν and Q^2 are fixed once (x,Q^2) is fixed, by Equation (116.7), so the only freedom left in Equation (116.20) is ϑ; and ϑ can be varied at fixed (ν,Q^2) only by varying the beam energy, from Equations (116.14) and (116.15). Since $\tan^2(\vartheta/2)$ appears linearly in Equation (116.19) and ε is a Möbius function of it, the cross section is linear in ε, which is Equation (116.21); matching the two forms identifies the combinations $\sigma_T \propto W_1$ and $\sigma_L \propto W_2\left(1 + \nu^2/Q^2c^2\right) - W_1$, whose ratio is Equation (116.11).

The practical difficulty is visible in the algebra. A precise slope needs a long lever arm in ε, which needs a large range of ϑ at fixed (x,Q^2), which needs a large range of E — and each

beam energy carries its own normalisation. The uncertainty on R is therefore dominated by the *relative* normalisation between data sets taken months apart at different energies, not by counting statistics, and this is why R was quoted with an uncertainty comparable to its own value while νW_2 was known to better than 10 %. Section 116.4.3 returns to why the physics conclusion survives that. □

116.3.3 Radiative corrections and the systematic budget

The largest correction in the experiment is not instrumental. An electron that radiates a photon has a different energy from the one recorded, so the cross section extracted at a nominal (E, E') is contaminated by events that occurred at other kinematics — above all by elastic events in which a hard photon was emitted, which migrate into the inelastic region and can dominate it. Mo and Tsai gave the treatment used [1404].

Definition 116.15 (The three radiative processes)**.** *Internal* corrections are the $O(\alpha)$ QED corrections to the scattering itself: the vertex correction, the electron self-energies, vacuum polarisation of the exchanged photon (Chapter 100), and real bremsstrahlung from the incoming or outgoing electron at the scattering vertex. The virtual and real pieces are separately infrared divergent and their sum is finite, which is the Bloch–Nordsieck cancellation. *External* corrections are bremsstrahlung in the bulk material of the target and its windows, before and after the scattering, governed by the number of radiation lengths traversed. *Ionization* loss shifts the energy by a smaller, calculable amount.

Proposition 116.16 (The equivalent radiator)**.** *In the peaking approximation — in which bremsstrahlung photons are taken to be emitted exactly along the incident or the scattered electron direction, which is accurate because the characteristic emission angle is $m_e c^2/E \approx 5\times10^{-5}$ at $E = 10\,\mathrm{GeV}$ — the internal radiative correction is equivalent to placing a radiator of thickness*

$$t_{\mathrm{eq}} = \frac{\alpha}{\pi}\left[\ln\frac{Q^2c^2}{m_e^2c^4} - 1\right] \tag{116.22}$$

radiation lengths before and after the target. At $Q^2c^2 = 4\,\mathrm{GeV}^2$ and $m_e c^2 = 0.510\,998\,95\,\mathrm{MeV}$ [2427] this is

$$t_{\mathrm{eq}} = \frac{7.2974\times10^{-3}}{\pi}\left[\ln\frac{4}{2.611\times10^{-7}} - 1\right] = 2.323\times10^{-3}\times 15.54 = 0.036\,,$$

so the radiative tail is generated by an effective 3.6 % of a radiation length, to be compared with the 0.008 to 0.034 radiation lengths of real target material computed in Section 116.2.3.

Rests on Definition 116.15 and Proposition 102.48.

Proof. *Derives Proposition 116.16.*

The bremsstrahlung spectrum from a thin radiator of thickness t is $\mathrm{d}N/\mathrm{d}k = t/k$ per unit photon energy k to leading logarithmic accuracy, so the only thing a radiator does at this order is supply the coefficient of $\mathrm{d}k/k$. The one-loop QED correction to the elastic vertex supplies exactly the same $\mathrm{d}k/k$ spectrum with coefficient $(\alpha/\pi)\,[\ln(Q^2c^2/m_e^2c^4) - 1]$, the logarithm being the collinear (mass) singularity regulated by the electron mass and the -1 the constant left by the infrared cancellation — the same structure as Proposition 102.48, with the photon in place of the gluon. Equating the two coefficients gives Equation (116.22). The approximation is a leading-logarithm one; the exact treatment of [1404] keeps the non-peaking contributions and the exact elastic tail, and it is the difference between the two that sets the uncertainty quoted below. □

The unfolding is then a deconvolution: the measured yield at (E, E') is an integral of the true cross section over all (E_s, E_p) with $E_s \le E$ and $E_p \ge E'$ weighted by the radiator

kernel, plus the elastic tail computed from the known form factors. The equation is solved iteratively, starting from an assumed cross section and re-radiating until the prediction reproduces the data. In the SLAC analysis the correction reached several tens of percent at the smallest E', where the elastic tail is largest, and was typically 10–30 % in the deep inelastic region.

The systematic budget of the experiment is therefore dominated by theory, not by hardware:

- radiative corrections, a few percent of the cross section, being of order 10 % of a correction of order 25 %;
- absolute normalisation — beam charge, target density, solid angle and efficiency — a few percent, tied to elastic scattering as described in Section 116.2.3;
- relative normalisation between run periods, which is what limits R (Proposition 116.14);
- pion contamination, reduced below the percent level by the Cherenkov and shower counters and measured from the data;
- target-wall subtraction and acceptance modelling, each at the percent level.

The quoted uncertainty on νW_2 in the deep inelastic region is a few percent point-to-point with an overall scale uncertainty of a few percent on top [1472].

116.4 Observations and data

116.4.1 The weak fall-off of the inelastic cross section

Phenomenon 116.17 (The inelastic rate falls only weakly with momentum transfer)**.** The cross section for $e + p \to e' + X$ in the deep inelastic region falls far more slowly with Q^2 than the elastic cross section from the same target: measured relative to the point-charge (Mott) cross section, the inelastic rate is approximately independent of Q^2, whereas the elastic rate falls as the fourth power of the dipole form factor [1395].

Rests on Phenomenon 116.4 and Equation (116.19)*.*

Derivation. Derives Phenomenon 116.17.

For scattering from a static charge distribution $\rho(\boldsymbol{r})$ the Born amplitude is the Fourier transform

$$F(\boldsymbol{q}) = \int \rho(\boldsymbol{r})\, \mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}/\hbar}\, \mathrm{d}^3 r\,, \tag{116.23}$$

normalized so that $F(0) = 1$, and the cross section is the point-charge one multiplied by $|F|^2$. If ρ is smooth on a scale R then F varies on the scale $\hbar/R$ in q and falls rapidly beyond it, so a distribution of root mean square radius near 0.8 fm [1088] suppresses the elastic rate steeply once $Q \gtrsim \hbar/R$ — which is the measured dipole behaviour of Phenomenon 116.4. The one way to obtain a rate that does *not* fall is a scattering centre with $F \equiv 1$, that is, one with no structure at the resolution probed. A cross section flat in Q^2 therefore says the electron is rebounding from something point-like inside the proton, exactly as Rutherford's large-angle alpha particles said the atom contained a small hard core; the soft extended proton of Section 116.1.1 cannot produce it. □

The size of the contrast is worth stating numerically, because it is the whole result, and the comparison must be made between like quantities. Over the range Q^2c^2 from 1 GeV^2 to 8 GeV^2, the elastic cross section *divided by* σ_{Mott} falls by a factor of about 3.4×10^2 (Phenomenon 116.4), while the ratio of the inelastic cross section to σ_{Mott} at fixed W above

$2\,\mathrm{GeV}/c^2$ changes by less than a factor of two [1395]. Between two and three orders of magnitude therefore separate the two behaviours, and no experimental systematic of the kind catalogued in Section 116.3.3 is of that size. Comparing the raw cross sections instead of their ratios to σ_{Mott} makes the contrast larger still, by the further factor of about ten that the Mott fall-off itself supplies.

116.4.2 Scaling of the structure functions

Phenomenon 116.18 (Bjorken scaling)**.** Plotted against the single variable $x = Q^2/2M\nu$, the measured structure function νW_2 collapses onto one curve: data taken at different beam energies, scattering angles and momentum transfers, covering Q^2 from about $1\,\mathrm{GeV}^2/c^2$ to $8\,\mathrm{GeV}^2/c^2$, lie on a common function of x alone, with no separate dependence on Q^2 within the errors [1397] — as had been predicted from current algebra [1393].

Rests on Phenomenon 116.6, Notation 116.13, and Equation (116.9)*.*

Derivation. *Derives Phenomenon 116.18.*

Regard the proton, in a frame where its momentum P is large, as a collection of free constituents, one of which carries a fraction ξ of its four-momentum [1394, 1401]. The electron scatters elastically off that one, so after absorbing the virtual photon of four-momentum q the struck constituent must again be on shell. Neglecting its mass against Q,

$$(\xi P + q)^2 = (\xi P)^2 \quad \Longrightarrow \quad 2\xi P \cdot q + q^2 = 0\,,$$

and with $q^2 = -Q^2$ and $P \cdot q = M\nu$ in the proton rest frame,

$$\xi = \frac{Q^2}{2M\nu} = x\,. \tag{116.24}$$

The measured x is therefore the momentum fraction of whatever was struck, and the inclusive cross section is the incoherent sum over constituents of a point-like elastic cross section, weighted by the probability of finding one at that fraction. That probability is a property of the proton and not of the probe, so the structure functions depend on x and not separately on Q^2: which is the observed collapse. The step that must eventually fail is the assumption that the constituents are free, and its failure is exactly the logarithmic Q^2 dependence of Section 116.6. □

Two things about the 1969 presentation deserve recording, because both are lessons about how such a result is established.

The original plots were made against $\omega = 1/x = 2M\nu/Q^2$ rather than against x, which spreads out the small-x region where the data then were; the modern convention is x, and the two are trivially related. And the collapse was demonstrated not by superposing curves but by plotting νW_2 at fixed ω against Q^2 and showing the result to be flat: a null test, in which the quantity that would carry the signature of a constituent size is displayed as a function of the variable it would depend on. Within the errors then available — a few percent point to point — no dependence was seen over the factor of eight in Q^2 covered [1379, 1397]. That the dependence is in fact present, and logarithmic, was established only when the lever arm in Q^2 grew by two further orders of magnitude (Sections 116.6.3 and 116.6.4).

116.4.3 The longitudinal-to-transverse ratio

This is the subsection to which Section 102.5 defers the experimental side of the Callan–Gross relation.

Phenomenon 116.19 (The longitudinal cross section is small)**.** The ratio $R = \sigma_L/\sigma_T$ of longitudinal to transverse virtual-photon absorption is measured to be small and consistent with zero, in the range 0.1 to 0.2 with comparable uncertainty, throughout the deep inelastic region [1397, 1472]. Equivalently the Callan–Gross relation $F_2(x) = 2xF_1(x)$ holds [1398].

Rests on Phenomenon 116.9, Proposition 116.14, and Equation (116.11)*.*

Derivation. Derives Phenomenon 116.19.

Work in the Breit frame, where the virtual photon transfers no energy and the struck constituent simply reverses its momentum, from $-p\hat{\boldsymbol{z}}$ to $+p\hat{\boldsymbol{z}}$. For a constituent of spin $\frac{1}{2}$ and negligible mass the vector coupling to the photon does not connect states of opposite chirality, so helicity is conserved; since the momentum reverses while the helicity does not, the projection of the spin on the fixed axis $\hat{\boldsymbol{z}}$ must reverse, and the constituent's angular momentum along that axis changes by ± 1 in units of $\hbar$. A transverse photon carries exactly $J_z = \pm 1$ and can supply it; a longitudinal photon carries $J_z = 0$ and cannot. Hence $\sigma_L = 0$ and $R = 0$ for spin-$\frac{1}{2}$ constituents. For spin-0 constituents the argument runs the other way: there is no spin to reverse, so J_z must be unchanged, only the longitudinal photon can be absorbed, and $R \to \infty$. The two hypotheses therefore predict opposite extremes of the same measured ratio, and the observed small R selects spin $\frac{1}{2}$. This is the sharpest of the early discriminators precisely because it is a ratio: it needs no absolute normalization and no knowledge of any structure function. □

Remark 116.20 (Why the conclusion survives the systematic budget)*.* Proposition 116.14 showed that R is the quantity most exposed to the relative normalisation between run periods, and the quoted uncertainty — of the same size as the central value — says so honestly. The conclusion is nevertheless not in doubt, and the reason is the structure of Phenomenon 116.9. The two hypotheses do not differ by a factor: spin $\frac{1}{2}$ gives $R = 0$ and spin 0 gives $R = \infty$, so what the measurement has to establish is only that R is finite and small. A systematic error large enough to move a measured $R = 0.18 \pm 0.10$ to a value consistent with a scalar constituent would have to be not a few percent but several hundred percent, which is excluded by the elastic normalisation of Section 116.2.3. The measurement is imprecise and the inference is not; distinguishing the two is the point of quoting the uncertainty.

The small non-zero value has since been understood and is itself a QCD prediction: gluon radiation gives a struck quark transverse momentum, which breaks the helicity argument at order α_s and generates $F_L \neq 0$. That R came out small rather than exactly zero is therefore, in retrospect, evidence for the interacting theory rather than against the parton picture.

116.4.4 Quark charges from the structure functions

Running the same apparatus on liquid deuterium gives, after correction for Fermi motion and the subtraction of the proton, the neutron structure function; and the ratio of the two is a direct measurement of the constituents' charges.

Proposition 116.21 (What the neutron-to-proton ratio measures)**.** *In the parton model with u and d quarks and isospin symmetry relating the neutron to the proton by $u \leftrightarrow d$,*

$$\frac{F_2^{en}(x)}{F_2^{ep}(x)} = \frac{4d(x) + u(x)}{4u(x) + d(x)}\,, \tag{116.25}$$

where u and d are the proton's distributions and the sea has been neglected. The ratio is bounded by $\frac{1}{4}$ and 4 for any *distributions, the extremes corresponding to pure u and pure d; the measured values lie inside those bounds and approach $\frac{1}{4}$ as $x \to 1$ [1394, 1472].*

Rests on Equation (116.9) *and Definition 102.5.*

Proof. *Derives Proposition 116.21.*

Substituting the charges $e_u = \frac{2}{3}e$ and $e_d = -\frac{1}{3}e$ into Equation (116.9) gives $F_2^{ep} = x[\frac{4}{9}u + \frac{1}{9}d]$, and isospin exchanges the two for the neutron, $F_2^{en} = x[\frac{4}{9}d + \frac{1}{9}u]$; dividing gives Equation (116.25), in which the overall factor $\frac{1}{9}$ and the common x cancel. The bounds follow by setting $d = 0$ or $u = 0$. The content is that the bounds depend only on the *charges*: constituents of charge ± 1 in units of e would give a ratio bounded by different numbers, and integer-charged constituents in any assignment reproducing the proton and neutron charges cannot produce a ratio approaching $\frac{1}{4}$ at large x. This is a measurement of e_u/e_d that never requires a free quark, and it is why the deuterium running mattered as much as the hydrogen running. □

Remark 116.22 (The Gottfried sum and the asymmetric sea). The same two structure functions give a sum rule. From the charges,

$$S_G := \int_0^1 \frac{F_2^{ep}(x) - F_2^{en}(x)}{x}\,\mathrm{d}x = \frac{1}{3} + \frac{2}{3}\int_0^1 \left[\bar{u}(x) - \bar{d}(x)\right]\mathrm{d}x\,, \tag{116.26}$$

because the valence content of the proton is uud and of the neutron udd, so that $\int_0^1 u_v = 2$ and $\int_0^1 d_v = 1$ and the valence part of the difference integrates to

$$(2-1)\times\tfrac{4}{9} + (1-2)\times\tfrac{1}{9} = \tfrac{4}{9} - \tfrac{1}{9} = \tfrac{1}{3}\,,$$

the charge weights being those of Proposition 116.21; the sea survives only in the combination shown. A symmetric sea therefore predicts $S_G = \frac{1}{3}$. The measured value is significantly smaller, near 0.24, which is direct evidence that the light-quark sea is flavour-asymmetric with $\bar{d} > \bar{u}$ — an asymmetry no perturbative gluon splitting can generate, since gluons produce flavours democratically. The measurement is the New Muon Collaboration's reevaluation of the Gottfried sum from muon scattering on hydrogen and deuterium [1879]; the same asymmetry is seen directly, in a different process, by the Drell–Yan measurement of Section 116.7.3.

116.4.5 The measured numbers

Table 116.1 collects the headline quantities of the electron-scattering programme and the constants used to interpret them; Table 116.2 does the same for the neutrino measurements analysed in Section 116.5.3, and Table 116.3 for the later high-precision programme. All three sit here, under this rubric, rather than beside the sections that use them: a reader looking for the chapter's numbers should find them in one place. Every value is given with the uncertainty its source quotes, and a value inferred here from cited inputs is labelled derived, with the arithmetic shown in the text and its error propagated.

116.5 Interpretation

116.5.1 Point-like constituents

What the data establish, stated as narrowly as possible: over the range of momentum transfer covered, the charged objects from which the virtual photon scatters exhibit no form factor. Equivalently, they have no measurable size down to the resolution the experiment reaches.

Proposition 116.23 (The resolution actually achieved)**.** *A virtual photon of momentum transfer Q resolves transverse distances of order*

$$\ell = \frac{\hbar}{Q} = \frac{\hbar c}{Qc}\,, \tag{116.27}$$

Table 116.1: Headline numbers of the SLAC–MIT deep inelastic programme and the constants used to interpret them. Energies in GeV carry their joule equivalent through Equation (116.1). The value of R is the one the collaboration used in extracting νW_2 and quotes as its measured average over the deep inelastic region; its uncertainty is dominated by relative normalisation, as Proposition 116.14 explains. The structure-function integral is quoted to two figures because that is the accuracy of the review it comes from, and the uncertainty attached to it here is that implied precision and not a quoted error. Rows that record a beam setting, an angular position or an analysis cut carry no uncertainty because they define the run conditions rather than measure them; every row that reports a measured or derived quantity carries one.

Quantity	Value	Year	Source
Beam energy range (setting; calibrated to a few parts in 10^3)	4.5–20 GeV, i.e. 7.2×10^{-10}–3.2×10^{-9} J	1968	[1363, 1395]
Scattering angles, first survey (setting)	6° and 10°	1968	[1395]
Q^2c^2 covered (kinematic reach)	0.7–8 GeV^2; in SI, Q^2 from 2.0×10^{-37} to 2.3×10^{-36} kg^2 m^2/s^2	1968	[1395]
Deep inelastic cut on W (analysis cut)	$W > 2\,\mathrm{GeV}/c^2$	1969	[1397]
Elastic suppression across that Q^2 range, relative to σ_{Mott} at 10°	factor $\approx 6.3 \times 10^2$ (raw cross section $\approx 8.6 \times 10^3$); derived from the dipole, whose own 10 % accuracy makes these factors good to a few tens of percent	1956	[1088]
Inelastic-to-Mott ratio across the same range	changes by less than a factor 2	1969	[1395]
$R = \sigma_L/\sigma_T$	0.18 ± 0.10	1969–72	[1397, 1472]
$\int_0^1 F_2^{eN}(x)\,\mathrm{d}x$ (isoscalar)	0.14 ± 0.01, the error being the precision to which the review quotes it	1972	[1472]
Resolution $\hbar c/(Qc)$ at $Q^2c^2 = 8\,\mathrm{GeV}^2$	7.0×10^{-17} m (derived; exact given Q, to which the 10^{-3} beam calibration propagates)	1968	Equation (116.27)
Proton mass	$(1.672\,621\,925\,95 \pm 0.000\,000\,000\,52) \times 10^{-27}$ kg	2022	[2431]
Proton mass energy	$(0.938\,272\,088\,16 \pm 0.000\,000\,000\,29)$ GeV	2024	[2427]
Proton rms charge radius	$(8.4075 \pm 0.0064) \times 10^{-16}$ m	2022	[2431]
Fine-structure constant	$(7.297\,352\,564\,3 \pm 0.000\,000\,001\,1) \times 10^{-3}$	2022	[2431]

Table 116.2: Neutrino deep inelastic scattering: the measured total cross sections, the ratio that tests the valence hypothesis, and the momentum fractions derived from them in Proposition 116.28. Uncertainties on the derived rows are propagated from the quoted ones only and exclude the flux normalisation, which is the larger error and which the text discusses. The mean squared charge compares the neutrino integral with the electron one of Table 116.1.

Quantity	Value	Year	Source
$\sigma^{\nu N}/E_\nu$	$(7.4\pm0.2)\times10^{-43}\,\mathrm{m^2/GeV}$	1973	[1497]
$\sigma^{\bar\nu N}/E_{\bar\nu}$	$(2.8\pm0.1)\times10^{-43}\,\mathrm{m^2/GeV}$	1973	[1497]
Ratio $\sigma^{\bar\nu}/\sigma^{\nu}$	0.378 ± 0.017; $\frac{1}{3}$ for pure quarks	1973	[1497]
$C = 2Mc^2G_F^2/\pi(\hbar c)^4$	$3.164 \times 10^{-42}\,\mathrm{m^2/GeV}$ (derived; exact to the constants it is built from)	1973	Equation (116.34)
Quark momentum fraction Q	0.230 ± 0.007 (derived)	1973	Equation (116.35)
Antiquark momentum fraction $\bar Q$	0.0119 ± 0.0043 (derived)	1973	Equation (116.35)
$\int_0^1 F_2^{\nu N}\mathrm{d}x$	0.484 ± 0.011 (derived)	1973	Equation (116.35)
Mean squared charge $\int F_2^{eN}/\int F_2^{\nu N}$	0.29 ± 0.02 (derived); $5/18 = 0.278$	1972–73	[1472, 1497]
Nucleon momentum in charged constituents	0.50 ± 0.04 (derived from $\int F_2^{eN}\mathrm{d}x$ and 5/18); reported as about one half on iron	1972–79	[1472, 1639]

Table 116.3: The later high-precision programme. Rows giving a beam setting or a published kinematic coverage carry no uncertainty because they state run conditions rather than measurements. A value read from a published curve rather than from a table is marked as such and is quoted with its reading precision, which is not the collaboration's error and is always the larger of the two. The strong coupling is the world average, to which deep inelastic determinations contribute.

Quantity	Value	Year	Source
BCDMS muon beam energies (setting)	100–280 GeV	1989	[1815]
BCDMS coverage (kinematic reach)	$0.06 < x < 0.8$; $7\,\mathrm{GeV}^2 < Q^2c^2 < 260\,\mathrm{GeV}^2$	1989	[1815]
HERA beam energies (setting)	27.5 GeV on 920 GeV, $\sqrt{s}\,c = 318\,\mathrm{GeV}$	2010–15	[2152, 2244]
Equivalent fixed-target energy	54 TeV (derived; exact given the beam energies)	2010–15	Equation (116.39)
HERA combined coverage (kinematic reach)	$6 \times 10^{-7} < x < 0.65$; $0.045\,\mathrm{GeV}^2 < Q^2c^2 < 5 \times 10^4\,\mathrm{GeV}^2$	2015	[2244]
Small-x exponent λ, read from the published curves	0.1 at $Q^2c^2 = 1\,\mathrm{GeV}^2$ and 0.3 at $100\,\mathrm{GeV}^2$, each to the reading precision ± 0.05	2015	[2244]
Gluon density $[xg](2 \times 10^{-3})$ at $Q^2c^2 = 20\,\mathrm{GeV}^2$	8 ± 2 (derived from a slope read off the data; the leading-order relation is itself good only to that accuracy)	2015	Equation (116.40)
$\alpha_s(m_Z c^2)$	0.1180 ± 0.0009	2024	[2427]
$F_2^{\mathrm{Fe}}/F_2^{\mathrm{D}}$ at $x = 0.65$, read from the published ratio curve	0.89 ± 0.01 reading precision	1983	[1712]
$F_2^{\mathrm{Fe}}/F_2^{\mathrm{D}}$ at $x = 0.05$, read from the published ratio curve	1.15 ± 0.01 reading precision	1983	[1712]
$\Gamma_1^p = \int_0^1 g_1^p \mathrm{d}x$ at $\langle Q^2 \rangle\, c^2 = 10.7\,\mathrm{GeV}^2$	$0.114 \pm 0.012 \pm 0.026$; Ellis–Jaffe expectation ≈ 0.19	1988	[1804]

so at the largest momentum transfer of the original survey, $Q^2c^2 = 8\,\mathrm{GeV}^2$ *and hence* $Qc = 2.83\,\mathrm{GeV}$*,*

$$\ell = \frac{3.161\,526\,77 \times 10^{-26}\,\mathrm{J\,m}}{2.83\,\mathrm{GeV} \times 1.602\,176\,634 \times 10^{-10}\,\mathrm{J/GeV}} = 7.0 \times 10^{-17}\,\mathrm{m}\,,$$

about one twelfth of the proton's charge radius $(8.4075 \pm 0.0064) \times 10^{-16}\,\mathrm{m}$ *[2431]. The absence of a form factor at that resolution is the whole of the experimental claim: it is an upper limit on a constituent size of about* $1 \times 10^{-16}\,\mathrm{m}$*, not a demonstration that the size is zero.*

Rests on Equations (116.1) *and* (116.23)*.*

Proof. *Derives Proposition 116.23.*

The Fourier transform Equation (116.23) relates a distribution of extent ℓ to a form factor varying on the momentum scale $\hbar/\ell$; a structure smaller than $\hbar/Q$ produces a form factor still equal to one at the Q probed, and is therefore invisible. The numerical evaluation uses only Equation (116.1) and the definition of $\hbar c$. □

Remark 116.24 (What the data do not say). Three limitations are worth stating explicitly, because the result was sometimes over-read at the time and is sometimes over-read now.

First, scaling says nothing about confinement. The experiment establishes that something point-like inside the proton absorbs the photon; it says nothing whatever about whether that something can be removed from the proton, and indeed the same experiment sees only hadrons in the final state. The two facts sat uncomfortably together until asymptotic freedom explained how a theory can be free at short distance and strong at long distance (Section 116.6.1).

Second, scaling does not by itself identify the constituents as the quarks of the spectroscopy. It says there are point-like charged objects. That they carry spin $\frac{1}{2}$ comes from Section 116.4.3, that they carry fractional charge from Section 116.4.4 and Section 116.5.3, and that their number and quantum numbers match the quark model from the combination.

Third, the alternatives were serious and were killed by the data, not by taste. Vector-meson dominance, in which the virtual photon converts into a ρ meson which then interacts hadronically, predicts a cross section falling with Q^2 like the square of a vector-meson propagator and cannot give a flat ratio to the Mott cross section. Regge-based and diffractive pictures predicted specific ν and Q^2 dependences that the scaling plot excludes. It is the null test of Section 116.4.2 — flat in Q^2 at fixed ω — that discriminates, and that is why it was presented that way.

Friedman's Nobel lecture [1844] is the best first-hand account of how the interpretation was arrived at, including how long it took: the 1968 data were presented as a puzzle, and the parton reading became the consensus only over the following three or four years, as the Callan–Gross test and the neutrino comparison came in.

116.5.2 The missing momentum fraction

This is the subsection to which Phenomenon 102.47 defers the details of the extraction.

Phenomenon 116.25 (Half the proton momentum is invisible to the photon)**.** The momentum fraction carried by the electrically charged constituents, obtained by integrating the measured structure function, is about one half rather than one [1472]. Comparing neutrino with electron scattering on an isoscalar target confirms the deficit independently and returns a mean squared constituent charge close to 5/18 in units of the elementary charge squared [1497, 1639].

Rests on Equation (116.9) *and Proposition 102.46.*

Derivation. *Derives Phenomenon 116.25.*

In the parton model $F_2(x) = \sum_i e_i^2\, x\, q_i(x)$, where $q_i(x)\mathrm{d}x$ is the number of constituents of charge e_i with momentum fraction in $\mathrm{d}x$. The proton's momentum is shared among all its constituents, so

$$\sum_{\text{all } i} \int_0^1 x\, q_i(x)\, \mathrm{d}x = 1\,, \tag{116.28}$$

the sum running over *every* constituent, charged or not. What the electron measures is the charge-weighted sum: dividing $\int F_2\, \mathrm{d}x$ by the mean squared charge gives the momentum carried by the charged constituents alone, and that comes out near one half. The remainder of Equation (116.28) is carried by constituents that do not couple to the photon. The mean squared charge itself is not assumed but measured, by comparing the electron and neutrino structure functions on an isoscalar target: the weak charged current couples with the same strength to every quark flavour, so the ratio of the two integrals is the mean squared electric charge, and for equal numbers of u and d quarks

$$\left\langle e^2 \right\rangle = \tfrac{1}{2}\left[\left(\tfrac{2}{3}\right)^2 + \left(\tfrac{1}{3}\right)^2\right] = \frac{5}{18}\,,$$

which is what is found [1639]. Numerically, the neutrino integral extracted in Section 116.5.3 is $\int F_2^{\nu N}\mathrm{d}x = 0.484 \pm 0.011$ and the electron one is 0.14 ± 0.01 [1472], the second error being the precision to which the review quotes the number rather than an error it states; their ratio is 0.29 ± 0.02, to be compared with $5/18 = 0.278$. Dividing the electron integral by $5/18$ instead gives the momentum fraction in charged constituents directly, $0.14 \pm 0.01/0.278 = 0.50 \pm 0.04$ — the "about one half" of the statement above, now with the error it carries. The neutral, non-scattering carrier of the missing momentum is the gluon of Chapter 102; the inference here is from a deficit, and the direct confirmation came later, from three-jet events in electron–positron annihilation (Section 102.6.2). □

The deficit is not a defect of the measurement but a prediction of the theory, and quantum chromodynamics says where the missing momentum must eventually settle.

Proposition 116.26 (The asymptotic sharing of momentum)**.** *Under the evolution equations of Theorem 102.49, the momentum fractions carried by quarks and by gluons approach fixed values determined by n_f alone:*

$$\langle x \rangle_{q+\bar{q}} \longrightarrow \frac{3n_f}{16 + 3n_f}\,, \qquad \langle x \rangle_{g} \longrightarrow \frac{16}{16 + 3n_f}\,, \tag{116.29}$$

which for $n_f = 4$ is $\frac{12}{28} = 0.43$ and $\frac{16}{28} = 0.57$. The observed near-equal sharing is therefore not a coincidence: it is where the evolution is heading.

Rests on Theorem 102.49, Corollary 102.50, and Equation (102.62).

Proof. *Derives Proposition 116.26.*

Take the momentum moment $N = 1$ of the coupled singlet equations, using the moment notation $\gamma_N = \int_0^1 z^N P(z)\, \mathrm{d}z$ of Corollary 102.50. Write $\Sigma := \int_0^1 x \sum_q [q(x) + \bar{q}(x)]\mathrm{d}x$ and $G := \int_0^1 x\, g(x)\, \mathrm{d}x$. Four coefficients are needed:

$$A_{qq} = \int_0^1 z\, P_{qq}(z)\, \mathrm{d}z = -\tfrac{4}{3}C_F = -\tfrac{16}{9}\,, \qquad A_{qg} = 2n_f \int_0^1 z\, P_{qg}(z)\, \mathrm{d}z = \frac{n_f}{3}\,,$$

the first from Equation (102.62) and the second from $P_{qg}(z) = T_F[z^2 + (1-z)^2]$ with $T_F = \frac{1}{2}$, since $\int_0^1 z[z^2 + (1-z)^2]\mathrm{d}z = \frac{1}{3}$ and there are $2n_f$ quark and antiquark species a gluon can convert into. The remaining two follow from momentum conservation without further

computation: the total momentum $\Sigma + G$ cannot change with Q^2, so $A_{qq} + A_{gq} = 0$ and $A_{qg} + A_{gg} = 0$, giving $A_{gq} = +\frac{16}{9}$ and $A_{gg} = -n_f/3$. The evolution is then

$$\frac{\mathrm{d}}{\mathrm{d}\ln Q^2}\begin{pmatrix}\Sigma\\ G\end{pmatrix} = \frac{\alpha_s\left(Q^2\right)}{2\pi}\begin{pmatrix}-\frac{16}{9} & \frac{n_f}{3}\\ \frac{16}{9} & -\frac{n_f}{3}\end{pmatrix}\begin{pmatrix}\Sigma\\ G\end{pmatrix}. \tag{116.30}$$

The matrix has eigenvalue 0, with eigenvector $(\Sigma, G) \propto (n_f/3,\, 16/9)$, and eigenvalue $-(\frac{16}{9} + \frac{n_f}{3})$, whose eigenvector decays. Since α_s falls only logarithmically the decay is slow, but its direction is fixed: the surviving combination is the null eigenvector, normalized by $\Sigma + G = 1$, which gives Equation (116.29) after dividing through by $\frac{1}{3}$. Note that the answer does not involve α_s, Λ_{QCD} or the initial distributions — only the group theory in C_F and T_F and the number of active flavours.

Measured values at Q^2c^2 near $10\,\mathrm{GeV}^2$ put the gluon fraction near 0.45 [2427], below the asymptotic 0.57 for $n_f = 4$, and rising slowly with Q^2 as the second eigenvector dies away — which is exactly the pattern the global fits of Section 116.6.5 find. □

116.5.3 Neutrino deep inelastic scattering

The electron probes the quarks with weights e_i^2. The charged weak current probes them with weights that are independent of electric charge and that distinguish quarks from antiquarks, so the two probes together separate the charge weights from the distributions. The weak-current theory is Chapter 101; the neutrino beams and the Gargamelle chamber are described in Chapter 104, where the same exposures gave the neutral current.

Phenomenon 116.27 (The neutrino cross section rises linearly with energy)**.** The total charged-current cross sections for $\nu_\mu + N \to \mu^- + X$ and $\bar{\nu}_\mu + N \to \mu^+ + X$ on an approximately isoscalar target rise in proportion to the neutrino energy, with

$$\frac{\sigma^{\nu N}}{E_\nu} = (7.4 \pm 0.2) \times 10^{-43}\,\mathrm{m}^2/\mathrm{GeV} = (4.62 \pm 0.12) \times 10^{-33}\,\mathrm{m}^2/\mathrm{J}\,, \tag{116.31}$$

$$\frac{\sigma^{\bar{\nu} N}}{E_{\bar{\nu}}} = (2.8 \pm 0.1) \times 10^{-43}\,\mathrm{m}^2/\mathrm{GeV} = (1.75 \pm 0.06) \times 10^{-33}\,\mathrm{m}^2/\mathrm{J}\,, \tag{116.32}$$

measured in the Gargamelle bubble chamber at CERN [1497]. A linear rise is what point-like constituents require and what a target with a form factor forbids.

Rests on Equations (104.3) *and* (116.9).

Derivation. *Derives Phenomenon 116.27.*

The four-fermion charged-current interaction of Chapter 101 has coupling $G_F = (1.435\,851\,2 \pm 0.000\,000\,7) \times 10^{-62}\,\mathrm{J\,m}^3$, equivalently $G_F/(\hbar c)^3 = (1.166\,378\,7 \pm 0.000\,000\,6) \times 10^{-5}/\mathrm{GeV}^2$ (Equation (104.3)), the uncertainty being the relative 5.1×10^{-7} of the second form carried over; it is a dimensionful coupling, and that is the whole argument. For the point process $\nu + q \to \mu^- + q'$ the amplitude is proportional to G_F and carries no propagator, so the squared amplitude is proportional to G_F^2 times the only invariant available, and the cross section is

$$\hat{\sigma}\left(\nu q\right) = \frac{G_F^2\,\hat{s}c^2}{\pi\left(\hbar c\right)^4}\,, \qquad \hat{\sigma}\left(\nu \bar{q}\right) = \frac{G_F^2\,\hat{s}c^2}{3\pi\left(\hbar c\right)^4}\,, \tag{116.33}$$

where $\hat{s}$ is the squared centre-of-mass four-momentum of the neutrino–parton system. It is written here with the same dimension as Q^2, namely $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$, so that $\hat{s}c^2$ is an energy squared and the convention is the one used for s at HERA in Proposition 116.33 and for the Drell–Yan variable in Equation (116.43); this chapter never gives s the dimension of an energy squared. The dimensions check: $G_F^2\hat{s}c^2$ carries $\mathrm{J}^4\,\mathrm{m}^6$ and $(\hbar c)^4$ carries $\mathrm{J}^4\,\mathrm{m}^4$, leaving m^2. The factor $\frac{1}{3}$ for antiquarks is the angular-momentum suppression: ν and q are both left-handed, so their total angular momentum along the beam vanishes and the scattering is

isotropic, while ν and $\bar{q}$ have $J = 1$ aligned and the $\mathrm{d}\sigma/\mathrm{d}y \propto (1-y)^2$ distribution integrates to a third.

With the struck parton carrying fraction x of the nucleon momentum, $\hat{s} = x\,s$ and $sc^2 = M^2c^4 + 2Mc^2E_\nu \approx 2Mc^2E_\nu$ for a stationary target, so integrating over the parton content gives a cross section *proportional to* E_ν:

$$\frac{\sigma^{\nu N}}{E_\nu} = C\left[Q + \frac{\bar{Q}}{3}\right], \qquad \frac{\sigma^{\bar{\nu}N}}{E_{\bar{\nu}}} = C\left[\frac{Q}{3} + \bar{Q}\right], \qquad C := \frac{2Mc^2G_F^2}{\pi\,(\hbar c)^4}, \tag{116.34}$$

where Q and $\bar{Q}$ are the momentum fractions carried by the quarks and antiquarks that the current can reach on an isoscalar nucleon. Evaluating the constant in SI,

$$\begin{aligned} C &= \frac{2 \times 1.503\,277 \times 10^{-10}\,\mathrm{J} \times \left(1.435\,851 \times 10^{-62}\,\mathrm{J\,m^3}\right)^2}{\pi\,(3.161\,526\,77 \times 10^{-26}\,\mathrm{J\,m})^4} \\ &= 1.975 \times 10^{-32}\,\mathrm{m^2/J} = 3.164 \times 10^{-42}\,\mathrm{m^2/GeV}\,. \end{aligned}$$

The linearity is thus a direct consequence of G_F having dimensions of $\mathrm{J\,m^3}$ together with the absence of any other scale in the target: a constituent with a size a would supply a form factor cutting the rise off at $E_\nu \sim \hbar^2/(2Ma^2)$, and no such cut-off is seen. □

Proposition 116.28 (The momentum fractions from the two cross sections)**.** *Solving Equation* (116.34) *for* Q *and* $\bar{Q}$ *with the measured values Equations* (116.31) *and* (116.32) *gives*

$$Q = 0.230 \pm 0.007\,, \qquad \bar{Q} = 0.0119 \pm 0.0043\,, \qquad \int_0^1 F_2^{\nu N}(x)\,\mathrm{d}x = 2\left(Q + \bar{Q}\right) = 0.484 \pm 0.011\,. \tag{116.35}$$

About half the nucleon's momentum is therefore carried by objects the weak current can reach, and the antiquark "sea" accounts for $(4.9 \pm 1.8)\,\%$ *of that at leading order — a fraction whose error is more than a third of itself, which is why no more than its first figure may be used.*

Rests on Equations (116.31), (116.32) *and* (116.34).

Proof. *Derives Proposition 116.28.*

Write $a := \sigma^{\nu N}/(CE_\nu) = Q + \bar{Q}/3$ and $b := \sigma^{\bar{\nu}N}/(CE_{\bar{\nu}}) = Q/3 + \bar{Q}$. From the measured values and the constant C just evaluated,

$$a = \frac{7.4 \times 10^{-43}}{3.164 \times 10^{-42}} = 0.2339\,, \qquad b = \frac{2.8 \times 10^{-43}}{3.164 \times 10^{-42}} = 0.0885\,.$$

Adding, $a + b = \frac{4}{3}(Q + \bar{Q})$, so $Q + \bar{Q} = \frac{3}{4}(a + b) = 0.2418$; and subtracting a from $3b$ gives $\frac{8}{3}\bar{Q} = 3b - a = 0.0316$, whence $\bar{Q} = 0.0119$ and $Q = 0.2299$. On an isoscalar nucleon the neutrino structure function is $F_2^{\nu N}(x) = x\sum_q [q(x) + \bar{q}(x)]$ with unit weights, and the sum over both nucleon types doubles the per-current fractions, so $\int F_2^{\nu N}\mathrm{d}x = 2(Q + \bar{Q}) = 0.484$.

The errors propagate from $\delta a = 0.006\,32$ and $\delta b = 0.003\,16$, which are the quoted relative errors of Equations (116.31) and (116.32) applied to a and b. Since $Q = \frac{9}{8}a - \frac{3}{8}b$ and $\bar{Q} = \frac{3}{8}(3b - a)$,

$$\delta Q = \sqrt{\left(\tfrac{9}{8}\delta a\right)^2 + \left(\tfrac{3}{8}\delta b\right)^2} = 0.0072\,, \qquad \delta\bar{Q} = \tfrac{3}{8}\sqrt{(3\delta b)^2 + (\delta a)^2} = 0.0043\,,$$

and $\delta\int F_2^{\nu N}\mathrm{d}x = \frac{3}{2}\sqrt{(\delta a)^2 + (\delta b)^2} = 0.011$. Note how much worse the antiquark fraction is determined than the sum: the difference $3b - a$ subtracts two numbers of comparable size, so its error is essentially the full error of a.

Three caveats belong with the number, and each is a real limitation. The uncertainties propagated are the collaboration's quoted ones and do not include the neutrino flux normalisation, which was uncertain at the 10 % level and would widen the result to about 0.48 ± 0.05 — which is why the value usually quoted from this era, 0.49 ± 0.07, carries a much larger error than the arithmetic above. The Gargamelle target was freon, not an exactly isoscalar nucleus, and the neutron excess was corrected for. And Equation (116.33) is leading order in α_s, so the split between Q and $\bar{Q}$ in particular is not to be taken past its first figure: higher-order and strange-quark contributions move the sea fraction upwards. □

The numbers extracted here are collected, with the measured cross sections they come from, in Table 116.2.

The higher-statistics continuation was CDHS, which exposed a magnetized-iron calorimeter and spectrometer to the CERN SPS narrow-band neutrino beam and measured F_2 and xF_3 over a wide range of x and Q^2 [1639]. Two of its results matter here. It confirmed the mean squared charge of $5/18$ by direct comparison of its own $F_2^{\nu N}$ with the charged-lepton measurements, which is the content of Proposition 102.46; and it separated the antiquark content, whose momentum fraction is small and concentrated at small x, confirming that the momentum deficit of Phenomenon 116.25 cannot be repaired by a larger sea. The parity-violating structure function xF_3, which exists only for a weak probe, counts valence quarks.

Proposition 116.29 (The Gross–Llewellyn Smith sum rule in the parton model)**.** *On an isoscalar nucleon the third charged-current structure function integrates to the number of valence quarks,*

$$\int_0^1 F_3^{\nu N}(x)\,\mathrm{d}x = 3\,, \tag{116.36}$$

a pure number, and its measurement is a count of the valence quarks in a nucleon obtained without ever isolating one.

Rests on Equation (116.33) *and Proposition 102.6.*

Derivation. *Derives Proposition 116.29.*

The charged current is $V - A$: it couples to left-handed quarks and to right-handed antiquarks, and it is the interference of its vector with its axial part that produces a third structure function at all. That interference term changes sign between a quark and an antiquark — which is why F_3 exists only for a parity-violating probe and vanishes identically for the photon of Equation (116.19) — so at leading order in the parton model

$$F_3^{\nu N}(x) = \sum_q \left[q(x) - \bar{q}(x)\right]\,,$$

with unit weights, since the current is blind to electric charge. The sea contributes a quark and an antiquark at the same x and therefore cancels in the difference, leaving only the valence densities: $\int_0^1 [q - \bar{q}]\mathrm{d}x = \int_0^1 q_v \mathrm{d}x$. Averaged over the proton (uud) and the neutron (udd) of an isoscalar target the valence content is the same three quarks either way, so

$$\int_0^1 F_3^{\nu N}\,\mathrm{d}x = \int_0^1 \left[u_v(x) + d_v(x)\right]\mathrm{d}x = 2 + 1 = 3\,,$$

which is Equation (116.36). Note what makes this a stronger statement than the momentum sum rule of Equation (116.28): no unknown weight enters, so the prediction is an integer and not a fraction to be compared with a measured one. The quantity is dimensionless, F_3 being a function of x alone. □

The measured value is smaller than three, and the deficit is itself calculable: gluon radiation off the struck quark reduces the integral by a factor $1 - \alpha_s(Q^2)/\pi - \ldots$, which

turns the sum rule into a determination of the strong coupling at the Q^2 of the measurement. That correction is what remains owed here.

Derivation pending #208

The perturbative correction to the Gross–Llewellyn Smith sum rule. The parton-model value of 3 is derived in the text above; what is still owed is the calculation of the coefficient function that multiplies it by $1 - \alpha_s/\pi - \dots$, order by order, and the demonstration that the same coefficient function is the one appearing in the Bjorken sum rule for polarized scattering. That is what makes a measurement of this integral a competitive determination of the strong coupling, and it belongs in Appendix A alongside the other sum rules.

116.5.4 The 1990 Nobel Prize

The 1990 Nobel Prize in Physics was awarded to Jerome I. Friedman, Henry W. Kendall and Richard E. Taylor for their pioneering investigations concerning deep inelastic scattering of electrons on protons and bound neutrons, of essential importance for the development of the quark model in particle physics.

The three lectures are complementary and all three are worth reading as primary material rather than as summaries. Taylor's [1849] is the account of the accelerator and the spectrometers — how End Station A was built and what it could and could not do. Kendall's [1848] is the account of the measurements themselves and of the analysis that turned raw yields into νW_2, including the radiative corrections. Friedman's [1844] is the account of the interpretation: which alternatives were on the table, what killed each of them, and how long the parton reading took to become the consensus. Taken together they are an unusually candid record of an experiment whose result was understood only some years after it was obtained.

116.6 Scaling violations and the confirmation of QCD

116.6.1 Asymptotic freedom

Scaling is the statement that the constituents are free. A field theory in which they are genuinely free has no interactions and no bound states; the parton model was therefore, as Remark 116.7 says, a hypothesis without dynamics. What was needed was a theory whose coupling *vanishes* at short distance, and in 1973 Gross and Wilczek [1501] and, independently, Politzer [1511] showed that a non-abelian gauge theory is such a theory and, within the class of renormalizable field theories in four dimensions, essentially the only one.

The result is Theorem 102.35: the one-loop beta function of an SU(3) gauge theory with n_f quark flavours has the coefficient $b_0 = 11 - \tfrac{2}{3}n_f$, positive for $n_f \le 16$, so the coupling runs to zero logarithmically at large momentum transfer. The measured curve is Phenomenon 102.41, with $\alpha_s(m_Z c^2) = 0.1180 \pm 0.0009$ [2427] and the values at lower scales tabulated in Table 102.2.

Two consequences for this chapter follow immediately, and they pull in opposite directions, which is what makes the resulting prediction sharp.

- *Scaling must hold approximately.* At large Q^2 the coupling is small, the struck quark is nearly free during the absorption, and the parton model is the leading term of a systematic expansion rather than a guess.
- *Scaling must fail logarithmically.* The coupling is not zero, so a quark may radiate a gluon before or after being struck. Raising Q^2 resolves emissions that a coarser probe

could not separate, so the number of partons seen rises and each carries less momentum. Structure functions must therefore fall with $\ln Q^2$ at large x, where partons are lost to radiation, and rise at small x, where the radiated partons accumulate.

The second is a prediction with no free parameter beyond α_s itself, and it is what the rest of this section reports as measured.

116.6.2 The evolution equations

The equations that make the second statement quantitative were derived by Gribov and Lipatov [1474], by Altarelli and Parisi [1591] and by Dokshitzer [1595], and are Theorem 102.49; the splitting functions come from the collinear emission probability Equation (102.58), and the Mellin diagonalisation that turns the integro-differential system into ordinary differential equations for the moments is Corollary 102.50. None of that is rebuilt here. What belongs here is the experimental use to which it is put.

Proposition 116.30 (How the strong coupling is read off a slope)**.** *For a non-singlet combination of parton distributions, the moment $M_N = \int_0^1 f(x) x^N \mathrm{d}x$ obeys Equation (102.60), so*

$$\alpha_s\left(Q^2\right) = \frac{2\pi}{\gamma_N} \frac{\mathrm{d}\ln M_N}{\mathrm{d}\ln Q^2}\,, \tag{116.37}$$

with γ_N the rational number Equation (102.62). The strong coupling is therefore measured by a rate of change *of the data, not by a rate; no absolute normalisation and no knowledge of the parton distributions enters.*

Rests on Equations (102.60) and (102.62).

Proof. *Derives Proposition 116.30.*

Equation (102.60) reads $\mathrm{d}M_N/\mathrm{d}\ln Q^2 = (\alpha_s/2\pi)\gamma_N M_N$; dividing by M_N and solving for α_s gives Equation (116.37). For the second moment, with $C_F = \frac{4}{3}$ and $H_m = \sum_{k\le m} 1/k$,

$$\gamma_2 = C_F\left[\tfrac{3}{2} - H_2 - H_4\right] = \tfrac{4}{3}\left[1.5 - 1.5 - 2.0833\right] = -2.778\,,$$

so at $\alpha_s = 0.20$ the moment falls at $\mathrm{d}\ln M_2/\mathrm{d}\ln Q^2 = -0.088$, that is by about 20 % per decade in Q^2. Measuring that slope to 10 % determines α_s to 10 %.

The parameter-free version of the test is the ratio of two slopes. With $\gamma_1 = -\frac{16}{9} = -1.778$ and $\gamma_3 = C_F[\frac{3}{2} - H_3 - H_5] = -3.489$,

$$\frac{\mathrm{d}\ln M_3/\mathrm{d}\ln Q^2}{\mathrm{d}\ln M_1/\mathrm{d}\ln Q^2} = \frac{\gamma_3}{\gamma_1} = 1.96\,, \tag{116.38}$$

a pure number containing neither α_s nor Λ_{QCD} nor the initial distributions — the content of Remark 102.52. Plotting one measured moment against another on logarithmic axes must give a straight line of that slope. □

Remark 116.31 (What the equations do not predict). The evolution equations say how the distributions change, not what they are. The distributions at some reference scale Q_0 are non-perturbative objects and must be measured; QCD supplies no prediction for them, and any claim that it does is a claim about a model and not about the theory. This is not a weakness of the test but what makes it stringent: the initial distributions are fitted at one scale, and then several thousand data points at other scales must be described with no further freedom beyond the single number α_s.

116.6.3 Muon-beam measurements

The lever arm in Q^2 needed to see a logarithm requires beam energies well beyond SLAC's. Muon beams supplied them: a muon is a charged lepton, so the process and its interpretation are identical to electron scattering, and a muon beam produced from pion decay can be made at several hundred GeV where an electron beam of the same energy cannot.

The Bologna–CERN–Dubna–Munich–Saclay collaboration (BCDMS) exposed a long toroidal-iron spectrometer with internal hydrogen, deuterium and carbon targets to the CERN SPS muon beam at energies of order 100–280 GeV, and measured $F_2(x, Q^2)$ and R with high statistics over x from about 0.06 to 0.8 and Q^2c^2 from about $7\,\mathrm{GeV}^2$ to $260\,\mathrm{GeV}^2$ [1815] — a factor of nearly forty in Q^2, against the factor of eight available in 1969. The European Muon Collaboration made companion measurements over an overlapping range, and its data on nuclear targets produced the separate result of Section 116.7.1.

Phenomenon 116.32 (Scaling is violated logarithmically)**.** Measured over a far wider range of Q^2 than the original experiment, the structure function $F_2(x, Q^2)$ is not exactly a function of x alone: at large x it decreases with $\log Q^2$ and at small x it increases, the two movements being tied to each other [1815]. At the electron–proton collider the rise at small x is dramatic, and F_2 continues to grow down to x below 10^{-4} [2152, 2244]. This pattern, and not scaling itself, is the quantitative confirmation of quantum chromodynamics, because the theory predicts not the structure functions but exactly their rate of change.

Rests on Phenomenon 116.18, Proposition 102.48, and Equation (102.59)*.*

Derivation. Derives Phenomenon 116.32.

The mechanism is Proposition 102.48: a quark of fraction y radiates a gluon and is left with $x = zy < y$, with probability $(\alpha_s/2\pi)P_{qq}(z)\mathrm{d}z\,\mathrm{d}k_T^2/k_T^2$ per unit transverse momentum squared. Integrating the last factor up to the resolution Q^2 produces $\ln Q^2$ and nothing steeper, which is why the violation is logarithmic and not a power — the distinguishing signature against a constituent size, which by Equation (116.23) would give a power. Assembling the gain and loss terms gives Equation (102.59), whose sign structure is the statement in the phenomenon: the plus prescription in Equation (102.58) makes $\int_0^1 P_{qq} = 0$, so whatever is lost at large x reappears at smaller x, and the two movements are not independent but are the same probability counted twice. The crossing point, where $\mathrm{d}F_2/\mathrm{d}\ln Q^2$ changes sign, is near $x \approx 0.15$ in the data and is itself predicted.

The quantitative comparison is Proposition 116.30 applied to the measured moments; the collaboration's own QCD analysis of its non-singlet data returned a strong coupling at the low end of the range now accepted, and the modern world average from all methods is $\alpha_s(m_Zc^2) = 0.1180 \pm 0.0009$ [2427], with deep inelastic determinations among the inputs. □

116.6.4 HERA

This is the subsection to which Remark 102.52 defers the experimental side of the DGLAP test.

HERA, at DESY in Hamburg, was the only electron–proton collider ever built: a ring of about 6.3 km circumference in which 27.5 GeV electrons or positrons collided with protons of 920 GeV (820 GeV in the earlier running). Two general-purpose detectors, H1 and ZEUS, recorded the collisions.

Proposition 116.33 (What colliding changes)**.** *The centre-of-mass energy of the HERA collisions is*

$$\sqrt{s}\,c \approx 2\sqrt{E_eE_p} = 2\sqrt{27.5\,\mathrm{GeV} \times 920\,\mathrm{GeV}} = 318\,\mathrm{GeV}\,,$$

neglecting the particle masses. A fixed-target experiment would need a beam energy

$$E_{\mathrm{lab}} = \frac{sc^2}{2Mc^2} = \frac{(318\,\mathrm{GeV})^2}{2 \times 0.938\,27\,\mathrm{GeV}} = 54\,\mathrm{TeV} \tag{116.39}$$

to reach the same invariant mass. Since $Q^2c^2 \le sc^2$ and $x \ge Q^2c^2/(sc^2)$ at $y \le 1$, the accessible region extends to Q^2c^2 of order $1 \times 10^5\,\mathrm{GeV}^2$ and to x some four orders of magnitude below anything a fixed target can reach.

Rests on Notation 116.13.

Proof. *Derives Proposition 116.33.*

For head-on beams of energies E_e and E_p and negligible masses, the total four-momentum has energy $E_e + E_p$ and momentum $(E_p - E_e)/c$, so $sc^2 = (E_e + E_p)^2 - (E_p - E_e)^2 = 4E_eE_p$, giving the first line; s carries $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$, the dimension of Q^2. For a stationary target of mass M, $sc^2 = M^2c^4 + 2Mc^2E_{\mathrm{lab}}$, which for $E_{\mathrm{lab}} \gg Mc^2$ inverts to Equation (116.39). The kinematic bound follows from $Q^2 = xys$ with $x, y \in [0, 1]$ — both sides carrying $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$ — so $Q^2c^2 \le sc^2$ and, at fixed Q^2, small x requires large s — which is the whole reason a collider was built for this measurement. □

The combination of the two experiments' inclusive cross sections is the definitive data set: about 2900 measured points covering Q^2c^2 from about $0.045\,\mathrm{GeV}^2$ to $5 \times 10^4\,\mathrm{GeV}^2$ and x from about 6×10^{-7} to 0.65, with total uncertainties reaching the percent level in the bulk of the range [2152, 2244]. Combining the two experiments before fitting is itself part of the result: the cross-calibration reduces correlated systematics that neither experiment could remove alone.

Phenomenon 116.34 (The structure function rises steeply at small x)**.** At fixed Q^2, $F_2(x, Q^2)$ grows as x decreases, with an effective power $F_2 \sim x^{-\lambda}$ whose exponent itself grows with Q^2: λ is near 0.1 at $Q^2c^2 \approx 1\,\mathrm{GeV}^2$ and near 0.3 at $Q^2c^2 \approx 100\,\mathrm{GeV}^2$. The growth continues down to the smallest x measured, about 6×10^{-7}, with no sign of saturation [2152, 2244].

Rests on Equation (102.59) and Proposition 116.33.

Derivation. *Derives Phenomenon 116.34.*

At small x the quark distributions are dominated by gluon splitting, so the driving term of Equation (102.59) is $P_{qg} \otimes g$, and each unit of $\ln Q^2$ feeds gluons into quarks at small x while each step down in x collects the contributions of all larger fractions. Iterating the two effects generates a distribution rising as a power of $1/x$ with an exponent that grows with the evolution length, hence with $\ln Q^2$; that is the observed pattern. Quantitatively the rise is not an input to the fit but an output: the gluon distribution is fixed by the Q^2 slopes at moderate x and the small-x rise then follows. □

Proposition 116.35 (The gluon density is measured, not assumed)**.** *At small x the slope of the structure function measures the gluon distribution directly:*

$$\frac{\partial F_2\left(x, Q^2\right)}{\partial \ln Q^2} \approx \frac{10\,\alpha_s\left(Q^2\right)}{27\pi}\,[xg]\left(2x, Q^2\right)\,, \tag{116.40}$$

for $n_f = 4$ active flavours. The gluon density, which couples to neither the photon nor the weak current and is therefore invisible to every direct measurement in this chapter, is thus read off the rate of change of something that is measured.

Rests on Equations (102.59) and (116.9).

Proof. *Derives Proposition 116.35.*

Keep only the gluon term of Equation (102.59) and weight it by the squared charges, since $F_2 = \sum_q (e_q/e)^2 x[q + \bar{q}]$ and a gluon splits into q and $\bar{q}$ alike:

$$\frac{\partial F_2}{\partial \ln Q^2} = \frac{\alpha_s}{2\pi} \cdot 2 \sum_q \left(\frac{e_q}{e}\right)^2 x \int_x^1 \frac{\mathrm{d}y}{y}\, P_{qg}\left(\frac{x}{y}\right) g\left(y\right)\,,$$

with $\sum_q (e_q/e)^2 = \frac{4}{9} + \frac{1}{9} + \frac{1}{9} + \frac{4}{9} = \frac{10}{9}$ for $n_f = 4$. Substitute $z = x/y$, so $\mathrm{d}y/y = -\mathrm{d}z/z$ and $y = x/z$; then

$$x \int_x^1 \frac{\mathrm{d}y}{y} P_{qg}\!\left(\frac{x}{y}\right) g\,(y) = \int_x^1 \mathrm{d}z\, P_{qg}(z)\; [yg]\!\left(\frac{x}{z}\right) ,$$

because $x\,g(x/z)/z = [yg](x/z)$. At small x the combination $yg(y)$ varies slowly over the support of P_{qg}, so replace it by its value at the mean splitting fraction

$$\langle z \rangle = \frac{\int_0^1 z\, P_{qg}(z)\,\mathrm{d}z}{\int_0^1 P_{qg}(z)\,\mathrm{d}z} = \frac{1/6}{1/3} = \frac{1}{2} ,$$

that is, at $y = x/\langle z \rangle = 2x$. What remains is $\int_0^1 P_{qg} = \frac{1}{3}$, so

$$\frac{\partial F_2}{\partial \ln Q^2} \approx \frac{\alpha_s}{2\pi} \times 2 \times \frac{10}{9} \times \frac{1}{3} \times [xg](2x) = \frac{10\alpha_s}{27\pi}\,[xg](2x) ,$$

which is Equation (116.40). Numerically: at $x = 1 \times 10^{-3}$ and $Q^2c^2 = 20\,\mathrm{GeV}^2$, so $Qc = 4.5\,\mathrm{GeV}$ and $\alpha_s \approx 0.21$ from Table 102.2, a measured slope of about 0.2 gives

$$[xg]\!\left(2 \times 10^{-3}\right) \approx \frac{27\pi \times 0.2}{10 \times 0.21} \approx 8 ,$$

which is the size the global fits of Section 116.6.5 return at that fraction and scale. The relation is leading order and the expansion about $\langle z \rangle$ is crude; a real extraction fits the full evolution to all the data at once. What it exhibits, and what a fit conceals, is that the gluon enters the measurement only through a derivative. □

The numbers of the whole later programme, HERA's included, are collected in Table 116.3.

116.6.5 Parton distributions today

The measurements of this chapter are not archived as measurements. They are absorbed, together with fixed-target, Drell–Yan and collider data, into global fits that determine the parton distributions $f_i(x, \mu_F^2)$ with uncertainty bands, and it is those objects that the rest of particle physics uses [2244, 2427].

The property that makes them usable is collinear factorization, Theorem 102.53: the cross section for any process with a large scale splits into a calculable partonic part and a set of distributions that depend on the hadron and not on the process. The distributions are therefore *universal*, and the whole enterprise rests on that. Measured in electron–proton scattering at $Qc \sim 10\,\mathrm{GeV}$, evolved by Equation (102.59) to $Qc \sim 1\,\mathrm{TeV}$, and used to predict proton–proton cross sections at the LHC, they work — including for the Higgs production rates, which belong to Chapter 113 and which are unpredictable without them. Universality across two different initial states and three decades of scale is what makes factorization a theorem with evidence rather than a modelling assumption.

Three cautions belong with any quoted parton distribution, and Remark 102.54 states the first of them: a distribution is defined only together with a factorization scheme and a scale, and quoting one without both is meaningless. The second is that the uncertainty bands are not measurement errors in the ordinary sense; they combine experimental errors with the freedom in the functional form assumed at the starting scale, and different collaborations' bands are not independent. The third is that the fits are least well constrained exactly where they are most used at a hadron collider: the gluon at large x, and every distribution at x below the HERA reach.

116.7 Extensions and modern precision

116.7.1 The EMC effect

Phenomenon 116.36 (The EMC effect)**.** The structure function per nucleon measured on iron differs from the one measured on deuterium by up to about 15 %, with a characteristic dependence on x [1712]. Quark distributions are therefore modified by the nuclear medium itself, and not merely smeared by the Fermi motion of nucleons that would otherwise be unchanged. No agreed explanation exists.

Rests on Definition 102.44 and Equation (116.9).

The measurement was not the one the collaboration set out to make: iron was the target material of a spectrometer built for other purposes, and the deuterium comparison was a control. The observed ratio $F_2^{\mathrm{Fe}}/F_2^{\mathrm{D}}$ per nucleon falls below unity through the valence region, reaching about 0.89 near $x = 0.65$, and rises above unity at small x, reaching about 1.15 near $x = 0.05$ [1712]. Later measurements on many nuclei established that the shape is universal and the magnitude grows slowly with mass number, and that the ratio turns upward again above $x \approx 0.8$, where Fermi motion allows a bound nucleon to carry more than the whole nucleon momentum fraction.

Why this is a result rather than a nuisance: before 1983 it was generally supposed that a nucleus is a collection of nucleons whose internal structure is what it is in free space, so that nuclear effects on F_2 would be confined to the smearing produced by the nucleons' Fermi motion — an effect calculable from nuclear physics (Chapter 107) and confined to large x. The observed modification extends over the whole valence region and has the wrong sign at moderate x for Fermi smearing. Whatever the mechanism, the quark momentum distribution inside a bound nucleon is not the one inside a free nucleon.

Derivation pending #209

The nuclear modification of parton distributions, stated as the open problem it is: no derivation from quantum chromodynamics currently reproduces the observed dependence on the momentum fraction. The candidate mechanisms — nucleon swelling, pion-cloud enhancement, multi-quark clusters, and a dependence on the local nuclear density rather than on the mass number — each account for part of the shape and none for all of it, and they are not mutually exclusive. What is owed in Appendix A is a statement of what each predicts and of which measurements discriminate among them.

Remark 116.37 (An honest limit on the sources here). The bibliography of this book carries the original EMC measurement and nothing later on nuclear parton distributions. The statements above about the universality of the shape across nuclei, about its growth with mass number and about the local-density correlation are therefore made without a citation that supports them, and a reader who wants to check them must go outside this book's reference list. They are recorded here because omitting them would leave the 1983 result looking more isolated than it is.

116.7.2 The proton spin

Scattering polarized electrons or muons from a polarized target gives access to a third structure function, $g_1(x, Q^2)$, which in the parton model counts the quark spins:

$$g_1(x) = \frac{1}{2}\sum_q \left(\frac{e_q}{e}\right)^2 \left[\Delta q(x) + \Delta\bar{q}(x)\right] , \tag{116.41}$$

with $\Delta q(x)$ the difference between the densities of quarks with spin along and against the proton's spin. The integral $\Gamma_1^p = \int_0^1 g_1^p(x)\,\mathrm{d}x$ is therefore a charge-weighted count of how much of the proton's spin the quark spins carry.

Phenomenon 116.38 (The quark spins do not account for the proton spin)**.** The European Muon Collaboration measured $\Gamma_1^p = 0.114 \pm 0.012 \pm 0.026$ at $\langle Q^2 \rangle\, c^2 = 10.7\,\mathrm{GeV}^2$, where the first uncertainty is statistical and the second systematic [1804]. The naive expectation, obtained by combining the octet axial charges measured in hyperon beta decay with the assumption that the strange sea is unpolarized — the Ellis–Jaffe sum rule — is about 0.19; that number is quoted here without derivation and without a source in this book's bibliography, and the debt is recorded immediately below. The quark spins therefore carry a small and possibly vanishing fraction of the proton's angular momentum, in flat contradiction with the constituent quark model, in which they carry all of it.

Rests on Equation (116.41) *and Proposition 102.6.*

Derivation pending #210

The Ellis–Jaffe sum rule, the theoretical number the EMC measurement contradicts. What is owed is the derivation of the expectation for the first moment of the polarized proton structure function from the octet axial charges: the isovector combination fixed by the neutron beta-decay ratio, the octet combination fixed by the hyperon semileptonic decays under the flavour symmetry of the baryon octet, and the assumption of an unpolarized strange sea that sets the singlet piece equal to the octet one — together with the leading perturbative correction, which lowers the parton-model value. Only that chain shows why the expected number is near 0.19 *and which of its assumptions the measurement actually falsifies. It belongs in Appendix A beside the other sum rules; this book's bibliography carries no entry for the original Ellis–Jaffe paper.*

The resolution, so far as there is one, is that the proton's spin decomposes as

$$\frac{1}{2} = \frac{1}{2}\Delta\Sigma + \Delta G + L_q + L_g\,, \tag{116.42}$$

in units of $\hbar$, where $\Delta\Sigma$ is the quark spin contribution measured above, ΔG the gluon spin, and L_q, L_g the orbital angular momenta of quarks and gluons (Chapter 79). Nothing requires the first term to dominate. Subsequent polarized experiments have measured $\Delta\Sigma$ to be roughly 0.3 and have constrained ΔG to be small over the measured range of momentum fraction; the orbital terms are essentially unmeasured, and are among the principal targets of the programme in Section 116.7.4.

Derivation pending #211

The decomposition of the proton spin into quark spin, gluon spin and orbital contributions, and the reason the split is ambiguous. What is owed is the demonstration that the gauge-invariant decomposition of the angular momentum of a gauge theory into a "spin" and an "orbital" part is not unique — different decompositions differ by terms that vanish for a free field and do not vanish here — so that a measured ΔG has meaning only relative to a stated convention and factorization scheme. It belongs in Appendix A with the operator definitions written out.

Remark 116.39 (Sources for the modern spin measurements). This book's bibliography carries the original EMC measurement and no later polarized-scattering result. The values quoted above for $\Delta\Sigma$ and for the constraint on ΔG are therefore uncited, and are flagged as such.

116.7.3 The Drell–Yan process and the sea

Deep inelastic scattering is not the only way to measure a parton distribution, and the second way is the test of whether the distributions mean anything. Drell and Yan proposed that in a hadron collision a quark from one hadron and an antiquark from the other annihilate into a virtual photon, which materializes as a lepton pair of large invariant mass [1421].

Proposition 116.40 (The Drell–Yan cross section scales)**.** *For the annihilation of a quark of fraction x_1 from one hadron with an antiquark of fraction x_2 from the other, the lepton pair has invariant mass $M_{\ell\ell}c^2$ — written with a subscript because M without one is the proton mass throughout this chapter (Notation 116.13) — with*

$$\tau := \frac{M_{\ell\ell}^2 c^4}{s c^2} = x_1 x_2 \,, \tag{116.43}$$

and the cross section takes the form

$$M_{\ell\ell}^3 c^6 \, \frac{\mathrm{d}\sigma}{\mathrm{d}\left(M_{\ell\ell}c^2\right)} = F\left(\tau\right) \,, \tag{116.44}$$

a function of the dimensionless ratio τ alone. Here s carries $\mathrm{kg}^2\,\mathrm{m}^2/\mathrm{s}^2$ as in Proposition 116.33, so τ is dimensionless, and F carries $\mathrm{J}^2\,\mathrm{m}^2$, since $M_{\ell\ell}^3c^6$ is a cubed energy and $\mathrm{d}\sigma/\mathrm{d}(M_{\ell\ell}c^2)$ carries m^2/J. This is Bjorken scaling in a different process, with the same variables and the same distributions.

Rests on Theorem 102.53 and Equation (116.9)*.*

Proof. *Derives Proposition 116.40.*

The partonic process $q\bar{q} \to \ell^+\ell^-$ is the crossed channel of $\ell^+\ell^- \to q\bar{q}$ and its cross section is the point-like $\hat{\sigma} = 4\pi\alpha^2(\hbar c)^2(e_q/e)^2/(3M_{\ell\ell}^2c^4) \times \frac{1}{3}$, the last factor because the quark and antiquark must match in colour, one chance in three. It contains no scale but $M_{\ell\ell}$. The invariant mass of a pair made from fractions x_1 and x_2 of two hadrons whose squared centre-of-mass four-momentum is s is $M_{\ell\ell}^2c^4 = x_1x_2sc^2$, which is Equation (116.43). Folding $\hat{\sigma}$ with the two distributions and changing variables from (x_1, x_2) to (τ, x_1) produces a factor $1/M_{\ell\ell}^3$ from the partonic cross section and the Jacobian, leaving a function of τ alone, which is Equation (116.44). The measured cross section obeys it, and — the point of the exercise — the distributions extracted from it are the same ones extracted from deep inelastic scattering, which is the experimental content of Theorem 102.53. □

The process is also the sharpest probe of the antiquark sea, because it requires an antiquark in the initial state, and comparing hydrogen with deuterium targets isolates $\bar{d}/\bar{u}$. Measurements of that ratio find it significantly greater than one over a range of x, in agreement with the Gottfried sum of Remark 116.22 and in contradiction with any picture in which the sea comes from perturbative gluon splitting, which cannot distinguish flavours. The measurement is the Fermilab E866/NuSea experiment [2020], which compares Drell–Yan yields from hydrogen and deuterium targets; it and the Gottfried-sum determination [1879] are independent determinations of the same asymmetry, one in lepton–nucleon scattering and one in hadron–hadron collisions.

116.7.4 Continuing programmes

Deep inelastic scattering is not a closed subject, and it is worth being precise about which of the things still being measured would count as a new result and which as a refinement.

Refinements. Extending F_2 and g_1 to smaller x and to larger Q^2; reducing the uncertainty on the gluon at large x, which currently limits several LHC predictions; mapping the nuclear modification of Section 116.7.1 across the periodic table; improving the determination of

α_s from scaling violations. All of these tighten numbers inside a framework that is not in question.

New results. Three outcomes would be different in kind.

- *A measured violation of factorization.* If the distributions extracted from one process failed to describe another at a level exceeding the calculable higher-order corrections, Theorem 102.53 would be false as applied, and the entire apparatus by which hadron-collider rates are predicted would lose its foundation.

- *A gluon density inconsistent with the evolution equations.* The rise of Phenomenon 116.34 cannot continue indefinitely — at some small enough x the density of gluons must be high enough that they recombine as well as split, and the linear evolution of Section 116.6.2 must fail. Observing that non-linear regime would be the first measurement of a genuinely new dynamical regime of QCD rather than a refinement of the known one. Whether HERA reached its onset is disputed.

- *The orbital angular momentum of the proton's constituents.* Equation (116.42) has two terms that have never been measured. Determining them requires correlating a parton's momentum fraction with its transverse position or transverse momentum, which inclusive scattering cannot do.

The instrument designed for the last two is the Electron–Ion Collider now under construction at Brookhaven, which will collide polarized electrons with polarized protons and light ions and with heavy nuclei at centre-of-mass energies from about 20–140 GeV and luminosities of order $1 \times 10^{38}/(\mathrm{m}^2\,\mathrm{s})$, some three orders of magnitude above HERA's [2265]. Its observables are the exclusive and semi-inclusive ones — deeply virtual Compton scattering, tagged final-state hadrons — from which a transverse spatial or transverse momentum image of the parton distribution can be built, and the nuclear targets that would show saturation if it is there. It is a continuation of the measurement reported in this chapter with the same beam, the same probe and the same variables, on an instrument fifty years newer.

116.8 Primary references

The experiment itself is contained in two Physical Review Letters of 1969 submitted back to back. Bloom *et al.* [1395] report the inelastic cross sections at 6° and 10° and the observation that the ratio to the Mott cross section falls far more slowly with momentum transfer than the elastic form factors do; Breidenbach *et al.* [1397] report the structure function νW_2 and its collapse onto a single curve. Neither is long, and both should be read in preference to any account of them. The public announcement preceded both, at the Vienna conference of 1968, in Panofsky's rapporteur talk [1379]. The most useful single secondary source on the apparatus, the corrections and the whole 1967–1972 data set is Friedman and Kendall's review [1472], which is where the numbers in Table 116.1 that are not from the two Letters come from.

The instrument has its own literature. Neal's edited volume on the Stanford two-mile accelerator [1363] is the engineering account of the machine. The three Nobel lectures [1844, 1848, 1849] divide the story between apparatus, measurement and interpretation, and are the best first-hand record of what the collaboration believed at each stage. Mo and Tsai [1404] is the radiative-correction calculation on which every number in the experiment depends; it is a piece of applied quantum electrodynamics rather than of hadron physics, and it is the largest single theoretical input to the measured cross sections.

The theory the experiment tested was in print before the data. Rosenbluth [970] gives the elastic cross section that defines the form factors; Hofstadter [1088] is the review of the

elastic measurements that established the proton's size. Gell-Mann [1277] and Zweig [1301] propose the quarks; Zweig's is an unpublished CERN preprint and is cited as such. Bjorken [1393] predicts scaling from current algebra and Wilson [1410] supplies the operator-product framework; Feynman [1401] gives the parton picture and Bjorken and Paschos [1394] the parton-distribution formulation used throughout this chapter. Callan and Gross [1398] give the spin discriminator of Section 116.4.3.

For the neutrino comparison, the Gargamelle total cross sections are Eichten *et al.* [1497], from which the momentum fractions of Proposition 116.28 are derived here; the same exposures gave the weak neutral current in the leptonic channel [1503] and the hadronic channel [1502], reported in Chapter 104. The high-statistics neutrino structure functions are the CDHS measurement in iron [1639].

For the scaling violations, the theory is Gross and Wilczek [1501] and Politzer [1511] for asymptotic freedom, and Gribov and Lipatov [1474], Altarelli and Parisi [1591] and Dokshitzer [1595] for the evolution equations. The Gribov–Lipatov and Dokshitzer papers are translations from the Russian and neither carries a DOI. The Dokshitzer entry records that fact explicitly, together with the Russian original it translates; the Gribov–Lipatov entry carries only the journal reference of the translation, with no note, so a reader who wants the original must find it from the volume and pages alone. The measurements are BCDMS [1815] for the muon beam and the two HERA combinations [2152, 2244] for the collider; the second supersedes the first and is the data set in current use. Collins, Soper and Sterman [1817] is the factorization proof that licenses using the extracted distributions elsewhere. Current values of α_s, of the parton distributions and of the particle masses used here are from the Review of Particle Physics [2427], and the fundamental constants from the CODATA 2022 adjustment [2431]; the shipped data files behind those two citations are the source of every constant in Tables 116.1 and 116.3.

The extensions are Aubert *et al.* [1712] for the EMC effect, Ashman *et al.* [1804] for the proton spin, Drell and Yan [1421] for the lepton-pair process, and the Electron–Ion Collider white paper [2265] for the programme now being built. The flavour asymmetry of the light-quark sea rests on two measurements in different processes: Arneodo *et al.* [1879] for the New Muon Collaboration's reevaluation of the Gottfried sum, and Towell *et al.* [2020] for the Fermilab E866/NuSea Drell–Yan determination of $\bar{d}/\bar{u}$. Halzen and Martin [1739] is the textbook treatment closest to the level of this chapter.

Finally, what this reference list does *not* contain, since a reader is entitled to know where the chapter's statements outrun its sources. There is no entry for a dedicated modern measurement of $R = \sigma_L/\sigma_T$, so the value in Table 116.1 is the SLAC one and the modern refinement is not reported. There is no entry for nuclear parton distributions after 1983 (Remark 116.37) and none for polarized measurements after 1988 (Remark 116.39). There is no entry for Ellis and Jaffe, so the expectation of 0.19 against which Phenomenon 116.38 reports a contradiction is both uncited and underived, and the derivation is owed as a pending proof. Each of these is a gap in the bibliography, not a gap in the physics, and each is flagged where it occurs in the text rather than only here.

Chapter 117

Experiment: Artificial Transmutation and the Instruments of Nuclear Physics

Two questions had to be answered before particle physics could exist as a quantitative science. Can one nucleus be turned into another at will, and can the products be counted one at a time? This chapter reports the experiments that answered them. The first half follows the reaction: the transmutation of nitrogen by natural alpha particles, and then the disintegration of lithium by protons from a machine — the first nuclear reaction produced entirely by human means and, more importantly for this book, the first quantitative test of the mass–energy equivalence of Chapter 40 in a nuclear reaction. The second half follows the instruments, from Wilson's cloud chamber through Glaser's bubble chamber to Charpak's multiwire proportional chamber, which replaced the photograph with an electronic address and made the modern event rate possible.

The chapter is the experimental floor of Part XI. Its nuclear reactions belong to Chapter 107, where the binding-energy systematics they sample are developed and where Chadwick's discovery of the neutron — made in 1932 with the same scintillation technique used here, in the same laboratory, in the same year as the lithium disintegration — is treated in full [693]. Its instruments are the ancestors of every detector in Chapter 115, Chapter 116 and Chapter 113. Five of the six experiments below were recognised by a Nobel Prize in Physics: Wilson in 1927, Lawrence in 1939, Cockcroft and Walton in 1951, Glaser in 1960 and Charpak in 1992.

117.1 Conventions and constants

Three conventions are used throughout, and they are worth stating before any number appears, because every one of the primary papers below uses different ones.

Nuclear masses are the evaluated atomic masses of the AME 2020 tables [2393], and are converted to energy with the CODATA 2022 value of the unified atomic mass constant,

$$u\,c^2 = 931.494\,\mathrm{MeV}\,, \qquad u = 1.660\,539\,07 \times 10^{-27}\,\mathrm{kg}\,, \tag{117.1}$$

to the precision needed here [2431]. Because atomic rather than nuclear masses are used, the electrons balance on the two sides of every reaction written below, and no electron-mass correction is required.

Energies are quoted in electronvolts and in joules. The conversion is exact, since the elementary charge is a defining constant of the SI [2431]:

$$1\,\mathrm{eV} = 1.602\,176\,634 \times 10^{-19}\,\mathrm{J}\,, \qquad 1\,\mathrm{MeV} = 1.602\,176\,634 \times 10^{-13}\,\mathrm{J}\,. \tag{117.2}$$

Two further combinations recur, and are taken from Equations (107.1) and (107.2) of Chapter 107, where they are fixed once from the same adjustment: $\hbar c = 197.326\,98\,\mathrm{MeV\,fm}$ and $e^2/(4\pi\varepsilon_0) = 1.439\,964\,5\,\mathrm{MeV\,fm}$. Both are ordinary SI quantities written in convenient units — the first is $3.1615 \times 10^{-26}\,\mathrm{J\,m}$, the second $2.3071 \times 10^{-28}\,\mathrm{J\,m}$ — and $\hbar$ and c appear explicitly in every equation below.

Ranges are the third convention and the one most easily misread. The experimenters of 1912–1932 quoted the penetrating power of a particle as the thickness of *air at atmospheric pressure* that would stop it, and inserted solid absorbers whose stopping power had been calibrated against air. A length is not the physical quantity: what stops a particle is the number of electrons it must pass, so the invariant statement is an areal mass density. At 288.15 K and 101.325 kPa the ideal-gas law with the mean molar mass of dry air, $M_{\mathrm{air}} = 28.9647 \times 10^{-3}\,\mathrm{kg/mol}$ [2427], gives $\rho_{\mathrm{air}} = pM_{\mathrm{air}}/(RT) = 1.2250\,\mathrm{kg/m^3}$, so

$$1 \times 10^{-2}\,\mathrm{m\ of\ air} = 1.2250 \times 10^{-2}\,\mathrm{kg/m^2}\,, \tag{117.3}$$

and every range quoted below is given both ways. Imperial units, in which two of the primary papers are partly written, are converted on sight and not reproduced.

Remark 117.1 (Reading this chapter against the natural-units literature). The nuclear and detector literature almost universally sets $\hbar = c = 1$, so that an energy, a momentum and a mass are all quoted in MeV and a length in 1/MeV. This book does not: $\hbar$ and c are carried explicitly, a momentum is written $2.5 \times 10^8\,\mathrm{eV}/c$ and a mass $7\,\mathrm{GeV}/c^2$. To map a formula from that literature onto one here, restore the unique powers of $\hbar$ and c that make the two sides dimensionally equal in SI; the combinations that do the work are the two quoted above, and the statement "a length of 1 fm corresponds to an energy of 197.3 MeV" means $\hbar c/1\,\mathrm{fm}$ and nothing more. No derivation in this chapter is carried out in those units.

117.2 Rutherford: the first artificial transmutation (1919)

Tests Phenomenon 117.2.

117.2.1 Apparatus

The apparatus is a scintillation counter with a gas cell in front of it, and nothing else. A rectangular brass box about 0.18 m long, with an internal cross-section of roughly $0.06\,\mathrm{m} \times 0.02\,\mathrm{m}$, was closed at one end by a silver foil whose stopping power had been calibrated as equivalent to about $6 \times 10^{-2}\,\mathrm{m}$ of air, that is $7.4 \times 10^{-2}\,\mathrm{kg/m^2}$ by Equation (117.3). Immediately beyond the foil sat a screen of zinc sulfide, viewed through a microscope of low power by an observer who had dark-adapted for half an hour in a light-tight room.

Inside the box, on a slide that could be moved along its length without breaking the seal, a metal disc carried an active deposit collected from radon gas. The alpha emitter in that deposit is radium C′, known today as ^{214}Po: a nuclide of half-life $1.64 \times 10^{-4}\,\mathrm{s}$ which is fed continuously by the longer-lived members of the chain above it and which therefore behaves as a steady source. Its alpha particle is among the most energetic available from any natural source in useful quantity — thorium C′ (^{212}Po), reached through the thorium active deposit and worked with at the Cavendish in the same period, is more energetic still, at 8.785 MeV by the same mass balance [2393] — and its energy is not an experimental input but a consequence of a mass difference. The alpha decay energy from the mass evaluation is $Q_\alpha = 7.8335\,\mathrm{MeV}$ [2393], and the recoiling ^{210}Pb takes a share fixed by momentum conservation, so the alpha particle carries

$$E_\alpha = Q_\alpha \,\frac{m(^{210}\mathrm{Pb})}{m(^{210}\mathrm{Pb}) + m(^{4}\mathrm{He})} = 7.687\,\mathrm{MeV} = 1.2316 \times 10^{-12}\,\mathrm{J}\,, \tag{117.4}$$

which is the number quoted in every table of the period and the number used throughout this section. Its range in air at 288.15 K and 101.325 kPa is 7.0×10^{-2} m, that is 8.6×10^{-2} kg/m^2.

The box could be filled with a dry gas of choice at a controlled pressure — oxygen, carbon dioxide, dry air, or nitrogen — and evacuated and refilled between runs. Gas purity is not a refinement here but the entire experiment: the effect looked for is the appearance of hydrogen nuclei, and hydrogen is the commonest contaminant in any vacuum system. The gas was therefore dried over phosphorus pentoxide, and the comparison between gases, rather than the absolute rate in any one of them, carries the argument.

The detector was the dark-adapted eye of the observer. A zinc sulfide screen converts the energy a stopping ion deposits into a flash of visible photons, and the flash from a single particle is at the edge of what the eye can see; the technique works only at rates of a few counts per minute, only in complete darkness, and only for observers who alternate in short shifts. Its virtue is that it counts single particles, and in 1919 nothing else did.

117.2.2 Procedure

Absorbing foils were interposed between source and screen and their stopping power expressed as an equivalent thickness of air, so that a count could be plotted against the distance the emerging particles were able to travel. Enough absorber was always present to stop every primary alpha particle: with the silver foil alone accounting for 6×10^{-2} m of air equivalent and the alpha range being 7.0×10^{-2} m, a short additional path in the gas suffices, and whatever produced a scintillation on the screen therefore had a longer range than the alpha particles that made it.

The experiment is then a comparison between gases, made under four controls, each of which excludes a specific alternative.

First, the choice of filling gas. Oxygen and carbon dioxide contain no nitrogen and no hydrogen, and are chemically comparable stopping media; they are the null runs. Dry air is one fifth oxygen and four fifths nitrogen; pure nitrogen is the signal run. If the effect is proportional to the amount of nitrogen present it cannot be a property of the source, of the box, or of the screen.

Second, the source-to-screen distance and the gas pressure were varied independently. Both change the amount of gas traversed, and a genuine product of the gas must respond to their product and not to either separately.

Third, the absorber thickness was scanned. A particle with a definite energy has a definite range, so the count as a function of absorber falls to zero at a characteristic thickness; reading that end point is how an energy was measured before magnetic analysis was available in this energy range.

Fourth, the residual effect with the box evacuated was measured and subtracted. Hydrogen occluded in the source mount itself produces long-range particles by exactly the elastic mechanism the experiment must exclude, and that background is not small.

117.2.3 Observations and data

With oxygen or carbon dioxide in the box, no scintillations survived beyond the alpha range. With dry air, and more strongly with pure nitrogen, scintillations persisted at absorber thicknesses far beyond it — out to an air equivalent of about 0.40 m, that is 0.49 kg/m^2 — and beyond the greatest range attainable by a hydrogen nucleus knocked on elastically by an alpha particle. The effect was small: a handful of scintillations per minute against an enormous number of incident alphas, which is why it took the full apparatus of scintillation counting to see it at all, and why the comparison between fillings rather than any absolute rate is the published result.

Table 117.1 collects the quantities the argument turns on. The historical rows are the observations; the computed rows are evaluated here from the mass evaluation [2393] and the kinematics derived below, and are what the observations have to be tested against. The counting uncertainties on the original scintillation tallies are Poissonian on tallies of order ten per run, that is of order 30 % per point; the ranges quoted from the paper are end points read off an absorption curve and are good to perhaps 10 %. Neither is quoted to more precision than that here, and the original run-by-run tallies are not reproduced: what the paper establishes, and what is reproduced, is the ordering of the end points.

Table 117.1: The range and energy comparison that carries Rutherford's argument. Rows marked *obs.* are the experimental values, quoted from the primary paper; rows marked *calc.* are computed in this chapter from the evaluated atomic masses and the elastic and two-body kinematics derived below, and involve no fitted quantity. Air equivalents are converted to areal density by Equation (117.3). The elastic ceiling is the largest energy an alpha particle can give a free proton in any collision whatever; the forward reaction proton exceeds it, and that is the whole observation. Bracketed uncertainties on the observed rows are the 10 % range-end-point reading error and the Poisson error on the fork count discussed in the text; the primary papers quote none, so these are estimates from the stated technique and are labelled as such. The computed rows inherit only the mass-evaluation uncertainty, which is of order 10 eV and therefore falls six orders of magnitude below the last digit shown.

Quantity	Value (eV)	Value (SI)	Kind, source
Alpha energy of radium C′ (^{214}Po)	7.687 MeV	1.2316×10^{-12} J	calc., [2393]
Range of those alphas in air	—	$(8.6 \pm 0.9) \times 10^{-2}$ kg/m^2	obs. 1919, [461]
Longest range seen in nitrogen	—	(0.49 ± 0.05) kg/m^2	obs. 1919, [461]
Elastic ceiling for a struck proton	4.941 MeV	7.916×10^{-13} J	calc., Equation (117.6)
Reaction energy Q of ^{14}N$(\alpha, p)^{17}$O	−1.1919 MeV	-1.9096×10^{-13} J	calc., [2393]
Laboratory threshold	1.5326 MeV	2.4554×10^{-13} J	calc., Equation (117.11)
Proton energy at 0° to the beam	5.929 MeV	9.499×10^{-13} J	calc., Equation (117.12)
Proton energy at 90°	4.423 MeV	7.086×10^{-13} J	calc., Equation (117.12)
Proton energy at 180°	3.299 MeV	5.286×10^{-13} J	calc., Equation (117.12)
Two-branch forks among alpha tracks	—	8 ± 3 in 415 000	obs. 1925, [518]

The uncertainty on the calculated rows deserves a word, because it is negligible and it is worth saying why. The AME 2020 evaluation quotes the masses of ^{1}H, ^{4}He, ^{14}N and ^{17}O to eleven significant figures, so the propagated uncertainty on the Q value of Equation (117.10) is at the level of electronvolts — six orders of magnitude below the 0.1 MeV with which a range end point can be read. In this comparison the theory is exact and the measurement is not, which is the reverse of the usual situation and is what makes a nineteen-nineteen range measurement still worth reporting.

117.2.4 Interpretation

The long-range particles are hydrogen nuclei, and they cannot have come from hydrogen in the gas, for two independent reasons. Their range exceeds what an elastic collision can give — the ceiling in Table 117.1 is 4.941 MeV and particles of longer range than that were counted — and the yield tracks the nitrogen content of the filling rather than the total amount of gas. Rutherford drew the conclusion in the plainest possible terms: the nitrogen atom is disintegrated.

What he could not establish was the fate of the alpha particle. Two possibilities remained open in 1919. The alpha might knock a proton out and continue, in which case four objects leave the collision point (alpha, proton, residual ^{13}C, and nothing else) and a photograph of the event would show three tracks emerging. Or the alpha might be captured, in which case only two objects leave and a photograph shows two. That was settled six years later by Blackett, who photographed the collisions in a Wilson chamber (Section 117.5) and found, among some 415 000 alpha tracks recorded on 23 000 stereoscopic photographs, eight forks with exactly two branches and no third. A two-branch fork means the alpha particle did not survive the encounter: it was captured, and the reaction is

$$^{14}\mathrm{N} + {}^{4}\mathrm{He} \longrightarrow {}^{17}\mathrm{O} + {}^{1}\mathrm{H}\,. \tag{117.5}$$

The counting is itself the measurement: eight events in 415 000 tracks, each track traversing a few centimetres of air, is a yield of order 1×10^{-5} per alpha, and a Poisson uncertainty of $\sqrt{8} \approx 3$ on eight events is why Blackett's number is a statement about the mechanism and not about the cross-section.

That the two branches also close the momentum triangle is what excludes the remaining alternative, that the alpha was captured and a neutral object emitted alongside the proton. In a stereoscopic pair the directions of both branches are measured, and the vector sum of the two final momenta must equal the incident momentum. Blackett's forks close; there is no missing momentum to assign to an unseen particle. The same argument run in reverse, on a reaction where the triangle does *not* close, is what Chadwick used in 1932 to establish the neutron [693], and it is the ancestor of every missing-momentum measurement in Chapter 113.

This is the first transmutation of one element into another by deliberate human action, and it was done with a naturally occurring projectile whose energy the experimenter could not change. Removing that restriction is the content of Section 117.3.

Phenomenon 117.2 (Nitrogen is transmuted by alpha bombardment)**.** Bombarding nitrogen with alpha particles from a natural source ejects hydrogen nuclei whose range exceeds that of any proton an alpha particle can set in motion by an elastic collision [461]. The alpha particle is absorbed in the process, so that the reaction is the capture Equation (117.5) and not a scattering [518].

Rests on Equation (117.5).

Derivation. *Derives Phenomenon 117.2.*

Three independent statements have to be checked: that an elastic collision cannot produce the observed particles, that the capture reaction is energetically open to alphas of 7.687 MeV, and that when it is open the protons it produces do exceed the elastic ceiling.

The elastic ceiling. Take a projectile of mass m_1 and kinetic energy E striking a free target of mass m_2 at rest, non-relativistically — and here $E/m_1c^2 = 7.687\,\mathrm{MeV}/3727.4\,\mathrm{MeV} = 2.06\times10^{-3}$, with the alpha-particle mass energy from [2431], so the non-relativistic treatment is ample. Conservation of momentum and of kinetic energy in the head-on case give the target the energy

$$E_2^{\max} = \frac{4m_1m_2}{(m_1+m_2)^2}\,E\,, \tag{117.6}$$

which is the largest transfer any elastic collision can achieve, at any angle, for any impact parameter, and independently of the force law: only the two masses enter. For an alpha particle on a proton the mass numbers alone would give $16/25 = 0.64$, but the ceiling is a number the argument leans on, so it is evaluated from the same atomic masses as everything else: $4m_1m_2/(m_1+m_2)^2 = 0.642\,74$ and

$$E_2^{\max} = 0.642\,74 \times 7.687\,\mathrm{MeV} = 4.941\,\mathrm{MeV} = 7.916 \times 10^{-13}\,\mathrm{J}\,. \tag{117.7}$$

Protons of longer range than this were seen, and no elastic process can make them. The same formula applied to an alpha on a nitrogen nucleus gives a factor 0.6915, so elastic recoils of nitrogen carry up to 5.32 MeV — energetic, but a nitrogen nucleus of that energy has a range in air of a few millimetres and cannot reach the screen.

The reaction energy. Form the mass balance of Equation (117.5) from the evaluated atomic masses [2393]. Summing the two sides,

$$m\left({}^{14}\mathrm{N}\right) + m\left({}^{4}\mathrm{He}\right) = 18.005\,677\,u\,, \tag{117.8}$$

$$m\left({}^{17}\mathrm{O}\right) + m\left({}^{1}\mathrm{H}\right) = 18.006\,957\,u\,, \tag{117.9}$$

so the products are *heavier* than the reactants by $0.001\,280\,u = 2.1247 \times 10^{-30}\,\mathrm{kg}$ and the reaction energy is negative,

$$Q = \left[m\left({}^{14}\mathrm{N}\right) + m\left({}^{4}\mathrm{He}\right) - m\left({}^{17}\mathrm{O}\right) - m\left({}^{1}\mathrm{H}\right)\right]c^2 = -1.1919\,\mathrm{MeV} = -1.9096 \times 10^{-13}\,\mathrm{J}\,. \tag{117.10}$$

An endothermic reaction needs more than $|Q|$ in the laboratory, because the centre of mass must keep moving and its kinetic energy is unavailable; demanding that the invariant available energy suffice to create the products at rest in their own centre of mass gives the threshold

$$E_{\mathrm{th}} = |Q|\left(1 + \frac{m({}^{4}\mathrm{He})}{m({}^{14}\mathrm{N})}\right) = 1.5326\,\mathrm{MeV} = 2.4554 \times 10^{-13}\,\mathrm{J}\,. \tag{117.11}$$

Radium C′ supplies 7.687 MeV, five times the threshold, so the reaction is open.

The proton energy. Being open is not enough; the surplus has to end up in the proton in the observable amount. For a two-body reaction $1 + 2 \to 3 + 4$ with target 2 at rest, non-relativistic throughout, conservation of energy and of momentum give the energy of product 3 at laboratory angle θ as

$$\sqrt{E_3} = v + \sqrt{v^2 + w}\,, \qquad v = \frac{\sqrt{m_1 m_3 E_1}}{m_3 + m_4}\cos\theta\,, \qquad w = \frac{m_4 Q + (m_4 - m_1)\,E_1}{m_3 + m_4}\,, \tag{117.12}$$

where E_1 is the projectile energy and the masses may be taken in any consistent unit, the ratios being all that enter. Both v^2 and w carry the SI dimension of energy, so $\sqrt{E_3}$ is an energy to the half power on both sides and the relation is dimensionally homogeneous.

Equation (117.12) is used six times in this chapter, so it is derived rather than quoted. Let p_1, p_3, p_4 be the laboratory momenta and θ the angle of product 3 to the beam. Momentum conservation gives $\boldsymbol{p}_4 = \boldsymbol{p}_1 - \boldsymbol{p}_3$, hence

$$p_4^2 = p_1^2 + p_3^2 - 2p_1p_3\cos\theta\,, \tag{117.13}$$

and energy conservation, with the reaction energy Q released into kinetic energy, gives $E_4 = E_1 + Q - E_3$. Non-relativistically $p^2 = 2mE$ throughout — legitimate here because $E/mc^2 \le 2.1 \times 10^{-3}$ for every particle involved — so Equation (117.13) becomes

$$2m_4\,(E_1 + Q - E_3) = 2m_1E_1 + 2m_3E_3 - 2\sqrt{4m_1m_3E_1E_3}\,\cos\theta\,. \tag{117.14}$$

Dividing by $2\,(m_3 + m_4)$ and collecting the terms in E_3 and in $\sqrt{E_3}$ turns this into $E_3 - 2v\sqrt{E_3} - w = 0$ with exactly the v and w of Equation (117.12); solving the quadratic in $\sqrt{E_3}$ and discarding the negative root, which would make E_3 negative whenever $w > 0$, gives $\sqrt{E_3} = v + \sqrt{v^2 + w}$. With $m_1 = m(^4\mathrm{He})$, $m_2 = m(^{14}\mathrm{N})$, $m_3 = m(^1\mathrm{H})$, $m_4 = m(^{17}\mathrm{O})$, $E_1 = 7.687\,\mathrm{MeV}$ and Q from Equation (117.10), the bracket w is $4.423\,\mathrm{MeV}$ — which is $E_p(90°)$ itself, since v vanishes there — and

$$E_p(0°) = 5.929\,\mathrm{MeV}\,, \qquad E_p(90°) = 4.423\,\mathrm{MeV}\,, \qquad E_p(180°) = 3.299\,\mathrm{MeV}\,. \tag{117.15}$$

The forward protons exceed the elastic ceiling of $4.941\,\mathrm{MeV}$ by $0.988\,\mathrm{MeV}$, a margin of 20 % in energy and considerably more in range, since a proton's range grows faster than its energy. Backward protons do not exceed it, which is consistent: the effect appears in the forward hemisphere, is a small fraction of the total yield, and is exactly what a scintillation screen placed beyond an absorber selects.

All three statements come from the same mass table and from elementary kinematics, and none of them is available to a hydrogen-contamination explanation, which is bounded by Equation (117.6) whatever the amount of hydrogen present. □

Remark 117.3 (What this experiment does not measure). It is worth being exact about the limits, because the experiment is often described as though it had measured a cross-section. It did not. The observable is a count of scintillations above a range threshold, with an efficiency set by a human eye, a solid angle known to perhaps a factor of two, and a source strength known from an ionisation measurement. What is established at high confidence is a qualitative statement of a kind that no amount of precision could improve on — that particles of a range no elastic collision can produce are emitted from nitrogen and from no other gas tried — and the identification of the reaction had to wait six years for a different instrument. The quantitative rows of Table 117.1 are the modern calculation of what should have been seen, not a modern measurement of what was.

117.2.5 Primary references

The observation is Rutherford's [461], the fourth and last paper of a series in the *Philosophical Magazine* on the collision of alpha particles with light atoms; the first three establish the scintillation technique and the elastic behaviour of hydrogen and of the other light gases, which is what makes the fourth readable as a controlled comparison rather than as an isolated claim. It is worth reading for its caution: Rutherford states the anomaly, the controls that exclude contamination, and explicitly declines to say what became of the alpha particle.

Blackett's paper [518] is the identification, and it is a different kind of document — an exhaustive scan of a photographic record, with the eight forks reproduced and measured. The two together are the pattern this chapter follows throughout: a counting experiment establishes that something happens, and an imaging experiment establishes what. Wilson's instrument [394], reported in Section 117.5, is what made the second half possible, and it is seven years older than the anomaly it resolved.

117.3 Cockcroft and Walton: lithium split by accelerated protons (1932)

Tests Phenomena 40.6, 117.4 and 117.5.
Assuming Theorem 9.76.

117.3.1 Apparatus

The apparatus divides into a high-voltage generator, an accelerating tube, and a scintillation counter of the kind already described in Section 117.2.

The generator is the part that carries the names. A transformer supplied an alternating potential of peak value V_0 of order 100 kV, and a cascade of capacitors and rectifiers converted it to a steady direct potential several times larger. The principle is worth stating because it is the reason the machine existed. In a cascade of n stages, the alternating column of capacitors is charged through the rectifiers on alternate half cycles, each stage of the direct column ends up at $2V_0$ above the one below it, and the output is

$$V_{\text{out}} = 2nV_0 \,. \tag{117.16}$$

With four stages and $V_0 = 100\,\text{kV}$ this is 800 kV, which is what the Cavendish machine reached; in practice 100 kV to 700 kV was used. No component ever holds more than $2V_0$ across it, which is what makes the arrangement buildable at all, and the same circuit — now called a Cockcroft–Walton generator — is still the first stage of many accelerator chains.

The direct potential was applied across a sealed accelerating tube built of glass cylinders about a metre long and 0.3 m in diameter, with intermediate electrodes so that the drop was shared and no single gap had to hold the whole voltage. That constraint is physical, not merely engineering: the dielectric strength of air at atmospheric pressure is about $3 \times 10^6\,\text{V/m}$, so 800 kV requires a clearance of at least 0.27 m in air even between ideal electrodes, and several times that between real ones with sharp edges and dust. It is the reason the electrostatic route to high energies has a ceiling of a few megavolts, and hence the reason for Section 117.4.

Protons were drawn from a hydrogen discharge at the top of the tube, a canal-ray source running at a few kilovolts, delivering a beam current of order $1 \times 10^{-5}\,\text{A}$ at the target with the tube continuously pumped to a residual pressure of order $1 \times 10^{-3}\,\text{Pa}$. The target was lithium metal, deposited on a backing and set at an angle to the beam so that the products could leave sideways. They left through a mica window whose stopping power had been calibrated against air, and were counted as scintillations on a zinc-sulfide screen under a microscope, exactly as in Section 117.2; further mica sheets placed in front of the screen measured their range.

117.3.2 Procedure

The measurement has three parts, and only the third identifies the reaction.

The accelerating potential was set and measured — by a sphere gap and a resistance chain — and the scintillation rate recorded as a function of it, so that the yield curve could be followed downwards towards the point where the effect disappeared into the background. The importance of pushing the curve downwards rather than upwards is that the interesting statement is a lower limit on where the reaction is still detectable, which is a statement about the barrier and not about the apparatus.

The range of the emitted particles was then measured by absorption in mica, converted to an equivalent range in air by the calibration, and hence to an energy through the range–energy relation for helium nuclei established with natural alpha sources. The particles' behaviour in absorbers — the shape of the absorption curve near its end point, and the specific ionisation, which follows Equation (115.15) — identified them as helium nuclei rather than protons or electrons.

Finally, two screens were placed on opposite sides of the target and their scintillations examined for coincidence, with an observer at each. This is the step that turns a detection into an identification. If the particles are emitted singly, the two observers see uncorrelated flashes at a rate set by chance; if they are emitted in pairs travelling in opposite directions,

the coincidence rate exceeds the accidental rate by a large factor. The kinematics of the proposed reaction makes that test sharp, as Equation (117.24) below shows.

117.3.3 Observations and data

Scintillations appeared with accelerating potentials as low as about 125 kV, and the yield rose rapidly as the potential was raised. The particles had a range in air of about 8.4×10^{-2} m, that is $0.103\,\mathrm{kg/m^2}$, which for a helium nucleus corresponds to a kinetic energy of about 8.6 MeV, that is 1.38×10^{-12} J; their behaviour in absorbers was that of ordinary alpha particles. The coincidence test showed them emitted in pairs, in opposite directions.

Table 117.2 sets the measured quantities beside the predictions computed here. Their accuracy is limited on the experimental side by the reading of a range end point, good to a few per cent, and by the calibration of the range–energy relation for helium nuclei; on the calculated side it is limited by nothing that matters, the mass-evaluation uncertainty on the Q value being of order 10 eV.

Table 117.2: Cockcroft and Walton's lithium disintegration: measured against calculated. The calculated alpha energies come from the two-body kinematics of Equation (117.12) applied to Equation (117.17) at a proton energy of 300 keV, which is representative of the potentials at which the range measurement was made; the mass difference is from the evaluated atomic masses. The last row is the reason the coincidence test works: at these energies the two alpha particles are back to back in the laboratory to within a few degrees. Bracketed uncertainties on the observed rows are estimates from the stated technique — a few per cent on a range end point and on its conversion to energy, and the sphere-gap calibration on the potential — since the primary papers quote none; the onset potential is in addition a limit of detection set by the scintillation background, not a physical threshold. The calculated rows carry the mass-evaluation uncertainty of order 10 eV, far below the last digit shown.

Quantity	Value (eV)	Value (SI)	Kind, source
Lowest potential showing the effect	—	(125 ± 5) kV	obs. 1932, [694]
Range of the products in air	—	$(0.103 \pm 0.004)\,\mathrm{kg/m^2}$	obs. 1932, [695]
Energy inferred from that range	(8.6 ± 0.3) MeV	$(1.38 \pm 0.05) \times 10^{-12}$ J	obs. 1932, [695]
Mass lost, $^7\mathrm{Li} + {}^1\mathrm{H} \to 2\,{}^4\mathrm{He}$	—	3.0922×10^{-29} kg	calc., [2393]
Energy released, $Q = \Delta m\, c^2$	17.3462 MeV	2.7792×10^{-12} J	calc., Equation (117.21)
Alpha energy at 90° to the beam	8.785 MeV	1.4076×10^{-12} J	calc., Equation (117.12)
Alpha energy at 0°	9.639 MeV	1.5443×10^{-12} J	calc., Equation (117.12)
Alpha energy at 180°	8.008 MeV	1.2830×10^{-12} J	calc., Equation (117.12)
Departure of the pair from collinearity	—	5.3°	calc., Equation (117.24)

The second table is the sub-barrier behaviour, and it is computed rather than observed. Table 117.3 evaluates the semiclassical barrier transmission for a proton incident on a lithium nucleus at each of the accelerating potentials used, from the Gamow exponent of Equation (9.93). The point of tabulating it is that the numbers are not small in the way one

expects of a tunnelling problem: the barrier here is low and thin, the exponent is of order unity to five, and a transmission of 6×10^{-3} at the lowest potential is entirely consistent with a countable rate. It is the *classical* prediction — exactly zero at every potential in the table — that the observation contradicts.

Table 117.3: Barrier transmission for a proton on ^{7}Li, computed here in SI from Equation (9.93) with a contact radius $R = 4.08\,\mathrm{fm}$ and the reduced mass $\mu = 1.4626 \times 10^{-27}\,\mathrm{kg}$. V is the accelerating potential, E the energy in the centre of mass, b the classical turning point, 2γ the Gamow exponent and $T = \mathrm{e}^{-2\gamma}$ the transmission. The last column is the relative thick-target yield of Equation (117.31), normalised to the lowest potential; it is the quantity a yield curve actually measures, and it rises far more steeply than T alone. The classical value of T is zero in every row, since the barrier height is 1.06 MeV. Nothing here is a measurement, so no row carries an experimental uncertainty; what the numbers inherit is the 4 % uncertainty of the contact radius R, which moves 2γ in the first row by about 0.05.

V	E (centre of mass)	b	2γ	T	Y/Y_0
125 kV	109.3 keV	39.5 fm	5.04	6.5×10^{-3}	1.00
150 kV	131.2 keV	32.9 fm	4.32	1.33×10^{-2}	2.24
200 kV	174.9 keV	24.7 fm	3.31	3.64×10^{-2}	7.02
250 kV	218.6 keV	19.8 fm	2.63	7.18×10^{-2}	15.4
300 kV	262.3 keV	16.5 fm	2.14	1.18×10^{-1}	27.5
400 kV	349.8 keV	12.4 fm	1.46	2.31×10^{-1}	62.4
500 kV	437.2 keV	9.9 fm	1.02	3.60×10^{-1}	109
700 kV	612.1 keV	7.1 fm	0.48	6.17×10^{-1}	225

117.3.4 Interpretation

Two alpha particles emitted back to back, with nothing else, identifies the reaction uniquely as

$$^{7}\mathrm{Li} + {}^{1}\mathrm{H} \longrightarrow {}^{4}\mathrm{He} + {}^{4}\mathrm{He}\,. \tag{117.17}$$

This is the first nuclear reaction driven by artificially accelerated particles: unlike Section 117.2, the projectile energy is now a knob on the apparatus, and the yield curve is a measurement rather than an accident of which radioactive source was to hand.

Its importance for this book, however, is quantitative. The energy released was measured directly, from the range of the products, and compared with the energy predicted by the difference of the masses — a prediction that has nothing to do with nuclear physics and everything to do with Phenomenon 40.6. The two agree. Cockcroft and Walton made the comparison in 1932 with the mass-spectrograph values then available, which gave a mass difference of about $0.018\,u$ and hence an energy release close to 17 MeV, against the $2 \times 8.6\,\mathrm{MeV} = 17.2\,\mathrm{MeV}$ they measured; with the modern evaluation the prediction is 17.3462 MeV (Equation (117.21)) and the kinematically correct comparison at 90° is 8.785 MeV per alpha against a measured 8.6 MeV, a discrepancy of 2 % and entirely within the accuracy of a range measurement. This is the first quantitative confirmation of mass–energy equivalence in a nuclear reaction, and it was obtained from a table of atomic weights and a ruler laid against an absorption curve.

The comparison is worth appreciating for how little it assumes. The left-hand side of Equation (117.21) is measured by a mass spectrograph, an instrument that deflects ions in electric and magnetic fields and knows nothing of nuclear forces. The right-hand side is measured by the distance an alpha particle travels in mica. The only bridge between

them is $E = mc^2$. Had the two disagreed, no nuclear model would have been at fault; the relativistic energy–momentum relation of Chapter 40 would have been.

A second reading of the same data was equally consequential. The reaction was observed at proton energies an order of magnitude below the height of the Coulomb barrier between a proton and a lithium nucleus, which classical mechanics forbids outright. The experiment is therefore also a direct confirmation of barrier penetration [600, 603, 625], whose other early evidence — alpha decay — is developed in Theorem 107.63 of Chapter 107. It is a cleaner confirmation than alpha decay in one respect and a dirtier one in another. Cleaner, because the energy of the incident particle is set by the experimenter and can be varied, so the exponential dependence predicted by Equation (9.87) can be traced out rather than inferred from a correlation across nuclides. Dirtier, because the absolute yield involves the nuclear matrix element and the thick-target energy loss as well as the barrier, so only the shape of the curve is a clean test.

Phenomenon 117.4 (Lithium disintegrates into two alpha particles)**.** Lithium bombarded with protons accelerated through a few hundred kilovolts emits helium nuclei in pairs, in nearly opposite directions, each of kinetic energy near 8.6 MeV [694, 695]. The total energy released is equal, within the accuracy of the measurement, to the mass lost by the system, converted at the rate $E = mc^2$.

Rests on Equations (40.6)*,* (117.12) *and* (117.17)*.*

Derivation. *Derives Phenomenon 117.4.*

Write the mass balance of Equation (117.17) with the evaluated atomic masses [2393]:

$$m\left({}^{7}\mathrm{Li}\right) + m\left({}^{1}\mathrm{H}\right) = 7.016\,003\,4\,u + 1.007\,825\,0\,u = 8.023\,828\,4\,u\,, \tag{117.18}$$

$$2\,m\left({}^{4}\mathrm{He}\right) = 2 \times 4.002\,603\,3\,u = 8.005\,206\,5\,u\,. \tag{117.19}$$

The system is lighter after the reaction than before by

$$\Delta m = 0.018\,622\,0\,u = 3.0922 \times 10^{-29}\,\mathrm{kg}\,, \tag{117.20}$$

and by Equation (117.1) the energy released is

$$Q = \Delta m\,c^2 = 3.0922{\times}10^{-29}\,\mathrm{kg}{\times}\left(2.997\,924\,58 \times 10^{8}\,\mathrm{m/s}\right)^2 = 2.7792{\times}10^{-12}\,\mathrm{J} = 17.3462\,\mathrm{MeV}\,. \tag{117.21}$$

Note that the electron count balances — three electrons on each side, since lithium is $Z = 3$ and each helium is $Z = 2$ — so atomic masses may be used without correction, and that Δm is 0.23 % of the total mass, which is why a mass spectrograph of the period could see it.

Now share it. Because the two products are identical, the reaction is symmetric in the centre of mass and each alpha particle takes half the available energy there; in the laboratory the pair is boosted along the beam. Applying Equation (117.12) with $m_1 = m({}^{1}\mathrm{H})$, $m_2 = m({}^{7}\mathrm{Li})$, $m_3 = m_4 = m({}^{4}\mathrm{He})$, Q from Equation (117.21) and $E_1 = 300\,\mathrm{keV}$:

$$E_\alpha(0^\circ) = 9.639\,\mathrm{MeV}\,, \quad E_\alpha(90^\circ) = 8.785\,\mathrm{MeV}\,, \quad E_\alpha(180^\circ) = 8.008\,\mathrm{MeV}\,, \tag{117.22}$$

the three summing correctly in pairs to $Q + E_1 = 17.646\,\mathrm{MeV}$ for the forward–backward pair. The screens in the coincidence experiment sat transverse to the beam, where the prediction is 8.785 MeV per particle, and the measured 8.6 MeV agrees to 2 %.

Two checks complete the argument. First, that the crude statement “each alpha takes half” is a good approximation and why: with $E_1 \ll Q$ the incident momentum is small beside the momenta of the products. An alpha particle of 8.785 MeV has

$$p_\alpha c = \sqrt{E_\alpha^2 + 2E_\alpha m_\alpha c^2} = 256.1\,\mathrm{MeV}\,, \qquad p_\alpha = 1.368 \times 10^{-19}\,\mathrm{kg\,m/s}\,, \tag{117.23}$$

using $m_\alpha c^2 = 3727.4\,\mathrm{MeV}$ [2431], while a proton of 300 keV has $p_p c = 23.7\,\mathrm{MeV}$, that is $1.27 \times 10^{-20}\,\mathrm{kg\,m/s}$. Second, the angular consequence: if one alpha leaves at 90°, the other must carry the whole incident longitudinal momentum, so the pair departs from collinearity by

$$\delta = \arctan\frac{p_p}{p_\alpha} = \arctan\frac{23.7\,\mathrm{MeV}/c}{256.1\,\mathrm{MeV}/c} = 5.3^\circ\,. \tag{117.24}$$

Five degrees is small enough that two screens set at 180° both intercept the pair, which is why the coincidence test worked, and large enough to have been detectable had the apparatus been built to look for it.

Nothing in this argument is nuclear. The only physical input beyond bookkeeping is $E = mc^2$ (Equation (40.6)), and the experiment measures the two sides of Equation (117.21) independently — the left from a mass spectrograph, the right from an absorption curve. □

Phenomenon 117.5 (The reaction proceeds far below the Coulomb barrier)**.** Disintegration is observed with protons accelerated through as little as about 125 kV [694], an order of magnitude below the electrostatic barrier that a proton must surmount to reach a lithium nucleus. A classical particle of that energy never arrives; the observed yield is the transmission of the barrier by tunnelling [600, 603].

Rests on Theorem 9.76 and Equations (9.93) *and* (107.2).

Derivation. *Derives Phenomenon 117.5.*

The barrier. Two nuclei of charges $Z_1 e$ and $Z_2 e$ touch when their centres are separated by $R \approx r_0\left(A_1^{1/3} + A_2^{1/3}\right)$ with $r_0 \approx 1.4\,\mathrm{fm}$, and up to that separation the only force acting is the Coulomb repulsion, so the barrier height is

$$B = \frac{Z_1 Z_2 e^2}{4\pi\varepsilon_0 R}\,. \tag{117.25}$$

With $e^2/(4\pi\varepsilon_0) = 1.4400\,\mathrm{MeV\,fm}$ from Equation (107.2), and for a proton on lithium, $Z_1 Z_2 = 3$ and $R = 1.4\,\mathrm{fm} \times (1 + 7^{1/3}) = 4.08\,\mathrm{fm}$, giving

$$B = 1.059\,\mathrm{MeV} = 1.697 \times 10^{-13}\,\mathrm{J}\,. \tag{117.26}$$

The classical statement. The relevant energy is the one available in the centre of mass, not the laboratory energy: with a proton of 125 keV on a lithium nucleus,

$$E = E_{\mathrm{lab}}\frac{m_{\mathrm{Li}}}{m_{\mathrm{Li}} + m_p} = 109.3\,\mathrm{keV} = 1.751 \times 10^{-14}\,\mathrm{J}\,, \tag{117.27}$$

a factor 9.7 below Equation (117.26). A classical proton of that energy turns around at $b = Z_1 Z_2 e^2/(4\pi\varepsilon_0 E) = 39.5\,\mathrm{fm}$, nearly ten times the radius at which the nuclear force acts, and the yield would be exactly zero rather than merely small. There is no classical parameter to adjust: the observation is not of a rate lower than expected but of a rate where none was possible.

The quantum statement. The transmission of a Coulomb barrier between a contact radius R and a turning point b is a solved problem in this book and is not rebuilt here. Theorem 9.76 gives the semiclassical transmission as $T \approx \mathrm{e}^{-2\gamma}$ with $\gamma = \hbar^{-1}\int\sqrt{2\mu(V-E)}\,\mathrm{d}r$ taken between the turning points (Equation (9.87)), and Example 9.81 evaluates that integral for exactly this potential, in SI, obtaining

$$\gamma = \frac{\sqrt{2\mu E}\,b}{\hbar}\left[\arccos\sqrt{\xi} - \sqrt{\xi\,(1-\xi)}\right], \qquad \xi = \frac{R}{b}\,, \tag{117.28}$$

which is Equation (9.93). Only three inputs are needed to use it. The reduced mass of the proton–lithium system is

$$\mu = \frac{m_p m_{\mathrm{Li}}}{m_p + m_{\mathrm{Li}}} = 1.4626 \times 10^{-27}\,\mathrm{kg}\,, \qquad \mu c^2 = 820.5\,\mathrm{MeV}\,, \tag{117.29}$$

built from the nuclear masses of [2393] with the electrons removed, since it is the nuclei that move. The turning point b and the ratio ξ follow from E as above. And $\hbar$ is $1.054\,572 \times 10^{-34}\,\mathrm{J\,s}$, which is what makes γ dimensionless: the numerator of Equation (117.28) is a momentum times a length, in $\mathrm{kg\,m/s} \times \mathrm{m}$, and dividing by $\mathrm{J\,s}$ leaves a pure number.

At $E = 109.3\,\mathrm{keV}$ the momentum scale is $\sqrt{2\mu E} = 7.157 \times 10^{-21}\,\mathrm{kg\,m/s}$, $b = 39.5\,\mathrm{fm}$, $\xi = 0.1032$, the bracket is 0.9396, and

$$2\gamma = 5.04\,, \qquad T = \mathrm{e}^{-5.04} = 6.5 \times 10^{-3}\,. \tag{117.30}$$

The whole of Table 117.3 is this calculation repeated.

The shape of the yield curve. T itself is not what a yield curve measures. A proton entering a thick lithium target loses energy continuously to atomic electrons and has a chance of reacting at every energy from its incident value down to zero, so the yield per incident proton is

$$Y(E_0) = n \int_0^{E_0} \frac{\sigma(E)}{|\mathrm{d}E/\mathrm{d}x|}\,\mathrm{d}E\,, \qquad \sigma(E) = \frac{S(E)}{E}\,\mathrm{e}^{-2\gamma(E)}\,, \tag{117.31}$$

with n the number density of lithium nuclei and $S(E)$ the astrophysical S factor of Equation (107.100), which is slowly varying because it is defined to absorb both the barrier and the geometrical $1/E$. Evaluating Equation (117.31) with S constant and $|\mathrm{d}E/\mathrm{d}x|$ taken as constant over this narrow range gives the relative yields 1.00, 2.24, 7.02, 15.4, 27.5, 62.4, 109 and 225 at the eight accelerating potentials of Table 117.3, which run from 125 kV to 700 kV; they are its last column. The measured curve does rise by more than two orders of magnitude across that range, and the reason it rises faster than T does is the integral, not the barrier. □

Remark 117.6 (What the barrier factor does and does not explain). The transmission in Table 117.3 is of order 1×10^{-2}, while the observed yield per incident proton is of order 1×10^{-8}. The six orders of magnitude between them are not a defect of the calculation and are not tunnelling. A proton of 125 keV in lithium metal has a range of order $1 \times 10^{-6}\,\mathrm{m}$ and makes of order 1×10^{5} collisions with atomic electrons before stopping, in the course of which it passes within nuclear distances of essentially no nucleus at all; the geometrical probability of an encounter, and the nuclear matrix element once an encounter occurs, supply the rest of the suppression. What the barrier factor explains is the *shape* of the curve and the fact that there is any yield whatever at 125 kV. Reading it as an absolute prediction would be exactly the error Remark 9.77 warns against for the semiclassical method in general: the exponent is the reliable output, the prefactor is not.

Remark 117.7 (The exponent is small here, and that is unusual). Barrier problems in this book are usually deep in the semiclassical regime: the alpha decay of Example 9.81 has $2\gamma = 67$ and a transmission of 7×10^{-30}. Here 2γ runs from 5.0 down to 0.5, so the thick-barrier form Equation (9.87) is being used near the edge of its validity, and the two turning points are not far apart on the Airy scale at the upper end of the table. Neither refinement of the prefactor is exact — Remark 9.77 is explicit that Equation (9.86) is not, and offers the uniform form $T = \left(1 + \mathrm{e}^{2\gamma}\right)^{-1}$ as the alternative — but both move in the same direction, *downwards*, and by how much is the point. At the lowest row, $2\gamma = 5.04$: $\mathrm{e}^{-2\gamma} = 6.47 \times 10^{-3}$, Equation (9.86) gives 6.45×10^{-3} and the uniform form 6.43×10^{-3}, so the correction is below 1 % where the physical argument is made. At the last row, $2\gamma = 0.48$, the same three read 0.617, 0.463 and 0.381: a correction of 25 % and 38 % respectively, in a row where the proton is nearly over the barrier and the notion of tunnelling has stopped being the right description. The rows that carry the physical argument are the first three, and there the approximation is sound.

117.3.5 Primary references

Three papers report this work and they should be read in order. The *Nature* letter [694] is the announcement, four weeks after the observation, and it is where the 125 kV figure and the identification of the products as alpha particles first appear. The first *Proceedings* paper [696] is about the machine and not about the physics: it is the reference for the cascade generator, the accelerating tube and the beam, and it is the document that made the technique reproducible elsewhere. The second [695] is the full report of the disintegration, with the yield curve, the absorption measurements and the coincidence test.

The tunnelling interpretation rests on Gamow [600] and, independently, Gurney and Condon [603, 625], all published four years earlier for alpha decay; the Cockcroft–Walton experiment was in fact undertaken because Gamow's calculation, applied in reverse, showed that a few hundred kilovolts might suffice. That is worth noticing: this is one of the few experiments of the period designed from a quantum-mechanical prediction rather than interpreted by one afterwards.

117.4 Lawrence and Livingston: the cyclotron (1932)

Tests Phenomenon 117.8.

117.4.1 Apparatus

A flat evacuated brass chamber, about 0.28 m across — eleven inches, in the units of the paper — placed between the circular pole faces of an electromagnet whose field is perpendicular to its plane and uniform to a fraction of a per cent over the working region. Inside it, two hollow D-shaped electrodes, the "dees", face each other across a narrow diametral gap and are connected to a radiofrequency oscillator. The interior of each dee is a field-free region, being a closed conductor: the whole accelerating action takes place in the gap, and the dees exist to shield the ion from the alternating field during the half revolution in which that field would decelerate it.

An ion source sits at the centre, a filament and a gas feed producing hydrogen ions in the middle of the gap. A deflecting electrode at the periphery, held at a few kilovolts, pulls the beam out of its last orbit and onto a collector. The chamber was pumped to a residual pressure of order 1×10^{-4} Pa, which is set not by any technical convenience but by the physics: the ion travels a total path length of order

$$L = \sum_{k=1}^{N} 2\pi r_k = 2\pi R \sum_{k=1}^{N} \sqrt{\frac{k}{N}} \approx \frac{4\pi}{3} N R \approx 73\,\mathrm{m}\,, \tag{117.32}$$

inside the machine — using $r_k = R\sqrt{k/N}$, since the energy grows linearly with the crossing count and the radius as its square root — and must not scatter out of resonance on the way. Put the requirement in areal density, which is what stops a particle. A proton of 1.22 MeV has a range in air of about 3.3×10^{-2} kg/m^2, while 73 m of air at 1 Pa and 288.15 K — a density of 1.21×10^{-5} kg/m^3 by Equation (117.3) scaled with pressure — presents only 8.8×10^{-4} kg/m^2. So 1 Pa does not stop the beam outright; the pressure that would is about 40 Pa, and the residual pressure has to be far below even that, because a single elastic scatter through a small angle already takes the ion out of resonance. At 1×10^{-4} Pa the gas-kinetic mean free path $k_B T/(\sqrt{2}\pi d^2 p)$, with a molecular diameter $d \approx 3 \times 10^{-10}$ m and $T = 300$ K, is 1.0×10^{2} m — longer than the 73 m orbit, and for a 1 MeV proton, whose scattering cross-section is far below gas-kinetic, longer still. That is the margin the pump had to buy.

The magnet is the expensive component and the one that sets the energy. Everything else in the machine handles a few kilovolts.

117.4.2 Procedure

Ions released at the centre are bent by the magnetic field into a circle and cross the gap twice per revolution. If the oscillator frequency is matched to the revolution frequency, each crossing finds the gap field reversed and therefore accelerating, so the ion gains qV_{gap} at every crossing while its orbit grows as the square root of its energy.

The experiment consists of three measurements. First, tuning: the magnetic field is swept at fixed oscillator frequency and the collected current recorded, which produces a resonance curve whose peak locates the condition $\omega_c = \omega_{\mathrm{osc}}$ and whose width measures how far off resonance the machine will still accelerate. Second, the current at resonance, which measures how much beam survives the 73 m of orbit of Equation (117.32). Third, the energy of the extracted beam, measured by absorption in foils against the known range–energy relation for protons — the same technique as Section 117.3, and the same one that provides the only independent check that the ions really did make a hundred and fifty turns.

The resonance curve is the crucial one, because it is what distinguishes this machine from a peculiar high-voltage device. A current that appears only in a narrow band of magnetic field, centred on the value that makes Equation (117.34) equal the oscillator frequency, cannot be explained by any static potential in the apparatus.

117.4.3 Observations and data

Protons of kinetic energy above 1.2 MeV were obtained from a peak voltage on the dees of a few kilovolts, with beam currents of order 1×10^{-9} A at the collector. The ratio of the two voltages is the whole point: at about 4 kV per gap crossing and two crossings per turn, the final energy corresponds to something like a hundred and fifty revolutions, and the accelerating voltage that has to be insulated anywhere in the machine is smaller than the beam energy in electronvolts by more than two orders of magnitude.

Table 117.4 collects the measured quantities and the machine parameters that follow from them. The field and frequency are not independent measurements but consequences of the resonance condition and the extraction radius, and are computed here; they are included because they are what the resonance curve actually determines.

117.4.4 Interpretation

The cyclotron removed the ceiling that high-voltage technique imposes. Cockcroft and Walton's method needs the full energy to exist as a potential difference somewhere in the laboratory, and the dielectric strength of air sets a limit of a few million volts; the cyclotron needs only the gap voltage, and buys energy with turns instead of volts. The exchange is not free — it is paid for in orbit length, in vacuum, and in magnetic-field uniformity — but all three are technical problems with technical solutions, whereas insulation is a material property.

Everything downstream in this treatise depends on that trade: the beams of Chapter 116, the colliding beams of Chapter 113, and the reactor and accelerator neutrino sources of Chapter 114 are all descendants of it. So is a large part of nuclear astrophysics, since the reaction cross-sections that Chapter 52 needs — the cross-sections whose Gamow-peak energies are computed in Theorem 107.85 — are measured on machines of this lineage, at energies where the direct astrophysical rate is unmeasurably small.

The classical cyclotron has one limit, and it is relativistic. As the ion's energy grows its revolution frequency falls, the resonance detunes, and acceleration stops. The cure is to modulate the frequency (the synchrocyclotron) or to raise the field in step with the energy at fixed radius (the synchrotron); both are corrections demanded by Chapter 40 and by nothing else, and they are the reason no accelerator built after the 1940s is a cyclotron in

Table 117.4: The 1932 cyclotron: what was measured and what follows. The proton energy and the beam current are the reported observations; the magnetic field, the revolution frequency and the turn count are computed here from Equation (117.36) and Equation (117.34) with the quoted chamber size, and are the parameters the resonance condition fixes. The last two rows are the relativistic limit of the design, and are the reason no later machine was built this way. Bracketed uncertainties on the observed rows are estimates from the stated technique, the paper quoting none: 5 % on an energy read from a foil absorption curve, 4 % on a radius set by the position of the deflector, and an order of magnitude on the collected current. The computed rows inherit them — the momentum to 2.5 %, the field and the frequency to 5 %, the turn count, the orbit length and the phase slip to about 14 % — and are quoted with the propagated figure in brackets.

Quantity	Value	Kind, source
Chamber diameter	$(0.28 \pm 0.01)\,\mathrm{m}$	obs. 1932, [703]
Extraction radius	$(0.114 \pm 0.005)\,\mathrm{m}$	obs. 1932, [703]
Proton kinetic energy	$(1.22 \pm 0.06)\,\mathrm{MeV}$, i.e. $(1.955 \pm 0.096) \times 10^{-13}\,\mathrm{J}$	obs. 1932, [703]
Beam current at the collector	order $1 \times 10^{-9}\,\mathrm{A}$	obs. 1932, [703]
Peak dee voltage	$(4.0 \pm 0.5)\,\mathrm{kV}$	obs. 1932, [703]
Proton momentum at extraction	$(2.557 \pm 0.063) \times 10^{-20}\,\mathrm{kg\,m/s}$	calc.
Magnetic field required	$(1.40 \pm 0.07)\,\mathrm{T}$	calc., Equation (117.33)
Revolution frequency	$(21.3 \pm 1.1)\,\mathrm{MHz}$	calc., Equation (117.34)
Number of revolutions	153 ± 20	calc.
Total orbit length	$(73 \pm 10)\,\mathrm{m}$	calc., Equation (117.32)
Relativistic frequency shift at extraction	$(1.30 \pm 0.06) \times 10^{-3}$	calc.
Accumulated phase slip over the acceleration	$(0.62 \pm 0.09)\,\mathrm{rad}$, i.e. $(36 \pm 5)^\circ$	calc., Equation (117.38)

the original sense. The 1932 machine sits exactly at the boundary, which is what makes it worth computing the phase slip below rather than merely asserting the limitation.

Phenomenon 117.8 (Cyclotron resonance)**.** A non-relativistic ion of charge q and mass m moving in a uniform magnetic field of magnitude B circulates with an angular frequency that does not depend on its speed or on the radius of its orbit. A fixed-frequency alternating voltage across a single gap therefore stays in step with the ion for hundreds of revolutions and accelerates it at every crossing, so that the final energy is set by the magnet and not by the applied voltage [703].

Derivation. *Derives Phenomenon 117.8.*

For circular motion in a uniform field perpendicular to the orbit, the magnetic force supplies the centripetal acceleration,

$$qvB = \frac{mv^2}{r} \quad \Longrightarrow \quad r = \frac{mv}{qB} = \frac{p}{qB}\,, \tag{117.33}$$

in SI a radius in metres when p is in kg m/s, q in coulombs and B in tesla. The angular frequency is therefore

$$\omega_c = \frac{v}{r} = \frac{qB}{m}\,, \tag{117.34}$$

independent of v and of r: the ion takes the same time to complete a small slow circle as a large fast one, which is exactly the property that lets one fixed frequency serve the whole acceleration. It is a peculiarity of the Lorentz force and of no other force law that this is so; a linear restoring force would give the same property, and an inverse-square attraction would not.

Numbers. At the extraction radius $R = 0.114\,\mathrm{m}$ a proton of $1.22\,\mathrm{MeV}$ has momentum $p = \sqrt{2m_pT} = 2.557 \times 10^{-20}\,\mathrm{kg\,m/s}$, using $m_p = 1.6726 \times 10^{-27}\,\mathrm{kg}$ [2431], so Equation (117.33) requires

$$B = \frac{p}{eR} = \frac{2.557 \times 10^{-20}\,\mathrm{kg\,m/s}}{1.602\,177 \times 10^{-19}\,\mathrm{C} \times 0.114\,\mathrm{m}} = 1.400\,\mathrm{T}\,, \tag{117.35}$$

an ordinary iron-cored electromagnet, and Equation (117.34) then gives $\omega_c/2\pi = eB/2\pi m_p = 21.3\,\mathrm{MHz}$, a free-space wavelength of 14 m and an entirely standard radiofrequency in 1932.

Energy from the magnet, not the voltage. Eliminating v between Equation (117.33) and the kinetic energy gives the extraction energy at the outer radius R,

$$T = \tfrac{1}{2}mv^2 = \frac{q^2B^2R^2}{2m}\,, \tag{117.36}$$

which contains the gap voltage nowhere. Checking: $e^2B^2R^2/2m_p = 1.955 \times 10^{-13}\,\mathrm{J} = 1.22\,\mathrm{MeV}$, as observed. The number of crossings needed is $N_{\mathrm{cross}} = T/qV_{\mathrm{gap}} = 1.22\,\mathrm{MeV}/4\,\mathrm{keV} = 305$, that is 153 revolutions, and the gap voltage merely fixes how long the ion must stay in the machine. Note the scaling: $T \propto B^2R^2$, so the energy is quadratic in the size of the magnet, which is why the next machines were bigger rather than cleverer.

The limit. Relativistically the momentum is γmv with $\gamma = (1 - v^2/c^2)^{-1/2}$, so Equation (117.34) becomes $\omega = qB/\gamma m$: the frequency falls as the ion becomes energetic, and the resonance that Equation (117.34) guarantees is lost. For protons at $1.22\,\mathrm{MeV}$ the shift is

$$\gamma - 1 = \frac{T}{m_pc^2} = \frac{1.22\,\mathrm{MeV}}{938.27\,\mathrm{MeV}} = 1.30 \times 10^{-3}\,, \tag{117.37}$$

using the proton mass energy of [2427]. The consequence is cumulative and that is what has to be estimated. Suppose the energy grows linearly with turn number n, so that

$\gamma_n - 1 \approx (n/N)(\gamma_N - 1)$; each turn the ion arrives at the gap late by a fraction $\gamma_n - 1$ of a period, and after N turns the accumulated phase error is

$$\Delta\phi = 2\pi \sum_{n=1}^{N} (\gamma_n - 1) \approx \pi N \, (\gamma_N - 1) = \pi \times 153 \times 1.30 \times 10^{-3} = 0.62\,\mathrm{rad}\,, \qquad (117.38)$$

that is 36°. Acceleration continues as long as the ion arrives within a quarter period of the correct phase, so 36° is tolerable and the machine works. At ten times the energy the same estimate gives $\Delta\phi \approx 62\,\mathrm{rad}$, since both N and $\gamma_N - 1$ grow with T and the slip therefore grows as T^2; the ion would be decelerated for most of its life and never reach the rim. The classical cyclotron works precisely in the regime where Chapter 40 is not yet needed, and it stops working exactly where it is. □

Remark 117.9 (Why the resonance is not fragile). It is easy to read Equation (117.38) as saying that the machine requires the field and the frequency to be matched to a part in 10^3, and that is not quite right. What matters is the accumulated phase, so a static mismatch $\Delta\omega/\omega$ produces a slip $2\pi N \Delta\omega/\omega$, and tolerating a quarter period over 153 turns means $|\Delta\omega/\omega| < 1.6 \times 10^{-3}$ — which is a demanding but attainable tolerance on an iron magnet, and is precisely the width of the resonance curve that the experiment measured. The measured width is therefore not an instrumental artefact but a direct reading of the turn count, and it is the strongest evidence in the paper that the ions really were accelerated many times rather than once.

117.4.5 Primary references

The single reference is Lawrence and Livingston's *Physical Review* paper [703], whose title — the production of high-speed light ions without the use of high voltages — states the whole result. It should be read alongside [696], published the same year, since the two describe opposite solutions to the same problem and each is explicit about the limitation of the other's approach. Neither paper reports a nuclear reaction; the cyclotron's first disintegrations followed within months, using the lithium target of Section 117.3 as the obvious first check that the beam was real.

117.5 Wilson: the expansion cloud chamber (1912)

Tests Phenomenon 117.10.

117.5.1 Apparatus

A shallow cylindrical chamber with glass walls and roof, of order 0.16 m in diameter and a few centimetres deep, containing dust-free air saturated with water vapour. Its floor is a piston whose sudden withdrawal expands the gas; the expansion is completed in a time of order $1 \times 10^{-2}\,\mathrm{s}$, short compared with the time in which heat can reach the gas from the walls, so it is adiabatic and therefore cools the gas, leaving the vapour supersaturated.

Three further elements make it an instrument rather than a demonstration. The expansion is stopped mechanically at a *preset* ratio, because the ratio is the control variable and must be reproducible to better than a per cent. The chamber is illuminated from the side by a bright flash — the illumination must be transverse, since the droplets are seen by scattered light against a dark background — and photographed, in the developed form stereoscopically, so that the track can be reconstructed in three dimensions. And a clearing field of order $1 \times 10^3\,\mathrm{V/m}$ between electrodes above and below the gas sweeps out the ions left by previous events between expansions, without which the chamber accumulates a fog of old tracks.

Dust is the enemy and its removal is the reason the instrument took fifteen years to develop. Every dust grain is a condensation nucleus, and a chamber with dust in it fogs at any expansion. Wilson removed it by repeated expansions with the condensate allowed to settle, each cycle sweeping the remaining particles down with the droplets they nucleated.

117.5.2 Procedure

The expansion ratio is the control. Below a threshold no condensation occurs at all; above a first threshold droplets form on ions; above a second, higher one the vapour condenses on everything and the chamber fogs uniformly. Working between the two thresholds makes ions, and only ions, into condensation nuclei — and the existence of a window between the thresholds, rather than a single onset, is the physical fact on which the instrument rests. It is derived below.

The operating cycle is then fixed by the physics of droplet growth. The chamber is expanded in synchronism with the passage of the radiation under study — in the developed form, triggered by a counter telescope that has already registered the particle. The illumination is flashed a few hundredths of a second later: long enough for the droplets to grow by condensation to a size that scatters visible light efficiently, which requires a radius of order $1 \times 10^{-6}\,\mathrm{m}$, and short enough that diffusion has not yet blurred the trail. A water molecule in air at $270\,\mathrm{K}$ has a diffusion coefficient of order $2 \times 10^{-5}\,\mathrm{m^2/s}$, so in $2 \times 10^{-2}\,\mathrm{s}$ an ion wanders $\sqrt{2Dt} \approx 9 \times 10^{-4}\,\mathrm{m}$ — under a millimetre, which is why the track is still sharp at that delay and would not be at one second.

After the photograph the chamber is recompressed, the clearing field applied, and the cycle repeated, at a rate of a few per minute. That duty cycle — seconds of dead time for each millisecond of sensitivity — is the instrument's defining weakness and is what Section 117.7 eventually removed.

117.5.3 Observations and data

The photographs show the paths of individual ionising particles as sharp lines of droplets. Alpha particles give dense, straight, sharply terminated trails, occasionally with a sudden deflection near the end where a nuclear encounter has occurred; fast beta particles give thin, tortuous trails; X-rays give no trail at all but a scatter of short electron tracks starting at points along the beam.

That contrast is quantitative and is the first thing the instrument measures. The specific ionisation of a charged particle behaves as Equation (115.15), so a slow or multiply charged particle ionises far more densely than a fast singly charged one. For an alpha particle of $7.687\,\mathrm{MeV}$ depositing its whole energy in $7.0 \times 10^{-2}\,\mathrm{m}$ of air, the mean deposit is $1.10 \times 10^{8}\,\mathrm{eV/m}$, that is $1.76 \times 10^{-11}\,\mathrm{J/m}$; at a mean expenditure of about $34\,\mathrm{eV}$ — $5.4 \times 10^{-18}\,\mathrm{J}$ — per ion pair in air [2427], that is roughly $3.2 \times 10^{6}/\mathrm{m}$ of track. A minimum-ionising electron in the same gas loses about $2.2 \times 10^{5}\,\mathrm{eV/m}$, that is $3.5 \times 10^{-14}\,\mathrm{J/m}$, and makes about $6.5 \times 10^{3}/\mathrm{m}$. The ratio, some five hundred, is exactly the difference between a dense unbroken trail and a sparse dotted one, and it is why the two species are distinguishable by eye in a photograph.

The thresholds themselves are the chamber's calibration, and are collected in Table 117.5. The expansion ratios are Wilson's; the temperatures and supersaturations are computed here from them by Equations (117.39) and (117.40), with no free parameter — the initial temperature is the only input and the saturation vapour pressure cancels.

The tabulated droplet densities of the original paper are not transcribed here. What is reproduced is the calibration that makes the instrument an instrument: the two thresholds, their ratio, and the prediction of both from the thermodynamics of a charged drop.

Table 117.5: The condensation window of a Wilson chamber. The expansion ratio $r = V_2/V_1$ is the experimental control [394]; T_2 and the supersaturation S are computed here from Equations (117.39) and (117.40) for air initially saturated at $T_1 = 293.15\,\mathrm{K}$, using $\gamma = 1.40$ and the Clausius–Clapeyron relation with a latent heat of $2.50 \times 10^6\,\mathrm{J/kg}$. The last column is the critical supersaturation predicted by Equation (117.46) for a singly charged nucleus, or by the neutral nucleation barrier Equation (117.43) where marked; the agreement between the observed thresholds and the predictions is the content of Phenomenon 117.10. The expansion ratio is set mechanically and is reproducible to better than 0.5 %, which is the bracketed uncertainty; T_2 and S carry what that propagates to through Equations (117.39) and (117.40). The barrier in the last row is quoted with the constant $\sigma = 0.0765\,\mathrm{N/m}$ used throughout the derivation, and would fall to $36\,k_B T$ with the surface tension of supercooled water at 257.7 K; the difference is the honest size of the model's grip on the third figure.

$r = V_2/V_1$	T_2	S	What is observed, and what is predicted
1.250 ± 0.005	$(268.1 \pm 0.4)\,\mathrm{K}$	4.11 ± 0.11	droplets on negative ions; charged-nucleus threshold predicted at $S = 4.47$
1.310 ± 0.005	$(263.1 \pm 0.4)\,\mathrm{K}$	5.64 ± 0.15	droplets on positive ions as well; same prediction, and the sign asymmetry is outside the model
1.380 ± 0.005	$(257.7 \pm 0.4)\,\mathrm{K}$	8.08 ± 0.23	dense fog on no nucleus at all; neutral barrier here is $34\,k_B T$, the onset of macroscopic homogeneous nucleation

117.5.4 Interpretation

Before this apparatus, radiation was studied through the aggregate effects of very many particles — an ionisation current, a photographic blackening, a scintillation rate. The cloud chamber makes a single particle individually visible and individually measurable, and with a magnetic field applied it measures momentum and sign of charge from the curvature, through $p_\perp = ZeB\rho$ (Equation (115.14)).

Everything that follows in this book from the inspection of individual events begins here: the two-branch forks that identified Equation (117.5) [518], the electron–positron pairs photographed by Blackett and Occhialini [714] and treated in Chapter 95, and the cosmic-ray showers and strange particles of Chapter 115. In each case the decisive information is not a rate but a picture: how many branches, which way they curve, whether the momenta balance.

Its weaknesses defined the next two instruments. The gas is thin — a cubic metre of air holds 1.2 kg of matter and a cubic metre of liquid holds a tonne — so interactions are rare and the chamber is a poor target; and the vapour must be re-expanded and allowed to settle, so the chamber is dead for most of every minute. Section 117.6 fixes the first, Section 117.7 the second.

Phenomenon 117.10 (Ion tracks are made visible by condensation)**.** In a gas supersaturated with vapour, droplets condense preferentially on the ions left by the passage of a charged particle, and on nothing else, provided the supersaturation lies between the threshold for condensation on ions and the threshold for condensation on neutral molecules. The trail of droplets marks the particle's path and can be photographed [394].

Rests on Equation (115.15).

Derivation. *Derives Phenomenon 117.10.*

The claim has two halves — that an expansion produces a calculable supersaturation, and that a charge lowers the supersaturation at which a droplet can grow — and the instrument exists because the two thresholds so produced are different.

The supersaturation from the expansion. Air is expanded from volume V_1 to V_2 fast enough to be adiabatic and slowly enough to be reversible, so pV^γ is constant with $\gamma = c_p/c_V = 1.40$ for a diatomic gas, and $TV^{\gamma-1}$ is constant. Writing $r = V_2/V_1$,

$$T_2 = T_1\, r^{1-\gamma}\,. \tag{117.39}$$

The water vapour is a minor component and is carried along: its partial pressure falls both because the volume grew and because the temperature fell, by the ideal-gas law at fixed particle number, $p_{v2} = p_{v1}\,(V_1/V_2)\,(T_2/T_1) = p_{v1} r^{-\gamma}$. The saturation vapour pressure falls far faster, by the Clausius–Clapeyron relation integrated with a constant latent heat L of vaporisation per unit mass and a specific gas constant $R_v = R/M_{\mathrm{H_2O}} = 461.5\,\mathrm{J/(kg\,K)}$: $p_{\mathrm{sat}}(T_2) = p_{\mathrm{sat}}(T_1)\exp\left[-\,(L/R_v)\,(1/T_2 - 1/T_1)\right]$. Since the chamber starts saturated, $p_{v1} = p_{\mathrm{sat}}(T_1)$ and that quantity cancels entirely: the supersaturation $S = p_{v2}/p_{\mathrm{sat}}(T_2)$ is

$$S = r^{-\gamma}\exp\left[\frac{L}{R_v}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)\right], \tag{117.40}$$

a function of the expansion ratio and the initial temperature alone. It requires no vapour-pressure table, which is what makes it a prediction rather than a fit; the one measured property it does need is the latent heat, and that enters only through the exponential. With $L = 2.50 \times 10^6\,\mathrm{J/kg}$ and $T_1 = 293.15\,\mathrm{K}$, Equation (117.39) gives $T_2 = 268.1\,\mathrm{K}$ at $r = 1.25$ and Equation (117.40) gives $S = 4.11$; the three rows of Table 117.5 are this calculation repeated.

Why a charge helps. Consider forming a spherical droplet of radius ρ from vapour at supersaturation S, the droplet carrying a charge q at its centre. Three terms contribute to

the free energy of formation. The surface costs $4\pi\rho^2\sigma$ with σ the surface tension. The bulk gains, because the vapour is supersaturated: each molecule transferred from vapour to liquid lowers the free energy by $k_B T \ln S$, and a droplet of radius ρ holds $\frac{4}{3}\pi\rho^3 n_l$ of them, with the number density of liquid water — mass density over molar mass, times the Avogadro constant, so that it is not an independent input either —

$$n_l = \frac{1.000 \times 10^3\,\mathrm{kg/m^3} \times 6.022\,140\,76 \times 10^{23}/\mathrm{mol}}{18.0153 \times 10^{-3}\,\mathrm{kg/mol}} = 3.343 \times 10^{28}/\mathrm{m^3}\,. \tag{117.41}$$

And the electrostatic self-energy of the charge falls as the droplet grows around it, because the charge's field is being moved out of vacuum and into a medium of relative permittivity ε_r. The geometry matters and is easy to get backwards: the *droplet* is the dielectric, so it is the region $a < r < \rho$ between the bare ion of radius a and the droplet surface whose permittivity changes, while the field beyond ρ is unaltered. The energy stored there falls from $(q^2/8\pi\varepsilon_0)\,(1/a - 1/\rho)$ to $(q^2/8\pi\varepsilon_0\varepsilon_r)\,(1/a - 1/\rho)$, so relative to the bare ion the change is $-\,(q^2/8\pi\varepsilon_0)\,(1 - 1/\varepsilon_r)\,(1/a - 1/\rho)$, whose ρ-independent piece is a constant of the ion and drops out. Collecting the terms that depend on ρ,

$$\Delta G(\rho) = 4\pi\rho^2\sigma - \tfrac{4}{3}\pi\rho^3 n_l k_B T \ln S + \frac{q^2}{8\pi\varepsilon_0\rho}\left(1 - \frac{1}{\varepsilon_r}\right), \tag{117.42}$$

which is Thomson's expression [332], in SI, with every term in joules. Setting $q = 0$ recovers the classical nucleation problem: the surface term wins at small ρ and the bulk term at large, so there is a barrier at $\rho_c = 2\sigma/\left(n_l k_B T \ln S\right)$ of height

$$W_c = \frac{16\pi\sigma^3}{3\left(n_l k_B T \ln S\right)^2}\,, \tag{117.43}$$

and nothing condenses unless a thermal fluctuation supplies W_c.

The two thresholds. With $q \neq 0$ the third term dominates at small ρ, so ΔG rises to $+\infty$ as the droplet shrinks back onto the bare ion — but it *falls* as ρ grows, with a downhill slope $q^2\,(1 - 1/\varepsilon_r)\,/8\pi\varepsilon_0\rho^2$ that diverges as $\rho \to 0$, while the surface term's uphill slope $8\pi\rho\sigma$ vanishes there. Near the ion the free energy is therefore downhill throughout, and the barrier, if one survives at all, is pushed out to larger ρ and lowered. Above some supersaturation it disappears altogether, and a droplet grows on the ion without any fluctuation at all. Setting $\mathrm{d}\Delta G/\mathrm{d}\rho = 0$ and asking when the resulting equation has no root gives the condition directly. Dividing $\mathrm{d}\Delta G/\mathrm{d}\rho = 0$ through by $4\pi\rho^2$, the stationarity condition reads

$$n_l k_B T \ln S = \frac{2\sigma}{\rho} - \frac{q^2\,(1 - 1/\varepsilon_r)}{32\pi^2\varepsilon_0\rho^4}\,. \tag{117.44}$$

The right-hand side rises from $-\infty$, peaks, and falls as $2\sigma/\rho$; its maximum is at

$$\rho_* = \left[\frac{q^2\,(1 - 1/\varepsilon_r)}{16\pi^2\varepsilon_0\sigma}\right]^{1/3}, \tag{117.45}$$

where the second term is one quarter of the first, so the peak value is $\frac{3}{4} \times 2\sigma/\rho_*$. If the left-hand side exceeds that peak there is no stationary point at all, ΔG decreases monotonically, and the droplet grows freely. The threshold is therefore

$$\ln S_{\mathrm{crit}} = \frac{3\sigma}{2\,n_l k_B T\,\rho_*}\,. \tag{117.46}$$

Numbers. At $T = 268.1\,\mathrm{K}$, with $\sigma = 0.0765\,\mathrm{N/m}$, $\varepsilon_r = 88$ for water at that temperature, and $q = e = 1.602\,177 \times 10^{-19}\,\mathrm{C}$, Equation (117.45) gives $\rho_* = 6.19 \times 10^{-10}\,\mathrm{m}$ — about

33 water molecules — and Equation (117.46) gives $S_{\mathrm{crit}} = 4.47$. The observed threshold for condensation on ions is $S = 4.11$, from the first row of Table 117.5. Meanwhile at that same supersaturation the neutral barrier Equation (117.43) is $2.45 \times 10^{-19}\,\mathrm{J} = 66\,k_BT$, so the probability of a spontaneous fluctuation forming a droplet is of order e^{-66} and nothing whatever condenses on neutral molecules. At the third row, $S = 8.08$ and $T = 257.7\,\mathrm{K}$, the same barrier has fallen to $1.21 \times 10^{-19}\,\mathrm{J} = 34\,k_BT$. The prefactor here is the number density of *vapour* molecules and not the liquid density n_l: the partial pressure of the water vapour after the expansion is of order $1 \times 10^3\,\mathrm{Pa}$, so p/k_BT is of order $1 \times 10^{23}/\mathrm{m}^3$. With molecular attempt frequencies of order $1 \times 10^{12}/\mathrm{s}$ and a Boltzmann factor $\mathrm{e}^{-34} = 1.7 \times 10^{-15}$, the nucleation rate is of order $1 \times 10^{20}/(\mathrm{m}^3\,\mathrm{s})$ — that is 1×10^{14} droplets per cubic centimetre per second, a dense fog immediately. That is the second threshold. The conclusion is insensitive to the prefactor by a wide margin: getting it wrong by five orders of magnitude, which is the size of the gap between the vapour and liquid densities, is worth a change of 12 in W_c/k_BT — and W_c/k_BT moves from 66 to 34 across the two rows.

The window between $S = 4.5$ and $S = 8$ is therefore not an empirical convenience but a consequence of Equation (117.42): the charge removes the barrier while the neutral vapour still has one. Operating inside it makes ions, and only ions, into condensation nuclei, which is the statement of Phenomenon 117.10. □

Remark 117.11 (Where this derivation is honest and where it is not). Two things in the calculation above deserve flagging rather than burying. First, $\rho_* = 0.62\,\mathrm{nm}$ contains about thirty molecules, and applying a macroscopic surface tension and a bulk permittivity to an object that size is not defensible in detail; that the answer comes out within 10 % of the measurement is better than the method deserves, and the right claim is that the mechanism and the order of magnitude are established, not the third figure. Second, Equation (117.42) depends on the charge only through q^2 and therefore predicts the same threshold for positive and negative ions, whereas Wilson measured $r = 1.25$ for negative and $r = 1.31$ for positive, a difference of 37 % in S. The asymmetry is real and is outside this model entirely: it involves the orientation of the permanent dipole of the water molecule at the droplet surface, which no theory built from a scalar ε_r can see. Reporting the model as though it accounted for both thresholds would misstate what it does.

Third, the thermophysical inputs are not cited, because this bibliography carries no source for them: the latent heat of vaporisation $2.50 \times 10^6\,\mathrm{J/kg}$, the surface tension $0.0765\,\mathrm{N/m}$ and the static permittivity $\varepsilon_r = 88$ are standard tabulated properties of water taken at the stated temperature, and the reader should treat them as handbook values rather than as claims this book supports. They matter unequally: S depends on L through an exponential, ρ_* on $\sigma^{-1/3}$ and only logarithmically on ε_r, and W_c on σ^3. The surface tension is the one that carries the third figure, and it is also the one that is least defensible at this droplet size, as the first point above says. Holding σ fixed at its 268.1 K value across the table, rather than letting it run with temperature, is what separates the $34\,k_BT$ quoted in the last row of Table 117.5 from the $36\,k_BT$ the temperature-dependent value would give.

117.5.5 Primary references

Wilson's 1912 paper [394] is the instrument paper and reads like one: most of it is about dust, valves, timing and the photography, and the tracks appear at the end as the demonstration that the apparatus works. The physics of the condensation window is older — it is Wilson's own work of the eighteen-nineties on the two expansion thresholds — and the theory of the charged drop is Thomson's [332], given there in the chapter on the condensation of vapour on ions.

The papers that made the instrument famous are not Wilson's. Blackett's identification of the nitrogen reaction [518], Blackett and Occhialini's photographs of electron–positron

pairs [714], and the cosmic-ray work of Chapter 115 are all cloud-chamber results, and each is a case where the answer was visible in a photograph and inaccessible to any counting experiment then available.

117.6 Glaser: the bubble chamber (1952)

Tests Phenomenon 117.12.

117.6.1 Apparatus

A small, scrupulously clean glass bulb of a few cubic centimetres, filled with diethyl ether and held under pressure at a temperature above its normal boiling point of 307.7 K. In the working condition the liquid sat near 413 K, where its saturated vapour pressure is about 1.48 MPa, roughly fifteen atmospheres; the bulb was held above that pressure so that the liquid stayed liquid. Releasing the pressure to about 0.10 MPa leaves the liquid superheated by $\Delta p \approx 1.38$ MPa: it is far above its boiling point at the prevailing pressure and yet, in the absence of nucleation sites, does not boil.

A radioactive source could be brought up to the bulb or removed, or interposed behind lead, and the onset of boiling was registered — in the first experiments by timing, later photographically.

Cleanliness is the apparatus. A superheated liquid is metastable against boiling everywhere, and the barrier that protects it, Equation (117.50) below, is enormous only for a *homogeneous* liquid. A dissolved gas bubble, a dust grain, or a scratch on the glass provides a surface of large radius of curvature at which the barrier is absent, so the vessel boils at once and no measurement is possible. Glass was chosen for its smoothness, the bulbs were sealed after prolonged degassing, and the ether was purified; the experimental difficulty of the whole subject is in that sentence.

117.6.2 Procedure

The bulb is taken through a cycle: compress, heat, expand into the superheated state, wait. The quantity measured is the delay between the expansion and the onset of boiling, recorded many times over with the source present and with it absent, so that a shift in the distribution of delays is a statistical statement rather than an anecdote.

Two features of that protocol matter. The delay is a random variable, because nucleation is a stochastic process — a barrier crossing has an exponentially distributed waiting time — so the observable is a distribution and not a number, and the comparison must be between distributions. And the null run is not “no source” but “source shielded”, which controls for everything about the thermal cycle while changing only the radiation reaching the liquid.

The degree of superheat was varied, since the barrier Equation (117.50) depends on it as $(\Delta p)^{-2}$ and therefore very steeply: too little superheat and even a radiation track cannot nucleate, too much and the liquid boils spontaneously and the chamber is useless. Finding the window is the same experimental problem as finding Wilson’s condensation window in Section 117.5, and has the same two-sided structure.

117.6.3 Observations and data

Superheated ether that stayed liquid for a long time when shielded boiled promptly when an ionising source was brought near, and the distribution of delays shifted with the source strength. The nucleation is therefore caused by the radiation. Photographs of bubbles strung out along the paths of the ionising particles — the bubble chamber proper — followed shortly after.

Table 117.6 gives the thermodynamic state of the liquid in the working condition, with the critical bubble it implies. The temperature and the pressures are the operating point of the experiment; the surface tension, critical radius and barrier are computed here, and the surface tension in particular is an estimate rather than a measurement, obtained by scaling the room-temperature value with $(1 - T/T_c)^{1.26}$ to the working temperature, which is the corresponding-states form [879]. It is flagged as such because the barrier depends on its cube.

Table 117.6: The superheated state in Glaser's bulbs, and the critical bubble it implies. Rows marked *est.* are computed here from corresponding-states scaling and the Clausius–Clapeyron relation and are order-of-magnitude statements, not measurements; the barrier depends on σ^3 and inherits three times the relative uncertainty of σ. The last two rows are the comparison that decides the mechanism: the barrier is far too high for a thermal fluctuation and far too low to stop a charged particle's energy deposit. The two temperatures and the released pressure are the operating point and are quoted with the uncertainty an operating point of this kind carries; the rows marked *est.* have no meaningful bracket, since their uncertainty is the validity of the scaling and not a measurement error, and the caveat above is the honest statement of it. The two rows marked *tabulated* are handbook properties of diethyl ether for which this bibliography carries no source.

Quantity	Value	Kind
Normal boiling point of diethyl ether	307.7 K	tabulated, uncited
Critical point	466.7 K, 3.64 MPa	tabulated, uncited
Working temperature	(413 ± 5) K	obs. 1952, [1000]
Saturated vapour pressure there	1.48 MPa	est.
Pressure after release	(0.10 ± 0.01) MPa	obs. 1952, [1000]
Superheat Δp	1.38 MPa	est.
Surface tension at 413 K	3.9×10^{-3} N/m	est., [879]
Critical bubble radius r_c	5.7×10^{-9} m	calc., Equation (117.48)
Nucleation barrier W_c	5.2×10^{-19} J, i.e. 3.3 eV	calc., Equation (117.50)
$W_c / k_B T$	91.5	calc.
Energy a minimum-ionising particle deposits over $2r_c$	1.6 eV, i.e. 2.6×10^{-19} J	est.
Energy a 5 MeV alpha deposits over $2r_c$	1.6×10^{3} eV, i.e. 2.6×10^{-16} J	est.

The measured delay distributions are not transcribed. What the table establishes is the quantitative frame in which they are read, and the frame is one-sided. A barrier of $91.5\,k_B T$ is essentially never crossed by a thermal fluctuation — the derivation below puts homogeneous nucleation at about one event per clean cubic centimetre per week — while it is crossed at once where a heavily ionising particle has passed. The delays of seconds to minutes actually observed in the shielded runs are therefore *not* homogeneous nucleation: they are set by residual heterogeneous sites and by the ambient background radiation, which is why the cleanliness of the bulb is the apparatus and why the comparison is made between distributions rather than against a computed spontaneous rate.

117.6.4 Interpretation

The bubble chamber is the cloud chamber with the phase transition run backwards, and the exchange is decisive: the sensitive medium is now a liquid, roughly a thousand times denser than a gas, so it is a target as well as a detector. Air at 288.15 K has a density of $1.225\,\mathrm{kg/m^3}$ and diethyl ether about $714\,\mathrm{kg/m^3}$, a factor 580; liquid hydrogen, at $70.8\,\mathrm{kg/m^3}$ [2427], is still a factor 58. Interactions that a cloud chamber would see once a month happen continuously, and the whole event — production point, decay point, and every charged secondary — is recorded in one picture.

Filled with liquid hydrogen the chamber becomes a pure proton target, which is what made it the workhorse of hadron physics; the Gargamelle heavy-liquid chamber's photographs of neutrino interactions with no outgoing muon or electron [1502] are the discovery of the weak neutral current, and hence part of the evidential base of Chapter 116 and of the electroweak theory. That result is a good illustration of the instrument's character: the signature is the *absence* of a track, which is a statement no counting experiment could make and only a complete picture of the final state can support.

Its limitation is the one Charpak removed. A bubble chamber cannot be triggered: the liquid is sensitive only during the few milliseconds after the expansion, so it must be expanded on a schedule synchronised with the beam and photographed whether or not anything interesting happened, and the film must then be scanned and measured by human beings. The rate is set by mechanics and by scanning tables, not by physics.

Phenomenon 117.12 (Ionising radiation nucleates bubbles in a superheated liquid)**.** A liquid held above its boiling point without boiling begins to boil promptly when ionising radiation passes through it, and the bubbles form along the path of the ionising particle [1000].

Rests on Equation (115.15).

Derivation. *Derives Phenomenon 117.12.*

Mechanical equilibrium. A spherical bubble of radius r in a liquid holds its vapour at a pressure exceeding the liquid's by the Laplace term: balancing the force on a hemisphere, the pressure difference across the surface times the cross-section πr^2 equals the surface tension σ times the circumference $2\pi r$, so

$$p_{\mathrm{vap}} - p_{\mathrm{liq}} = \frac{2\sigma}{r}\,, \tag{117.47}$$

in SI a pressure in pascals when σ is in N/m and r in metres. In a liquid superheated by $\Delta p = p_{\mathrm{vap}} - p_{\mathrm{liq}} > 0$, Equation (117.47) is satisfied at exactly one radius,

$$r_c = \frac{2\sigma}{\Delta p} = \frac{2 \times 3.9 \times 10^{-3}\,\mathrm{N/m}}{1.38 \times 10^{6}\,\mathrm{Pa}} = 5.7 \times 10^{-9}\,\mathrm{m}\,, \tag{117.48}$$

and that equilibrium is unstable: a bubble smaller than r_c has too much curvature, is crushed and collapses, while one larger than r_c finds the vapour pressure winning and grows without limit.

The barrier. Nothing happens spontaneously because reaching r_c costs work. The free energy of a bubble of radius r is the surface term $4\pi r^2\sigma$ less the work $\frac{4}{3}\pi r^3 \Delta p$ done against the pressure difference,

$$W(r) = 4\pi r^2\sigma - \tfrac{4}{3}\pi r^3 \Delta p\,, \tag{117.49}$$

whose derivative $8\pi r\sigma - 4\pi r^2 \Delta p$ vanishes at $r = r_c$, confirming Equation (117.48), and whose value there is the barrier

$$W_c = \frac{16\pi\sigma^3}{3\,(\Delta p)^2} = 5.2 \times 10^{-19}\,\mathrm{J} = 3.3\,\mathrm{eV}\,. \tag{117.50}$$

Compared with $k_B T = 5.70 \times 10^{-21}\,\mathrm{J}$ at 413 K this is $91.5\,k_B T$, so the Boltzmann factor is $\mathrm{e}^{-91.5} = 1.8 \times 10^{-40}$: with of order 1×10^{28} molecular sites per cubic metre and attempt frequencies of order $1 \times 10^{12}/\mathrm{s}$, the homogeneous nucleation rate is of order $1.8/(\mathrm{m}^3\,\mathrm{s})$, that is $1.8 \times 10^{-6}/\mathrm{s}$ in a clean cubic centimetre — one event a week, against a cycle time of seconds. That is why the liquid can be kept superheated at all. It is also why the observed delays cannot be homogeneous nucleation: the calculation is not a prediction of the shielded-run delay distribution but a demonstration that homogeneous nucleation contributes nothing to it.

Why a track nucleates. A charged particle passing through deposits energy in a narrow cylinder along its path, in localised amounts far larger than thermal. Take a minimum-ionising particle in ether: the mass stopping power is about $0.2\,\mathrm{MeV\,m^2/kg}$, so at a liquid density of $714\,\mathrm{kg/m^3}$ — a handbook value for which this bibliography carries no source — it loses about $1.43 \times 10^8\,\mathrm{eV/m}$, that is $2.29 \times 10^{-11}\,\mathrm{J/m}$, and over the critical diameter $2r_c = 11.3\,\mathrm{nm}$ it deposits about 1.6 eV, that is $2.6 \times 10^{-19}\,\mathrm{J}$ — which is *below* W_c. A 5 MeV alpha particle, with a range in ether of some tens of micrometres, deposits about 1×10^3 times more per unit length and delivers of order 1.6 keV, that is $2.6 \times 10^{-16}\,\mathrm{J}$, over the same distance, far above W_c.

Two consequences follow and both are observed: the boiling delay collapses when a sufficiently ionising source is present, and the bubbles appear *along the track*, because that is where the energy was deposited. Note also from Equation (117.50) that the barrier falls as $(\Delta p)^{-2}$, steeply with increasing superheat, which is why the chamber must be expanded into a narrow window and photographed at once — the operational counterpart of the two thresholds in Phenomenon 117.10. □

Remark 117.13 (The energy budget is not as simple as the comparison above). The comparison at the end of the derivation is the standard one and it is too generous. Not all the energy a particle deposits within a critical diameter is available to the nucleus: most of it goes into electronic excitation and into heating a region much larger than r_c, and only the fraction thermalised inside the critical volume, within the time the bubble needs to reach r_c, can pay for the barrier. The efficiency is of order a few per cent, which is why real chambers require a deposit one to two orders of magnitude above W_c, and why the bubble density along a track is a usable measure of $\mathrm{d}E/\mathrm{d}x$ — Equation (115.15) — rather than a threshold effect. The correct treatment follows the local temperature field produced by the track and asks when a supercritical bubble appears in it; it is a heat-conduction problem with a source, and it is what fixes the operating superheat of a real chamber.

Derivation pending #212

The thermal-spike calculation of bubble nucleation: the temperature field around an ionising track from the heat equation with a line source, the fraction of the deposited energy thermalised within the critical radius before the bubble can grow, and the resulting threshold in $[\mathrm{d}E/\mathrm{d}x]$ *as a function of the superheat. It belongs in Appendix A; the derivation above establishes the barrier and the mechanism but treats the energy delivery as instantaneous and perfectly local.*

117.6.5 Primary references

Glaser's paper [1000] is a two-page letter, and it is about the delay statistics of boiling in a superheated liquid; the track photographs that give the instrument its name came afterwards. It is worth reading as an example of an experiment whose published result is a shift in a distribution — there is no picture of a bubble in it — and whose importance is entirely in what the shift implies.

The instrument's scientific yield is documented elsewhere in this book rather than in Glaser's paper. The Gargamelle neutral-current photographs [1502] are the case discussed above; the hydrogen-chamber results on hadron spectroscopy underlie Chapter 116, and the technique's decline is recorded in Section 117.7.

117.7 Charpak: the multiwire proportional chamber (1968)

Tests Phenomenon 117.14.

117.7.1 Apparatus

A plane of fine parallel anode wires, of the order of 20 µm in diameter and spaced 2 mm apart, stretched midway between two parallel cathode planes about 8 mm away on either side, the whole in a gas mixture of a noble gas with a polyatomic quenching additive. The wires are held at a positive potential of a few kilovolts with respect to the cathodes.

Each of those dimensions is doing work. The wire must be thin because the field at its surface, and hence the avalanche gain, depends on its radius — Equation (117.54) — and a thick wire gives no multiplication at usable voltages. The spacing must be small because it sets the position resolution directly. The cathode gap must be several times the spacing, or the cells stop being independent and the field near each wire is distorted by its neighbours. And the quenching additive is not optional: a pure noble gas de-excites by emitting ultraviolet photons that liberate photoelectrons from the cathode metres away, so the avalanche propagates and the counter goes into permanent discharge. A polyatomic molecule absorbs those photons into vibrational modes and dissipates them, confining the avalanche to the wire that started it.

The decisive feature, however, is not the mechanics but the readout: every wire has its own amplifier and its own discriminator, so the chamber emits a pattern of logic pulses rather than an image. In 1968 that was newly affordable, and it is the reason the paper was written when it was.

117.7.2 Procedure

A charged particle crossing the gas leaves a track of electron–ion pairs — of order 100 of them in 8 mm of argon at atmospheric pressure, at a mean expenditure of about 26 eV, that is 4.2×10^{-18} J, per pair [2427]. The electrons drift towards the nearest anode wire through the low-field region between the cathodes, and in the last few tens of micrometres, where the field rises as $1/r$ and exceeds the threshold for ionisation by collision, each initiates an avalanche whose gain is set by the wire voltage and the gas.

The measurements reported are those any new counter owes. The gas gain was measured against anode voltage, by comparing the collected charge with the known primary ionisation. The detection efficiency was measured against voltage with an external trigger — a scintillator telescope defining a particle's passage — which produces the characteristic plateau, a range of voltage over which efficiency is near unity and insensitive to the setting, and finding that plateau is what makes a counter usable. The time resolution was measured against the same trigger. And, the result that was not obvious in advance, the pulses on wires adjacent to the struck one were recorded, to establish that a chamber with wires two millimetres apart really does behave as a row of independent counters and not as one large one.

117.7.3 Observations and data

Each wire behaved as an independent proportional counter, with adjacent wires showing negligible cross-talk despite being only millimetres apart. Detection efficiency was high over

a plateau of several hundred volts, the position was given to within the wire spacing, and both the time resolution — of the order of the maximum electron drift time computed in Table 117.7, which is what bounds it — and the rate a single wire could sustain were better than any photographic technique by orders of magnitude.

Uncertainties are owed on all of this and the paper quotes none, so what Table 117.7 carries are estimates from the mechanical tolerance of a wound wire plane and from the stability of a high-voltage supply, each flagged in the table. The efficiency and the time resolution are reported here as the paper reports them, in words and without a figure, because assigning them a numerical uncertainty would mean inventing the measurement they belong to; what the argument below needs from them is only that the plateau exists and that the resolution is drift-limited, and both are qualitative statements.

Table 117.7 gives the geometry, the reported performance, and the electrostatic quantities those imply, computed here from Equations (117.53) and (117.54) and from Equations (117.56) and (117.57). Table 117.8 is the avalanche gain against anode voltage, computed from Equation (117.55) with representative Townsend coefficients for argon; it is included because the steepness of that dependence is the whole reason a proportional chamber has an operating plateau at all, and because it is a closed-form consequence of the $1/r$ field.

117.7.4 Interpretation

This is the change of era. A cloud or bubble chamber produces a photograph, and a photograph must be developed, scanned and measured by a person; the experiment's rate is therefore set by human labour. A bubble chamber cycles at a few hertz at best, and a scanner works through pictures at a rate of order one per minute, so a large experiment of the nineteen-sixties accumulated of order 1×10^6 pictures over years and employed rooms full of people to measure them. A multiwire chamber produces a number, immediately, on a wire, and a computer can read it; a single wire sustains of order 1×10^5/s and the limit is the electronics.

Triggering becomes possible with it — the apparatus can be told to record only events satisfying a condition, evaluated in the time between one particle and the next — and with it the whole strategy of searching for rare processes in an overwhelming background, which is how every result in Chapter 113 was obtained. Modern detectors record of order 1×10^9 interactions per second and select a handful for storage, and the reason they can is that the sensitive element gives an electronic address rather than an image.

The device also founded a family. Measuring the drift time of the electrons, rather than merely which wire fired, turns the wire spacing into a far finer coordinate: an electron drifting at 5×10^4 m/s covers 50 µm in a nanosecond, so timing to a nanosecond gives a resolution an order of magnitude better than Equation (117.56) — that is the drift chamber. Extending the drift volume to metres and reading the arrival pattern on an endplate gives the time projection chamber; replacing wires with etched electrodes on a substrate gives the micropattern detectors of current practice. All of them are read out as numbers, and all of them descend from this experiment.

Phenomenon 117.14 (Each anode wire is an independent counter)**.** In a plane of parallel anode wires only millimetres apart between two cathode planes, the avalanche produced by an ionising particle develops on a single wire and induces a signal there, with negligible response on its neighbours. The chamber therefore reports position as the address of the wire that fired, at a rate limited by electronics rather than by photography [1367].

Rests on Theorem 58.10.

Derivation. *Derives Phenomenon 117.14.*

Table 117.7: The multiwire proportional chamber: geometry, performance and the electrostatics that follow. Geometry and performance are the reported values [1367]; the capacitance, line charge, surface field, multiplication radius, position resolution and drift and ion times are computed here in the derivation below. The signal charge assumes a gain of 1×10^4. Bracketed uncertainties on the observed geometry are estimates from the mechanical tolerance of a wound wire plane, the paper quoting none; the computed rows are exact consequences of that geometry and inherit it, the capacitance and everything built on it to about 1.5 %. The efficiency row carries no bracket for the reason given in the text, and the primary ion-pair count is an order-of-magnitude estimate while the gain is a chosen reference value.

Quantity	Value	Kind, source
Anode wire diameter	$(20 \pm 1)\,\mu\text{m}$	obs. 1968, [1367]
Wire spacing s	$(2.00 \pm 0.05)\,\text{mm}$	obs. 1968, [1367]
Anode–cathode gap L	$(8.0 \pm 0.1)\,\text{mm}$	obs. 1968, [1367]
Anode potential	3 kV to 4 kV, stable to 10 V	obs. 1968, [1367]
Detection efficiency, over a plateau several hundred volts wide	near unity	obs. 1968, [1367]
Capacitance per unit length of one wire	3.47 pF/m	calc., Equation (117.53)
Line charge at 3 kV	$1.04 \times 10^{-8}\,\text{C/m}$	calc.
Field at the wire surface	$1.87 \times 10^{7}\,\text{V/m}$	calc., Equation (117.54)
Radius within which multiplication occurs	62 µm	calc.
Primary ion pairs in the gap	about 100	est.
Signal charge at gain 1×10^4	$1.6 \times 10^{-13}\,\text{C}$	calc.
Position resolution	0.58 mm	calc., Equation (117.56)
Maximum electron drift time	160 ns	calc.
Ion signal time constant t_0	1.8 ns	calc., Equation (117.57)
Total ion collection time	1.14 ms	calc., Equation (117.58)

Table 117.8: Avalanche gain against anode potential, computed here from Equation (117.55) for the geometry of Table 117.7 in argon at 101.3 kPa, with Townsend coefficients $A = 9.0/(\text{m Pa})$ and $B = 135\,\text{V}/(\text{m Pa})$ representative of argon, and a multiplication threshold $E^* = 3 \times 10^6\,\text{V/m}$. The gain rises by nearly four orders of magnitude for a factor 2 in voltage, which is why the operating point is chosen on an efficiency plateau and not by tuning the gain.

Anode potential	Surface field	Multiplication radius	Gain M
2.0 kV	$1.25 \times 10^{7}\,\text{V/m}$	42 µm	1.5×10^{1}
2.5 kV	$1.56 \times 10^{7}\,\text{V/m}$	52 µm	6.8×10^{1}
3.0 kV	$1.87 \times 10^{7}\,\text{V/m}$	62 µm	3.6×10^{2}
3.5 kV	$2.18 \times 10^{7}\,\text{V/m}$	73 µm	2.1×10^{3}
4.0 kV	$2.50 \times 10^{7}\,\text{V/m}$	83 µm	1.3×10^{4}
4.5 kV	$2.81 \times 10^{7}\,\text{V/m}$	94 µm	8.1×10^{4}

The field. Model one wire as a long straight conductor of radius a carrying charge λ per unit length. Gauss's theorem over a coaxial cylinder gives

$$E(r) = \frac{\lambda}{2\pi\varepsilon_0 r}\,, \tag{117.51}$$

in V/m when λ is in C/m, and hence a potential varying only logarithmically, $V \propto \ln(r/a)$. The periodic geometry has to be summed, and the sum is worth doing because it fixes λ and hence every electrostatic number in this section. Put the wires along y at $y = ns$, $n \in \mathbb{Z}$, each carrying λ, and let x measure distance from the wire plane. Superposing the logarithmic potentials of the whole row and using the product formula $\sin(\pi w)/(\pi w) = \prod_{n\geq 1}(1 - w^2/n^2)$, applied to the complex combination $w = (y + \mathrm{i}x)/s$, gives the closed form

$$V(x,y) = -\frac{\lambda}{4\pi\varepsilon_0}\ln\left[2\left(\cosh\frac{2\pi x}{s} - \cos\frac{2\pi y}{s}\right)\right] + \text{const}\,. \tag{117.52}$$

Two limits of Equation (117.52) are all that is needed. Close to one wire, $r = \sqrt{x^2 + (y - ns)^2} \ll s$, expanding both hyperbolic and circular functions to second order gives $2(\cosh - \cos) \to (2\pi r/s)^2$ and hence $V \to -(\lambda/2\pi\varepsilon_0)\ln(2\pi r/s)$, which recovers Equation (117.51) and shows that the row looks like a single wire from close up. Far from the plane, $|x| \gg s$, the cosine is negligible against $\cosh(2\pi x/s) \to \tfrac{1}{2}\mathrm{e}^{2\pi|x|/s}$, and the potential becomes linear, $V \to -(\lambda/2\varepsilon_0)\,|x|/s$: the wire plane looks like a charged sheet, as it must. That second limit is the reason the cathode gap has to be several times the wire spacing: at the $L/s = 4$ of this chamber the terms dropped are smaller than the one kept by a factor 2×10^{-11}, while at $L/s = 1$ they would not be negligible and the cells would stop being independent. Subtracting the second limit at the cathode, $|x| = L$, from the first at the wire surface, $r = a$, gives the working potential $V = (\lambda/2\pi\varepsilon_0)\,[\pi L/s - \ln(2\pi a/s)]$, so that the capacitance per unit length of one wire is

$$C = \frac{\lambda}{V} = \frac{2\pi\varepsilon_0}{\dfrac{\pi L}{s} - \ln\dfrac{2\pi a}{s}} = 3.47 \times 10^{-12}\,\mathrm{F/m} \tag{117.53}$$

for $a = 10\,\mu\mathrm{m}$, $s = 2\,\mathrm{mm}$ and $L = 8\,\mathrm{mm}$, so at $V = 3\,\mathrm{kV}$ the line charge is $\lambda = CV = 1.04 \times 10^{-8}\,\mathrm{C/m}$ and the field at the wire surface is

$$E(a) = \frac{\lambda}{2\pi\varepsilon_0 a} = 1.87 \times 10^{7}\,\mathrm{V/m}\,. \tag{117.54}$$

Two facts follow from the $1/r$ dependence, and between them they are the whole device.

First: the multiplication is local. Avalanche multiplication requires an electron to gain the ionisation energy of the gas between collisions, that is a field above some threshold E^* of order $3 \times 10^6\,\mathrm{V/m}$ in argon at atmospheric pressure; by Equation (117.51) the region where $E > E^*$ is a cylinder of radius $\lambda/2\pi\varepsilon_0 E^* = 62\,\mu\mathrm{m}$, a few wire radii. The multiplication is therefore confined to the immediate neighbourhood of one wire, thirty times closer to it than to its neighbours, and the gain does not depend on where in the gas volume the original ionisation occurred — which is what makes the signal proportional to the deposited charge, and what keeps the wires independent.

The gain itself follows in closed form. The first Townsend coefficient — the number of ionising collisions an electron makes per metre — is well represented by $\alpha = Ap\exp(-Bp/E)$ with p the pressure, and the multiplication is $M = \exp\int \alpha\,\mathrm{d}r$ taken inward from $E = E^*$ to $E = E(a)$. Changing variable from r to E using Equation (117.51), so that $r = k/E$ with $k = \lambda/2\pi\varepsilon_0$ and $\mathrm{d}r = -k\,\mathrm{d}E/E^2$, the integral is elementary:

$$\ln M = Apk\int_{E^*}^{E(a)} \frac{\mathrm{e}^{-Bp/E}}{E^2}\,\mathrm{d}E = \frac{Ak}{B}\left(\mathrm{e}^{-Bp/E(a)} - \mathrm{e}^{-Bp/E^*}\right)\,. \tag{117.55}$$

With $A = 9.0/(\mathrm{m\,Pa})$ and $B = 135\,\mathrm{V}/(\mathrm{m\,Pa})$ for argon, $p = 1.013 \times 10^5\,\mathrm{Pa}$ and $k = \lambda/2\pi\varepsilon_0$ proportional to V through Equation (117.53), this generates Table 117.8: a gain of 15 at 2 kV and 1.3×10^4 at 4 kV. The extreme steepness is structural — $\ln M$ is roughly linear in V, so M is exponential in it — and it is why the operating point of a proportional chamber is chosen by finding the efficiency plateau rather than by setting a gain.

Second: the cells are defined by the field, not by walls. The drift region between the cathodes is a low-field region in which electrons simply move to the nearest wire along the field lines, and the division of the plane into cells belongs to the field geometry: no walls are needed between adjacent counters, which is why the wires can be packed at millimetre pitch. A particle's coordinate is then the address of the wire that fired, uniformly distributed over the cell of width s, so the resolution is the standard deviation of a uniform distribution,

$$\sigma_x = \frac{s}{\sqrt{12}} = \frac{2\,\mathrm{mm}}{3.464} = 0.58\,\mathrm{mm}\,. \tag{117.56}$$

Third: the signal is fast because it is induced by the ions. The electrons produced in the avalanche are collected in a fraction of a nanosecond and induce almost nothing, having been created within a few micrometres of the wire; the signal is the induced charge from the positive ions drifting *away* from the wire through the whole logarithmic field. An ion of mobility μ obeys $\mathrm{d}r/\mathrm{d}t = \mu E(r) = \mu k/r$, so $r^2(t) = a^2 + 2\mu k t$ and the induced charge grows as $\ln(1 + t/t_0)$ with

$$t_0 = \frac{a^2}{2\mu k} = \frac{\pi\varepsilon_0 a^2}{\mu\lambda} = 1.8\,\mathrm{ns}\,, \tag{117.57}$$

for $\mu = 1.5 \times 10^{-4}\,\mathrm{m^2/(V\,s)}$ [2427]. The signal therefore rises on a nanosecond scale even though full ion collection is slow. The same $r^2(t)$ run out to the cathode, at $r = L$ and not $L/2$ — L is the whole anode-to-cathode gap of Table 117.7, which is also the distance the electron drift time of that table is computed over — gives

$$t_{\max} = \frac{L^2 - a^2}{2\mu k} \approx \frac{\pi\varepsilon_0 L^2}{\mu\lambda} = 1.14\,\mathrm{ms}\,, \tag{117.58}$$

six hundred thousand times t_0, since $t_{\max}/t_0 = (L/a)^2$. Differentiating the signal with a short time constant keeps the fast leading edge and discards the long tail, which is what makes the coordinate available promptly enough to be used in a trigger. The residual limit on rate is the space charge of those slow ions, which is what fixes the 1×10^5/s per wire quoted above. □

Remark 117.15 (What is representative and what is measured here). The Townsend coefficients used in Equation (117.55) and the ion mobility used in Equation (117.57) are representative values for argon at atmospheric pressure, not values measured in Charpak's chamber, which ran on a gas mixture whose composition changes both by factors of order unity. They are used to show that the closed form reproduces the observed orders of magnitude — a gain of 1×10^4 at a few kilovolts, a multiplication region of tens of micrometres, a nanosecond leading edge — and the argument does not depend on their precise values. The measurement of electron transport in argon on which such coefficients ultimately rest is Townsend and Bailey's [495].

117.7.5 Primary references

The paper is Charpak and collaborators' [1367], in *Nuclear Instruments and Methods*, and it is short. Its significance is easy to miss on a first reading because it claims very little: that a plane of closely spaced wires can be operated with each wire as an independent proportional counter, with the gains, efficiencies and time resolutions tabulated. The claim

that was not obvious — and that the paper's referees would have been right to doubt — is the independence of the wires at millimetre spacing, which Equation (117.54) makes plausible and the measurements established.

What followed is not in this paper and is not any single paper. The technique displaced the bubble chamber over the following decade, and the detectors of Chapter 116, Chapter 114 and Chapter 113 are all, in their tracking elements, its descendants.

117.8 Summary of the evidence

Table 117.9: The reactions and the instruments reported in this chapter. The first two rows are nuclear reactions, the third is the machine that freed the projectile energy from the insulation limit, and the last three are the detectors that made reactions countable one at a time. The three detectors are best read by what each removed: the invisibility of the single particle, the thinness of the target, and the photograph.

Experiment	Year	Result
Rutherford	1919	first artificial transmutation; nitrogen yields protons of up to 5.93 MeV against an elastic ceiling of 4.94 MeV
Cockcroft–Walton	1932	first accelerator-driven nuclear reaction, and the first quantitative nuclear test of $E = mc^2$: alpha particles of about 8.6 MeV measured against 8.79 MeV predicted from a mass difference of 3.09×10^{-29} kg
Lawrence–Livingston	1932	protons of 1.22 MeV from 4 kV per gap, in 153 turns at 1.40 T
Wilson	1912	individual charged particles made visible as droplet trails, in a supersaturation window between $S = 4.1$ and $S = 8.1$
Glaser	1952	the sensitive medium becomes a liquid 580 times denser than air, hence target and detector at once
Charpak	1968	position read as an electronic address to 0.58 mm, at 1×10^5/s per wire instead of a photograph

Table 117.9 contains no fitted parameter and no theoretical input beyond mass–energy equivalence, elementary electrostatics, the semiclassical barrier transmission of Section 9.6, and classical nucleation theory. The first two rows establish that nuclei can be rearranged at will and that the energy bookkeeping of Chapter 40 holds when they are; the third makes the projectile energy an adjustable quantity rather than a gift of nature; the last three establish that the rearrangements can be counted, one at a time, at rates that rose by roughly six orders of magnitude across the half-century the table spans. Neither half is of any use without the other, which is why they are reported together here rather than split between a nuclear chapter and a detector appendix.

Two threads run through all six and are worth naming, because they recur in every later experiment in this part. The first is that the decisive measurement is almost never the one the experiment appears to be making. Rutherford's result is a comparison between

gases, not a count; Cockcroft and Walton's is a coincidence rate, not a yield; Lawrence's is the *width* of a resonance curve, which is what proves the turn count; Glaser's is a shift in a distribution of delays. In each case the number that carries the physics is a ratio or a correlation, chosen because it is insensitive to the quantities the experimenter cannot control.

The second is that every one of the six instruments is a threshold device operated inside a deliberately chosen window. The cloud chamber must sit between two supersaturations, the bubble chamber between two superheats, the proportional chamber between the onset of multiplication and the onset of discharge, the scintillation counter between the eye's sensitivity and its fatigue, the cyclotron between resonance and relativistic detuning, the cascade generator between usable voltage and breakdown. Locating those windows is what the *Procedure* of each experiment above actually describes, and it is the part of experimental physics that no theory supplies.

Part XII

Statistical Mechanics

Chapter 118

Statistical Mechanics

Thermodynamics, developed in Part VI, states relations between measured macroscopic quantities without ever asking what matter is made of; statistical mechanics derives those same relations from the mechanics of the constituents, and in doing so predicts things thermodynamics cannot — the magnitude of fluctuations, the absolute value of the entropy, and the point at which the classical description must fail. This chapter opens Part XII by building that bridge: phase space and Liouville's theorem inherited from Chapter 22, the Boltzmann and Gibbs definitions of entropy, the microcanonical, canonical and grand canonical ensembles with their partition functions, the thermodynamic limit in which they agree, and the classical ideal gas as the case where every step can be carried through in closed form. It states the ergodic hypothesis explicitly and reports its status honestly — proved for a small class of systems, assumed for the rest — rather than passing over the gap in the foundations.

The chapter is deliberately classical: the counting is corrected for indistinguishability where the measurements demand it (the Gibbs paradox and the Sackur–Tetrode entropy), but the quantum statistics that explain why are deferred to Chapter 120, the kinetic and transport theory to Chapters 55 and 124, and phase transitions to Chapter 123. Its direct experimental sequel is Chapter 119, where the fluctuations predicted here are measured and Avogadro's constant extracted from them. Founding sources are Boltzmann [196] and Gibbs [304]; the modern treatments used throughout are [1656, 2180], with the thermodynamic side in [1749].

Derivation pending #213

Statistical Mechanics: all derivations of this chapter are pending.

118.1 From mechanics to thermodynamics

118.1.1 Why a statistical description

[Reserved: the impossibility in practice and the irrelevance in principle of following $\sim 10^{23}$ trajectories; Maxwell's introduction of a distribution of molecular velocities as the object of study rather than the trajectories themselves [154], and Boltzmann's transport equation for its evolution [183]; the division of labour with Chapter 55 (dynamics of the distribution) and Chapter 54 (relations among the averages); what "equilibrium" means operationally.]

118.1.2 Phase space and Liouville's theorem

[Reserved: the $6N$-dimensional phase space of Chapter 22, the ensemble density $\rho(q,p,t)$, and Liouville's theorem $\partial_t \rho + \{\rho, \mathcal{H}\} = 0$ as the statement that the flow preserves phase-space

volume, with the symplectic geometry of Chapter 24 behind it; stationarity of any ρ that depends on the phase point only through conserved quantities; Gibbs's formulation of the whole subject in these terms [304].]

118.1.3 Macrostates, microstates and coarse graining

[Reserved: the distinction between a microstate and the macrostate specified by a few extensive variables; the multiplicity W of a macrostate; the coarse-grained density and why the fine-grained Gibbs entropy is constant under Liouville evolution while the observed entropy is not — the Ehrenfests' analysis of the issue [370]; the cell size and its cancellation from all entropy differences, with the absolute value fixed only by h (Chapter 120).]

118.2 Entropy and the Boltzmann principle

118.2.1 The combinatorial definition

[Reserved: Boltzmann's 1877 counting of complexions — the distribution of a fixed energy among discrete cells, the multiplicity of each distribution, and the identification of the most probable distribution with equilibrium [196]; the Stirling limit; the logarithm as the only function turning multiplicative multiplicities into an additive quantity; the recovery of the Maxwell–Boltzmann distribution as the maximiser.]

118.2.2 The relation between entropy and multiplicity

[Reserved: $S = k \log W$, written in that form by Planck when he introduced the constant k in the radiation analysis [300]; the constant as a conversion factor between energy and temperature, now exact by the 2019 redefinition of the kelvin [2333] with the value quoted in Chapter 2 and [2392]; the sense in which the relation is a definition and the sense in which it is a testable claim.]

118.2.3 The H-theorem and the reversibility objections

[Reserved: the functional $H = \int f \log f \, \mathrm{d}^3 v$ and Boltzmann's proof that it decreases under the collision term [183]; Loschmidt's reversibility objection — the reversed microstate has increasing H [195]; the recurrence objection built by Zermelo [273] on Poincaré's recurrence theorem [247], and the estimated recurrence time; where the arrow enters — the molecular-chaos assumption — stated as an assumption and not concealed; the initial-condition question left open and referred to Chapter 48.]

118.2.4 The Gibbs entropy

[Reserved: $S = -k \int \rho \log \rho \, \mathrm{d}\Gamma$ and its discrete form $-k \sum_i p_i \log p_i$ [304]; agreement with the Boltzmann expression in the thermodynamic limit and disagreement away from it; the concavity and additivity properties; its identification with the Shannon functional of Section 118.8.1.]

118.3 Ensembles

118.3.1 The microcanonical ensemble

[Reserved: the postulate of equal a priori probabilities on the energy shell, the density of states $\Omega(E, V, N)$, and $S = k \log \Omega$ [304]; temperature, pressure and chemical potential as

derivatives of S; the shell thickness and its irrelevance; the two-subsystem derivation of the zeroth law and of the equality of temperatures at equilibrium.]

118.3.2 The canonical ensemble

[Reserved: a system in contact with a reservoir, the Boltzmann factor $\mathrm{e}^{-\beta E_i}$, and the partition function $Z = \sum_i \mathrm{e}^{-\beta E_i}$ [304]; the Helmholtz free energy $F = -kT \log Z$ as the generating function of every thermodynamic quantity; the energy distribution and its sharpness; the classical phase-space integral with the $1/(N!h^{3N})$ prefactor justified in Section 118.4.3; standard development in [1656].]

118.3.3 The grand canonical ensemble

[Reserved: exchange of particles as well as energy, the fugacity $z = \mathrm{e}^{\beta\mu}$, and the grand partition function $\Xi = \sum_N z^N Z_N$ [304]; the grand potential $\Phi = -kT \log \Xi = -pV$; particle-number fluctuations and their relation to the isothermal compressibility; why this is the natural ensemble for the quantum gases of Chapter 120.]

118.3.4 Equivalence of ensembles

[Reserved: the coincidence of the three ensembles for all intensive quantities as $N \to \infty$, and the $O(N^{-1/2})$ relative size of the differences; the Legendre-transform structure relating S, F and Φ; the conditions under which equivalence fails — long-range interactions (Section 118.5.3) and at a first-order transition; rigorous statements in [1407].]

118.3.5 Partition functions in practice

[Reserved: factorisation for non-interacting degrees of freedom; translational, rotational and vibrational partition functions of a molecule and the resulting heat capacities, compared with measured values for diatomic gases; the classical virial expansion for weak interactions; the systematic use of $\log Z$ as a cumulant generator, linking to Chapter 11; thermodynamic identities collected in [1749].]

118.4 The classical ideal gas

118.4.1 The Maxwell–Boltzmann distribution

[Reserved: the speed distribution $f(v) \propto v^2 \mathrm{e}^{-mv^2/2kT}$ [154] and Boltzmann's generalisation to an arbitrary external potential [171]; the mean, root mean square and most probable speeds; the direct measurement of the distribution in a potassium and thallium atomic beam by Miller and Kusch, agreeing with the predicted form to about 1 % [1076]; the barometric formula as the same law in gravity, which is the observable used in Chapter 119.]

118.4.2 Equipartition and its failure

[Reserved: $\tfrac{1}{2}kT$ per quadratic degree of freedom [171]; the Dulong–Petit law for solids [64] as its most successful instance; the failures Maxwell singled out as the greatest difficulty facing the molecular theory — the missing vibrational and rotational contributions to diatomic heat capacities, and the fall of solid heat capacities at low temperature [191]; the resolution by level quantisation, carried out in Chapters 68 and 125 and Chapter 120.]

118.4.3 The Gibbs paradox

[Reserved: the spurious entropy of mixing between two samples of the same gas, and Gibbs's own statement and discussion of it [193]; the $1/N!$ correction and the resulting extensivity of S; the fact that classical mechanics gives no reason for the factor, so that the paradox is evidence for indistinguishability before quantum mechanics supplies it (Chapters 83 and 120); the operational reading in terms of which mixings can be undone.]

118.4.4 The Sackur–Tetrode entropy

[Reserved: the absolute entropy of a monatomic ideal gas, $S = Nk[\log(V/N\lambda^3) + \frac{5}{2}]$ with the thermal wavelength $\lambda = h/\sqrt{2\pi mkT}$, obtained independently by Sackur [380] and Tetrode [393]; the appearance of Planck's constant in a classical result and what that signals; the vapour-pressure test — Tetrode's comparison with mercury vapour data, and the chemical-constant measurements that followed — as the first quantitative confirmation; the Sackur–Tetrode constant among the CODATA quantities [2392].]

118.5 The thermodynamic limit

118.5.1 Existence and extensivity

[Reserved: the limit $N \to \infty$, $V \to \infty$ at fixed N/V; van Hove's proof that the free energy per particle converges for interactions with a hard core and a sufficiently rapid decay [934], and the systematic treatment in [1407]; stability and tempering as the hypotheses; why the limit is what makes thermodynamics sharp rather than approximate.]

118.5.2 Analyticity and its failure

[Reserved: the partition function of a finite system as an analytic function of β, so that no finite system has a phase transition; the Yang–Lee account of how non-analyticity appears in the limit through the pinching of the real axis by zeros of the partition function [1014]; the transfer of this to Chapter 123.]

118.5.3 Long-range forces and non-extensive systems

[Reserved: systems in which the energy is not extensive — self-gravitating matter above all; negative heat capacity and the gravothermal catastrophe [1375]; the inequivalence of ensembles that follows, and why a self-gravitating system has no maximum-entropy equilibrium; the treatment of stellar and compact matter in Chapters 49 and 52, where these caveats are load-bearing.]

118.6 The ergodic hypothesis: status

118.6.1 What the hypothesis is asked to do

[Reserved: the identification of time averages along a trajectory with ensemble averages over the energy shell; the Ehrenfests' distinction between the original ergodic hypothesis (the trajectory passes through every point), which is false for dimensional reasons, and the quasi-ergodic hypothesis [370]; the role the assumption actually plays — justifying the microcanonical postulate of Section 118.3.1 — and the alternatives to it.]

118.6.2 The ergodic theorems

[Reserved: Birkhoff's pointwise ergodic theorem, giving almost everywhere convergence of the time average [674], and von Neumann's mean ergodic theorem in L^2 [705]; metric transitivity as the condition under which the limit is the ensemble average; Khinchin's argument that only sum functions of many degrees of freedom need behave well, which weakens what must be proved [936].]

118.6.3 Systems proved ergodic

[Reserved: Sinai's proof of ergodicity and mixing for a gas of hard elastic spheres in a box [1433]; hyperbolicity and sensitive dependence as the mechanism (Chapter 32); the smallness of the class — no realistic interatomic potential has been shown ergodic — stated plainly.]

118.6.4 Honest status of the foundations

[Reserved: the Fermi–Pasta–Ulam–Tsingou numerical experiment, in which a weakly nonlinear chain failed to equipartition and instead recurred [1065], and the KAM tori that explain it; the resulting position — statistical mechanics works far better than its proofs justify — recorded as an open problem rather than argued away; the pragmatic defence by timescales; forward reference to Chapter 133.]

118.6.5 Thermalisation in isolated quantum systems

[Reserved: the eigenstate thermalisation hypothesis of Deutsch [1842] and Srednicki [1887], in which individual energy eigenstates already encode thermal expectation values; the measured approach to thermal equilibrium of an isolated lattice of ultracold bosons through the growth of entanglement entropy [2272]; the relation to decoherence and open systems in Chapter 87.]

118.7 Fluctuations

118.7.1 Energy and particle-number fluctuations

[Reserved: $\langle \Delta E^2 \rangle = kT^2 C_V$ from the canonical ensemble and the analogous compressibility relation in the grand canonical ensemble [304]; the relative size $O(N^{-1/2})$, which is why thermodynamics appears deterministic; the inversion of the argument — a measured fluctuation determines k and hence Avogadro's constant — which is the strategy of Chapter 119; Einstein's general fluctuation formula [361].]

118.7.2 Critical opalescence

[Reserved: the divergence of the compressibility near a critical point, the resulting long-wavelength density fluctuations, and the strong scattering of light that makes a critical fluid turn milky; Smoluchowski's kinetic account [349] and Einstein's quantitative theory of the scattered intensity [361]; the observation as a direct visual demonstration that fluctuations are real; critical exponents deferred to Chapter 123.]

118.7.3 Thermal noise

[Reserved: Johnson's measurement of a voltage noise across a resistor proportional to resistance and to absolute temperature and independent of material [608], and Nyquist's derivation of $\langle V^2 \rangle = 4kTR\,\Delta f$ from equilibrium statistical mechanics alone [615]; the measurement as a second independent determination of k; the general fluctuation–dissipation statement developed in Chapter 124.]

118.8 Entropy, information and inference

118.8.1 The Shannon functional

[Reserved: Shannon's uniqueness derivation of $-\sum p_i \log p_i$ from continuity, monotonicity and the composition rule [921]; its formal identity with the Gibbs entropy of Section 118.2.4; the care needed in reading that identity physically — the physical entropy carries units of J/K *and refers to a specified macroscopic description.]*

118.8.2 Maximum entropy as inference

[Reserved: Jaynes's derivation of the canonical and grand canonical distributions by maximising the Shannon entropy subject to the known expectation values, with the Lagrange multipliers becoming β and $\beta\mu$ [1114]; what this reformulation buys — a uniform derivation and a clear account of which assumptions are doing the work — and what it does not settle, namely why the resulting distributions describe the system after a finite time; Lagrange multipliers as in Chapter 16.]

118.8.3 Information and thermodynamic cost

[Reserved: Szilard's one-molecule engine and the entropy cost of a measurement [638]; Landauer's principle, that erasing one bit dissipates at least $kT \log 2$ [1213]; the experimental verification with a colloidal particle in a double-well optical trap, confirming the bound at the level of a few percent of kT [2191]; the exorcism of Maxwell's demon that follows, and its relation to the second law as stated in Chapter 54.]

118.8.4 Negative absolute temperature

[Reserved: a bounded-energy spectrum admitting population inversion and hence $\partial S/\partial E < 0$; the nuclear spin system of lithium fluoride prepared by Purcell and Pound, which relaxed through an inverted state with a measurable negative spin temperature [986]; Ramsey's demonstration that such states are consistent thermodynamic equilibria hotter than any positive temperature [1096]; the motional degrees of freedom of an ultracold lattice gas prepared at negative temperature [2214]; why this does not violate the second law.]

118.8.5 Beyond equilibrium

[Reserved: the Jarzynski equality relating the free-energy difference to an exponential average of the work done in arbitrarily fast processes [1938], and its verification by mechanically unfolding a single RNA molecule [2033]; the second law recovered as an inequality from an equality, with rare trajectories of negative entropy production observed; the systematic development in Chapter 124.]

Chapter 119

Experiment: Brownian Motion and Avogadro's Number

At the start of the twentieth century the existence of atoms was still a live question: the energetic school held that thermodynamics needed no molecules, and no measurement had yet counted them. Brownian motion settled it. The theory of Chapter 118 predicts that a particle large enough to be watched under a microscope, but small enough for the bombardment it receives to be unbalanced, must wander, and that the wandering must obey a quantitative law containing Avogadro's constant and nothing else that is unknown. Perrin measured that law four independent ways — from sedimentation equilibrium, from translational displacements, from rotational displacements, and from diffusion — and each gave the same number to within his stated errors. That agreement, not any single value, is what ended the argument.

This chapter reports the measurement as an experiment: the emulsions and optics Perrin used, the counting procedure, the observed numbers with their uncertainties in SI units, the interpretation, and the modern repetitions that reach the regime Einstein himself declared unobservable — the instantaneous velocity of a Brownian particle. Written out it will use the structured `experiment` environment of the treatise, in the order of the sections below. Its theoretical neighbours are Chapter 118 for the fluctuation formulae, Chapter 55 for the molecular picture, Chapter 124 for the general fluctuation–dissipation relation, and Chapter 11 for the stochastic processes the episode created. Primary sources are Brown [82], Einstein [318], Smoluchowski [331], Langevin [344] and Perrin [358, 409].

Derivation pending #214

Experiment: Brownian Motion and Avogadro's Number: all derivations of this chapter are pending.

119.1 Historical context and the prediction under test

119.1.1 Brown's observation

[Reserved: the ceaseless irregular motion of pollen-derived particles suspended in water, and Brown's decisive control — the same motion in particles ground from window glass, from rock and from a fragment of the Sphinx, which excluded any vital cause [82]; the seventy years of failed explanations (convection, evaporation, capillarity, electricity) and the observations that excluded each; the qualitative facts any theory had to reproduce — the motion never stops, is faster for smaller particles, and is faster in less viscous liquids.]

Phenomenon 119.1 (Ceaseless irregular motion of suspended grains)**.** Particles about a micrometre across, suspended in a liquid and watched under a microscope, execute a perpetual irregular motion that never ceases, is more vigorous the smaller the particle and the less viscous the liquid, and does not depend on the chemical nature or the origin of the particle: Brown found the same agitation in pollen-derived grains, in particles ground from window glass and from rock, and in a fragment of the Sphinx, which excludes any vital cause [82]. No external agency — convection, evaporation, illumination or capillarity — has been found that switches it off, and the motion persists indefinitely in a sealed, thermally equilibrated cell.

Derivation pending #215

Molecular origin of the agitation: the unbalanced momentum delivered by molecular impacts on a grain of radius a, and the reason the relative size of the resulting fluctuation grows as the grain shrinks

119.1.2 The atomic hypothesis under attack

[Reserved: the positivist objection that atoms are unobservable and therefore not physics, argued from the economy of thought [225]; the energetic programme's claim that thermodynamics is complete without them; what would count as an answer — not a plausibility argument but a measurement of how many molecules there are; Perrin's own framing of the question [409], and the connection to the epistemology of Chapter 1.]

119.1.3 Einstein's prediction

[Reserved: the 1905 paper deriving, from the osmotic pressure of the suspended particles and Stokes drag, the diffusion coefficient $D = RT/(6\pi\eta a N_A)$ and the mean square displacement $\langle x^2 \rangle = 2Dt$ [318]; the crucial point that the displacement grows as $\sqrt{t}$, not as t, so that a velocity measured over any accessible interval is meaningless — the statement Einstein made explicitly and that Section 119.7.3 eventually overturned; the second paper extending the treatment and adding rotational diffusion $\langle \theta^2 \rangle = RTt/(4\pi\eta a^3 N_A)$ [326].]

119.1.4 Smoluchowski and Sutherland

[Reserved: Smoluchowski's independent kinetic derivation by direct collision counting, differing from Einstein's coefficient by a numerical factor and reaching the same scaling [331]; Sutherland's independent statement of the same diffusion relation, obtained while estimating molecular masses from solution data [324]; the resulting name Stokes–Einstein–Sutherland relation, and the honest attribution.]

119.1.5 The Langevin equation

[Reserved: the phenomenological equation of motion $m\ddot{x} = -6\pi\eta a\dot{x} + F(t)$ with a random force of zero mean and vanishing correlation time, and Langevin's derivation of $\langle x^2 \rangle = 2Dt$ from it in a page — what he called an infinitely simpler demonstration [344]; the momentum relaxation time $\tau_p = m/(6\pi\eta a)$ that the overdamped limit discards, and which reappears as the observable of Section 119.7.3; the equation as the first stochastic differential equation.]

119.2 Apparatus

119.2.1 The gamboge and mastic emulsions

[Reserved: gamboge resin and mastic emulsified in water and purified by repeated fractional centrifuging to obtain grains uniform in radius to a few percent; typical radii from $0.2\,\mu\mathrm{m}$ *to* $0.5\,\mu\mathrm{m}$ *and densities near* $1.2\times10^{3}\,\mathrm{kg/m^{3}}$*; the months of preparation required for a usable fraction, and why monodispersity is the controlling systematic of the whole measurement [358, 409].]*

119.2.2 Microscope, cell and recording

[Reserved: the shallow observation cell of depth about $100\,\mu\mathrm{m}$ *sealed against evaporation and convection; the short depth of focus used to select a horizontal layer; the calibrated eyepiece grid and the camera lucida for recording successive positions at fixed time intervals of* $30\,\mathrm{s}$*; temperature control and its uncertainty; the counting of grains per layer by direct enumeration [358].]*

119.2.3 Calibration of the grain radius

[Reserved: three independent determinations of the grain radius — from Stokes-law sedimentation velocity, from direct microscopic measurement of a chain of grains, and from weighing a counted number of grains — and their mutual agreement as the internal check on the most sensitive input; the viscosity of water at the working temperature and its uncertainty; the propagation of these into the final result [358], in the manner of Chapter 2 and [1945].]

119.3 Procedure

119.3.1 Sedimentation equilibrium

[Reserved: the vertical distribution of grains in equilibrium as a barometric law with the molecular mass replaced by the buoyant mass of a grain, so that the scale height is measurable under a microscope; the counting of grains at four levels separated by tens of micrometres; the exponential fit and its slope giving N_A *directly; the demonstration that a visible suspension obeys the same statistics as a gas [358].]*

Phenomenon 119.2 (Sedimentation equilibrium of a visible suspension)**.** A dilute suspension of uniform grains, left undisturbed, settles into a stationary vertical distribution in which the number density falls off exponentially with height,

$$n(z) = n(0)\,\mathrm{e}^{-m^{*}gz/k_{B}T}\,, \qquad m^{*} = \tfrac{4}{3}\pi a^{3}\,(\rho-\rho_{f})\,, \tag{119.1}$$

where m^{*} is the buoyant mass of a grain of radius a and density ρ suspended in a fluid of density ρ_{f}. Perrin measured the scale height by counting grains at four levels separated by tens of micrometres and found the law obeyed over a fourfold change of concentration [358]. A suspension one can see therefore obeys the same barometric statistics as a gas one cannot.

Derivation. Treat the grains as a dilute solute, so rare that they do not interact with one another; their osmotic pressure is then that of an ideal gas, $p = nk_{B}T$. In mechanical equilibrium the gradient of that pressure must support the net downward force per unit volume, which is the weight of the grains less the buoyancy of the fluid they displace,

$$\frac{\mathrm{d}p}{\mathrm{d}z} = -nm^{*}g\,. \tag{119.2}$$

Substituting $p = nk_BT$ at uniform temperature gives $k_BT\,\mathrm{d}n/\mathrm{d}z = -nm^*g$, a first-order linear equation whose solution is Equation (119.1). Equivalently, the grains are distributed over the potential energy $U = m^*gz$ with the Boltzmann weight e^{-U/k_BT}; the two readings agree, which is precisely the point at issue, since the second treats a visible object as a statistical-mechanical degree of freedom. Because m^* is known from the measured radius and densities, the slope of $\ln n$ against z delivers $k_B = R/N_A$, and hence N_A, from a photograph. □

119.3.2 Displacement statistics

[Reserved: the recording of several thousand successive horizontal displacements over fixed intervals; the histogram of displacements tested against the predicted Gaussian; the mean square displacement per unit time compared with $\langle x^2\rangle = 2Dt$ and hence with Section 119.1.3 [318, 358]; the explicit test that the increments are independent, by checking $\langle x^2\rangle$ against interval length.]

Phenomenon 119.3 (The displacement law)**.** Measured along any fixed horizontal axis, the displacement of a suspended grain over an interval t has zero mean and a variance proportional to the interval itself, not to its square,

$$\left\langle x^2(t)\right\rangle = 2Dt\,, \qquad D = \frac{k_BT}{6\pi\eta a} = \frac{RT}{6\pi\eta a N_A}\,, \tag{119.3}$$

for a sphere of radius a in a fluid of viscosity η, and the histogram of displacements is Gaussian. The root mean square displacement therefore grows as $\sqrt{t}$, so the ratio of an observed displacement to the interval over which it was recorded diverges as that interval is shortened: a Brownian "velocity" read off a finite interval is a property of the stopwatch and not of the particle. Equation (119.3) was predicted by Einstein [318], obtained independently by Sutherland [324] and by Smoluchowski [331], and confirmed on emulsions of gamboge and mastic by Perrin [358].

Derivation. Follow Langevin [344]. Resolve the force on the grain into the systematic Stokes drag it would feel if the fluid were a continuum and a residual random force $F(t)$ of zero mean, uncorrelated with the position of the grain,

$$m\ddot{x} = -6\pi\eta a\,\dot{x} + F(t)\,, \qquad \langle F(t)\rangle = 0\,, \qquad \langle xF\rangle = 0\,. \tag{119.4}$$

Multiply by x and use $x\ddot{x} = \mathrm{d}(x\dot{x})/\mathrm{d}t - \dot{x}^2$:

$$m\frac{\mathrm{d}}{\mathrm{d}t}\langle x\dot{x}\rangle - m\left\langle \dot{x}^2\right\rangle = -6\pi\eta a\,\langle x\dot{x}\rangle\ . \tag{119.5}$$

The grain is one mechanical degree of freedom in thermal equilibrium with the liquid, so equipartition fixes $m\langle\dot{x}^2\rangle = k_BT$. Writing $z = \langle x\dot{x}\rangle = \frac{1}{2}\mathrm{d}\langle x^2\rangle/\mathrm{d}t$ turns Equation (119.5) into the linear equation

$$m\frac{\mathrm{d}z}{\mathrm{d}t} + 6\pi\eta a\,z = k_BT\,, \tag{119.6}$$

whose solution relaxes to the constant $z = k_BT/(6\pi\eta a)$ over the momentum relaxation time $\tau_p = m/(6\pi\eta a)$, which for Perrin's sub-micrometre resin grains in water is a small fraction of a microsecond and so utterly unresolvable at his 30 s sampling interval. For $t \gg \tau_p$, then, $\mathrm{d}\langle x^2\rangle/\mathrm{d}t = 2k_BT/(6\pi\eta a)$, and integrating from $x(0) = 0$ gives Equation (119.3) with $D = k_BT/(6\pi\eta a)$. Substituting $k_B = R/N_A$ puts Avogadro's constant into a quantity measurable with a microscope and a clock; every other symbol in Equation (119.3) is independently known. The Gaussian shape follows because the displacement over an interval long compared with τ_p is a sum of many independent increments, which is the central limit theorem of Chapter 11. □

119.3.3 Rotational Brownian motion

[Reserved: larger grains of about $13\,\mu\mathrm{m}$ *carrying visible internal inclusions used as angular markers; the measurement of the mean square angular displacement against Einstein's rotational prediction [326]; the very different power of the radius in the two laws, which makes their agreement a strong test rather than a repetition [358].]*

119.4 Observations

119.4.1 Measured displacements and distributions

[Reserved: tables of the observed mean square displacements with their standard errors, the fitted diffusion coefficients in m^2/s*, and the observed Gaussian form of the displacement histogram; the sedimentation scale heights; the rotational data; all quantities in SI with uncertainties, as required by the treatise convention [358].]*

119.4.2 Values of Avogadro's constant

[Reserved: the four independent routes giving values clustered near $6.8 \times 10^{23}/\mathrm{mol}$*, within roughly* $15\,\%$ *of the modern figure; Perrin's tabulation of the same constant obtained from thirteen unrelated phenomena — viscosity of gases, blackbody radiation, radioactivity, opalescence, blue of the sky, electric charge — agreeing to within their errors [409]; why the concordance of independent routes carries the evidential weight, an argument revisited in Chapter 1.]*

Phenomenon 119.4 (Concordance of Avogadro's constant)**.** Four measurements made on the same emulsions but resting on different physics — sedimentation equilibrium (Equation (119.1)), translational displacements (Equation (119.3)), rotational displacements, and diffusion of the grains themselves — return one and the same value of N_A to within their stated errors, and that value agrees to within roughly $15\,\%$ with values obtained from a dozen entirely unrelated phenomena, among them the viscosity of gases, blackbody radiation, the counting of radioactive decays, critical opalescence and the blue of the sky [358, 409]. The constant is today fixed by definition at $N_A = 6.022\,140\,76 \times 10^{23}/\mathrm{mol}$ [2333]. It is the concordance, and not the accuracy of any single route, that closed the question of whether molecules are real.

Derivation pending #216

The rotational displacement law for a sphere, in which the mean square angular displacement grows linearly in time with a coefficient carrying the inverse cube of the grain radius rather than its first power — the different power being what makes agreement between the two routes an independent check and not a repetition

119.4.3 Uncertainty budget

[Reserved: the dominant contributions — grain radius, polydispersity, viscosity, temperature drift, finite observation interval, and the two-dimensional projection of a three-dimensional walk; the systematic from tracking a grain that leaves the focal layer; comparison with the modern uncertainty conventions of Chapter 2 and [1945].]

119.5 Interpretation

119.5.1 The fluctuation–dissipation content

[Reserved: the relation $D = kT/(6\pi\eta a)$ read as a link between a fluctuation (D) and a dissipation (η) at one temperature [318, 324]; the same structure in the thermal noise of Chapter 118 and in the general theorem of Chapter 124; the physical content — the same molecular collisions that damp a motion also drive it, so the two coefficients cannot be independent.]

119.5.2 Why this settled the atomic hypothesis

[Reserved: the difference between explaining a phenomenon by atoms and counting the atoms; Perrin's argument that a definite N_A obtained concordantly from unrelated phenomena leaves no economical alternative to their reality [409]; Ostwald's and the energeticists' public change of position; the modern reading of this as the standard example of the argument from consilience.]

119.5.3 The second law as a statistical statement

[Reserved: the visible violation of the second law in a suspended grain, which rises against gravity for part of every second; Smoluchowski's analysis of the fluctuation-driven limits on any perpetual-motion device built from them [331], and its relation to the Landauer analysis in Chapter 118; the entropy statement of Chapter 54 restated as a statement about overwhelming probability, not impossibility.]

119.5.4 Recognition

[Reserved: the 1926 Nobel Prize in Physics awarded to Perrin for his work on the discontinuous structure of matter, and especially for his discovery of sedimentation equilibrium; Perrin's Nobel lecture as his own summary of the evidence [554]; the delayed and partial recognition of Smoluchowski, who died in 1917.]

119.6 Mathematical aftermath

119.6.1 The Wiener process

[Reserved: Wiener's construction of a measure on continuous paths realising Einstein's law, and the proof that almost every path is continuous and nowhere differentiable [507]; why nowhere-differentiability is the mathematical form of Einstein's warning about velocity in Section 119.1.3; the process as the basic object of Chapter 11.]

119.6.2 Ornstein–Uhlenbeck and the velocity correlation

[Reserved: the Ornstein–Uhlenbeck solution of the Langevin equation, giving the exponentially decaying velocity autocorrelation $\langle v(0)v(t)\rangle = (kT/m)\mathrm{e}^{-t/\tau_p}$ and recovering $\langle x^2\rangle = 2Dt$ only for $t \gg \tau_p$ [672]; the ballistic regime $\langle x^2\rangle = (kT/m)t^2$ at short times, and the equipartition value of the velocity variance — the prediction tested in Section 119.7.3.]

119.6.3 The Fokker–Planck description

[Reserved: the evolution equation for the probability density in position and velocity, its equivalence to the Langevin description, and the Maxwell–Boltzmann stationary solution;

Chandrasekhar's review as the standard synthesis of the whole subject [869]; forward reference to Chapter 124 for transport coefficients and to Chapter 66 for the same equation in a plasma.]

119.7 Modern repetitions and precision

119.7.1 Kappler's torsion balance

[Reserved: a small mirror on a quartz fibre in a low-pressure gas, whose angular fluctuations obey $\langle\theta^2\rangle = kT/\kappa$ by equipartition alone, independent of pressure over four decades; Kappler's determination of N_A to about 1 % from these fluctuations [682]; the experiment as the cleanest instance of the fluctuation formulae of Chapter 118 for a single degree of freedom.]

119.7.2 Optical tweezers

[Reserved: the single-beam gradient-force trap [1767] as the modern apparatus — a micrometre bead held in a harmonic potential of known stiffness, with position read out interferometrically at nanometre and microsecond resolution; the power spectrum of the trapped bead as a direct measurement of both D and τ_p; the same instrument used for the single-molecule work cited in Chapter 118.]

119.7.3 The instantaneous velocity

[Reserved: Li, Kheifets, Medellin and Raizen's measurement of the instantaneous velocity of a silica bead in air, resolving the ballistic regime and recovering the equipartition value $\langle v^2\rangle = kT/m$ [2160]; the extension to liquids, where hydrodynamic memory modifies the correlation function and the simple Ornstein–Uhlenbeck form fails [2234]; the explicit overturning of Einstein's judgement that this velocity could never be measured, and what made it possible — trap stiffness, detection bandwidth and low pressure.]

Phenomenon 119.5 (The ballistic regime and equipartition)**.** Resolved on time scales short compared with the momentum relaxation time τ_p of Equation (119.6), the motion of a Brownian particle is not diffusive but ballistic: the mean square displacement grows as t^2 rather than as t, the trajectory acquires a well-defined instantaneous velocity, and the variance of that velocity takes the equipartition value

$$\left\langle v^2 \right\rangle = \frac{k_B T}{m} \,. \tag{119.7}$$

This was measured for a silica bead of micrometre scale held in an optical trap in air, with the position read out at nanometre and sub-microsecond resolution [2160]; in a liquid the same measurement finds the simple exponential velocity correlation replaced by a slower, hydrodynamic-memory form, so that Equation (119.7) is approached but the Ornstein–Uhlenbeck description of Section 119.6.2 fails in detail [2234]. The measurement overturns Einstein's explicit judgement [318] that this velocity could never be observed.

Derivation pending #217

The velocity autocorrelation of the Ornstein–Uhlenbeck process obtained from the Langevin equation, its short-time ballistic limit, and the crossover to the diffusive law at the momentum relaxation time; and separately the hydrodynamic-memory kernel that replaces it for a sphere in a dense fluid

119.7.4 Avogadro's constant today

[Reserved: the silicon-sphere X-ray crystal density route and the watt-balance route that superseded Brownian determinations; the 2019 redefinition fixing N_A exactly at $6.022\,140\,76 \times 10^{23}/\mathrm{mol}$ by convention, so that the quantity Perrin measured is now a defined constant [2333]; the current values of the related constants [2392]; what a modern Brownian measurement now tests instead — the Boltzmann constant, the viscosity, or the apparatus itself; the SI framework of Chapter 2.]

Chapter 120

Quantum Statistics

Classical statistical mechanics counts states as though the particles carried labels, and the answer is wrong: the entropy is not extensive until a factor $1/N!$ is inserted by hand (Chapter 118), the heat capacities of gases and solids collapse at low temperature, and a metal's conduction electrons contribute almost nothing to its specific heat while contributing everything to its conductivity. This chapter replaces the counting. Identical particles are indistinguishable in principle, the states of N of them are either totally symmetric or totally antisymmetric under exchange, and the two cases give the Bose–Einstein and Fermi–Dirac distributions — from which the Planck spectrum, the degeneracy pressure that holds up a white dwarf, the linear electronic heat capacity of a metal, Pauli paramagnetism, Landau diamagnetism and Bose–Einstein condensation all follow. Each is stated below with the measurement that established it.

The chapter takes the exchange symmetry itself from Chapter 83 and the spin–statistics theorem from Chapter 109, and hands its results on to Chapter 121 (the atomic condensate as a laboratory system), Chapters 125 and 126 (solids), Chapter 130 (paired and condensed phases) and Chapter 49 (degenerate stellar matter). Founding sources are Bose [509], Einstein [512, 522], Fermi [539] and Dirac [537]; the standard modern treatments are [1656, 2180].

Derivation pending #218

Quantum Statistics: all derivations of this chapter are pending.

120.1 Indistinguishability

120.1.1 Counting states for identical particles

[Reserved: the difference between Boltzmann counting, in which exchanging two particles gives a new microstate, and the counting used by Bose, in which it does not [509]; occupation-number representation and the specification of a state by $\{n_i\}$ alone; the resulting combinatorics for unrestricted and restricted occupancy; the symmetrisation postulate and the exchange operator, developed in Chapter 83.]

120.1.2 The exclusion principle

[Reserved: Pauli's formulation — no two electrons in an atom share all four quantum numbers — introduced to explain the closing of electron shells and the anomalous Zeeman multiplet structure [529]; the periodic table and atomic spectra as the evidence base (Chapters 70 and 88); the restatement as antisymmetry of the many-electron wavefunction and the Slater determinant.]

Phenomenon 120.1 (Exclusion)**.** The electrons of a many-electron atom do not accumulate in the lowest orbital. The chemical periods close at atomic numbers $Z = 2, 10, 18, \ldots$, the first ionization energy peaks at exactly those values and drops abruptly at the next, and the alkali spectra are those of a single valence electron outside an inert core: no two electrons of an atom share all four quantum numbers [529]. Nor is this a rule that softens at high precision. Passing a fresh current through a copper strip, so that the conduction electrons arriving at a given atom have never been there before, and searching the X-ray spectrum for a transition into an already-filled K shell, bounds the probability of a Pauli-violating state below about 1.7×10^{-26} [1837].

Derivation pending #219

Exclusion derived rather than postulated: the symmetrisation of the state of identical particles, the vanishing of a totally antisymmetric state with two coincident single-particle labels, and the spin–statistics theorem that assigns antisymmetry to half-integer spin

120.1.3 The spin–statistics theorem

[Reserved: Pauli's proof that, in a relativistic quantum field theory with a positive-definite energy and local commutativity, half-integer spin fields must anticommute and integer spin fields must commute [854]; the failure of the alternative assignment — negative energies or negative norms — rather than mere inelegance; the axiomatic form of the theorem in Chapter 109 and its relation to the CPT theorem of Chapter 105.]

120.1.4 Composite particles

[Reserved: Ehrenfest and Oppenheimer's rule that a bound system of an even number of fermions behaves as a boson and an odd number as a fermion, with the validity conditions — the exchange must not resolve the internal structure [679]; the worked cases ^{4}He *(boson) against* ^{3}He *(fermion), whose radically different low-temperature behaviour is the direct experimental demonstration; Cooper pairs and excitons as the same mechanism (Chapter 130).]*

120.1.5 Experimental limits on violations

[Reserved: the Ramberg–Snow experiment, in which a fresh current is passed through a copper strip and the X-ray spectrum searched for transitions to an already-filled K shell, bounding the probability of a Pauli-violating state below about 1.7×10^{-26} *[1837]; later and stronger bounds from nuclear and electron stability; why an exact conservation law deserves a direct test rather than an assumption.]*

120.2 The two distributions

120.2.1 Bose's derivation of the Planck law

[Reserved: Bose's counting of photon states in phase-space cells of volume h^3*, which derives the Planck spectrum without invoking classical electrodynamics at any point [509]; Einstein's recognition and translation of the paper; the relation to the blackbody measurements of Chapter 68 and to the cosmic microwave spectrum of Chapter 51, the most precise blackbody ever measured; the photon chemical potential vanishing because photon number is not conserved.]*

120.2.2 The Bose–Einstein distribution

[Reserved: Einstein's extension of Bose's counting to a gas of material particles, giving $\langle n_i \rangle = [\mathrm{e}^{\beta(\epsilon_i - \mu)} - 1]^{-1}$ [512]; the constraint $\mu \leq \epsilon_0$; the enhancement of multiple occupancy relative to classical counting, which is the statistical statement behind stimulated emission (Chapter 122).]

120.2.3 Fermi–Dirac statistics

[Reserved: Fermi's quantisation of the ideal monatomic gas with the exclusion principle imposed [539] and Dirac's independent derivation from the antisymmetry of the wavefunction, with his identification of which particles obey which statistics [537]; the distribution $\langle n_i \rangle = [\mathrm{e}^{\beta(\epsilon_i - \mu)} + 1]^{-1}$; the step function at $T = 0$ and the thermal smearing of width $\sim kT$ about the chemical potential.]

120.2.4 The classical limit

[Reserved: both distributions reducing to $\mathrm{e}^{-\beta(\epsilon - \mu)}$ when the occupancies are small, i.e. when the thermal de Broglie wavelength is much less than the interparticle spacing; the degeneracy parameter $n\lambda^3$ and its value for air at room temperature against a metal's conduction electrons; the recovery of the Sackur–Tetrode entropy of Chapter 118 with the $1/N!$ now derived rather than inserted [380, 393].]

120.2.5 Grand canonical treatment

[Reserved: why the grand canonical ensemble is the natural one — the occupation numbers are then independent and $\log \Xi$ factorises over modes; the fugacity, the Bose and Fermi functions $g_\nu(z)$ and $f_\nu(z)$, and the resulting equations of state; the quantum virial expansion and the statistical "exchange pressure" that is repulsive for fermions and attractive for bosons in the absence of any interaction [1656].]

120.3 The ideal Bose gas

120.3.1 Einstein's condensation

[Reserved: the saturation of the excited-state population, so that below a critical temperature a macroscopic fraction of the particles must occupy the single-particle ground state [522]; Einstein's own statement that the phenomenon occurs without any interaction, purely from the statistics; the initial scepticism and the delay before it was taken to be physical.]

120.3.2 Critical temperature and condensate fraction

[Reserved: $kT_c = 2\pi\hbar^2 n^{2/3}/[m\,\zeta(3/2)^{2/3}]$ in three dimensions, the condensate fraction $1 - (T/T_c)^{3/2}$, and the $T^{3/2}$ heat capacity with its cusp at T_c [522, 1656]; the dimensional statement — no condensation of the ideal gas in a homogeneous system of fewer than three space dimensions — and the modification by a trapping potential; numerical values for helium and for a dilute alkali vapour.]

120.3.3 Superfluid helium-4

[Reserved: the abrupt loss of viscosity below $2.17\,\mathrm{K}$ measured independently by Kapitza [817] and by Allen and Misener [809]; London's identification of the lambda transition with Bose–Einstein condensation, noting that the ideal-gas T_c at the density of liquid helium is

3.1 K, *close to the observed* 2.17 K *[818]; the strong interactions that make the identification qualitative, the condensate fraction of only about* 10 %*, and the full account in Chapter 130.]*

120.3.4 The weakly interacting Bose gas

[Reserved: Bogoliubov's diagonalisation of the weakly interacting Bose Hamiltonian, giving a phonon-like linear excitation spectrum at long wavelength and a depletion of the condensate [898]; Landau's criterion for superfluidity, that a critical velocity exists whenever the excitation spectrum has no low-lying free-particle branch [858]; why the ideal Bose gas, despite condensing, is not a superfluid.]

120.3.5 Dilute atomic condensates

[Reserved: the observation of condensation in rubidium-87 at 170 nK *by Anderson and coworkers [1893] and in sodium at higher atom number by Davis and coworkers [1898]; the bimodal momentum distribution as the signature; laser and evaporative cooling, apparatus and uncertainties treated in Chapter 121; the condensate as a nearly ideal realisation of Section 120.3.1, seventy years after the prediction.]*

Phenomenon 120.2 (Condensation without interaction)**.** A gas of identical bosons cooled at fixed density undergoes a phase transition at a temperature set by the density and the mass alone, below which a macroscopic fraction of the atoms occupies one and the same single-particle state. The transition is observed in a dilute vapour of rubidium-87 at 170 nK and in sodium at higher atom number [1893, 1898], where the interactions are so weak that the ideal-gas prediction [522] applies with per-cent corrections; and it is observed in liquid helium-4, which loses its viscosity abruptly below 2.17 K [809, 817] at a temperature close to the ideal-gas value of 3.1 K computed at the density of the liquid [818]. No attraction between the particles is involved: what condenses them is the counting rule.

Derivation pending #220

Saturation of the excited-state population of the ideal Bose gas: that the sum over excited modes of the Bose occupation is bounded above at fixed temperature and volume when the chemical potential reaches the ground-state energy, so that any further particles must enter the ground state; the resulting critical temperature, condensate fraction and heat-capacity cusp in three dimensions

120.4 The ideal Fermi gas

120.4.1 Fermi energy and degeneracy pressure

[Reserved: the filled Fermi sphere at $T = 0$*, the Fermi wavevector* $k_F = (3\pi^2 n)^{1/3}$*, the Fermi energy and Fermi temperature, and the ground-state pressure* $P = \frac{2}{5} n \epsilon_F$ *which survives at zero temperature [539]; numerical values for the conduction electrons of copper (*$\epsilon_F \approx 7$ eV*,* $T_F \approx 8 \times 10^4$ K*), showing that a metal at room temperature is a strongly degenerate gas; the Fermi surface as an observable object.]*

120.4.2 The Sommerfeld expansion

[Reserved: Sommerfeld's application of Fermi statistics to the electron theory of metals [620], resolving the long-standing failure of the Drude model to explain why the electrons contribute a full Wiedemann–Franz conductivity but almost no heat capacity; the expansion

in kT/ϵ_F and the linear electronic heat capacity $C = \gamma T$; the measured low-temperature form $C = \gamma T + \beta T^3$ of a metal, whose two terms separate the electrons from the phonons of Chapter 125; band-structure corrections in Chapter 126.]

Phenomenon 120.3 (The linear electronic heat capacity of a metal)**.** The conduction electrons of a metal carry the whole of its electrical and thermal current, as a free gas of one carrier per atom would, and yet contribute to its heat capacity about two orders of magnitude less than the $\frac{3}{2}k_B$ per electron that classical equipartition demands. Between about 1 K and 5 K the heat capacity of a normal metal is measured to be

$$C = \gamma T + \beta T^3 \,, \tag{120.1}$$

so that C/T plotted against T^2 is a straight line whose intercept γ is electronic and whose slope β is the lattice contribution of Chapter 125; the separation was carried out for copper, silver and gold [1061]. A term linear in T, and a coefficient this small, are what Fermi statistics predict and what Maxwell–Boltzmann statistics cannot produce [620].

Derivation. Let $g(\epsilon)$ be the density of one-electron states per unit volume, counting both spins. At temperature T the occupation $f(\epsilon) = [\mathrm{e}^{\beta(\epsilon-\mu)} + 1]^{-1}$ differs from the zero-temperature step only within a shell of width of order k_BT about μ. Hence only about $g(\epsilon_F)k_BT$ electrons per unit volume are thermally active, and each carries an excess energy of order k_BT, so the thermal energy density rises above its ground-state value by an amount of order $g(\epsilon_F)(k_BT)^2$, and the heat capacity is of order $k_B^2 T g(\epsilon_F)$ — linear in T, not constant. The coefficient follows from the Sommerfeld expansion of $\int H(\epsilon) f(\epsilon) \mathrm{d}\epsilon$ in powers of k_BT/μ, whose leading correction is $(\pi^2/6)(k_BT)^2 H'(\mu)$; applied to $H = \epsilon g(\epsilon)$ and differentiated with respect to T it gives

$$c_V = \frac{\pi^2}{3} k_B^2 \, T \, g(\epsilon_F) \,, \tag{120.2}$$

which is Equation (120.1) with $\gamma = \frac{1}{3}\pi^2 k_B^2 g(\epsilon_F)$. For the free electron gas $g(\epsilon_F) = 3n/(2\epsilon_F)$ and Equation (120.2) becomes $c_V = \frac{1}{2}\pi^2 n k_B (T/T_F)$ with $k_BT_F = \epsilon_F$, smaller than the classical $\frac{3}{2}nk_B$ by the factor $(\pi^2/3)(T/T_F)$. With $T_F \approx 8 \times 10^4$ K for copper this factor is about 10^{-2} at room temperature, which is the observed suppression. The measured γ is thus a direct measurement of the density of states at the Fermi level. □

120.4.3 Pauli paramagnetism

[Reserved: Pauli's calculation of the spin susceptibility of a degenerate electron gas, temperature-independent and smaller than the Curie law by a factor $\sim T/T_F$ [586]; the resolution of the observed weak, temperature-independent paramagnetism of the alkali metals; the susceptibility as a measurement of the density of states at the Fermi level; the wider magnetism of Chapter 129.]

Phenomenon 120.4 (Pauli paramagnetism)**.** The alkali metals are weakly paramagnetic with a susceptibility that is essentially independent of temperature, in flat contradiction with the Curie law $\chi \propto 1/T$ obeyed by the same number of localized moments, and smaller than the Curie value at room temperature by about two orders of magnitude [586].

Derivation. In a field B the two spin populations acquire energies shifted by $\mp\mu_B B$. They share one chemical potential, so the shift is absorbed by transferring electrons from the minority to the majority band until the two Fermi levels coincide; to first order in the field the transferred density is $\frac{1}{2}g(\epsilon_F)\mu_B B$ from each band, giving a magnetization

$$M = \mu_B^2 g(\epsilon_F) B \,, \qquad \chi = \frac{\mu_0 M}{B} = \mu_0 \mu_B^2 g(\epsilon_F) \,, \tag{120.3}$$

in which the temperature appears nowhere: only the electrons within k_BT of the Fermi surface can flip, and their number is proportional to T while the polarization each contributes is proportional to $1/T$, so the two cancel. Dividing Equation (120.3) by the Curie susceptibility $\chi_C = n\mu_0\mu_B^2/k_BT$ of n free spins one half, and using $g(\epsilon_F) = 3n/(2\epsilon_F)$, gives $\chi/\chi_C = \frac{3}{2}(T/T_F)$, of order 10^{-2} at room temperature — the observed suppression, and the same degeneracy factor that suppresses the heat capacity in Phenomenon 120.3. The measured susceptibility is therefore a second, independent determination of $g(\epsilon_F)$. □

120.4.4 Landau diamagnetism and quantum oscillations

[Reserved: Landau's demonstration that orbital quantisation in a magnetic field gives a diamagnetic contribution of exactly minus one third of the Pauli susceptibility for free electrons [660]; the Landau levels and their degeneracy; the de Haas–van Alphen oscillations of the susceptibility periodic in $1/B$, discovered in bismuth [655], which measure extremal Fermi-surface cross sections directly; the same levels underlying the quantum Hall measurements of Chapter 128.]

120.4.5 Degenerate Fermi gases in the laboratory

[Reserved: DeMarco and Jin's cooling of potassium-40 to $T/T_F \approx 0.5$, with the onset of degeneracy seen as a deviation of the released energy from the classical value [1971]; the condensation of fermionic atom pairs across a Feshbach resonance and the crossover between a paired condensate and a Bardeen–Cooper–Schrieffer superfluid [2065]; the connection to Chapter 130.]

120.5 Degenerate matter in astrophysics

120.5.1 White dwarfs

[Reserved: Fowler's identification of the electron degeneracy pressure of Section 120.4.1 as what supports a white dwarf against gravity, the first astrophysical application of the new statistics [541]; Chandrasekhar's relativistic treatment and the limiting mass near 1.4 solar masses, above which no degenerate configuration exists [676]; the observed white-dwarf mass distribution and the type Ia supernova connection, treated in Chapters 49 and 52.]

Phenomenon 120.5 (Degeneracy pressure holds up a dead star)**.** A white dwarf is a star of roughly solar mass compressed to roughly the radius of the Earth. It has no nuclear source, radiates freely, and is cooling — and yet it does not contract. The pressure that supports it does not vanish with the temperature, and is supplied by the exclusion principle acting on the electrons [541]. The support is not unlimited: since the electrons become relativistic as they are compressed, a degenerate configuration exists only below a limiting mass near 1.4 solar masses [676], and the observed white-dwarf masses respect it. The same argument applied to neutrons is bounded by the measured pulsar mass of 1.97 ± 0.04 solar masses, obtained from the Shapiro delay in a binary and sufficient by itself to exclude the softest nuclear equations of state [2155].

Derivation pending #221

The ground-state pressure of the ideal Fermi gas, its persistence at zero temperature, the softening of the equation of state when the Fermi momentum becomes relativistic, and the resulting limiting mass for a self-gravitating degenerate sphere

120.5.2 Neutron stars

[Reserved: neutron degeneracy pressure and the nuclear-matter corrections that dominate it, so that the maximum mass is set by the equation of state rather than by the ideal-gas result; the measurement of a pulsar of 1.97 ± 0.04 *solar masses through the Shapiro delay, which excludes the softest equations of state [2155]; the nuclear physics in Chapter 107 and the relativistic structure equations in Chapter 49.]*

120.6 Correlations as direct evidence

120.6.1 Photon bunching

[Reserved: the Hanbury Brown and Twiss measurement of a positive correlation between the photocurrents of two detectors illuminated by the same thermal source [1083]; the initial disbelief and the resolution — the effect is a consequence of Bose statistics, not of any interaction; intensity interferometry as a technique for stellar angular diameters; the quantum-optical treatment of $g^{(2)}(0)$ *in Chapter 122.]*

120.6.2 Bunching and antibunching compared

[Reserved: the direct side-by-side experiment of Jeltes and coworkers, measuring the two-particle correlation of clouds of metastable ^{4}He *(bunching) and* ^{3}He *(antibunching) released from the same apparatus [2109]; the identical preparation of the two isotopes, which makes the opposite sign of the correlation an isolated demonstration of the statistics; the correlation length as the source coherence length.]*

Phenomenon 120.6 (Bunching and antibunching)**.** Identical particles arriving at two detectors from a chaotic source are correlated even though nothing couples them. Hanbury Brown and Twiss found the photocurrents of two detectors illuminated by one thermal light source to be positively correlated at small detector separation, an effect with no classical-particle explanation and none in any interaction [1083]. The sign of the correlation is fixed by the statistics alone, as the decisive control shows: clouds of metastable helium-4 and of helium-3, prepared and released from the same apparatus under the same conditions, give a two-particle correlation that is a peak for the boson and a dip for the fermion [2109].

Derivation pending #222

The two-particle detection amplitude for identical particles from a chaotic source, the interference of the direct and exchanged terms, and the resulting second-order correlation of two at zero separation for bosons against zero for fermions, with the source coherence length as the correlation scale

120.6.3 Exchange effects in scattering

[Reserved: the interference of direct and exchange amplitudes in the scattering of identical particles, and Mott's cross section for two electrons with the resulting oscillatory term [663]; the factor of two enhancement at 90° *for identical bosons and the corresponding suppression for identical fermions; the measured alpha–alpha scattering pattern as the classic demonstration; scattering formalism in Chapter 86.]*

120.7 Beyond the two statistics

120.7.1 Why three space dimensions admit only two

[Reserved: the topology of the configuration space of identical particles in three space dimensions, whose exchange paths form the permutation group, so that only the two one-dimensional representations — symmetric and antisymmetric — are available [1603]; the spin–statistics theorem of Section 120.1.3 fixing which particles take which; the absence of any observed violation, per Section 120.1.5.]

120.7.2 Quasiparticle statistics in planar systems

[Reserved: electrons confined to a plane within a three-dimensional sample, for which the exchange paths form the braid group and the emergent quasiparticles may carry fractional exchange phases [1603]; the strict statement of scope — these are collective excitations of a physical three-dimensional material, not fundamental particles, and the treatise makes no claim about physics in fewer than three space dimensions; the fractional quantum Hall measurements that bear on it are reported in Chapter 128.]

Chapter 121

Experiment: Bose–Einstein Condensation

Bose–Einstein condensation is the one phase transition that requires no interaction whatsoever: it follows from the counting rule for identical bosons alone, which is why Chapter 120 can derive it for the ideal gas and why Chapter 83 is its real premise. This chapter is the experimental counterpart. It presents the 1995 JILA and MIT condensates in full phenomenological detail [1893, 1898] — apparatus, cooling sequence, measured numbers with their uncertainties — together with the seventy years of technique that separate Einstein's prediction [522] from its realization in a dilute alkali vapour, and with the modern repetitions that have turned a once-heroic measurement into a routine laboratory tool. The delay was not conceptual: a condensate of the kind Einstein described needs a gas held at a temperature six orders of magnitude below anything a cryostat can reach, in a container with no walls, at densities low enough that three-body recombination does not convert it to a solid first. Every element of the apparatus in Section 121.2 exists to meet one of those three constraints.

The chapter sits between the statistics that predict the effect (Chapter 120) and the interacting condensed phases of Chapter 130, where the same macroscopic wavefunction appears in a strongly correlated liquid; its coherence measurements are the atomic counterpart of the optical ones in Chapter 122, and its matter-wave interference closes the argument opened in Chapter 71. When written out, the chapter will use the structured `experiment` environment throughout, with apparatus, procedure, observations, interpretation and primary references as separate fields, and with all quantities in SI.

Derivation pending #223

Experiment: Bose–Einstein Condensation: all derivations of this chapter are pending.

121.1 The prediction under test

121.1.1 Bose statistics and Einstein's condensation

[Reserved: Bose's re-derivation of Planck's law by counting cells in phase space rather than by assuming a classical field [509]; Einstein's extension of the counting to a gas of massive particles [512] and, in the second paper, the conclusion that below a finite temperature a macroscopic fraction of the particles occupies the single-particle ground state [522]; why the effect is purely statistical, arising from the symmetry of the many-body state (Chapter 83) and not from any attraction; the ideal-gas thermodynamics derived in Chapter 120.]

121.1.2 The condensation criterion

[Reserved: the thermal de Broglie wavelength $\lambda_{\mathrm{dB}} = h/\sqrt{2\pi m k_B T}$ and the criterion $n\lambda_{\mathrm{dB}}^3 \geq \zeta(3/2) \approx 2.612$ for the homogeneous ideal gas [522]; the modified criterion $k_B T_c = \hbar\bar{\omega}(N/\zeta(3))^{1/3}$ for the harmonic trap that every experiment actually uses [1970]; the numerical consequence that a vapour at $n \sim 1 \times 10^{19}/\mathrm{m}^3$ condenses only below about 1 µK, six decades colder than liquid helium; the standard monograph treatment [2133].]

121.1.3 Seventy years of near misses

[Reserved: London's identification of the helium-4 lambda transition as a Bose–Einstein condensation distorted by strong interactions [818], and why a liquid with a condensate fraction near 10 % cannot test Einstein's ideal-gas prediction (the interacting case is Chapter 130); the spin-polarized atomic hydrogen programme as the deliberate attempt at a weakly interacting Bose gas [1776, 1811], its recombination-limited densities, and the switch to alkali vapours that could be laser-cooled.]

121.2 Apparatus

121.2.1 Laser cooling

[Reserved: radiation pressure as a mechanical force on neutral particles [1412]; the proposal to cool a gas with red-detuned light [1547]; optical molasses — six counter-propagating beams producing a viscous damping force and temperatures near the Doppler limit $k_B T_D = \hbar\Gamma/2$ [1750]; the magneto-optical trap that adds a quadrupole field to make the force position-dependent [1796]; Zeeman slowing of the atomic beam that loads it; the level structures involved belong to Chapter 88.]

121.2.2 Sub-Doppler cooling

[Reserved: the measurement that found sodium at (43 ± 20) µK, well below the 240 µK Doppler limit, and so falsified the accepted theory of molasses [1810]; the polarization-gradient (Sisyphus) mechanism that explains it, in which an atom climbs a light shift and is optically pumped to the bottom of the next well [1818]; the recoil limit $k_B T_R = \hbar^2 k^2/m$ as the residual floor; why sub-Doppler temperatures still leave phase-space density a factor $\sim 10^6$ short of condensation.]

Phenomenon 121.1 (Cooling below the accepted limit)**.** Laser-cooled sodium in optical molasses is measured at (43 ± 20) µK, well below the 240 µK Doppler limit $k_B T_D = \hbar\Gamma/2$ that the accepted theory of molasses predicted and that had been treated as a floor [1810]. The measurement was a falsification, not a refinement: it forced the recognition of a second cooling mechanism that the two-level model does not contain, and the temperature it reaches instead is set by the photon recoil.

Derivation pending #224

The polarization-gradient (Sisyphus) mechanism: the spatially modulated light shifts of the ground-state sublattice in a standing wave of varying polarization, the optical pumping that preferentially transfers an atom from a hill to the bottom of the next well, the resulting friction coefficient, and the recoil energy as the residual floor

121.2.3 Magnetic traps

[Reserved: the Zeeman potential $U = \mu_B g_F m_F |B|$ and the first magnetic confinement of neutral atoms [1761]; Majorana spin flips at the zero of a pure quadrupole field, and the two cures — the JILA time-orbiting potential trap that rotates the zero faster than the atoms can follow [1908] and the MIT optical plug that repels atoms from it [1898]; why only weak-field-seeking states can be trapped, and why Earnshaw's theorem forbids a static maximum.]

121.2.4 Evaporative cooling

[Reserved: forced evaporation — selectively removing the highest-energy atoms with a radio-frequency knife and letting elastic collisions rethermalize the remainder — proposed and demonstrated for spin-polarized hydrogen [1776, 1811]; the runaway condition relating the ratio of good (elastic) to bad (inelastic) collisions; the price paid in atom number, typically a factor 10^3 lost for a factor 10^6 gained in phase-space density; why this last stage, and not laser cooling, is what actually reaches degeneracy.]

121.2.5 Imaging and thermometry

[Reserved: destructive absorption imaging after ballistic expansion, in which the released cloud maps momentum onto position and the optical depth is fitted to a Bose-distributed column density; non-destructive dispersive (phase-contrast) imaging, which permits repeated observation of one condensate [1914]; how temperature is extracted from the thermal wings rather than from any thermometer in contact with the gas; systematic uncertainties in magnification, atom number and the resonant cross-section, which dominate the error budget quoted in Section 121.4.2.]

121.3 Procedure

121.3.1 The JILA rubidium-87 sequence

[Reserved: the full 1995 cycle — vapour-cell magneto-optical trap, polarization-gradient molasses, optical pumping into $|F = 2, m_F = 2\rangle$, transfer to the time-orbiting potential trap, and radio-frequency evaporation over about $70\,\mathrm{s}$ [1893, 1908]; the endpoint of roughly 2×10^3 condensed atoms of rubidium-87 at $170\,\mathrm{nK}$ and a peak density near $2.5 \times 10^{18}\,\mathrm{m}^{-3}$; the anisotropic expansion after release as the signature that survived every check.]

121.3.2 The MIT sodium-23 sequence

[Reserved: the contrasting design — a Zeeman-slowed sodium beam, a dark-spot magneto-optical trap, and a plugged quadrupole trap — reaching some 5×10^5 condensed atoms, two orders of magnitude more than JILA, at a transition temperature near $2\,\mu\mathrm{K}$ [1898]; why the larger condensate is what made the coherence experiments of Section 121.4.4 possible; the independence of the two apparatus designs as the strongest argument against an artefact.]

121.3.3 Lithium-7 and attractive interactions

[Reserved: the third 1995 result, in lithium-7, whose negative scattering length makes the condensate mechanically unstable above a critical atom number [1896]; the observed limit of order 10^3 atoms and its later refinement; why this case tests the interaction-dependent part of the theory that rubidium and sodium, both repulsive, cannot.]

121.4 Observations

121.4.1 The bimodal velocity distribution

[Reserved: the primary datum — a narrow, anisotropic peak emerging from a broad isotropic thermal background as the evaporation endpoint is lowered through T_c [1893, 1898]; why the anisotropy is decisive: a thermal cloud expands isotropically whatever the trap shape, while a condensate inherits the inverted aspect ratio of the trapping potential through the uncertainty relation; the three control observations that excluded a cold thermal cloud, an imaging artefact and a mechanical compression.]

Phenomenon 121.2 (The condensate appears as a second component)**.** As the endpoint of the evaporation is lowered through a critical temperature, the velocity distribution of the released cloud ceases to be a single broad isotropic Gaussian and becomes bimodal: a narrow peak grows out of the broad thermal background and takes over as the temperature is lowered further. The narrow component is *anisotropic*, and expands fastest along the axis in which the trap was tightest — the inverse of the shape it had in the trap — while the thermal background expands isotropically whatever the trap geometry [1893, 1898].

Derivation. The anisotropy is the discriminating observation, and it follows from the uncertainty relation alone. A thermal cloud in equilibrium at temperature T has, whatever the shape of the confining potential, an isotropic Maxwell–Boltzmann momentum distribution of width $\sqrt{mk_BT}$ in every direction; after release its size grows as $\sqrt{k_BT/m}\,t$ equally in all three directions, so a long expansion always drives it towards a sphere. A condensate, by contrast, occupies one single-particle state, the ground state of a harmonic trap of frequencies ω_i, whose widths and momentum widths are

$$\sigma_i = \sqrt{\frac{\hbar}{m\omega_i}}\,, \qquad \Delta p_i = \frac{\hbar}{2\sigma_i} = \tfrac{1}{2}\sqrt{m\hbar\omega_i}\,. \tag{121.1}$$

The in-trap aspect ratio is therefore $\sigma_1/\sigma_2 = \sqrt{\omega_2/\omega_1}$, while after a free expansion long enough that the initial size is negligible the observed size is $\Delta p_i t/m \propto \sqrt{\hbar\omega_i/m}\,t$ and the aspect ratio is $\sqrt{\omega_1/\omega_2}$ — exactly inverted. The tightly confined direction is the one with the largest momentum spread and so expands fastest. No thermal cloud, at any temperature, can produce that inversion, which is why the anisotropy and not the narrowness of the peak is what identifies the condensate. □

121.4.2 Condensate fraction and transition temperature

[Reserved: the quantitative test — condensate fraction $N_0/N = 1 - (T/T_c)^3$ for an ideal gas in a harmonic trap, measured against T/T_c together with the released energy [1921]; the measured transition temperature and the several-per-cent negative shift from the ideal-gas value attributable to finite N and to mean-field repulsion; the tabulated SI values, uncertainties and systematic error budget that will constitute the dataset of this chapter; comparison with the trapped-gas theory [1970].]

Phenomenon 121.3 (Condensate fraction and transition temperature)**.** The condensed fraction of a harmonically trapped Bose gas rises from zero at a sharp transition temperature according to

$$\frac{N_0}{N} = 1 - \left(\frac{T}{T_c}\right)^3, \qquad k_BT_c = \hbar\bar{\omega}\left(\frac{N}{\zeta(3)}\right)^{1/3}, \tag{121.2}$$

with $\bar{\omega}$ the geometric mean trap frequency. Both the fraction and the released energy were measured against T/T_c and found to follow Equation (121.2) [1921]; the measured T_c lies a few per cent *below* the ideal-gas value, by an amount attributable to the finite atom number

and to the mean-field repulsion between the atoms [1970]. A prediction made for a gas that does not interact thus survives contact with one that does, to within the corrections that interaction requires.

Derivation. For a three-dimensional harmonic trap with frequencies ω_i and $\bar{\omega} = (\omega_1\omega_2\omega_3)^{1/3}$, the number of single-particle states with energy below E is $E^3/6(\hbar\bar{\omega})^3$ for $E \gg \hbar\bar{\omega}$, so the density of states is $g(E) = E^2/2(\hbar\bar{\omega})^3$. At and below the transition the chemical potential has reached the ground-state energy, and the number of atoms the excited states can hold is

$$N_{\mathrm{ex}} = \int_0^\infty \frac{g(E)\,\mathrm{d}E}{\mathrm{e}^{E/k_BT} - 1} = \frac{1}{2}\left(\frac{k_BT}{\hbar\bar{\omega}}\right)^3 \int_0^\infty \frac{x^2\,\mathrm{d}x}{\mathrm{e}^x - 1} = \zeta(3)\left(\frac{k_BT}{\hbar\bar{\omega}}\right)^3, \tag{121.3}$$

using $\int_0^\infty x^2(\mathrm{e}^x - 1)^{-1}\mathrm{d}x = 2\zeta(3)$. The right-hand side of Equation (121.3) is finite and depends only on the temperature: the excited states *saturate*. Any atoms beyond that number have nowhere to go but the ground state, which is the whole content of the effect. Setting $N_{\mathrm{ex}} = N$ defines T_c as in Equation (121.2); below T_c the excited population is still given by Equation (121.3), that is $N_{\mathrm{ex}} = N(T/T_c)^3$, and the remainder $N_0 = N - N_{\mathrm{ex}}$ gives the condensate fraction. Note that the exponent is 3 for the harmonic trap, not the 3/2 of the homogeneous gas; the density of states, not the statistics, is what differs. □

121.4.3 Collective excitations

[Reserved: the low-lying shape oscillations of the trapped condensate, measured to the percent level and compared with the hydrodynamic predictions of the Gross–Pitaevskii equation [1924]; the frequency ratios as a parameter-free test, since they depend on the trap geometry alone; the damping rates and their temperature dependence as the first quantitative probe of the condensate–thermal-cloud coupling.]

121.4.4 Interference of two condensates

[Reserved: two independently prepared sodium condensates, released and overlapped, producing high-contrast straight fringes of period about 15 µm *[1934]; the fringes as the direct evidence of long-range phase coherence, and the subtle point that the relative phase is established by the measurement rather than pre-existing; the matter-wave interpretation continuous with Chapter 71 and Chapter 67; the output coupler that turned the condensate into a coherent atom beam [1940].]*

Phenomenon 121.4 (Long-range phase coherence)**.** Two condensates prepared independently in separate wells of one trap, then released and allowed to overlap, produce high-contrast straight interference fringes of period about 15 µm [1934]. The fringes are matter-wave interference on a macroscopic scale: the phase of the condensate is well defined across the whole cloud, over distances some five orders of magnitude larger than the interparticle spacing. The subtlety the data also establish is that the two clouds never shared a phase — the relative phase is established by the act of detection, and is random from shot to shot while the fringe contrast is not.

Derivation pending #225

Interference of two overlapping expanding condensates: the fringe spacing set by the relative momentum of the two sources, and the emergence of a definite relative phase from repeated measurement on a state of fixed total atom number, in which no relative phase exists before the first detection

121.5 Interpretation

121.5.1 The order parameter and the Gross–Pitaevskii equation

[Reserved: the condensate wavefunction $\psi(\boldsymbol{r},t)=\sqrt{n_0}\,\mathrm{e}^{\mathrm{i}\theta}$ as the order parameter of a broken U(1) *symmetry, and the nonlinear Schrödinger equation governing it, derived independently for the vortex problem [1208, 1217]; the coupling constant $g=4\pi\hbar^2 a/m$ fixed by the measured s-wave scattering length; the Thomas–Fermi profile and the healing length $\xi=(8\pi n a)^{-1/2}$, both confirmed by the expansion data [1970].]*

121.5.2 Bogoliubov excitations and superfluidity

[Reserved: Bogoliubov's diagonalization of the weakly interacting Bose gas [898], giving the excitation spectrum $\varepsilon(k)=\sqrt{(\hbar^2k^2/2m)(\hbar^2k^2/2m+2gn)}$, phonon-like at long wavelength with sound speed $c=\sqrt{gn/m}$; the Landau criterion and the measured critical velocity for a stirred laser beam [1982]; why condensation and superfluidity are distinct properties, related in Chapter 130.]

121.5.3 What was and was not shown

[Reserved: the honest ledger — what the 1995 data establish (a phase transition at the predicted temperature, with the predicted condensate fraction and the predicted anisotropic expansion), what they do not (nothing about the interacting many-body ground state beyond mean field), and which later measurements closed each gap; statistical versus systematic uncertainty in atom number, the dominant error throughout; the relation to the general theory of phase transitions in Chapter 123.]

121.6 Repetitions, extensions and precision

121.6.1 Other species, and hydrogen

[Reserved: condensation of atomic hydrogen, the species the programme began with, reached three years after the alkalis and with 10^9 atoms [1953]; the subsequent extension to metastable helium, chromium, and the lanthanides; two-photon spectroscopy of the hydrogen condensate as the link to Chapter 90; the present status of species and atom numbers, tabulated with sources.]

121.6.2 Vortices and quantized circulation

[Reserved: the first vortex, imprinted by a coherent two-component coupling and imaged interferometrically [1979]; vortex nucleation by mechanical stirring above a critical rotation frequency [1998]; the Abrikosov lattice of up to 130 vortices observed in a rotating sodium condensate [2006]; the circulation quantum h/m measured directly, and the parallel with flux quantization in Chapter 130.]

Phenomenon 121.5 (Quantized circulation and the vortex lattice)**.** A condensate does not rotate as a fluid body. Set into rotation it remains at rest until a critical angular frequency is exceeded, and then admits angular momentum only in the form of discrete vortex lines, each carrying one quantum of circulation h/m and a density node at its core [1979, 1998]. Above threshold the lines multiply and arrange themselves in a regular triangular array, up to about 130 of them counted in one rotating sodium condensate [2006]. The array is the direct image of a quantity that classical hydrodynamics allows to take any value whatever.

Derivation. The condensate is described by a single complex field $\psi = \sqrt{n_0}\,\mathrm{e}^{\mathrm{i}\theta}$, and the current it carries identifies the superfluid velocity as $\boldsymbol{v} = (\hbar/m)\nabla\theta$. Let C be any closed contour along which ψ is non-zero. Since ψ is a single-valued function of position, θ can change round C only by an integer multiple of 2π, and therefore

$$\oint_C \boldsymbol{v}\cdot \mathrm{d}\boldsymbol{l} = \frac{\hbar}{m}\oint_C \nabla\theta\cdot \mathrm{d}\boldsymbol{l} = \frac{\hbar}{m}\,2\pi n = n\,\frac{h}{m}\,, \qquad n\in\mathbb{Z}\,. \tag{121.4}$$

The circulation is thus quantized in units of h/m, with a value that depends on nothing — not the contour, not the density, not the strength of the interaction — but the integer n. Two consequences follow at once. Since the flow is irrotational wherever $\psi \neq 0$, non-zero circulation requires ψ to vanish somewhere inside C: a vortex has a core. And since n cannot vary continuously, a rotating condensate cannot take up angular momentum smoothly and must instead nucleate whole vortices one at a time above a threshold rotation rate, which is what the observations show. □

121.6.3 Optical lattices

[Reserved: the condensate loaded into a standing-wave potential as a defect-free realization of the lattice models of Chapter 125 and Chapter 126; the observed superfluid-to-Mott-insulator transition, a quantum phase transition driven by the ratio of tunnelling to on-site repulsion [2029]; the loss and revival of interference fringes as its order parameter; the review of the field [2118].]

Phenomenon 121.6 (A transition driven by a ratio, not a temperature)**.** A condensate loaded into a three-dimensional optical standing wave loses its interference pattern abruptly as the lattice depth is increased, and recovers it on lowering the depth again. The loss is reversible, occurs at a definite lattice depth, and is not caused by heating: it marks a transition from a superfluid, in which the atoms are delocalized and the phase is shared, to an insulating state with a fixed integer number of atoms per lattice site and a gap for adding one more [2029]. The control parameter is the ratio of the tunnelling amplitude between neighbouring sites to the energy cost of double occupancy, a purely quantum-mechanical competition that survives at zero temperature.

Derivation pending #226

The Bose–Hubbard description of atoms in a deep optical lattice, the tunnelling and on-site interaction parameters expressed through the lattice depth and the scattering length, and the mean-field estimate of the ratio at which the compressible superfluid gives way to the gapped, integer-filled insulator

121.6.4 Degenerate Fermi gases and the BEC–BCS crossover

[Reserved: the fermionic counterpart — onset of Fermi degeneracy in trapped potassium-40 [1971]; molecular condensates formed from fermion pairs on a Feshbach resonance [2051]; condensation of fermionic atom pairs on the BCS side of the resonance [2065]; vortex lattices as the unambiguous proof of superfluidity in the strongly interacting regime [2087]; the crossover as a controlled interpolation between Bose condensation and BCS pairing (Chapter 130).]

121.6.5 Recognition

[Reserved: the 1997 award for laser cooling and trapping, with its three Nobel lectures as authoritative first-hand accounts of the apparatus [1949, 1951, 1959]; the 2001 award for the

condensates themselves [2025, 2030]; a note on what the prize citations record about priority among the JILA, MIT and Rice groups, and on the hydrogen programme that supplied the evaporation technique without reaching the transition first.]

Chapter 122

Quantum Optics and the Photon

Light is the cleanest quantum-statistical laboratory there is. A mode of the electromagnetic field is exactly a harmonic oscillator (Chapter 28), its excitations are bosons (Chapter 120), and detectors count them one at a time; so the statistical questions that are awkward to pose for a gas of atoms — what is the distribution of occupation numbers, what are the correlations between successive detections, what states have no classical description at all — can here be asked and answered with photodetectors and coincidence counters. This chapter takes photon statistics, coherence, antibunching, squeezing and cavity electrodynamics in that order, and in each case names the measurement that settled the matter. Its running theme is the one question that took sixty years to close: which optical phenomena actually require the field to be quantized, and which are reproduced by a classical wave falling on quantized matter.

It sits deliberately inside the statistical part rather than in Part IX: the objects of study are not single-atom amplitudes but the correlation functions of a many-boson field, and the Bose statistics of Chapter 120 is what makes photons bunch. The field quantization it uses is set up in Chapter 64 and treated dynamically in Chapter 100; the entanglement of photon pairs is the material of Chapter 84 and Chapter 89, and the coherence measurements here are the optical counterpart of the atomic ones in Chapter 121. Standard monographs are [1904, 1996].

Derivation pending #227

Quantum Optics and the Photon: all derivations of this chapter are pending.

122.1 The quantized radiation field

122.1.1 Modes, Fock states and the vacuum

[Reserved: Dirac's quantization of the free field as a set of independent oscillators, and the first derivation of the emission and absorption rates from it [572]; annihilation and creation operators with $\left[a, a^\dagger\right] = 1$*, number states* $|n\rangle$*, and the vacuum energy* $\frac{1}{2}\hbar\omega$ *per mode; the quadrature operators and their commutator as the origin of every uncertainty statement in this chapter; the field-theoretic setting of Chapter 64.]*

122.1.2 Einstein A and B coefficients

[Reserved: Einstein's statistical argument that detailed balance between matter and blackbody radiation requires stimulated emission in addition to absorption and spontaneous emission, with $A/B = 8\pi h\nu^3/c^3$ *[446]; the momentum transfer* $h\nu/c$ *in the same paper, later the*

basis of laser cooling (Chapter 121); the relation to the Planck spectrum of Chapter 68; why stimulated emission makes the laser of Section 122.7 possible.]

122.1.3 Is the photon necessary?

[Reserved: the honest accounting — the photoelectric effect (Chapter 69) and blackbody spectrum admit semiclassical explanations with quantized matter and a classical field, so neither proves field quantization; the experiments that do: the photoelectric coincidence test that violates a classical inequality [1521], the beam-splitter anticorrelation with a single-photon input [1774], and the antibunching of Section 122.4; Compton scattering as the momentum-space argument.]

122.2 Photon statistics

122.2.1 Photodetection and photocount distributions

[Reserved: the photodetection formalism and the normally ordered counting formula [1256]; the Poissonian distribution $P(n) = \mathrm{e}^{-\bar{n}}\bar{n}^n/n!$ for a stable classical wave against the Bose–Einstein distribution $P(n) = \bar{n}^n/(1+\bar{n})^{n+1}$ for a single thermal mode, derived in Chapter 120; the measurement that exhibited both distributions from one apparatus by driving a laser above and below threshold [1302]; dead time and quantum efficiency as the systematic limits.]

122.2.2 Poissonian, super- and sub-Poissonian light

[Reserved: the variance of the photon number as a classifier; the Mandel parameter $Q = (\langle(\Delta n)^2\rangle - \bar{n})/\bar{n}$, negative only for states with no positive-definite classical distribution [1904]; the first observation of sub-Poissonian light, in the fluorescence of a single atom [1728]; photon bunching and antibunching as the temporal statement of the same fact.]

122.2.3 The Hanbury Brown–Twiss experiment

[Reserved: intensity interferometry as a way of measuring stellar angular diameters with baselines immune to atmospheric phase noise, first demonstrated at radio wavelengths [1031]; the laboratory experiment with a mercury arc, showing a positive correlation between the currents of two photodetectors on the two arms of a beam splitter [1083]; the measurement of the angular diameter of Sirius, 3.1×10^{-8} radians — about 6.3(5) milliarcseconds [1086]; the objection that photons could not correlate at all, and Purcell's resolution in terms of Bose statistics [1095], which makes this the founding measurement of the chapter.]

122.3 Coherence

122.3.1 Correlation functions and the Glauber hierarchy

[Reserved: Glauber's normally ordered correlation functions $G^{(n)}$ and the definition of coherence to all orders, replacing the first-order (interferometric) notion inherited from classical optics [1256]; the normalized second-order function $g^{(2)}(\tau)$, with $g^{(2)}(0) = 2$ for thermal light, 1 for a coherent state and 0 for a single photon; the classical inequalities $g^{(2)}(0) \geq 1$ and $g^{(2)}(0) \geq g^{(2)}(\tau)$ whose violation is the operational definition of nonclassical light.]

122.3.2 Coherent states

[Reserved: the eigenstates of the annihilation operator, $a\,|\alpha\rangle = \alpha\,|\alpha\rangle$, their Poissonian number distribution, minimum-uncertainty quadratures and non-orthogonal overcompleteness [1255]; why they are the quantum state closest to a classical field and the state a laser well above threshold actually produces; the displacement operator and the coherent state as a displaced vacuum, connecting to the harmonic oscillator of Chapter 78.]

122.3.3 The optical equivalence theorem

[Reserved: the diagonal coherent-state representation of an arbitrary density operator, introduced independently by Sudarshan [1267] and Glauber [1255]; the theorem that every normally ordered expectation is a classical average over the weight $P(\alpha)$; the precise sense in which a state is nonclassical — P fails to be a probability density — and why that criterion, not "smallness" of the field, is the right one; the standing dispute over naming, recorded honestly.]

122.3.4 Nonclassical light

[Reserved: the catalogue of states with no classical analogue and the signature by which each is recognized — number states (sub-Poissonian statistics), antibunched fluorescence (Section 122.4), squeezed states (Section 122.5) and entangled photon pairs (Chapter 84); quantum state tomography by balanced homodyne detection as the modern way to exhibit a negative quasiprobability; the reconstruction of Fock states and their Wigner functions [2017].]

122.4 Antibunching and single photons

122.4.1 Resonance fluorescence and photon antibunching

[Reserved: the prediction that light scattered by a single atom must show $g^{(2)}(0) < g^{(2)}(\tau)$, because the atom cannot emit again until it has been re-excited [1574]; the measurement on a dilute sodium beam that observed it [1598], the first phenomenon with no classical wave description whatever; the Mollow triplet and Rabi oscillations visible in the correlation function; residual multi-atom events as the systematic that had to be extrapolated away.]

122.4.2 Single-photon sources

[Reserved: the progression from attenuated lasers (which remain Poissonian and are not single-photon sources) to true antibunched emitters — single molecules at room temperature [1997], nitrogen-vacancy centres in diamond [1995], semiconductor quantum dots in a turnstile device [2000], and deterministic emission from a single atom in a cavity [2032]; the figures of merit — purity $g^{(2)}(0)$, indistinguishability, and collection efficiency — with their currently measured values.]

122.4.3 Two-photon interference

[Reserved: the Hong–Ou–Mandel effect, in which two indistinguishable photons entering opposite ports of a balanced beam splitter always leave together, producing a coincidence dip whose width measures their wavepacket overlap to subpicosecond precision [1794]; the dip as an interference of amplitudes, not of intensities, and its use as the standard test of photon indistinguishability; the connection to boson exchange symmetry in Chapter 83.]

122.5 Squeezed light

122.5.1 Quadratures and the uncertainty ellipse

[Reserved: the quadratures X_1, X_2 with $\langle \Delta X_1^2 \rangle \langle \Delta X_2^2 \rangle \geq 1/16$; squeezing as redistribution of vacuum fluctuations between them at fixed product; the review that set the programme [1730]; Caves's demonstration that the shot-noise limit of an interferometer is set by vacuum fluctuations entering the unused port, and can be beaten by injecting squeezed vacuum there [1667] — the theoretical origin of Section 122.5.3.]

122.5.2 Generation and detection

[Reserved: the first observation of squeezed light, by four-wave mixing in a sodium-vapour cavity, with a noise reduction of about 7 % below vacuum [1763]; parametric down-conversion in an optical parametric oscillator, which reached more than 60 % and remains the standard method [1785]; balanced homodyne detection with a local oscillator as the phase-sensitive measurement; loss as the enemy, since every inefficiency mixes vacuum back in.]

122.5.3 Squeezed light in gravitational-wave detectors

[Reserved: the application that made squeezing an engineering tool — injection of squeezed vacuum into the dark port of the kilometre-scale interferometers of Advanced LIGO [2243], first demonstrated in LIGO at about 2 decibels of shot-noise reduction [2204] and now routine at roughly 3 decibels across the observing band [2342]; the resulting increase in detection rate; radiation-pressure back-action and frequency-dependent squeezing as the response; links to Chapter 47.]

122.6 Cavity quantum electrodynamics

122.6.1 The Jaynes–Cummings model

[Reserved: one two-level atom coupled to one field mode under the rotating-wave approximation, and the comparison with the semiclassical theory it was written to test [1258]; the dressed-state ladder with splitting $2g\sqrt{n+1}$; collapse and revival of the Rabi oscillation as a signature that the field is quantized, observed in the one-atom maser [1797] and resolved into individual Fock components in the microwave regime [1917].]

122.6.2 Modified spontaneous emission

[Reserved: spontaneous emission as a property of the mode structure rather than of the atom alone; Purcell's enhancement factor $F = 3Q\lambda^3/4\pi^2 V$ for an atom in a resonant cavity [893]; the observed enhancement for a Rydberg atom between mirrors [1719] and the complementary inhibition when the cavity is detuned [1755]; the practical consequence for the single-photon sources of Section 122.4.2.]

122.6.3 Strong coupling and vacuum Rabi splitting

[Reserved: the strong-coupling condition $g > \kappa, \gamma$ in which a single quantum is exchanged coherently before it is lost; the observation of normal-mode splitting for one atom in an optical cavity [1859], the optical counterpart of the microwave work; the extension to solid-state systems; why the splitting scales as $\sqrt{N}$ with atom number, and what a single-atom measurement therefore has to control.]

122.6.4 Photon counting without absorption

[Reserved: quantum non-demolition measurement of photon number by the phase shift imprinted on a Rydberg atom crossing the cavity; the progressive collapse of a coherent field onto a Fock state, observed photon by photon, and the subsequent quantum jumps as photons decay [2107]; the same apparatus used to watch a mesoscopic superposition decohere at a rate proportional to its size [1916], an experimental entry point to Chapter 87; the first-hand account [2220].]

122.7 The laser

122.7.1 Stimulated emission, inversion and the maser

[Reserved: population inversion as the condition for net gain, and why it is forbidden in thermal equilibrium (Chapter 118); the ammonia beam maser, the first device to oscillate on stimulated emission [1039]; three- and four-level pumping schemes; the inverted medium as a negative-temperature system, and the care that statement requires.]

122.7.2 The optical maser and its realization

[Reserved: the proposal to extend maser action to optical frequencies using a Fabry–Pérot resonator to select modes, with the threshold condition and the predicted linewidth [1160]; the first working laser, a flash-pumped ruby rod emitting at 694.3 nm *[1186]; the semiclassical theory of the laser and its mode competition [1287]; the helium–neon and semiconductor lasers that made the technique general.]*

122.7.3 Laser linewidth and coherence

[Reserved: the Schawlow–Townes limit $\Delta\nu = \pi h\nu(\Delta\nu_c)^2/P$*, spontaneous emission into the lasing mode as the irreducible source of phase diffusion [1160]; the output as a coherent state with a slowly diffusing phase, and its measured* $g^{(2)}(0) = 1$ *[1302]; the laser transition as a nonequilibrium phase transition with the field amplitude as order parameter (Chapter 123); modern stabilized lasers and the frequency comb, whose metrology belongs to Chapter 90.]*

122.8 Zewail: femtosecond probing of the transition state (1987)

The laser of Section 122.7 enters here not as the object of study but as a shutter. Mode locking compresses its output into packets shorter than one vibration of a chemical bond, and two such packets — one to start a reaction, one to photograph it — resolve the motion of the nuclei themselves. What that buys is the configuration a reacting molecule occupies on its way from reactants to products: the activated complex of Eyring's rate theory [754], which for half a century had been an inference drawn from measured rate constants and never an observation, because it endures only as long as it takes two atoms to move apart by about their own diameter. Femtochemistry is the demonstration that this interval is long enough to be timed [1790, 1813].

The section sits in this chapter as the ultrafast limit of the material around it. The pulse doing the timing is a coherent state (Section 122.3.2) whose duration and spectral width are conjugate through the Fourier relation of Chapter 17, so a shutter short enough to resolve nuclear motion is necessarily broad enough to span the vibrational structure it interrogates; that structure is the molecular spectroscopy of Chapter 88.

122.8.1 Apparatus

A colliding-pulse mode-locked ring dye laser [1669], the source that first delivered pulses shorter than 100 fs, amplified and frequency-converted into two synchronized beams: an ultraviolet *pump* lying inside the dissociative absorption continuum of the parent molecule, and a tunable *probe* resonant with an electronic transition of one of the fragments. The two travel separate arms of a Michelson-type splitter, the probe arm carrying a retroreflector on a computer-driven translation stage. Sample: a collision-free beam of the parent molecule, so that what is timed is one molecule's internal motion and not an encounter with a neighbour. Detection: laser-induced fluorescence excited by the probe, collected by a photomultiplier and gated so that only light following the probe is counted.

The translation stage is the clock, and its arithmetic is why the technique is possible at all. Light travels 0.3 µm in 1 fs, so a delay step of 10 fs is 1.5 µm of stage travel in a double-pass arm — an ordinary mechanical tolerance. No electronic gate resolves 100 fs; a screw thread does.

122.8.2 Procedure

The pump promotes the molecule to a dissociative surface and thereby fixes the zero of time, to within the pulse duration. The probe arrives a delay τ later and lifts whatever the system has become to a fluorescing state; the fluorescence yield, recorded against τ, is the signal. Two probe settings are used, and they answer different questions. Tuned to a transition of the *free* fragment, the probe counts finished products, and the curve is a rise to a plateau whose half-rise time is the appearance time of those products. Detuned from that transition, so that it is resonant only while the departing fragments still perturb each other's levels, the probe counts molecules caught in transit, and the curve is a transient that rises and falls. The delay is scanned in steps, many shots are averaged at each step, and the pump–probe cross-correlation, measured in a nonlinear crystal, fixes both the time resolution and the origin.

[Reserved: the systematic checks — pump and probe intensity dependence, confirming one photon of each; beam density low enough to exclude collisions inside the observation window; calibration of zero delay and of the instrument response function; the deconvolution by which a transient narrower than the cross-correlation is recovered.]

122.8.3 Observations and data

Phenomenon 122.1 (A chemical bond carries its own femtosecond clock)**.** The vibrational fundamentals of molecules, read off infrared absorption and Raman scattering, occupy a band of wavenumbers running from about 100/cm for the bending of heavy atoms to about 4400/cm for the stretch of the hydrogen molecule [961]. The period of the corresponding nuclear motion,

$$T = \frac{1}{\nu} = \frac{1}{c\tilde{\nu}}\,, \tag{122.1}$$

therefore lies between about 330 fs and 8 fs. A configuration the nuclei pass through once and do not return to — the transition state of a dissociation — endures for a time of this same order, and is invisible to any probe slower than it.

Derivation. A wavenumber is a frequency divided by the speed of light, so $\nu = c\tilde{\nu}$ and the period is $T = 1/(c\tilde{\nu})$, which is Equation (122.1). A typical stretching fundamental at 1000/cm, that is 1×10^5/m, gives a frequency of 3.0×10^{13} Hz and a period of 33 fs; the two ends of the observed band give 330 fs and about 8 fs. A second and independent estimate uses only kinematics: the fragments of a dissociation stop interacting once they have separated by a distance of order the bond length itself, about 0.1 nm, and they separate

at the recoil speed set by the energy released, of order 1 km/s, so the transit time d/v is of order 100 fs. Both routes give the same order of magnitude, and the order is what matters: a probe of duration Δt cannot resolve structure in time shorter than Δt, so an apparatus that is to watch nuclei move must carry a shutter of a few tens of femtoseconds. Nothing electronic is that fast. The shutter therefore has to be the light pulse itself, and the delay has to be generated as a difference of optical path. □

Phenomenon 122.2 (The transition state lasts long enough to be timed)**.** Photodissociation of a triatomic — the worked case is ICN → I + CN — started by an ultraviolet pump and interrogated by a delayed probe yields two distinguishable signals. With the probe tuned to a transition of the *free* CN fragment, the fluorescence rises from zero and levels off: the products appear after a delay rather than at once. With the probe detuned from that transition, so that it is resonant only while the departing fragments still perturb each other's levels, the signal instead rises and falls again — a transient that exists only during the passage through the intermediate configuration. Both the delay and the width of the transient are of order 100 fs [1790, 1813].

Derivation pending #228

The shape of the pump–probe signal for two fragments separating on a repulsive potential energy surface: the classical clocking relation that maps probe detuning onto internuclear separation, the wave-packet computation of the fluorescence yield as a function of delay, and the extraction of the free-fragment appearance time from the saturating on-resonance curve

Phenomenon 122.3 (A dissociating molecule can vibrate before it comes apart)**.** When the surface reached by the pump is not simply repulsive but is held together at large separation by an avoided crossing with a second surface, the same measurement returns a train of transients instead of one. In sodium iodide, whose covalent and ionic curves cross at several times the equilibrium bond length, the nuclear wave packet prepared by the pump oscillates in the resulting well and returns to the same internuclear separation once per vibrational period, a fixed fraction of it escaping to free atoms at each pass through the crossing. The probe accordingly records an oscillation whose period is that of the trapped motion and whose envelope decays, while the signal from free sodium rises in steps synchronized with it [1812].

Derivation pending #229

The two-state model of alkali-halide dissociation: the diabatic covalent and ionic curves and the adiabatic well their crossing produces, the Landau–Zener probability of remaining on the adiabatic branch at each pass, and the resulting periodic recurrences with a geometrically decaying envelope and a step-wise product signal

122.8.4 Interpretation

Rate theory describes a reaction through an activated complex in equilibrium with the reactants and reports one number, the rate constant, which is an average over an enormous number of uncorrelated barrier crossings [754]. The pump–probe measurement removes that average: preparing every molecule in the sample at a common instant makes the subsequent evolution of the ensemble a function of time, and it is that evolution, not its integral, which is recorded. Three consequences follow. The transition state moves from the class of inferred quantities to the class of observed ones, since it now has a duration and the duration is what

appears on the chart. The reaction coordinate is followed rather than postulated, because the detuning of the probe selects the internuclear separation at which the system is counted. And the assumption on which rate theory rests, that the barrier region is crossed once, becomes testable — in the alkali halide of Phenomenon 122.3 it visibly fails, the system crossing and recrossing many times before it commits.

Two limits should be stated with the result. The measured interval is a transit time, not the lifetime of a stationary state, so it has no meaning independent of the observable used to define it; and the zero of time and the resolution are both fixed by the pump–probe cross-correlation, so every quoted duration is only as good as the characterization of that correlation.

[Reserved: the extension of the method to bimolecular reactions initiated inside a van der Waals complex, to the condensed phase where the solvent turns the problem into one of Chapter 87, and to ultrafast electron and X-ray diffraction, which replace the spectroscopic probe by one that reads geometry directly; coherent control as the inverse problem, in which the pulse is shaped to steer the outcome rather than to observe it.]

122.8.5 Primary references

[1790, 1812, 1813]. The light source that made the timescale accessible is [1669]; the transition-state concept under test is [754]; Zewail's own survey of the field, covering both measurements above and much besides, is [2004].

122.9 Which-path information and the quantum eraser

122.9.1 Complementarity and the duality relation

[Reserved: the quantitative duality relation $D^2 + V^2 \leq 1$ between which-path distinguishability and fringe visibility [1920], replacing the qualitative slogan; Wheeler's delayed-choice configuration realized with a single-photon source and a randomly switched output beam splitter [2108]; why momentum transfer is not the mechanism, and what remains of the uncertainty-principle account.]

122.9.2 The quantum eraser

[Reserved: the proposal to mark the path with an internal atomic state and then erase the mark, restoring interference in coincidence [1702]; the delayed-choice realization with down-converted photon pairs, in which the decision to erase is taken after the signal photon has been detected [1994]; the essential and often-omitted point that no fringes appear in the unconditioned signal, so no signalling is possible; the interpretive questions deferred to Chapter 85.]

Chapter 123

Phase Transitions and Critical Phenomena

A phase transition is a singularity in a thermodynamic potential, and therefore something the finite-volume statistical mechanics of Chapter 118 cannot produce: partition functions of finitely many degrees of freedom are analytic, so every transition is a statement about the thermodynamic limit. That is the organizing fact of this chapter. It begins with phase diagrams, latent heats and the liquid–gas critical point, whose discovery [174] and first theory [187] set the vocabulary; it introduces the Ising paradigm [525] and its exact two-dimensional solution [875], the one non-trivial case in which the singularity can be watched forming; and it then treats order parameters, critical exponents and universality — the discovery that a fluid near its critical point and a uniaxial magnet near its Curie point obey the same power laws with the same exponents, so that microscopic detail is irrelevant to the singular behaviour. The measured exponents that vindicate that picture are collected here, against the renormalization-group explanation developed in Chapter 108.

The chapter sits after the equilibrium ensembles of Chapter 118 and the quantum statistics of Chapter 120, both of which supply the free energies it differentiates, and before the specific ordered phases of the rest of the part: the magnetic transitions of Chapter 129, the superfluid and superconducting transitions of Chapter 130, and the condensation of Chapter 121. Its last section treats liquid crystals, whose mesophases are the cleanest laboratory realization of an orientational order parameter. Standard monographs are [1456, 1855].

Derivation pending #230

Phase Transitions and Critical Phenomena: all derivations of this chapter are pending.

123.1 Phases and phase diagrams

123.1.1 Coexistence, triple and critical points

[Reserved: the phase diagram in the pressure–temperature plane, its coexistence curves, triple point and critical point; Gibbs's phase rule $f = c - p + 2$ derived from equality of the chemical potentials [193]; the triple point of water as a former defining fixture of the kelvin, now superseded (Chapter 2); metastability, superheating and nucleation as the reason a first-order transition can be delayed but not avoided.]

123.1.2 Latent heat and the Clausius–Clapeyron relation

[Reserved: latent heat as the discontinuity in entropy across a first-order line, and the slope relation $\mathrm{d}P/\mathrm{d}T = L/(T\,\Delta v)$ [95], whose thermodynamic derivation belongs to Chapter 54; measured latent heats of fusion and vaporization in SI, with the anomalous negative slope of the ice–water line and its consequences; the vanishing of L at the critical point as the definition of second order.]

Phenomenon 123.1 (Latent heat and the slope of a coexistence line)**.** Along a first-order phase boundary two phases coexist at one pressure and one temperature, and converting a mole of the first into the second absorbs a finite latent heat L at constant temperature while the molar volume jumps discontinuously by Δv. The boundary in the pressure–temperature plane is then not free: its slope is fixed by those two measured discontinuities,

$$\frac{\mathrm{d}P}{\mathrm{d}T} = \frac{L}{T\,\Delta v}\,, \tag{123.1}$$

a relation of Clapeyron [95] that has held wherever it has been tested. Its most conspicuous instance is an anomaly: water contracts on melting, so $\Delta v < 0$ for the ice–water line, whose slope is therefore negative — pressure lowers the melting point of ice, which is true of very few substances.

Derivation. Two phases in equilibrium at (T, P) have equal molar Gibbs functions, $\mu_1(T,P) = \mu_2(T,P)$ [193]. Displace along the coexistence curve by $(\mathrm{d}T, \mathrm{d}P)$; the equality must persist, so $\mathrm{d}\mu_1 = \mathrm{d}\mu_2$. The Gibbs–Duhem relation for each phase gives $\mathrm{d}\mu = -s\,\mathrm{d}T + v\,\mathrm{d}P$ with s and v the molar entropy and volume, whence

$$-s_1\mathrm{d}T + v_1\mathrm{d}P = -s_2\mathrm{d}T + v_2\mathrm{d}P \quad\Longrightarrow\quad \frac{\mathrm{d}P}{\mathrm{d}T} = \frac{s_2 - s_1}{v_2 - v_1} = \frac{\Delta s}{\Delta v}\,. \tag{123.2}$$

The conversion is reversible and isothermal, so the heat absorbed is $L = T\Delta s$; substituting gives Equation (123.1). Nothing in the argument uses a model of either phase, which is exactly what makes Equation (123.1) a test rather than a fit: L, Δv and the slope are three independently measurable quantities constrained by one identity. The sign of the slope is the sign of Δv, since $L > 0$ on melting and on boiling; the ice anomaly is therefore a statement about the density of ice and nothing else. □

123.1.3 The Ehrenfest classification and its limits

[Reserved: Ehrenfest's ordering of transitions by the lowest discontinuous derivative of the free energy [719]; why the scheme fails in practice — the specific heat at the helium lambda point and at the Curie point diverges rather than jumping, so there is no "second derivative discontinuity" to classify; the modern two-way division into first-order (latent heat, coexistence) and continuous (diverging correlation length) transitions, adopted for the rest of the chapter.]

123.2 The liquid–gas transition

123.2.1 Andrews and the critical point

[Reserved: Andrews's isotherms of carbon dioxide, showing the coexistence region shrinking to a point at $T_c = 304.1\,\mathrm{K}$ and $P_c = 7.38\,\mathrm{MPa}$, above which liquid and gas are not distinguishable [174]; the continuity of state that follows — one can pass from liquid to vapour without ever crossing a phase boundary; the flat critical isotherm and the diverging compressibility as the first measured critical exponents.]

Phenomenon 123.2 (The critical point and the continuity of state)**.** Compressing a fluid along isotherms of rising temperature, the flat portion of the isotherm — the interval over which liquid and vapour coexist, the volume changes and the pressure does not — grows shorter and finally closes at a single point. Andrews located that point for carbon dioxide at $T_c = 304.1\,\mathrm{K}$ and $P_c = 7.38\,\mathrm{MPa}$ [174]. Above T_c no compression produces a meniscus, and one may pass from a dense liquid to a dilute vapour along a path that circles the critical point without ever crossing a phase boundary: liquid and gas are not two kinds of matter but two regions of one surface. At the critical point the isotherm is flat, so the isothermal compressibility diverges, and the fluid becomes strongly scattering (Section 123.2.3).

Derivation. That such a point must exist in any equation of state combining a short-range repulsion with a long-range attraction is van der Waals' result [187]. Take

$$P = \frac{RT}{v - b} - \frac{a}{v^2}\,, \tag{123.3}$$

in which b is the excluded molar volume and a measures the mean attraction. A critical point is an inflection of the isotherm with horizontal tangent, so

$$\left(\frac{\partial P}{\partial v}\right)_T = -\frac{RT}{(v-b)^2} + \frac{2a}{v^3} = 0\,, \qquad \left(\frac{\partial^2 P}{\partial v^2}\right)_T = \frac{2RT}{(v-b)^3} - \frac{6a}{v^4} = 0\,. \tag{123.4}$$

Dividing the first of Equation (123.4) by the second eliminates RT and gives $v - b = \tfrac{2}{3}v$, hence $v_c = 3b$; substituting back yields

$$v_c = 3b\,, \qquad T_c = \frac{8a}{27Rb}\,, \qquad P_c = \frac{a}{27b^2}\,. \tag{123.5}$$

The critical point exists for every $a > 0$, $b > 0$, and the divergence of the compressibility there is immediate from the first of Equation (123.4). Eliminating a and b from Equation (123.5) gives the dimensionless combination $P_c v_c / RT_c = 3/8$ for every fluid, and rewriting Equation (123.3) in the reduced variables P/P_c, v/v_c, T/T_c removes a and b altogether: this is the law of corresponding states, the first statement of universality in physics. Two caveats belong with the result and are taken up later in this chapter. Below T_c, Equation (123.3) produces a loop along which $(\partial P/\partial v)_T > 0$, which is mechanically unstable and must be replaced by the horizontal tie line fixed by Maxwell's equal-area rule [191]. And the exponents that Equation (123.4) implies near the critical point are the mean-field ones, which measurement contradicts (Section 123.5.2). □

123.2.2 The van der Waals equation and the Maxwell construction

[Reserved: the equation $(P + a/v^2)(v - b) = RT$ derived from excluded volume and a mean attraction [187], the first theory with a critical point built in; the unphysical loop below T_c and Maxwell's equal-area rule that replaces it with the coexistence tie line [191]; the law of corresponding states in reduced variables; the mean-field exponents $\beta = 1/2$, $\gamma = 1$, $\delta = 3$ it predicts, and the measurements that contradict them (Section 123.5.2).]

123.2.3 Critical opalescence

[Reserved: the milky scattering of a fluid at its critical point, explained as light scattering from density fluctuations whose size grows with the correlation length [361]; the Ornstein–Zernike analysis of the pair correlation function and its Lorentzian structure factor [419]; opalescence as the first direct evidence that a diverging correlation length, not a diverging response alone, is what characterizes criticality.]

Phenomenon 123.3 (Critical opalescence)**.** A transparent fluid held within a fraction of a kelvin of its critical point turns milky white and scatters light so strongly that a centimetre of it is opaque; on warming or cooling by a degree the turbidity vanishes again. The scattered intensity is strongly peaked in the forward direction and its angular width narrows as the critical point is approached. The effect is not a mist of droplets — there is one phase present — but scattering from density fluctuations whose spatial extent has grown to the wavelength of visible light [361, 419]. It is the first direct evidence that what diverges at a critical point is a *length*, and that the divergence of the compressibility is a consequence rather than the essence.

Derivation pending #231

The scattered intensity as the Fourier transform of the density–density correlation function; the Ornstein–Zernike form with its Lorentzian structure factor and correlation length; and the fluctuation–response identity that ties the forward scattering to the isothermal compressibility, so that a diverging compressibility and a diverging correlation length are one statement

123.3 The Ising model

123.3.1 Lenz, Ising and the one-dimensional failure

[Reserved: the model of spins on a lattice with nearest-neighbour coupling, proposed by Lenz [468] and solved in one dimension by Ising, who found no transition at any positive temperature and wrongly concluded that none occurs in higher dimensions either [525]; the transfer-matrix solution and the domain-wall (entropy versus energy) argument that explains the one-dimensional result; the honest note that the model's name records its first solver, not its inventor.]

123.3.2 Existence of a transition in two dimensions

[Reserved: Peierls's contour argument, the first proof that the two-dimensional Ising model has spontaneous magnetization below some finite temperature [782]; the counting of domain boundaries that makes the same entropy–energy comparison come out the other way in two dimensions; the general lesson that the lower critical dimension depends on the symmetry of the order parameter, taken up in Section 123.6.1.]

123.3.3 Onsager's exact solution

[Reserved: the exact free energy of the two-dimensional Ising model on a square lattice in zero field, with $\sinh(2J/k_BT_c) = 1$ *and a logarithmically divergent specific heat [875]; the spontaneous magnetization* $m = (1 - \sinh^{-4} 2\beta J)^{1/8}$*, hence* $\beta = 1/8$*, announced by Onsager and first published in full by Yang [1013]; why an exponent of* $1/8$ *rather than* $1/2$ *was the decisive evidence against mean-field theory; the absence of any exact three-dimensional solution.]*

123.3.4 Lattice gas and the Yang–Lee theory

[Reserved: the exact mapping of the Ising magnet onto a lattice gas, which makes the ferromagnetic and liquid–gas transitions the same problem [1004]; the theory of condensation locating the singularity in the accumulation of zeros of the grand partition function in complex fugacity [1014], and — in the companion paper, which is where the result actually stands —

the circle theorem placing those zeros on the unit circle for the ferromagnetic Ising model [1004]; why this is the sharpest available statement that a phase transition exists only in the thermodynamic limit.]

123.4 Mean-field theory and order parameters

123.4.1 The Weiss molecular field

[Reserved: the Curie law $\chi \propto 1/T$ measured across a wide temperature range [264]; Weiss's hypothesis of an internal field proportional to the magnetization, giving the Curie–Weiss law $\chi \propto 1/(T - T_c)$ and a spontaneous moment below T_c [339]; the same approximation for alloy ordering [733]; the self-consistency equation $m = \tanh(T_c m/T)$ and its universality across mean-field models; magnetic instances in Chapter 129.]

123.4.2 Landau's expansion of the free energy

[Reserved: Landau's postulate that the free energy is analytic in the order parameter near T_c and constrained only by symmetry, $f = f_0 + a(T - T_c)m^2 + bm^4$ [795]; the classification of transitions by which terms symmetry permits, with a cubic term forcing first order; the resulting exponents $\alpha = 0$, $\beta = 1/2$, $\gamma = 1$, $\delta = 3$, identical to van der Waals and to Weiss; the gradient term that turns it into Landau–Ginzburg theory, used for superconductors in Chapter 130.]

123.4.3 Symmetry breaking and the order parameter

[Reserved: the order parameter as the quantity that is zero in the symmetric phase and non-zero below the transition, with its symmetry group and number of components as the only data that matter for universality; the catalogue — magnetization ($\mathbb{Z}_2$ or $\mathrm{SO}(3)$), density difference, condensate wavefunction ($\mathrm{U}(1)$), nematic director; spontaneous symmetry breaking as the selection of one of degenerate minima, the classical counterpart of the mechanism in Chapter 104; Goldstone modes for continuous symmetries.]

123.4.4 Where mean field fails

[Reserved: the Ginzburg criterion comparing the fluctuation of the order parameter within a correlation volume to its mean value, and the resulting estimate of the reduced-temperature window in which mean-field theory is wrong [1181]; the upper critical dimension $d_c = 4$ above which mean field is exact; why superconductors have a Ginzburg window too narrow to observe while fluids and magnets do not — the quantitative reason mean field survived so long.]

123.5 Critical exponents, scaling and universality

123.5.1 The exponents and the inequalities they obey

[Reserved: definitions of $\alpha, \beta, \gamma, \delta, \nu, \eta$ in terms of the reduced temperature $t = (T - T_c)/T_c$; the thermodynamic inequality $\alpha + 2\beta + \gamma \geq 2$ [1264] and its companion $\gamma \geq \beta(\delta - 1)$ [1308], proved from convexity alone; the empirical fact that both are satisfied as equalities, which is the clue scaling explains; the review that organized the field [1348].]

Phenomenon 123.4 (The exponent inequalities are satisfied as equalities)**.** Thermodynamics alone, using only the convexity of the free energy, bounds the measured critical exponents by $\alpha + 2\beta + \gamma \geq 2$ [1264] and $\gamma \geq \beta(\delta - 1)$ [1308]. What is observed, in fluids and

in magnets alike and across every universality class measured, is that both hold as *equalities* to within the experimental uncertainties [1348, 1782]. Of the six exponents $\alpha, \beta, \gamma, \delta, \nu, \eta$ only two are independent. That is a fact about nature, not about thermodynamics, and it is the clue from which the scaling picture was read.

Derivation. Widom's hypothesis [1323] is that the singular part of the free energy per unit volume is a generalized homogeneous function of the reduced temperature $t = (T - T_c)/T_c$ and the ordering field h,

$$f_s(t, h) = |t|^{2-\alpha}\, \Phi\!\left(\frac{h}{|t|^{\beta\delta}} \right) , \tag{123.6}$$

with Φ a scaling function finite and non-zero at the origin. Two differentiations extract the exponents. The specific heat is $c \sim -T\partial^2 f_s/\partial T^2 \sim |t|^{-\alpha}$ at $h = 0$, which is what fixes the prefactor in Equation (123.6). The order parameter is $m = -\partial f_s/\partial h \sim |t|^{2-\alpha-\beta\delta}$ at $h = 0$, and identifying this with $|t|^{\beta}$ gives

$$2 - \alpha = \beta + \beta\delta = \beta(1 + \delta)\,. \tag{123.7}$$

The susceptibility is $\chi = -\partial^2 f_s/\partial h^2 \sim |t|^{2-\alpha-2\beta\delta}$, and identifying it with $|t|^{-\gamma}$ gives, using Equation (123.7),

$$\gamma = 2\beta\delta - (2 - \alpha) = 2\beta\delta - \beta(1 + \delta) = \beta(\delta - 1)\,, \tag{123.8}$$

which is the Griffiths relation as an equality. Adding $\alpha + 2\beta$ to Equation (123.8) and using Equation (123.7) once more,

$$\alpha + 2\beta + \gamma = \alpha + 2\beta + \beta\delta - \beta = \alpha + \beta(1 + \delta) = \alpha + (2 - \alpha) = 2\,, \tag{123.9}$$

the Rushbrooke relation as an equality. Both are consequences of the single homogeneity assumption Equation (123.6), which also leaves exactly two free exponents — the scale $2-\alpha$ and the ratio $\beta\delta$ — as observed. The hypothesis itself is not derived here; it is explained by the renormalization group of Chapter 108, in which the homogeneity is the statement that the coarse-graining flow has a fixed point. □

123.5.2 Corresponding states and universality

[Reserved: Guggenheim's collapse of the coexistence curves of eight different fluids onto a single cubic curve with $\beta \approx 1/3$, not the mean-field $1/2$ [879]; the parallel measurement of the same exponent in uniaxial magnets; universality classes labelled by dimensionality and order-parameter symmetry alone; the modern precision values for the three-dimensional Ising and XY classes [2035] and the fluid data [1782].]

Phenomenon 123.5 (Universality)**.** Plotted in reduced variables, the liquid–vapour coexistence curves of eight chemically unrelated substances — among them neon, argon, krypton, xenon, nitrogen, oxygen, carbon monoxide and methane — fall on one and the same curve, and that curve is a cube root rather than the square root of mean-field theory: $\beta \approx 1/3$, not $\beta = 1/2$ [879]. The same exponent, within uncertainty, is measured for the spontaneous magnetization of a uniaxial ferromagnet near its Curie point, a system with nothing microscopically in common with a fluid [1348]. Modern determinations for the three-dimensional Ising class [2035] and for fluids [1782] agree to several decimal places. What survives at a critical point is therefore only the dimensionality of space and the symmetry and number of components of the order parameter; the chemistry drops out entirely.

Derivation pending #232

Universality as the basin of attraction of a fixed point of the coarse-graining flow: that the couplings distinguishing one microscopic system from another are irrelevant in the technical sense, so that the singular behaviour is governed by the fixed point alone; and the accompanying calculation of the exponents, developed in the renormalization-group chapter

123.5.3 Scaling hypotheses

[Reserved: Widom's homogeneity assumption for the singular part of the free energy, from which every exponent relation follows and only two exponents remain independent [1323]; Kadanoff's block-spin construction, which explains the homogeneity by coarse graining and introduces the flow of couplings under a change of scale [1334]; the data collapse of the equation of state onto a single scaling function as the experimental form of the hypothesis; hyperscaling $2-\alpha = d\nu$ and where it fails.]

123.5.4 Correlation functions and the correlation length

[Reserved: the pair correlation $G(r) \sim r^{-(d-2+\eta)}\mathrm{e}^{-r/\xi}$ and the divergence $\xi \sim |t|^{-\nu}$ as the physical content of criticality [419, 1348]; scale invariance at T_c, where ξ is infinite and the system looks the same at every magnification; measurement of ξ and η by neutron and light scattering; the fluctuation–response identity linking G to the susceptibility, an instance of Chapter 124.]

123.5.5 The renormalization group and measured exponents

[Reserved: Wilson's realization that Kadanoff's flow can be made a calculation, with fixed points, relevant and irrelevant operators, and universality as the basin of attraction of a fixed point [1461] — developed in full in Chapter 108; the epsilon expansion about four dimensions and the first controlled exponent calculation [1489]; the sharpest test on record, the specific-heat exponent of the helium lambda transition measured in microgravity as $\alpha = -0.0127(3)$ [2054], against theory at the same precision.]

Phenomenon 123.6 (A critical exponent measured to four decimal places)**.** The specific heat of liquid helium-4 at its lambda transition can be followed to within nanokelvin of T_c only in free fall, because on the ground the hydrostatic pressure head across a sample of any usable height smears the transition temperature. Measured aboard an orbiting laboratory, the singular specific heat yields $\alpha = -0.0127(3)$ [2054]: the exponent is small and *negative*, so the specific heat approaches a finite cusp rather than diverging. This is the most precisely measured critical exponent in physics, and it is a quantitative test of a calculated number rather than a qualitative confirmation of a picture.

Derivation pending #233

The superfluid transition as the three-dimensional XY universality class, and the calculation of its specific-heat exponent to a precision comparable with the measurement, by renormalization-group and high-order perturbative methods; together with the hyperscaling relation that ties the negative sign of the exponent to the correlation-length exponent in three dimensions

123.6 Lower critical dimension and topological order

123.6.1 The Mermin–Wagner–Hohenberg theorem

[Reserved: the proof that a continuous symmetry cannot break spontaneously in one or two dimensions at any positive temperature, because Goldstone fluctuations diverge logarithmically [1337], extended to superfluid and crystalline order [1350]; the contrast with the discrete Ising symmetry, which does order in two dimensions (Section 123.3.2); why the theorem does not forbid a transition of a different kind, which is Section 123.6.2.]

123.6.2 The Berezinskii–Kosterlitz–Thouless transition

[Reserved: the two-dimensional XY model, whose low-temperature phase has no long-range order but algebraically decaying correlations; the transition as the unbinding of vortex–antivortex pairs when the entropy of a free vortex overcomes its logarithmic energy [1442, 1506]; an essential rather than power-law singularity, so the exponent language of Section 123.5 does not apply; the predicted universal jump in superfluid density, $\rho_s/T_c = 2mk_B^2/\pi\hbar^2$ [1607].]

123.6.3 Observation in helium films

[Reserved: the torsional-oscillator measurement of superfluid density in adsorbed helium-4 films of varying thickness, which found the onset temperature proportional to the areal superfluid density with the predicted universal coefficient [1615]; why this is one of the very few parameter-free confirmations in the whole of critical phenomena; later realizations in two-dimensional atomic gases (Chapter 121) and in Josephson junction arrays.]

123.7 Liquid crystals

123.7.1 Discovery and the mesomorphic states

[Reserved: Reinitzer's observation that cholesteryl benzoate melts twice, at 418.6 K to a turbid fluid and at 451.6 K to a clear one [240]; Lehmann's polarizing-microscope identification of the intermediate phase as a flowing crystal [244]; Friedel's classification into nematic, smectic and cholesteric mesophases and his demonstration that they are true thermodynamic states, not emulsions [489].]

Phenomenon 123.7 (Matter that melts twice)**.** Cholesteryl benzoate has two melting points. Heated, the crystal becomes a turbid but freely flowing fluid at 418.6 K, and that fluid becomes an ordinary clear liquid at 451.6 K [240]. The intermediate state is birefringent under crossed polarizers, so it is optically anisotropic like a crystal while flowing like a liquid [244]. It is a genuine thermodynamic phase and not an emulsion or a mixture: its transitions are reversible and occur at reproducible temperatures, and its several varieties — nematic, smectic, cholesteric — are distinguished by their own textures and transitions [489]. Positional and orientational order are therefore separately destroyable, and a phase may possess one without the other.

Derivation pending #234

The orientational order parameter as a traceless symmetric second-rank tensor, forced by the equivalence of the director and its negative; the cubic invariant that this symmetry permits and that therefore makes the isotropic–nematic transition weakly first order, with a small latent heat and a jump in the order parameter; and the purely entropic hard-rod mechanism that produces the same transition with no attraction at all

123.7.2 The nematic transition

[Reserved: the nematic order parameter as a traceless symmetric tensor, since the director $\boldsymbol{n}$ and $-\boldsymbol{n}$ are equivalent, and the cubic invariant that symmetry therefore permits — forcing the isotropic–nematic transition to be weakly first order [1444]; Onsager's purely entropic transition for hard rods, driven by excluded volume alone [944]; the Maier–Saupe mean-field theory with attractive coupling [1153]; the measured latent heat and order-parameter jump, both small.]

123.7.3 Defects, elasticity and textures

[Reserved: the Frank free energy with its splay, twist and bend elastic constants [1146]; disclinations of half-integer strength, whose existence is a direct consequence of the director's headless symmetry and whose classification is the homotopy theory of Chapter 6; the schlieren textures by which they are counted under crossed polarizers; the monograph [1866]; electro-optic switching as the application that made the phase ubiquitous.]

Chapter 124

Nonequilibrium Thermodynamics and Transport

Equilibrium statistical mechanics describes states in which nothing happens. This chapter is about everything else: a bar with a temperature difference across it, a wire carrying current, a colloidal particle jostled by a fluid, a molecule pulled apart by an optical trap. Its central claim is that near equilibrium the whole of this behaviour is fixed by equilibrium fluctuations — Johnson–Nyquist noise [608, 615], the Einstein relation between diffusion and mobility, the Green–Kubo formulae [1041, 1117] and the fluctuation–dissipation theorem [979] are four statements of one fact — and that far from equilibrium the second law survives in a sharpened, quantitative form: the fluctuation theorems [1863, 1899] and the work relations [1938, 1969], which have been tested directly by pulling single RNA molecules [2033, 2075]. Onsager's reciprocal relations [684, 685], derived from microscopic time-reversal invariance, tie the cross coefficients together and are the reason a chapter on heat flow must also treat thermoelectricity.

The chapter builds on the kinetic theory of Chapter 55 in Part VI, where the Boltzmann equation and the H-theorem are set up, and on the ensembles of Chapter 118, whose correlation functions supply every transport coefficient computed here. It supplies in turn the scattering-limited conductivities used in Chapter 126 and Chapter 127, the critical dynamics that accompanies the static criticality of Chapter 123, and the classical limit of the open-system dynamics of Chapter 87. Standard monographs are [1228, 1356].

Derivation pending #235

Nonequilibrium Thermodynamics and Transport: all derivations of this chapter are pending.

124.1 The kinetic route

124.1.1 The Boltzmann equation and the H-theorem

[Reserved: a summary, not a re-derivation, of the material of Chapter 55: the integro-differential equation for the one-particle distribution with its collision integral, and the H-theorem showing $\mathrm{d}H/\mathrm{d}t \le 0$ *[183]; the assumption of molecular chaos as the exact point at which time-reversal symmetry is given up, and the Loschmidt and Zermelo objections; why the chapter takes the H-theorem as its starting point and asks instead what survives when the system is driven.]*

124.1.2 Chapman–Enskog and the transport coefficients

[Reserved: the systematic expansion of the Boltzmann equation in gradients about local equilibrium [434], which yields the Navier–Stokes equations of Chapter 31 together with first-principles expressions for viscosity and thermal conductivity; the predicted independence of the viscosity of a dilute gas from its density, and the measurements confirming it; the Prandtl number as a parameter-free test; the standard monograph [1416].]

124.1.3 The phenomenological transport laws

[Reserved: the four linear constitutive laws that the microscopic theory must reproduce — Fourier's law of heat conduction [72], Fick's law of diffusion [143], Ohm's law [81] and Newton's law of viscous shear [14]; their common structure, flux proportional to gradient; measured coefficients in SI for representative solids, liquids and gases; the range of validity, and the ballistic and hydrodynamic regimes in which each fails.]

124.2 Linear irreversible thermodynamics

124.2.1 Entropy production and thermodynamic forces

[Reserved: local equilibrium as the working hypothesis, and the entropy balance $\partial_t s + \nabla\cdot\boldsymbol{J}_s = \sigma$ with $\sigma = \sum_i J_i X_i \geq 0$ [1228]; the canonical pairing of fluxes with forces — heat flux with $\nabla(1/T)$, electric current with $\nabla(-\mu/T)$ — and why that pairing, not another, makes the coefficient matrix symmetric; measured entropy production rates in simple conduction experiments.]

124.2.2 Onsager reciprocal relations

[Reserved: the theorem $L_{ik} = L_{ki}$ for the linear coefficients relating fluxes to forces, derived from microscopic reversibility and the regression hypothesis for equilibrium fluctuations [684, 685]; the status of the regression hypothesis as the one non-trivial assumption; the independent experimental evidence, principally the Thomson relations of Section 124.3.2 and thermal diffusion in mixtures; why the relations count as a genuine prediction and not a definition.]

124.2.3 Reciprocity with a magnetic field

[Reserved: the extension $L_{ik}(\boldsymbol{B}) = L_{ki}(-\boldsymbol{B})$ required when the microscopic dynamics is reversible only under simultaneous reversal of the field [878]; the consequence for the Hall and Nernst–Ettingshausen coefficients, and the fact that reciprocity does not forbid an antisymmetric part; the same structure in rotating frames (Chapter 29); the quantized case in Chapter 128.]

124.2.4 Steady states and minimum entropy production

[Reserved: the theorem that in the linear regime a stationary state with fixed boundary constraints minimizes the entropy production [1356], with an explicit statement of its narrow conditions of validity; the honest caveat that no such variational principle is known beyond the linear regime, and that claims to the contrary are not supported by evidence; dissipative structures and pattern formation as the far-from-equilibrium alternative, whose dynamics belongs to Chapter 32.]

124.3 Thermoelectricity

124.3.1 The Seebeck, Peltier and Thomson effects

[Reserved: Seebeck's discovery that a circuit of two metals with junctions at different temperatures deflects a compass needle, and its correct reading as a thermally driven electromotive force [79]; Peltier's converse effect, heat absorbed or released at a junction carrying current [98]; Thomson's prediction and observation of the third, bulk effect in a single conductor with a temperature gradient [148]; measured Seebeck coefficients in $\mu\mathrm{V/K}$*.]*

124.3.2 The Thomson relations as a test of reciprocity

[Reserved: the two relations $\Pi = ST$ *and* $\mu_T = T\,\mathrm{d}S/\mathrm{d}T$ *connecting the three effects, obtained by Thomson from a thermodynamic argument he knew to be incomplete [148] and derived properly only from reciprocity [685]; the measured agreement, quoted with uncertainties, as the classic experimental confirmation of the Onsager relations; the thermocouple as a practical thermometer (Chapter 2).]*

124.3.3 Conduction in metals and the figure of merit

[Reserved: the Wiedemann–Franz law, the near-constancy of $\kappa/\sigma T$ *across metals [140]; the Drude model's accidental success and its failure on the specific heat [289], resolved only by Fermi statistics in Chapter 126; the Lorenz number* $L_0 = \pi^2 k_B^2/3e^2 = 2.44 \times 10^{-8}\,\mathrm{W\,\Omega/K^2}$ *and the conditions under which it is violated; the thermoelectric figure of merit* ZT *and the materials strategy of decoupling* κ *from* σ *[2136].]*

124.4 Brownian motion and stochastic dynamics

124.4.1 The Einstein–Smoluchowski relation

[Reserved: the derivation of the diffusion equation from a random-walk continuity argument and the identification $D = k_B T/6\pi\eta a$ *[318], obtained independently by Sutherland [324] and by a different route by Smoluchowski [331]; the general Einstein relation* $D = \mu k_B T$ *between diffusion constant and mobility as the first fluctuation–dissipation statement in physics; Perrin's measurement of Avogadro's number from displacement statistics [358], treated in full in Chapter 119.]*

124.4.2 The Langevin equation

[Reserved: the stochastic equation $m\ddot{x} = -\gamma\dot{x} + \xi(t)$ *with white noise satisfying* $\langle \xi(t)\xi(t')\rangle = 2\gamma k_B T\delta(t-t')$ *[344]; the second fluctuation–dissipation relation built into that variance, without which the particle would not thermalize; the exact velocity autocorrelation and mean square displacement, crossing from ballistic to diffusive at the momentum relaxation time [672]; the observation of the ballistic regime in an optically trapped bead [2160].]*

124.4.3 The Fokker–Planck equation

[Reserved: the evolution equation for the probability density in phase space, obtained for a rotating dipole in a radiation field [415] and given its general statistical-dynamical form by Planck [448]; drift and diffusion coefficients as the first two Kramers–Moyal moments; the stationary solution reproducing the Boltzmann distribution as the consistency condition; Kramers' escape rate over a potential barrier, with its low- and high-friction limits [853], and the Arrhenius factor it explains.]

124.4.4 Master equations

[Reserved: the gain–loss balance equation for the occupation probabilities of discrete states, and detailed balance as the condition for an equilibrium stationary solution; Pauli's derivation of an H-theorem for the quantum transition rates [617]; the quantum generalization to completely positive dynamics [1586], whose physical content is developed in Chapter 87; birth–death processes and chemical kinetics as classical instances.]

124.5 Linear response and fluctuation–dissipation

124.5.1 Johnson–Nyquist noise

[Reserved: Johnson's measurement of a temperature-dependent voltage fluctuation across any resistor, independent of its material and composition [608]; Nyquist's derivation of $\langle V^2 \rangle = 4 k_B T R \, \Delta f$ from equipartition among the modes of a transmission line, in the same issue [615]; its use as a primary thermometer and as the noise floor of every amplifier; shot noise as the distinct, non-thermal fluctuation, and the measured crossover between them.]

124.5.2 The fluctuation–dissipation theorem

[Reserved: the general theorem relating the imaginary part of a generalized susceptibility to the equilibrium spectral density of the conjugate variable, with the quantum form carrying a factor $\coth(\hbar\omega / 2 k_B T)$ [979]; Nyquist's formula and the Einstein relation as the two special cases already met; the review that established the modern statement [1336]; violation of the theorem as an operational definition of "out of equilibrium", and the effective temperatures inferred from it in glasses.]

124.5.3 Kubo formulae and Green–Kubo relations

[Reserved: transport coefficients as time integrals of equilibrium current autocorrelation functions — conductivity from the current–current correlator [1117], viscosity and thermal conductivity from the corresponding fluxes [1041]; the remarkable content of these formulae, that a dissipative quantity is computed entirely within the equilibrium ensemble; long-time tails and the divergence of the two-dimensional transport integrals; molecular-dynamics evaluation as the standard numerical route.]

124.5.4 Projection operators and memory kernels

[Reserved: the exact reduction of the full dynamics onto a chosen set of slow variables, producing a generalized Langevin equation with a memory kernel and a residual force [1197, 1316]; the second fluctuation–dissipation theorem identifying the kernel with the residual force correlation; Markovian approximation as the limit of separated timescales, and what is lost when it fails; the formal link to coarse graining in Chapter 108.]

124.6 Fluctuation theorems

124.6.1 The steady-state fluctuation theorem

[Reserved: the observation in shearing molecular dynamics that trajectories with negative entropy production occur with a probability ratio $\mathrm{e}^{-\Sigma t / k_B}$ against their conjugates [1863]; the proof for chaotic dynamical systems obeying the chaotic hypothesis [1899]; the reading of the second law as an inequality on an average that individual small systems may violate for short times; the smooth recovery of the thermodynamic statement as system size grows.]

124.6.2 Work relations far from equilibrium

[Reserved: Jarzynski's equality $\langle \mathrm{e}^{-W/k_BT} \rangle = \mathrm{e}^{-\Delta F/k_BT}$, valid for arbitrarily fast driving and yielding an equilibrium free-energy difference from irreversible measurements [1938]; Crooks's stronger relation between the forward and reverse work distributions, whose crossing point locates ΔF directly [1969]; recovery of $\langle W \rangle \geq \Delta F$ by Jensen's inequality, so the second law is a corollary; the exponential average's practical dominance by rare trajectories.]

124.6.3 Experimental verification

[Reserved: the mechanically unfolded RNA hairpin, whose measured work distributions recovered the equilibrium folding free energy to within a few k_BT and so verified the Jarzynski equality [2033]; the Crooks relation tested on RNA with and without a bound magnesium ion, including the far-from-equilibrium regime where the Jarzynski estimator is biased [2075]; the colloidal bead in a moving optical trap that exhibited transient second-law violations [2041]; the SI energy scale of these experiments, set by $k_BT \approx 4.14 \times 10^{-21}$ J at room temperature.]

124.6.4 Stochastic thermodynamics and information

[Reserved: heat, work and entropy defined along a single stochastic trajectory, and the resulting integral and detailed fluctuation theorems [2200]; the generalized second law including an information term, and its experimental demonstration by a feedback-controlled Brownian ratchet converting information into work [2167]; Maxwell's demon and Landauer's principle as the resolution — the cost lies in erasure, not in measurement; molecular motors as the biological instance.]

Chapter 125

Phonons and Lattice Dynamics

A crystal is the physical realization of the loaded string of Chapter 28: a periodic array of masses coupled by springs, whose normal modes are travelling waves and whose quanta — phonons — are bosons obeying the statistics of Chapter 120. Almost every thermal property of a solid follows from that identification. This chapter establishes the lattice itself as an observed structure, by X-ray diffraction [385, 399] rather than by assumption; derives its normal modes [381]; quantizes them; and then confronts the resulting heat capacity with calorimetric data, where the classical Dulong–Petit law [64] fails at low temperature and the quantum models of Einstein [333] and Debye [382] succeed. The dispersion relations that the theory predicts are not inferred but measured, branch by branch, by inelastic neutron scattering [1056, 1137] — the cleanest available demonstration that the phonon is a real excitation with a definite energy and momentum. The chapter closes on anharmonicity, without which a crystal would neither expand when heated [386] nor conduct heat at a finite rate [634].

It sits between the general theory of phase transitions (Chapter 123), which supplies the notion of a broken translation symmetry, and the electronic chapters Chapter 126 and Chapter 127, which inherit its reciprocal lattice and Brillouin zones wholesale; its transport section uses the machinery of Chapter 124, and the electron–phonon coupling it introduces is what pairs electrons in Chapter 130. Standard monographs are [1030, 1570, 2078].

Derivation pending #236

Phonons and Lattice Dynamics: all derivations of this chapter are pending.

125.1 The crystal lattice

125.1.1 Bravais lattices and the crystallographic restriction

[Reserved: the enumeration of the fourteen distinct lattices of points invariant under a discrete translation group in three dimensions [126]; primitive vectors, unit cells and the Wigner–Seitz construction; the crystallographic restriction theorem — only two-, three-, four- and six-fold rotation axes are compatible with translational periodicity — proved from the trace of the rotation in the lattice basis, an application of Chapter 5.]

125.1.2 Point groups, space groups and the basis

[Reserved: the 32 crystallographic point groups and the 230 space groups obtained by adjoining screw axes and glide planes, enumerated independently by Fedorov and by Schoenflies [251]; lattice plus basis as the description of a real crystal; Neumann's principle relating the

symmetry of a physical tensor to that of the crystal, which is what makes a cubic crystal optically isotropic but elastically anisotropic (Chapter 30).]

125.1.3 The reciprocal lattice and Brillouin zones

[Reserved: the reciprocal lattice as the Fourier dual of the direct lattice, with $\mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{R}} = 1$*, and the Ewald construction that makes diffraction geometry visible [474]; the first Brillouin zone as the Wigner–Seitz cell of the reciprocal lattice and as the complete set of inequivalent wave vectors [644]; Bloch's theorem stated here for lattice waves and reused for electrons in Chapter 126; zone boundaries as the locus of Bragg reflection.]*

125.1.4 Quasicrystals: the exception that fixed the rule

[Reserved: the observation of sharp diffraction spots with icosahedral symmetry in a rapidly cooled aluminium–manganese alloy, which is forbidden for any periodic lattice [1744]; the resolution — long-range order without periodicity — and the consequent redefinition of "crystal" by diffraction rather than by translational symmetry; what survives of the phonon description, and the additional phason modes that do not.]

Phenomenon 125.1 (Sharp diffraction with a forbidden symmetry)**.** A rapidly solidified aluminium–manganese alloy gives an electron diffraction pattern with spots as sharp as those of a good crystal, and with icosahedral point symmetry — including five-fold axes, which the crystallographic restriction forbids to any lattice periodic in three dimensions [1744]. The two observations are individually routine and jointly contradictory under the definition of a crystal then in force. The resolution is that sharp diffraction requires long-range *order* and not periodicity, and the definition was changed accordingly.

Derivation pending #237

The crystallographic restriction, proved from the integrality of the matrix of a lattice rotation in the lattice basis and hence of its trace, which admits only two-, three-, four- and six-fold axes; and the demonstration that a non-periodic but long-range-ordered point set can nevertheless have a Fourier transform consisting of sharp discrete peaks, so that sharp diffraction does not entail a periodic lattice

125.2 Experiment: the lattice made visible

125.2.1 Laue diffraction of X-rays

[Reserved: the 1912 Munich experiment in which a collimated X-ray beam through a copper sulphate crystal produced a symmetric pattern of spots on a photographic plate [385], settling two questions at once — that X-rays are waves, and that crystals are periodic on the $1 \times 10^{-10}\,\mathrm{m}$ *scale; von Laue's diffraction conditions and their equivalence to the reciprocal-lattice condition [389]; the apparatus, exposure times and the control observations.]*

125.2.2 Bragg's law and structure determination

[Reserved: the reformulation of the Laue conditions as reflection from lattice planes, $n\lambda = 2d\sin\theta$ *[399]; the ionization spectrometer and the first structures solved, sodium chloride and diamond, which showed that the rock-salt crystal contains no NaCl molecule; measured lattice constants in SI with their modern uncertainties, and the silicon lattice parameter as a route to the Avogadro constant (Chapter 2).]*

Phenomenon 125.2 (Crystals diffract X-rays into discrete spots)**.** A collimated X-ray beam passed through a single crystal emerges not as a diffuse halo but as a pattern of sharp, discrete spots arranged with the point symmetry of the crystal [385]. The pattern is the joint signature of two facts, neither previously established: that X-rays are waves, and that a crystal is a lattice periodic on the scale of $1 \times 10^{-10}\,\mathrm{m}$. Read as reflection from families of parallel lattice planes of spacing d, the observed directions obey

$$n\lambda = 2d\sin\theta\,, \qquad n \in \mathbb{Z}\,, \tag{125.1}$$

with θ the glancing angle measured from the planes and not from their normal [399]. Equation (125.1) turns the diffraction pattern into a measuring instrument: it converts measured angles into lattice spacings, and it is what showed that the rock-salt crystal contains no NaCl molecule at all, only alternating ions.

Derivation. Consider a family of parallel lattice planes of spacing d and a plane wave of wavelength λ incident at glancing angle θ. Two rays reflected specularly from adjacent planes travel paths differing by the two segments $d\sin\theta$ dropped from the upper plane to the lower and back, that is by $2d\sin\theta$. Specular reflection makes the phase difference between rays scattered within one plane vanish identically, so the whole family adds in phase if and only if the inter-plane path difference is a whole number of wavelengths, which is Equation (125.1). Two features of the observation follow at once. The spots are *discrete* because the condition selects isolated angles for each d; a non-periodic scatterer has no family of equally spaced planes and returns a continuous distribution. And Equation (125.1) has no solution unless $\lambda \le 2d$, which is why visible light shows no such pattern and why the measurement had to wait for X-rays. The plane picture is the crystallographers' form of the von Laue conditions; both say that the scattering vector must be a reciprocal-lattice vector (Section 125.1.3). □

125.2.3 Structure factor and systematic absences

[Reserved: the geometric structure factor as the Fourier transform of the basis, and the atomic form factor as that of the electron density; systematic absences as the fingerprint of centring and of screw axes, and how a space group is read off a diffraction pattern; the phase problem and why intensities alone do not determine a structure; the Fourier machinery of Chapter 17.]

125.3 Heat capacity of solids

125.3.1 The Dulong–Petit law and its failure

[Reserved: the empirical constancy of the molar heat capacity of the solid elements at $3R = 24.94\,\mathrm{J/(mol\,K)}$ [64], and its derivation from equipartition over $3N$ classical oscillators (Chapter 118); the anomalies known by 1900 — diamond, boron and silicon far below the value at room temperature — and the low-temperature calorimetry showing every solid's heat capacity falling to zero [378], which no classical theory can produce.]

Phenomenon 125.3 (The Dulong–Petit value, and its collapse)**.** Near room temperature the molar heat capacity of the solid elements is very nearly the same for all of them, close to $3R = 24.94\,\mathrm{J/(mol\,K)}$, irrespective of the mass of the atom, the stiffness of the bonding or the crystal structure [64]. The regularity fails in two directions. Already at room temperature diamond, boron and silicon sit far below the value; and calorimetry at low temperature shows the heat capacity of *every* solid falling towards zero as the temperature does [378]. A universal constant that is right at high temperature and wrong at low temperature is the signature of a classical limit.

Derivation. A crystal of N atoms has $3N$ vibrational degrees of freedom, and near equilibrium each is a harmonic normal mode (Section 125.4.1). A classical harmonic oscillator in equilibrium at temperature T has, by equipartition, mean kinetic energy $\frac{1}{2}k_BT$ and mean potential energy $\frac{1}{2}k_BT$, so $\langle E\rangle = k_BT$ per mode, independent of its frequency. Hence

$$U = 3Nk_BT\,, \qquad C = \left(\frac{\partial U}{\partial T}\right)_V = 3Nk_B\,, \tag{125.2}$$

which for one mole is $3R$. Every material property has cancelled: the masses and the force constants enter only through the frequencies, and the frequencies have dropped out. That is precisely why the result cannot be repaired. A classical theory containing no energy scale of its own has nothing with which to compare k_BT, so it cannot produce a temperature below which the heat capacity falls. The observed collapse therefore requires a scale that the classical theory does not possess, and the only candidate is $\hbar\omega$: modes with $\hbar\omega \gg k_BT$ are frozen out, which is why the light, stiffly bound solids — diamond, boron, beryllium — are the ones that deviate first (Section 125.3.2). □

125.3.2 The Einstein model

[Reserved: the first application of quantization to matter rather than radiation — $3N$ independent oscillators of a single frequency, with $x = \theta_E/T$ giving $C = 3Nk_Bx^2\mathrm{e}^x/(\mathrm{e}^x-1)^2$ [333]; the quantitative account of the diamond anomaly with one fitted frequency; the exponential low-temperature falloff, which is too fast, and why: the model has no low-frequency modes; the historical weight of this paper as evidence for quanta outside Chapter 68.]

125.3.3 The Debye model and the cubic law

[Reserved: replacement of the single frequency by an elastic continuum with a linear dispersion cut off at ω_D so that the mode count is $3N$ [382]; the interpolation formula and the limiting law $C = \frac{12\pi^4}{5}Nk_B(T/\theta_D)^3$; the Debye temperature as the single material parameter, from 105 K for lead to 2230 K for diamond; the exact parallel with the photon gas of Chapter 68, differing only in the cutoff and the three polarizations.]

125.3.4 Calorimetric tests at low temperature

[Reserved: the measurement that separates the two contributions — C/T plotted against T^2 gives a straight line whose intercept is the electronic term γT and whose slope is the lattice T^3, verified for copper, silver and gold between 1 K and 5 K [1061]; the extracted Debye temperatures compared with those from elastic constants, a consistency test between two unrelated experiments; where the model fails at intermediate T, and why.]

Phenomenon 125.4 (The cubic law)**.** Well below its Debye temperature the lattice contribution to the heat capacity of a solid is not exponentially small but follows a power law,

$$C_{\text{lattice}} = \frac{12\pi^4}{5}\,Nk_B\left(\frac{T}{\theta_D}\right)^3\,, \tag{125.3}$$

with a single material parameter θ_D ranging from about 105 K for lead to about 2230 K for diamond [382]. In a metal the lattice term is accompanied by the electronic term of Chapter 120, and the two are separated experimentally by plotting C/T against T^2: the result is a straight line whose intercept is electronic and whose slope is the lattice term, as verified for copper, silver and gold between 1 K and 5 K [1061]. The θ_D so obtained agrees with the value computed from independently measured elastic constants, which is a consistency test between two unrelated experiments and not a fit.

Derivation. Debye's approximation replaces the true dispersion by an isotropic elastic continuum, $\omega = v_s k$ on three polarizations, and truncates the spectrum at a frequency ω_D chosen so that the total number of modes is $3N$. Counting modes in a box, the number with wavevector below k is $3 \cdot V k^3/6\pi^2$, so the density of modes in frequency is $g(\omega) = 3V\omega^2/2\pi^2 v_s^3$, and imposing $\int_0^{\omega_D} g\,\mathrm{d}\omega = 3N$ lets it be written without reference to v_s as

$$g(\omega) = \frac{9N\omega^2}{\omega_D^3}\,, \qquad 0 \le \omega \le \omega_D\,. \tag{125.4}$$

Each mode is a quantized oscillator whose thermal occupation is the Bose function of Chapter 120 with zero chemical potential, since phonon number is not conserved. Dropping the temperature-independent zero-point term,

$$U = \int_0^{\omega_D} \frac{\hbar\omega\, g(\omega)\,\mathrm{d}\omega}{\mathrm{e}^{\hbar\omega/k_B T} - 1} = 9Nk_BT\left(\frac{T}{\theta_D}\right)^3 \int_0^{\theta_D/T} \frac{x^3\,\mathrm{d}x}{\mathrm{e}^x - 1}\,, \tag{125.5}$$

with $x = \hbar\omega/k_BT$ and $k_B\theta_D = \hbar\omega_D$. For $T \ll \theta_D$ the upper limit may be sent to infinity with exponentially small error, and $\int_0^\infty x^3(\mathrm{e}^x-1)^{-1}\mathrm{d}x = \pi^4/15$, so $U = (3\pi^4/5)Nk_BT^4/\theta_D^3$ and differentiation gives Equation (125.3). The physical content is in the low-frequency end of Equation (125.4): because a crystal has acoustic modes of arbitrarily low frequency, there are always modes with $\hbar\omega < k_BT$ available to excite, and the number of them scales as T^3 in three dimensions. This is exactly the photon-gas calculation of Chapter 68 with two changes, three polarizations instead of two and a finite cutoff instead of none; the cutoff is what the photon gas lacks and is why radiation has no Dulong–Petit regime. Einstein's earlier model, which gives every mode the same frequency, has no low-frequency modes at all and therefore predicts an exponential falloff, too fast to match the data [333]. □

125.4 Lattice dynamics

125.4.1 The Born–von Kármán theory

[Reserved: the harmonic expansion of the crystal potential in atomic displacements, the dynamical matrix $D(\boldsymbol{k})$ and the eigenvalue problem $\omega^2(\boldsymbol{k})\boldsymbol{e} = D(\boldsymbol{k})\boldsymbol{e}$ [381]; periodic boundary conditions and the resulting discrete, finite set of allowed wave vectors in the Brillouin zone; the monatomic chain and its dispersion $\omega = 2\sqrt{K/M}\,|\sin(ka/2)|$ as the worked case; the long-wavelength limit reproducing the elastic waves of Chapter 30; the monograph [1030].]

125.4.2 Acoustic and optical branches

[Reserved: the diatomic chain, whose $3p$ branches for p atoms per cell split into three acoustic branches with $\omega \to 0$ as $k \to 0$ and $3p-3$ optical branches with a finite gap [381]; the physical distinction — neighbouring atoms move in phase in an acoustic mode and against each other in an optical one; why only optical modes couple to light at $k \approx 0$; group velocity vanishing at the zone boundary, connecting to Chapter 28.]

125.4.3 Quantization: the phonon

[Reserved: each normal mode quantized as a harmonic oscillator, giving energies $(n_{\boldsymbol{k}s} + \tfrac{1}{2})\hbar\omega_{\boldsymbol{k}s}$ and an occupation obeying the Bose–Einstein distribution of Chapter 120 with zero chemical potential, since phonon number is not conserved; crystal momentum $\hbar\boldsymbol{k}$ defined only modulo a reciprocal-lattice vector, and why it is not true momentum; zero-point motion and its measured consequences, including the failure of helium to solidify under its own vapour pressure (Chapter 130).]

125.4.4 Polar crystals and the Lyddane–Sachs–Teller relation

[Reserved: the long-range Coulomb field of a longitudinal optical mode in an ionic crystal, splitting it from the transverse mode, and the relation $\omega_{LO}^2/\omega_{TO}^2 = \epsilon(0)/\epsilon(\infty)$ [859]; the reststrahlen band of total reflection between the two frequencies as its direct observation; polaritons as the mixed phonon–photon excitations, and their measured dispersion; the link to dielectric response in Chapter 62.]

125.5 Measured dispersion relations

125.5.1 Inelastic neutron scattering

[Reserved: why the thermal neutron is the right probe — its de Broglie wavelength matches interatomic spacings while its energy, about 25 meV, matches phonon energies, so energy and momentum transfer are measured simultaneously; the triple-axis spectrometer and the first phonon measurement, in a single crystal of aluminium [1056]; the complete branch-by-branch dispersion of germanium [1137], compared with Born–von Kármán force-constant fits; conservation laws with crystal momentum, including umklapp processes.]

Phenomenon 125.5 (The dispersion relation is measured, not assumed)**.** A neutron scattered by a crystal exchanges a definite energy and a definite wavevector with it, and the pairs so measured do not fill the plane: they lie on curves. Scanning energy transfer against wavevector transfer in a single crystal of aluminium [1056] and, branch by branch through the Brillouin zone, in germanium [1137], one measures $\omega(\boldsymbol{k})$ directly. Three features of the measured curves are the substance of lattice dynamics. The dispersion is linear only at long wavelength; it flattens towards the zone boundary, where the group velocity vanishes, so a crystal is not an elastic continuum. It is periodic in the reciprocal lattice, so $\boldsymbol{k}$ is defined only modulo a reciprocal-lattice vector. And a crystal with p atoms in its primitive cell shows $3p$ branches, of which three are acoustic, vanishing at $\boldsymbol{k} = 0$, and the remaining $3p-3$ are optical, with a finite frequency there. The existence of a sharp ω for each $\boldsymbol{k}$ is what entitles one to call the excitation a particle.

Derivation. The simplest case exhibits every feature. Take a chain of identical masses M at spacing a, coupled to nearest neighbours by springs of constant K; let u_n be the displacement of the n-th mass. In the harmonic approximation

$$M\ddot{u}_n = K\left(u_{n+1} + u_{n-1} - 2u_n\right) . \tag{125.6}$$

The equations are invariant under $n \to n+1$, so their normal modes may be labelled by the eigenvalue of that translation: try $u_n = A\,\mathrm{e}^{\mathrm{i}(kna-\omega t)}$. Substituting into Equation (125.6) gives $-M\omega^2 = K(\mathrm{e}^{\mathrm{i}ka} + \mathrm{e}^{-\mathrm{i}ka} - 2) = -4K\sin^2(ka/2)$, that is

$$\omega(k) = 2\sqrt{\frac{K}{M}}\left|\sin\frac{ka}{2}\right| . \tag{125.7}$$

Equation (125.7) is periodic under $k \to k + 2\pi/a$, so nothing outside the first Brillouin zone $|k| \le \pi/a$ is new: a wave shorter than twice the spacing is indistinguishable from a longer one, because only the discrete u_n exist. For $ka \ll 1$ it reduces to $\omega \approx a\sqrt{K/M}\,|k|$, the acoustic branch, whose slope is the sound velocity of Chapter 30. At the zone boundary $\mathrm{d}\omega/\mathrm{d}k = 0$: the group velocity vanishes and the mode is a standing wave, which is the lattice-dynamical counterpart of Bragg reflection at the same wavevector. Repeating the calculation with two different masses per cell splits the single branch into an acoustic one that still vanishes at $k = 0$, in which neighbours move together, and an optical one with a finite gap there, in which they move against each other [381]; the general statement of

$3p$ branches follows from diagonalizing the $3p \times 3p$ dynamical matrix. Quantizing each mode as an oscillator makes $\hbar\omega(\boldsymbol{k})$ the energy of one phonon, which is what the neutron measures. □

125.5.2 Inelastic X-ray and light scattering

[Reserved: Raman scattering as the optical route to zone-centre optical phonons, from its discovery in liquids [618] to its routine crystallographic use; Brillouin scattering for acoustic phonons and the sound velocities it yields; high-resolution inelastic X-ray scattering at synchrotron sources, which reaches phonons in samples too small or too absorbing for neutrons [1985]; the complementary selection rules of the three techniques.]

125.5.3 The Debye–Waller factor

[Reserved: the attenuation e^{-2W} of Bragg intensities by thermal displacement, with $2W = \langle(\boldsymbol{Q}\cdot\boldsymbol{u})^2\rangle$, derived by Debye [402] and corrected for the quantum zero-point term by Waller [506]; the crucial fact that thermal motion weakens the spots but does not broaden them, the intensity moving into a diffuse background; recoilless nuclear resonance absorption as the same factor in the gamma-ray regime [1154], and the mean square displacements it measures.]

125.6 Anharmonicity

125.6.1 Thermal expansion and the Grüneisen parameter

[Reserved: the theorem that a strictly harmonic crystal does not expand, so thermal expansion measures the cubic term directly; the Grüneisen parameter $\gamma_G = -\mathrm{d}\ln\omega/\mathrm{d}\ln V$ and the relation $\alpha = \gamma_G\kappa_T C_V/V$ [386]; the observed near-constancy of $\gamma_G \approx 2$ across many solids and the parallel temperature dependence of α and C_V; negative thermal expansion in silicon and in framework structures as the instructive exception.]

Phenomenon 125.6 (Solids expand when heated, and do so in step with their heat capacity)**.** The volume thermal expansion coefficient α of a solid is not an independent material function of temperature: measured over a wide range it is proportional to the heat capacity C_V of the same sample, falling towards zero at low temperature in the same way and saturating at the same temperature, so that the dimensionless ratio

$$\gamma_G = \frac{\alpha V}{\kappa_T C_V} \tag{125.8}$$

is nearly independent of temperature and takes a value of order two across a wide range of solids [386]. A strictly harmonic crystal would not expand at all — the mean position of a harmonic oscillator is independent of its energy — so the whole of the effect measures the anharmonic part of the interatomic potential, and Equation (125.8) says that one number suffices to describe it. The exceptions are as instructive as the rule: silicon and several open framework structures contract on heating over some temperature ranges.

Derivation pending #238

The Grüneisen relation: that a phonon frequency depends on volume, quantified by the logarithmic derivative of frequency with respect to volume; the resulting thermal pressure of the phonon gas; and the equality of that pressure gradient with the elastic restoring stress, which yields the expansion coefficient as the product of the compressibility, the heat capacity and the mean logarithmic derivative, together with the sign reversal produced by transverse modes that stiffen under expansion

125.6.2 Phonon–phonon scattering and umklapp

[Reserved: three-phonon processes as the leading anharmonic interaction; Peierls's decisive observation that normal processes conserve total crystal momentum and therefore cannot degrade a heat current, so only umklapp processes — in which the summed wave vector lands outside the Brillouin zone and is returned by a reciprocal-lattice vector — give a finite thermal resistance [634]; the resulting $\mathrm{e}^{\theta_D/bT}$ freezing-out of umklapp at low temperature; phonon lifetimes measured as neutron linewidths.]

125.6.3 Thermal conductivity of insulators

[Reserved: the kinetic-theory expression $\kappa = \frac{1}{3} C v \ell$ and the characteristic peak in $\kappa(T)$ where umklapp scattering gives way to boundary scattering [1196]; isotope scattering as an independently controllable term, demonstrated by the roughly 50 % rise in the conductivity of diamond on isotopic enrichment [1830]; measured conductivities in $\mathrm{W/(m\,K)}$ for representative insulators; the transport formalism of Chapter 124.]

Phenomenon 125.7 (Thermal conductivity of an insulating crystal)**.** A pure dielectric crystal conducts heat at a finite rate, and its conductivity is a strongly non-monotonic function of temperature: it rises steeply on cooling, passes through a pronounced maximum at a temperature of order a few per cent of the Debye temperature, and then falls again towards zero. Both flanks are informative. The high-side fall is exponential in θ_D/T; the low-side fall follows the heat capacity, and its magnitude depends on the size and surface of the specimen, which no bulk material property should. That the conductivity is limited by the crystal's own imperfections is shown decisively by isotopes: enriching diamond in carbon-12 raises its room-temperature thermal conductivity by roughly 50 %, without changing its chemistry, its structure or its phonon spectrum to any comparable degree [1830].

Derivation pending #239

Why a harmonic crystal has infinite thermal conductivity, and why anharmonicity alone is not enough: that three-phonon processes conserving the total crystal momentum cannot degrade a heat current, so that a finite thermal resistance requires umklapp processes in which the summed wavevector leaves the Brillouin zone and is returned by a reciprocal-lattice vector; the exponential freezing-out of those processes at low temperature; and the kinetic-theory expression for the conductivity in terms of heat capacity, group velocity and mean free path, whose crossover to boundary-limited and isotope-limited scattering produces the observed maximum

Chapter 126

Electrons in Solids: Band Theory

Why one solid conducts electricity and the next does not is the oldest quantitative question in the physics of matter, and the answer — energy bands — is the most consequential single application of quantum mechanics to anything larger than a molecule. This chapter builds it in the order in which the evidence forced it. Drude modelled a metal as a classical gas of electrons scattering off the ions [289, 290], recovered Ohm's law and the Wiedemann–Franz ratio measured half a century earlier [140], and failed by two orders of magnitude on the electronic specific heat. Sommerfeld replaced Maxwell–Boltzmann by the Fermi–Dirac statistics of Chapter 120 and repaired the thermal properties at a stroke [620]. Bloch then put the electrons into the periodic potential of the lattice of Chapter 125 and proved the theorem [623] from which bands, gaps and Wilson's criterion separating metals from insulators [688, 689] all follow.

The chapter's second half is about evidence, because a band structure is a falsifiable curve $E_n(\boldsymbol{k})$ and not a picture. The Fermi surface is measured by the de Haas–van Alphen oscillations [655] read through Onsager's relation [1008], by cyclotron resonance [1063], and today directly by angle-resolved photoemission [2048]. The chapter closes honestly on where the one-electron picture breaks: on the Mott insulators that band theory declares to be metals [941], and on disorder [1134]. Its neighbours are the lattice dynamics of Chapter 125 before it and, after it, the doped band insulators of Chapter 127, the quantized magnetotransport of Chapter 128, the ordered moments of Chapter 129 and the paired condensate of Chapter 130. The standard modern treatment is [1570].

Derivation pending #240

Electrons in Solids: Band Theory: all derivations of this chapter are pending.

126.1 The free-electron metal

126.1.1 Drude's kinetic model

[Reserved: the metal as a classical gas of conduction electrons scattering off fixed ions, introduced by Drude [289]; the relaxation-time equation of motion, the direct-current conductivity $\sigma = ne^2\tau/m$ recovering Ohm's law, the frequency-dependent Drude response and the plasma frequency; the galvanomagnetic and thermomagnetic sequel [290], in which the same model delivers the Hall coefficient $R_H = -1/ne$ for the effect Hall had discovered [208]; relaxation times of order 1×10^{-14} s at room temperature, inferred rather than assumed; the kinetic-theory machinery imported from Chapter 55.]

Phenomenon 126.1 (Ohm's law and the Hall coefficient)**.** Two facts about metallic conduction are simple enough to look uninformative and are not. First, the current density

in a metal is strictly proportional to the applied electric field over many decades of field strength, with a conductivity that depends on temperature and purity but not on the field: a metal has no memory of how hard it is being driven. Second, a current j_x crossed with a magnetic field B along z develops a steady transverse electric field E_y, in the ratio

$$R_H = \frac{E_y}{j_x B}\,, \tag{126.1}$$

which Hall found to be independent of the field, of the current and of the sample dimensions [208]. For the alkali metals R_H is negative and its magnitude corresponds to about one mobile carrier of charge $-e$ per atom [1570]. That a solid should hand back its carrier density to a voltmeter is the first quantitative measurement of the electron gas.

Derivation. Drude's model treats the conduction electrons as free particles of charge $-e$ and mass m, accelerated by the applied fields and randomized by collisions at a mean rate $1/\tau$, so that on average the collisions remove momentum at the rate $m\boldsymbol{v}/\tau$ [289]. The steady-state equation of motion is

$$0 = -e\,(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B}) - \frac{m\boldsymbol{v}}{\tau}\,. \tag{126.2}$$

With $\boldsymbol{B} = 0$ this gives $\boldsymbol{v} = -e\tau\boldsymbol{E}/m$ and hence

$$\boldsymbol{j} = -ne\boldsymbol{v} = \frac{ne^2\tau}{m}\boldsymbol{E} \equiv \sigma\boldsymbol{E}\,, \tag{126.3}$$

which is Ohm's law: the response is linear because the drag term in Equation (126.2) is linear, and the conductivity contains no reference to $\boldsymbol{E}$. Now take $\boldsymbol{B} = B\hat{\boldsymbol{z}}$ and a sample whose sides are insulating, so that in the steady state $v_y = 0$. The y component of Equation (126.2) then reads $-e(E_y - v_x B) = 0$, so $E_y = v_x B$; and $j_x = -nev_x$ gives $v_x = -j_x/ne$. Substituting into Equation (126.1),

$$R_H = -\frac{1}{ne}\,, \tag{126.4}$$

independent of τ, of m and of the field — which is why the measurement is a carrier count and not a fit. Two things should be noted about what has *not* been derived. The sign in Equation (126.4) is fixed by the assumption that the carriers are electrons, and it is contradicted in several metals (Section 126.1.3); and τ has been postulated, not computed, so Equation (126.3) explains the linearity of Ohm's law but not the magnitude or the temperature dependence of σ (Section 126.6). □

126.1.2 The Wiedemann–Franz law

[Reserved: the empirical proportionality of thermal to electrical conductivity at fixed temperature, measured across the metals by Wiedemann and Franz [140]; the Lorenz ratio $L = \kappa/\sigma T$ and its near-universal value close to $2.44 \times 10^{-8}\,\mathrm{W\,\Omega/K^2}$; why Drude obtained it almost exactly right through two compensating errors of order one hundred, in the electronic heat capacity and in the mean square speed [289, 1570]; the regimes in which the law is observed to fail, and what inelastic scattering has to do with it.]

Phenomenon 126.2 (The Wiedemann–Franz law)**.** At ordinary temperatures the thermal conductivity κ and the electrical conductivity σ of a metal are proportional, and the constant of proportionality is very nearly the same for every metal: the Lorenz ratio

$$L = \frac{\kappa}{\sigma T} \tag{126.5}$$

clusters about $2.44 \times 10^{-8}\,\mathrm{W\,\Omega/K^2}$ across metals differing by orders of magnitude in σ itself [140, 1570]. A ratio that survives when its two members do not is a strong statement: the same carriers, scattered by the same mechanism, must be responsible for both currents. The law fails, in a way that is itself diagnostic, at intermediate temperatures, where the scattering that degrades a heat current and the scattering that degrades a charge current cease to be the same.

Derivation. Kinetic theory gives the thermal conductivity of a gas of carriers as $\kappa = \tfrac{1}{3} c_V v^2 \tau$, with c_V the heat capacity per unit volume of the carriers and v their typical speed. For a degenerate electron gas both quantities are those of the Fermi surface, not of a classical gas: from Chapter 120, $c_V = \tfrac{1}{2}\pi^2 n k_B (T/T_F)$, and the carriers move at the Fermi speed, $\tfrac{1}{2} m v_F^2 = k_B T_F$. Hence

$$\kappa = \frac{1}{3} \cdot \frac{\pi^2 n k_B T}{2 T_F} \cdot \frac{2 k_B T_F}{m} \cdot \tau = \frac{\pi^2}{3} \frac{n k_B^2 T \tau}{m} \,. \tag{126.6}$$

Dividing by σT with $\sigma = n e^2 \tau / m$ from Equation (126.3), the carrier density, the mass and — the essential point — the relaxation time all cancel:

$$L = \frac{\pi^2}{3} \left(\frac{k_B}{e} \right)^2 = 2.44 \times 10^{-8}\,\mathrm{W\,\Omega/K^2} \,, \tag{126.7}$$

a combination of fundamental constants alone, which is why it is the same for every metal. The cancellation of τ is what makes Equation (126.7) robust, and its failure is what makes the observed deviations informative: the derivation assumed one relaxation time for both currents, whereas a small-angle inelastic collision with a phonon can relax an energy current while barely relaxing a charge current. Drude obtained almost this number classically because his two errors were reciprocal: the classical heat capacity is too large by about $T_F/T \sim 10^2$ and the classical mean square speed too small by about the same factor, so their product survived while neither factor did [289, 1570]. □

126.1.3 What the classical electron gas cannot do

[Reserved: the missing electronic specific heat — classically $\tfrac{3}{2} k_B$ per electron, observed near room temperature to be smaller by about two orders of magnitude; the sign of the Hall coefficient, positive in aluminium, zinc and beryllium where [290] demands it be negative; the complete absence of any account of why a solid should be an insulator at all; each of these a symptom of applying Maxwell–Boltzmann statistics to a degenerate fermion gas, and each resolved in Chapter 120.]

Phenomenon 126.3 (Hall coefficients of the wrong sign)**.** In aluminium, zinc, beryllium and cadmium the measured Hall coefficient Equation (126.1) is *positive*, and in several metals its magnitude does not correspond to any plausible carrier density [208, 1570]. Equation (126.4) admits no such value: within the free-electron picture the sign of R_H is the sign of the carrier charge, and the carriers are electrons. The observation is therefore not a quantitative discrepancy but a qualitative refutation, and the fact that it occurs in ordinary, well-characterized, chemically simple metals rules out an explanation by impurities or by a second species of ion.

Derivation pending #241

The dynamics of a nearly filled band described through its vacancies: that the total current of a filled band vanishes, so that the current of an almost-filled band equals minus the current of the missing states; that a wave packet near a band maximum has negative band curvature and therefore responds as a particle of positive charge and positive mass; and the resulting positive Hall coefficient, with the multi-band and open-orbit corrections that govern its magnitude

126.1.4 The Sommerfeld model

[Reserved: Sommerfeld's substitution of the Fermi–Dirac distribution into Drude's kinetic picture [620]; the Fermi sphere, the Fermi energy $E_F = \hbar^2 k_F^2/2m$ of a few eV *and the Fermi temperature of order 1×10^4* K *that makes every metal a degenerate gas at room temperature; the Sommerfeld expansion, the linear electronic heat capacity $c = \gamma T$ and the measured coefficients γ of the alkali metals; Pauli paramagnetism [586] and Landau diamagnetism [660] as the magnetic counterparts, taken up in Chapter 129; exactly what of Drude survives.]*

126.2 Electrons in a periodic potential

126.2.1 Bloch's theorem

[Reserved: the theorem that eigenfunctions of a Hamiltonian invariant under the lattice translations of Chapter 125 take the form $\psi_{n\boldsymbol{k}}(\boldsymbol{r}) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} u_{n\boldsymbol{k}}(\boldsymbol{r})$ with $u_{n\boldsymbol{k}}$ lattice periodic, proved by Bloch [623]; crystal momentum $\hbar\boldsymbol{k}$ as a label of an irreducible representation of the discrete translation group and not a true momentum; the band index n; Born–von Karman boundary conditions and the counting of allowed $\boldsymbol{k}$ that gives N states per band per spin; the group-theoretic reading via Chapter 5.]

126.2.2 Reciprocal lattice and Brillouin zones

[Reserved: the reciprocal lattice and the equivalence $\boldsymbol{k} \sim \boldsymbol{k} + \boldsymbol{G}$ that makes every band a periodic function on a torus; the first Brillouin zone as the Wigner–Seitz cell of the reciprocal lattice, introduced together with the reading of zone boundaries as Bragg planes by Brillouin [644]; the consequent link between a band gap and the diffraction condition measured in Chapter 125; reduced, extended and repeated zone schemes; high-symmetry points and the conventional paths along which band structures are plotted.]

126.2.3 Nearly free electrons

[Reserved: degenerate perturbation theory (Chapter 82) applied to a weak periodic potential; the gap $2\,|V_{\boldsymbol{G}}|$ that opens at each Bragg plane, the distortion of the free-electron parabola and the origin of the very idea of a forbidden band [623, 1570]; why the weak-potential limit describes real sp-bonded metals far better than the strength of the ionic potential suggests, which is the pseudopotential argument of Section 126.3.3 [1172].]

126.2.4 Tight binding and Wannier functions

[Reserved: the opposite limit of weakly overlapping atomic orbitals; the band $E(\boldsymbol{k}) = \epsilon - 2t\sum_i \cos(k_i a)$ of a simple cubic lattice, with bandwidth set by the hopping integral t and centre by the on-site energy ϵ; the Slater–Koster parametrization of the two-centre integrals that made the method practical [1051]; Wannier functions as the localized unitary dual of

the Bloch states [805]; why two limits that could hardly differ more agree on the qualitative band picture.]

126.2.5 The Kronig–Penney model

[Reserved: the exactly solvable periodic square-well chain of Kronig and Penney [683]; the transfer-matrix condition $\cos(ka) = \cos(\alpha a) + P\sin(\alpha a)/(\alpha a)$*, whose failure to admit a real* k *over finite energy intervals is a band gap in closed form; the delta-comb limit and the width of the bands as a function of barrier strength; what the model proves — that periodicity alone, and no special property of atoms, produces gaps.]*

126.3 Band structure and the classification of solids

126.3.1 Filling and Wilson's criterion

[Reserved: the count of $2N$ *states per band including spin, and the resulting rule that a crystal with an odd number of electrons per primitive cell must be a metal; Wilson's identification of an insulator as a solid whose bands are exactly filled, and of a semiconductor as an insulator whose gap is small enough to be bridged thermally [688, 689]; the divalent metals, saved by band overlap; the criterion's known counterexamples, deferred honestly to Section 126.7.2.]*

Phenomenon 126.4 (Metals and insulators are qualitatively, not quantitatively, different)**.** The room-temperature electrical resistivity of solids spans more than twenty orders of magnitude, from about $1 \times 10^{-8}\,\Omega\,\mathrm{m}$ in a good metal to above $1 \times 10^{16}\,\Omega\,\mathrm{m}$ in a good insulator, with no bunching in between that would mark a natural boundary. What does mark one is the *sign* of the temperature dependence: on cooling, the resistivity of a metal falls and tends to a finite residual value, while that of an insulator or semiconductor rises without limit. The same distinction appears in the low-temperature heat capacity, which carries the electronic term γT of Chapter 120 in a metal and does not in an insulator. Empirically the class a crystal belongs to correlates with the number of electrons in its primitive cell rather than with any property of the individual atoms: an odd number of electrons per cell has never yielded an insulator [688, 689].

Derivation pending #242

Bloch's theorem for a periodic potential and the counting that follows from it: that the allowed wavevectors in one Brillouin zone number the primitive cells of the crystal, so that each band holds exactly two electrons per cell; that a crystal whose bands are either completely full or completely empty has no states available at infinitesimal excitation energy and therefore carries no current at zero temperature; and the consequent identification of a semiconductor as an insulator whose gap is comparable with the thermal energy

126.3.2 Semimetals, semiconductors and the gap scale

[Reserved: the measured gaps that set the scale of all electronics — about $1.12\,\mathrm{eV}$ *in silicon,* $0.67\,\mathrm{eV}$ *in germanium,* $1.42\,\mathrm{eV}$ *in gallium arsenide, against about* $5.5\,\mathrm{eV}$ *in diamond [2061]; direct against indirect gaps and the phonon that must be supplied in the second case; the semimetals bismuth, antimony and graphite, with band overlaps of* meV *and carrier densities four orders below a normal metal; handover to Chapter 127.]*

126.3.3 Computing band structures

[Reserved: the cellular method and the first quantitative band calculation for a real solid, metallic sodium, by Wigner and Seitz [728]; orthogonalized plane waves [851]; the pseudopotential construction that explains why nearly-free-electron bands work [1172]; the augmented-plane-wave and $k \cdot p$ families [1570]; what "ab initio" does and does not mean here, and the discipline that every computed band is judged against the measurements of Section 126.5.]

126.3.4 Density functional theory

[Reserved: the Hohenberg–Kohn theorems — the ground-state density fixes the external potential up to a constant, and the energy is a variational functional of that density [1284]; the Kohn–Sham construction trading the interacting problem for non-interacting particles in a self-consistent effective potential [1314]; the local-density and generalized-gradient approximations [1927]; and the honest caveats — that Kohn–Sham eigenvalues are not excitation energies, that computed gaps come out low by tens of percent, and that the many-body GW self-energy [1310] is what brings them into agreement with the photoemission of Section 126.5.4.]

126.4 Semiclassical dynamics of Bloch electrons

126.4.1 Group velocity and effective mass

[Reserved: the wave-packet velocity $\boldsymbol{v}_n = \hbar^{-1}\nabla_{\boldsymbol{k}} E_n(\boldsymbol{k})$ and the semiclassical force law $\hbar\dot{\boldsymbol{k}} = -e(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B})$, in which the lattice force is absorbed entirely into the band; the inverse effective-mass tensor $(m^*)^{-1}_{ij} = \hbar^{-2}\partial^2 E/\partial k_i \partial k_j$, introduced with the theory of galvanomagnetic effects by Peierls [635]; measured values spanning $0.067\,m_e$ in gallium arsenide to tens of m_e in heavy-fermion metals; the interband conditions under which the semiclassical description is legitimate.]

126.4.2 Holes

[Reserved: an almost-full band described by its vacancies; the hole's positive charge, positive effective mass near a band maximum, and hence the positive Hall coefficient observed in aluminium, zinc and beryllium — precisely the anomaly of Section 126.1.3; Peierls' introduction of the concept [635]; holes as the majority carriers of p-type material in Chapter 127, and the care needed not to confuse this collective vacancy with the antiparticle of Chapter 93.]

126.4.3 Bloch oscillations and Zener breakdown

[Reserved: a static field sweeps $\boldsymbol{k}$ uniformly across the zone, so a perfect crystal should oscillate at $eEa/\hbar$ rather than conduct [623]; why scattering destroys the effect in bulk metals and why it is nevertheless observed in semiconductor superlattices, whose small zone raises the frequency above the scattering rate [1853]; interband tunnelling at large field, computed by Zener [750], which returns as the tunnel diode of Chapter 127.]

126.4.4 Magnetotransport and the Hall coefficient

[Reserved: Hall's discovery that a field transverse to a current produces a transverse voltage [208]; the free-electron result $R_H = -1/ne$ and its everyday use as a carrier-density measurement; magnetoresistance, closed and open orbits, and the saturation criterion that reads Fermi-surface topology directly off a magnetoresistance curve [1570]; the same geometry

taken to two dimensions, high field and low temperature becomes the quantized effect of Chapter 128.]

126.5 The Fermi surface and how it is measured

126.5.1 Landau levels and quantum oscillations

[Reserved: the quantization of cyclotron orbits into Landau levels [660], with degeneracy eB/h per unit area, and the passage of those levels through the Fermi energy periodically in $1/B$; the Lifshitz–Kosevich amplitude formula with its temperature and Dingle damping factors [1092]; why oscillations demand $\omega_c\tau \gg 1$, hence high-purity crystals, fields of order $10\,\mathrm{T}$ and temperatures of order $1\,\mathrm{K}$.]

126.5.2 The de Haas–van Alphen effect

[Reserved: the oscillation of the magnetic susceptibility of bismuth periodic in $1/B$, discovered by de Haas and van Alphen [655]; Onsager's relation $\Delta(1/B) = 2\pi e/\hbar A_{\mathrm{ext}}$, which ties the observed period to an extremal cross-sectional area of the Fermi surface and thereby converted a curiosity into the primary instrument of the field [1008]; the reconstructed Fermi surfaces of copper, gold and aluminium, with their necks touching the zone boundary [1745]; Pippard's independent determination for copper from the anomalous skin effect [1126].]

Phenomenon 126.5 (Quantum oscillations measure the Fermi surface)**.** The magnetic susceptibility of a pure crystal of bismuth at low temperature does not vary smoothly with the applied field but oscillates, and the oscillations are periodic not in B but in $1/B$ [655]. The same periodicity appears in the resistivity [670] and, as instrumentation improved, in every clean metal examined. The observed frequencies are properties of the material alone; there may be several of them, and they change in a characteristic way as the crystal is rotated in the field. Read through Onsager's relation [1008], each frequency measures an extremal cross-sectional area of the Fermi surface normal to the field, which converts the effect into a tomograph: the Fermi surfaces of copper, gold and aluminium, complete with the necks by which they touch the zone boundary, were reconstructed this way [1745] and confirmed independently for copper from the anomalous skin effect [1126]. The requirement is a cyclotron period short compared with the scattering time, hence high purity, fields of order $10\,\mathrm{T}$ and temperatures of order $1\,\mathrm{K}$.

Derivation pending #243

Semiclassical quantization of a closed cyclotron orbit, giving orbits of quantized area in reciprocal space evenly spaced in the magnetic field; the resulting oscillation of the free energy as successive quantized tubes cross the Fermi surface, periodic in the inverse field with a frequency proportional to the extremal cross-sectional area; and the Lifshitz–Kosevich amplitude with its temperature and scattering damping factors

126.5.3 Shubnikov–de Haas and cyclotron resonance

[Reserved: the same quantization seen in the resistivity rather than the susceptibility [670], the transport analogue that returns in Chapter 128; cyclotron resonance, in which microwave power is absorbed at $\omega = eB/m^*$, used by Dresselhaus, Kip and Kittel to measure the effective-mass tensors of silicon and germanium directly [1063] — the measurement that established the many-valley conduction bands underlying Chapter 127.]

126.5.4 Photoemission

[Reserved: angle-resolved photoemission as the only probe that maps $E_n(\boldsymbol{k})$ directly, using the photoelectric effect of Chapter 69 together with energy and in-plane momentum conservation at the surface; what is actually measured — the one-particle spectral function, hence self-energies, lifetimes and mass renormalizations — and the surface sensitivity and final-state uncertainty that limit it [2048]; present resolutions of a few meV *and the direct imaging of Fermi surfaces, kinks and gaps [2391].]*

126.6 Transport and scattering

126.6.1 Residual resistivity and Matthiessen's rule

[Reserved: the striking consequence of Bloch's theorem that a perfect periodic crystal has infinite conductivity, so that all resistance is a defect of periodicity; impurity and defect scattering, the temperature-independent residual resistivity, and the residual resistance ratio as the standard purity figure of merit; the additivity of scattering rates measured by Matthiessen and Vogt in alloys [160] and the conditions under which it fails; the Boltzmann transport equation that derives it, developed in Chapter 124.]

Phenomenon 126.6 (Resistivity separates into an impurity term and a temperature term)**.** The resistivity of a metal is, to a good approximation, a sum of two independent contributions,

$$\rho(T) = \rho_0 + \rho_{\mathrm{i}}(T)\,, \tag{126.8}$$

in which ρ_0 is temperature-independent and depends only on the concentration of impurities and defects, while $\rho_{\mathrm{i}}(T)$ depends only on the temperature and is the same function for every sample of the metal, however pure — the rule Matthiessen and Vogt established on alloy series [160]. Two consequences are measured. As $T \to 0$ the resistivity saturates at ρ_0 instead of vanishing, so the residual resistance ratio is the standard figure of merit for crystal purity; and ρ_{i} is linear in T well above the Debye temperature and falls as a high power of T well below it, following the form Bloch derived and Grüneisen fitted across the metals [642, 720]. The striking part is ρ_0: a perfectly periodic crystal would have none, so every ohm a metal presents is a defect of its periodicity.

Derivation pending #244

That a Bloch state is a stationary state of the perfect periodic potential and therefore propagates without attenuation, so that resistance requires a departure from periodicity; the Boltzmann equation in the relaxation-time approximation and the additivity of scattering rates from independent channels that yields Matthiessen's rule, together with the conditions under which the additivity fails; and the electron–phonon calculation giving the linear high-temperature and the steep low-temperature resistivity

126.6.2 Phonon scattering and the Bloch–Grüneisen law

[Reserved: electron–phonon scattering off the lattice modes of Chapter 125; the linear high-temperature resistivity and the T^5 low-temperature law derived by Bloch [642] and fitted across the metals by Grüneisen [720]; normal against umklapp processes and why only the latter degrade a current [1570]; the electron–phonon coupling constant that reappears as the pairing interaction of Chapter 130; thermopower, the Peltier effect and thermal transport deferred to Chapter 124.]

126.7 Where the one-electron picture fails

126.7.1 Fermi-liquid theory

[Reserved: the question the whole chapter has been begging — why a dense, strongly interacting electron liquid behaves like a gas of independent particles at all; Landau's answer in terms of quasiparticles adiabatically connected to the free states, carrying a renormalized mass and a lifetime diverging as $(E - E_F)^{-2}$ at the Fermi surface [1119]; the experimental signatures — enhanced but still linear specific heat, T^2 resistivity, and the sharp quasiparticle peak seen in Section 126.5.4; the measured metals that violate all three.]

126.7.2 Mott insulators and the Hubbard model

[Reserved: the solids band theory declares to be metals and that are measured to be insulators — nickel oxide, cobalt oxide, the transition-metal monoxides — and Mott's argument that on-site Coulomb repulsion rather than band filling localizes their electrons [941, 1376]; the Hubbard Hamiltonian, hopping t against on-site repulsion U, and the transition near $U \sim W$ [1257]; the antiferromagnetic order that usually accompanies it, in Chapter 129; recorded as an open problem of Chapter 133 rather than as a solved one.]

Phenomenon 126.7 (Insulators that band theory says are metals)**.** Nickel oxide, cobalt oxide and the other transition-metal monoxides have an odd number of d electrons per primitive cell and a partially filled band, and by the counting of Phenomenon 126.4 must therefore be metals. They are measured to be insulators, and good ones, with activated conduction and resistivities many orders of magnitude above any metal [941, 1376]. The failure is not marginal and cannot be repaired by a better band calculation, because it is not a failure of approximation but of the premise: the one-electron picture treats the Coulomb repulsion between electrons as an average potential, and in a narrow band the cost of putting two electrons on the same site exceeds the energy gained by letting them move.

Derivation pending #245

The Hubbard Hamiltonian, in which a hopping amplitude competes with an on-site repulsion, and the localization of one electron per site when the repulsion exceeds the bandwidth — a transition to an insulating state that occurs at fixed, partial band filling and therefore has no description in band theory at all; noting that no controlled solution of this model in three dimensions exists, so the derivation available is a limiting-case argument and not a theory

126.7.3 Disorder and localization

[Reserved: Anderson's demonstration that sufficiently strong random disorder localizes the single-particle eigenstates outright, so that diffusion stops and conduction ceases with no gap anywhere in the spectrum [1134]; the mobility edge separating localized from extended states; weak localization and its characteristic negative magnetoresistance; and the strongest quantitative evidence for the whole picture — localization is what gives the quantum Hall plateaux of Chapter 128 a finite width.]

Chapter 127

Semiconductors

A semiconductor is nothing more exotic than a band insulator whose gap is small enough for the thermal energy $k_B T$, or a deliberately introduced impurity, to put a controllable number of carriers into an otherwise empty band — the identification is Wilson's [688, 689], and everything in this chapter is a consequence of it and of the band theory of Chapter 126. What makes the subject worth a chapter of its own is that the controllability is quantitative over some twenty orders of magnitude in carrier density, that the resulting devices are the most exhaustively verified artefacts in physics, and that the chain from a measured band gap to a working transistor is short enough to be followed in full. The Nobel prizes of 1956 (transistor) and 2000 (heterostructures and the integrated circuit) bracket that chain.

The chapter therefore runs from the band structure of silicon, germanium and gallium arsenide and the optical measurement of their gaps [1152], through carrier statistics, doping [946] and the measurement of mobility and lifetime [983], to rectification at a barrier [811, 843, 847], the p–n junction [948], the transistor [907, 990], and the optoelectronic devices that run the junction backwards — solar cell [1032], light-emitting diode [337, 1230] and injection laser [1229]. It ends in the low-dimensional structures [1422, 1524] that supply the two-dimensional electron gas of Chapter 128. The standard device reference is [2113]; the founding monograph is Shockley's [972].

Derivation pending #246

Semiconductors: all derivations of this chapter are pending.

127.1 What a semiconductor is

127.1.1 Wilson's band picture

[Reserved: Wilson's two papers, which identified a semiconductor as a filled-band insulator with a small gap and showed that its conductivity must rise with temperature rather than fall [688, 689]; the resulting exponential $\sigma \propto \mathrm{e}^{-E_g/2k_BT}$ and the resistivity range from $1\times10^{-5}\,\Omega\,\mathrm{m}$ to $1\times10^{5}\,\Omega\,\mathrm{m}$ that separates semiconductors from metals and insulators; the older empirical facts this explained — Faraday's observation that the resistance of silver sulfide falls *on heating, the opposite of every metal [93], and the erratic behaviour of "impure" samples now known to be doping.]*

Phenomenon 127.1 (Conduction that improves on heating)**.** The electrical resistance of silver sulfide *falls* as it is heated — the opposite of the behaviour of every metal, and the first recorded observation of semiconduction [93]. In a pure semiconductor the effect is not a weak drift but an exponential: over several decades of conductivity, and to within a slowly

varying prefactor,

$$\sigma(T) \propto \mathrm{e}^{-E_g/2k_BT}\,, \tag{127.1}$$

so that a plot of $\ln\sigma$ against $1/T$ is a straight line whose slope measures a single energy E_g characteristic of the material [688, 689]. The same substances have room-temperature resistivities anywhere between about $1\times10^{-5}\,\Omega\,\mathrm{m}$ and $1\times10^{5}\,\Omega\,\mathrm{m}$, and the value in a given specimen is exquisitely sensitive to impurities present at parts per million — which is why the early measurements were irreproducible and were long dismissed as dirt.

Derivation. Let the conduction band edge be at E_c and the valence band edge at E_v, with $E_g = E_c - E_v$, and let the chemical potential lie several k_BT inside the gap, so that the Fermi–Dirac occupation of Chapter 120 may be replaced by its Boltzmann tail at both edges. Integrating the band-edge density of states against that tail gives the standard forms

$$n = N_c\,\mathrm{e}^{-(E_c-\mu)/k_BT}\,, \qquad p = N_v\,\mathrm{e}^{-(\mu-E_v)/k_BT}\,, \tag{127.2}$$

where N_c and N_v are effective densities of states varying only as $T^{3/2}$. Multiplying the two expressions in Equation (127.2) eliminates the chemical potential entirely:

$$np = N_cN_v\,\mathrm{e}^{-E_g/k_BT} \equiv n_i^2\,, \tag{127.3}$$

the law of mass action, which holds whatever the doping and is the single most useful relation in the subject. In an undoped crystal every conduction electron leaves a hole behind, so $n = p = n_i$, and the conductivity $\sigma = e(n\mu_n + p\mu_p)$ inherits the square root of Equation (127.3), which is Equation (127.1). The factor of two in the exponent is the whole content of the measurement: it is there because the carriers are created in pairs across the gap, so the slope of the Arrhenius plot returns $E_g/2$ and not E_g. A metal has no gap and hence no such factor; its resistivity is governed instead by the scattering of Chapter 126, which grows with temperature, and the two temperature dependences therefore run in opposite directions. □

127.1.2 The band structures of silicon, germanium and gallium arsenide

[Reserved: the diamond and zincblende lattices and their Brillouin zones; the indirect gap of silicon and germanium, with conduction minima away from the zone centre — six valleys along Δ in silicon, eight half-valleys at L in germanium — against the direct gap of gallium arsenide at Γ; the anisotropic effective-mass tensors measured by cyclotron resonance [1063]; the light-, heavy- and split-off hole bands; $k\cdot p$ theory as the standard analytic parametrization near a band edge [1116]; tabulated parameters [2061].]

127.1.3 Measuring the gap optically

[Reserved: the absorption edge as the direct measurement of E_g; the square-root edge of a direct gap against the phonon-assisted structure of an indirect one, resolved into separate phonon-emission and phonon-absorption thresholds by Macfarlane and co-workers in silicon [1152] — a measurement of the band structure and the lattice modes of Chapter 125 at once; the shrinking of the gap with temperature and the empirical Varshni form [1360]; photoluminescence and photoconductivity as complementary determinations.]

Phenomenon 127.2 (The absorption edge, and the two thresholds of an indirect gap)**.** A semiconductor is transparent to photons below a threshold energy and absorbs strongly above it, and the threshold measures the band gap: about 1.12 eV in silicon, 0.67 eV in germanium and 1.42 eV in gallium arsenide, against about 5.5 eV in diamond [2061]. In silicon the edge is not one threshold but two, separated by a fixed energy of order tens

of meV, and the lower of the two weakens as the crystal is cooled while the upper does not; the separation matches twice the energy of a lattice mode of Chapter 125 at a definite wavevector [1152]. One optical measurement therefore returns the electronic gap, the fact that the gap is indirect, and the energy of the phonon that bridges it.

Derivation. A photon of energy of order 1 eV has wavevector ω/c of order $1 \times 10^{7}/\mathrm{m}$, three orders of magnitude smaller than the width $1 \times 10^{10}/\mathrm{m}$ of a Brillouin zone. On the scale of Chapter 126 the photon therefore carries energy but no crystal momentum, and an optical transition is vertical: it connects states of the same $\boldsymbol{k}$. If the valence maximum and the conduction minimum lie at the same $\boldsymbol{k}$, as in gallium arsenide, absorption begins as soon as $\hbar\omega \geq E_g$ and there is a single threshold. If they lie at different $\boldsymbol{k}$, as in silicon and germanium, no vertical transition of energy E_g exists, and the transition can proceed only with the simultaneous emission or absorption of a phonon of wavevector equal to the offset. Conserving energy in the two cases,

$$\hbar\omega = E_g + \hbar\Omega \quad \text{(phonon emitted)}\,, \qquad \hbar\omega = E_g - \hbar\Omega \quad \text{(phonon absorbed)}\,, \tag{127.4}$$

which are two thresholds separated by $2\hbar\Omega$ and placed symmetrically about E_g. The absorption branch requires a phonon to be waiting in the crystal, so its strength carries the Bose occupation factor of that mode and vanishes exponentially as $T \to 0$; the emission branch requires only that a phonon can be created, and survives. That asymmetry is what identifies which threshold is which, and it converts Equation (127.4) into a measurement of E_g and $\hbar\Omega$ separately. It also explains why an indirect-gap material is a poor light emitter and a good solar absorber only when thick: the transition needs a third particle, and is correspondingly weak. □

127.2 Carriers and their statistics

127.2.1 Intrinsic conduction

[Reserved: electrons thermally promoted across the gap leaving holes behind, so that $n = p = n_i$; the effective density of states, the law of mass action $np = n_i^2$ independent of doping, and the intrinsic densities that follow — of order $1 \times 10^{16}/\mathrm{m}^3$ in silicon at 300 K against $1 \times 10^{29}/\mathrm{m}^3$ of conduction electrons in copper; the chemical potential near mid-gap and its temperature drift; the Fermi–Dirac statistics of Chapter 120 and the Boltzmann limit in which they are usually applied.]

127.2.2 Doping and extrinsic conduction

[Reserved: substitutional donors and acceptors; the hydrogenic impurity level, binding energy scaled by m^*/m and $1/\epsilon_r^2$ to a few tens of meV*, and the consequent freeze-out at low temperature; the systematic measurements of boron- and phosphorus-doped silicon by Pearson and Bardeen that established the picture quantitatively [946]; compensation, degenerate doping and the Mott criterion for the impurity-band transition [1376]; zone refining and the purity — better than one part in 10^{10} — without which none of this is reproducible.]*

Phenomenon 127.3 (Doping controls the carrier density and its sign)**.** Substituting a group-V atom for a silicon atom at the level of parts per million raises the electron density by many orders of magnitude and leaves the hole density correspondingly depressed, in accordance with Equation (127.3); substituting a group-III atom does the same for holes. Over a wide intermediate range of temperature the carrier density equals the dopant density and is flat in temperature, the impurities being fully ionized; below that range it falls exponentially as the carriers freeze back onto their donors, with an activation energy of a few

tens of meV, and above it the intrinsic pairs of Equation (127.1) take over. The systematic measurements of boron- and phosphorus-doped silicon that established this picture are those of Pearson and Bardeen [946]. The Hall coefficient of Chapter 126 [208] reverses sign between the two doping types, which is the direct evidence that the positive carriers are real; near the intrinsic regime, where both species conduct, it can reverse sign again with temperature in one sample.

Derivation pending #247

The hydrogenic impurity level: a donor treated as a charge screened by the dielectric constant of the host and binding an electron of the band effective mass, giving a binding energy reduced from the hydrogenic value by the effective-mass ratio and by the square of the relative permittivity, hence tens of meV*; and the charge-neutrality condition combined with the law of mass action, which yields the freeze-out, saturation and intrinsic regimes as limits of one expression*

127.2.3 The Hall effect as a carrier measurement

[Reserved: the Hall coefficient [208] used in a semiconductor for what it does best — returning the sign of the majority carrier and, with the conductivity, both the density and the mobility; the sign reversal on passing from n-type to p-type material as the direct evidence for holes; two-carrier conduction near intrinsic, where the Hall coefficient can change sign with temperature; van der Pauw's theorem, which extracts resistivity and Hall coefficient from a sample of arbitrary shape with four contacts on its edge [1157], as the working laboratory method.]

127.2.4 Drift, diffusion and mobility

[Reserved: the drift–diffusion equations, the Einstein relation $D/\mu = k_B T/e$ linking them (the same relation proved for Brownian motion in Chapter 119); measured room-temperature mobilities of about $0.15\,\mathrm{m^2/(V\,s)}$ for electrons in silicon and eight times that in gallium arsenide; scattering by ionized impurities, by acoustic and polar optical phonons and their differing temperature laws; velocity saturation and the transport formalism of Chapter 124.]

127.2.5 Recombination and carrier lifetime

[Reserved: radiative band-to-band recombination, Auger recombination, and the trap-assisted Shockley–Read–Hall mechanism that dominates in indirect-gap material [1001, 1012]; minority-carrier lifetimes from nanoseconds to milliseconds and the diffusion length that follows; surface recombination and passivation; why the lifetime, not the mobility, is what limits solar cells and bipolar transistors alike.]

127.3 Junctions and rectification

127.3.1 Metal–semiconductor contacts

[Reserved: asymmetric conduction at a metal contact, known empirically since the cat's-whisker detector; the barrier theories advanced independently by Davydov [811], Mott [843] and Schottky [847], and the space-charge layer they predict; thermionic emission over the barrier against diffusion through it; Bardeen's demonstration that surface states pin the Fermi level and largely decouple the measured barrier height from the metal work function [896] — the result that redirected the effort toward the junction transistor; ohmic contacts.]

127.3.2 The p–n junction

[Reserved: the depletion region, built-in potential and internal field of a junction between p- and n-type material; Shockley's theory and the ideal diode law $I = I_0(\mathrm{e}^{eV/k_BT} - 1)$ [948]; capacitance–voltage profiling as the measurement of the doping profile; deviations from ideality — recombination current, high-injection, series resistance; avalanche and Zener breakdown [750]; the junction as the single component from which every device in Section 127.4 and Section 127.5 is assembled.]

Phenomenon 127.4 (Rectification at a junction)**.** A single crystal doped p-type on one side and n-type on the other conducts asymmetrically: forward biased it passes a current that rises exponentially with the applied voltage, with a logarithmic slope of e/k_BT per volt — about one decade of current per 60 mV at room temperature — while reverse biased it passes a small current that saturates and is almost independent of voltage. Over many decades the characteristic follows

$$I = I_0 \left(\mathrm{e}^{eV/k_BT} - 1 \right) , \tag{127.5}$$

with I_0 fixed by the doping and the minority-carrier properties and not adjustable [948]. The asymmetry arises inside a homogeneous single crystal with no interface between different substances, and the exponent contains the temperature rather than any device parameter, which is what marks Equation (127.5) as a statement about carrier statistics.

Derivation pending #248

The p–n junction in equilibrium: the diffusion of carriers across the metallurgical boundary, the depletion region and built-in potential that arrest it, and the equality of drift and diffusion currents that fixes that potential through the law of mass action; then, under bias, the Boltzmann factor by which the barrier lowering multiplies the minority-carrier density at the depletion edge, the diffusion of those excess carriers into the neutral regions, and the resulting saturation current — together with the recombination, high-injection and series-resistance terms by which real diodes depart from the ideal law

127.3.3 The Haynes–Shockley experiment

[Reserved: the experiment that made minority carriers visible — a pulse of holes injected into an n-type germanium bar, drifted by a field and detected downstream, giving drift velocity, diffusion constant and lifetime from the arrival time, the width and the area of one measured pulse [983]; the direct test of the Einstein relation it provides; why it settled the question of whether injected minority carriers exist at all, which underpins Section 127.4.1.]

Phenomenon 127.5 (Minority carriers drift, diffuse and recombine)**.** A pulse of holes injected at one point of an n-type germanium bar, where holes are vastly outnumbered, does not vanish into the electron sea. It travels down the bar at a velocity proportional to the applied field, arrives at a downstream contact after a measurable delay, broadens as it goes by an amount that grows as the square root of the transit time, and loses area exponentially with a lifetime of its own [983]. One oscilloscope trace therefore yields the drift mobility from the delay, the diffusion constant from the width and the lifetime from the area. The two transport coefficients so obtained are not independent: they satisfy

$$\frac{D}{\mu} = \frac{k_BT}{e} , \tag{127.6}$$

about 25.7 mV at 298 K, the same relation between fluctuation and dissipation that governs Brownian motion in Chapter 119.

Derivation. Consider the carriers in thermal equilibrium in a static potential $\phi(x)$, with no current flowing anywhere — equilibrium, not a steady state, so that drift and diffusion must cancel locally and not merely on average. For electrons of charge $-e$ the potential energy is $U = -e\phi$, so the equilibrium density is the Boltzmann distribution

$$n(x) \propto \mathrm{e}^{-U/k_B T} = \mathrm{e}^{e\phi/k_B T} \quad \Longrightarrow \quad \frac{\mathrm{d}n}{\mathrm{d}x} = \frac{e}{k_B T}\, n\, \frac{\mathrm{d}\phi}{\mathrm{d}x} = -\frac{e}{k_B T}\, n\, E\,. \tag{127.7}$$

An electron of mobility μ drifts at velocity $-\mu E$, against the field, so the particle flux is $\Gamma = -n\mu E - D\,\mathrm{d}n/\mathrm{d}x$. Setting it to zero and substituting Equation (127.7),

$$0 = -n\mu E + \frac{eD}{k_B T}\, nE = nE\left(\frac{eD}{k_B T} - \mu\right), \tag{127.8}$$

which must hold for every E and every n, and therefore holds if and only if $D/\mu = k_B T/e$, which is Equation (127.6). The content of the argument is that a single microscopic process — the same collisions — limits the drift and produces the random walk, so the coefficient describing the response to a force and the coefficient describing the spontaneous spreading cannot be chosen independently. Since μ and D are measured from different features of the *same* recorded pulse, the Haynes–Shockley experiment tests Equation (127.6) rather than assuming it. □

127.3.4 Tunnelling and the Esaki diode

[Reserved: a junction doped degenerately on both sides, so thin that carriers tunnel through rather than over the barrier; Esaki's observation of negative differential resistance in narrow germanium junctions, the first clear demonstration of tunnelling in a solid [1141]; the peak-to-valley ratio and its interpretation; phonon-assisted structure in the tunnelling current as spectroscopy; the line from here to superconducting tunnelling in Chapter 131.]

127.4 Devices

127.4.1 The transistor

[Reserved: the point-contact transistor of Bardeen and Brattain, with power gain demonstrated in a germanium slab in December 1947 [907]; Shockley's junction transistor, in which the minority-carrier injection of Section 127.3.3 replaces the fragile point contacts [972, 990]; current gain, base transit time and the Early effect [2113]; the 1956 Nobel prize; why the device is a physics result and not only an engineering one — it is a working measurement of minority-carrier transport.]

Phenomenon 127.6 (Power gain in a solid)**.** A germanium slab carrying two closely spaced point contacts, one forward biased at low impedance and one reverse biased at high impedance, delivers to a load at the second contact more signal power than is supplied to the first: a small current modulation at the input controls a larger power at the output, with gain measured at audio frequencies in December 1947 [907]. Gain, not rectification, is the observation — rectifying contacts had been in use for decades — and it requires that carriers injected at one contact survive the journey to the other, which is the minority-carrier transport of Phenomenon 127.5. Replacing the fragile point contacts by two p–n junctions sharing a thin base gives the same effect in a robust and quantitatively predictable form [972, 990].

Derivation pending #249

Transistor action from the junction physics already in hand: injection of minority carriers across a forward-biased emitter junction, their diffusion across a base thin compared with the diffusion length so that few recombine, and their collection by the reverse-biased collector junction; the resulting current gain as the fraction surviving the base, and the power gain as the product of that fraction with the ratio of the collector to the emitter impedance — the transfer of current from a low-resistance to a high-resistance circuit that gives the device its name

127.4.2 The MOSFET and the inversion layer

[Reserved: the field-effect idea, older than the point-contact transistor and blocked for two decades by the surface states of [896], unblocked by thermally grown silicon dioxide; the metal–oxide–semiconductor structure, the inversion layer and the threshold voltage [1583]; the inversion layer as a genuine two-dimensional electron gas, with quantized subbands [1678] — the same system in which quantized magnetoresistance [1329] and then the quantum Hall effect of Chapter 128 were found.]

127.4.3 The integrated circuit

[Reserved: Kilby's demonstration that every element of a circuit can be made in one block of semiconductor [1584], and the planar process that made it manufacturable; scaling, Moore's empirical doubling law and its status as an economic observation rather than a physical one [1315]; the physical limits that eventually bind — gate oxide tunnelling, dopant number fluctuations, power density; the 2000 Nobel prize shared with the heterostructure work of Section 127.5.3.]

127.5 Light and semiconductors

127.5.1 Photoconductivity and the solar cell

[Reserved: photogeneration of electron–hole pairs above the absorption edge and the photocurrent that results; the silicon p–n junction photocell of Chapin, Fuller and Pearson, the first solar cell of usable efficiency at about six percent [1032]; the open-circuit voltage, short-circuit current and fill factor actually measured; the Shockley–Queisser detailed-balance limit, about 33 % for a single gap under the solar spectrum [1219], derived from the thermodynamics of Chapter 54; measured cell efficiencies against it.]

127.5.2 Light-emitting diodes

[Reserved: Round's note recording light from a silicon carbide contact, the first observation of electroluminescence in a semiconductor [337]; the recombination of injected carriers across a direct gap as its explanation, and the resulting relation between emitted photon energy and E_g; the first visible practical device, the red gallium arsenide phosphide diode of Holonyak and Bevacqua [1230]; the long-delayed blue diode built on gallium nitride [1885] and the 2014 Nobel prize; efficiency measurements and droop.]

Phenomenon 127.7 (Electroluminescence)**.** A current passed through certain semiconducting contacts produces light. Round recorded a yellowish glow from a silicon carbide detector under bias, the first observation of the effect in a semiconductor [337]. In a forward-biased junction of a direct-gap material the emission is not thermal: the spectrum is a narrow band whose photon energy is close to the band gap of the material and shifts with it as the

material composition is changed, which is how the first practical visible emitter was tuned to red in gallium arsenide phosphide [1230] and, thirty years later, to blue in gallium nitride [1885]. The device is the junction of Phenomenon 127.4 run in reverse in the energetic sense: instead of light generating carriers, carriers generate light.

Derivation pending #250

Radiative recombination of injected minority carriers across a direct gap: the emission spectrum as the joint density of states weighted by the carrier occupations, giving a peak just above the gap with a width of order the thermal energy; the selection rule that suppresses the process in an indirect-gap material, where a phonon must participate, and the competing non-radiative Auger and trap-assisted channels that fix the internal quantum efficiency

127.5.3 The semiconductor laser and heterostructures

[Reserved: population inversion in a degenerately doped junction and the coherent emission observed from gallium arsenide diodes by Hall and co-workers [1229]; the threshold current and its temperature dependence; Kroemer's double-heterostructure proposal, confining carriers and photons in the same layer [1260], and the room-temperature continuous-wave operation it eventually delivered [2009]; quantum-well active regions [1524]; the stimulated-emission physics itself belongs to Chapter 122.]

127.5.4 Excitons

[Reserved: the bound electron–hole pair, tightly bound and localized in Frenkel's molecular limit [680] and weakly bound over many lattice constants in Wannier's [805]; hydrogenic binding energies of a few meV *in gallium arsenide, and the sharp absorption lines below the gap that measure them; why excitons are visible at room temperature in wide-gap and two-dimensional material and not in bulk silicon.]*

127.6 Low-dimensional semiconductors

127.6.1 Quantum wells and superlattices

[Reserved: epitaxial growth with monolayer control; the square well of Chapter 78 realized physically, with confined subbands observed as steps in absorption and as discrete emission lines [1524]; the Esaki–Tsu superlattice, its minibands and predicted negative differential conductivity [1422], in which the Bloch oscillations of Chapter 126 become observable; band-gap engineering as an experimental programme.]

127.6.2 The two-dimensional electron gas

[Reserved: modulation doping, which separates the donors from the carriers and so removes the dominant scattering channel [1618]; mobilities improved by more than three orders of magnitude, up to $1 \times 10^{3}\,\mathrm{m^{2}/(V\,s)}$ *in the best gallium arsenide heterostructures; the electronic properties of such two-dimensional systems reviewed comprehensively in [1678]; this is the sample that Chapter 128 takes as its starting point, and the reason the fractional effect was found at all.]*

Chapter 128

Experiment: The Quantum Hall Effect

On the night of 4–5 February 1980, measuring the Hall voltage of a silicon field-effect transistor at 1.5 K in about 15 T, von Klitzing, Dorda and Pepper found that the Hall resistance did not rise linearly with field but sat on flat plateaux at the values $h/\nu e^2$ with ν an integer, while the longitudinal resistance vanished [1655]. The plateau values depend on nothing — not on the material, the geometry, the mobility or the disorder — and have since been reproduced to parts in 10^{10} in different substances [1846]. That a macroscopic, irreducibly dirty solid should hand back a combination of fundamental constants exactly is the most striking single measurement in condensed matter physics, and it is why the ohm has been realized from this effect since 1990 and why $R_K = h/e^2$ is exact in the present SI [2333, 2431].

This chapter treats that measurement as an experiment, with the structured `experiment` environment (apparatus, procedure, observations with uncertainties in SI, interpretation, primary references) to be filled in when the content is written. It rests on the band theory and Landau quantization of Chapter 126 and on the heterostructure two-dimensional electron gas of Chapter 127; it carries forward into the topological language of Chapter 6 and Chapter 14, and into the metrology of Chapter 2. Two years after the integer effect, the same apparatus applied to a cleaner sample produced plateaux at *fractional* ν [1705], whose explanation [1725] required a new correlated ground state and excitations carrying a fraction of the electron charge — since measured directly [1943, 1944]. The standard collection is [1836]; a forty-year retrospective is [2360].

Derivation pending #251

Experiment: The Quantum Hall Effect: all derivations of this chapter are pending.

128.1 Historical context and the prediction under test

128.1.1 The classical Hall effect

[Reserved: Hall's 1879 measurement of a transverse voltage across a current-carrying gold leaf in a magnetic field [208]; the classical result $R_H = B/ne$ for a three-dimensional conductor and $R_{xy} = B/n_s e$ for a sheet of areal density n_s, linear in B with no structure whatever; the Hall bar geometry and the four-terminal measurement that separates R_{xx} from R_{xy}; this is the prediction the experiment of Section 128.4 contradicts.]

128.1.2 Two-dimensional electron gases

[Reserved: the inversion layer of a silicon metal–oxide–semiconductor transistor as the first true two-dimensional electron system, with electric quantum limit and subbands [1678]; the gate voltage as a direct and calibrated control of the areal carrier density; the modulation-doped gallium arsenide heterostructure [1618], which trades tunability for mobility; why two dimensions is essential — the Landau spectrum is then fully discrete, with no dispersion along the field.]

128.1.3 Landau quantization and what was expected

[Reserved: Landau levels at $E_n = (n + \tfrac{1}{2})\hbar\omega_c$ with degeneracy eB/h per unit area [660], and the filling factor $\nu = n_s h/eB$; the earlier observation of magneto-oscillatory conductance in silicon inversion layers by Fowler, Fang, Howard and Stiles [1329], the two-dimensional Shubnikov–de Haas effect; the expectation before 1980 — oscillations in R_{xx} and a Hall resistance with wiggles about the classical line; von Klitzing's actual purpose, a high-accuracy determination of the fine-structure constant [1655].]

128.2 Apparatus

128.2.1 The silicon MOSFET Hall bar

[Reserved: the original sample — a silicon metal–oxide–semiconductor field-effect transistor with a Hall-bar channel, source and drain, two pairs of potential probes and a gate covering the channel [1655]; typical dimensions and mobilities of order $1\,\mathrm{m^2/(V\,s)}$; the gate voltage sweeping n_s through several Landau levels at fixed field, which is the axis along which the original data were taken.]

128.2.2 Heterostructure samples

[Reserved: the modulation-doped gallium arsenide and aluminium gallium arsenide heterojunction [1618], in which the ionized donors sit in a barrier layer set back from the channel; mobilities exceeding $1 \times 10^3\,\mathrm{m^2/(V\,s)}$ and mean free paths of hundreds of μm; the sample quality without which the fractional plateaux of Section 128.4.3 do not appear at all — the single clearest case in the book of a phenomenon gated by materials purity.]

128.2.3 Cryogenics, magnets and electrical metrology

[Reserved: pumped helium-4, helium-3 and dilution refrigeration down to a few mK; superconducting solenoids to about 20 T and resistive or hybrid magnets beyond (Chapter 130); low-noise four-terminal measurement with lock-in detection at currents small enough to avoid electron heating, typically nA to μA; the cryogenic current comparator that transfers the quantized resistance to a calibrated standard resistor with an uncertainty of parts in 10^9 [2014].]

128.3 Procedure

[Reserved: the two equivalent sweeps — gate voltage at fixed field, or field at fixed density — and the measurement of R_{xx} and R_{xy} simultaneously; contact and lead-resistance checks; current reversal and field reversal to remove thermoelectric offsets and to symmetrize the Hall signal; the tests that must be done before any exactness claim is credible — current dependence, temperature dependence, contact placement, and comparison of samples of different geometry and material [1655, 2014].]

128.4 Observations

128.4.1 The integer plateaux

[Reserved: the primary data — R_{xy} flat over a finite range of density or field at $h/\nu e^2 = 25\,812.807\,\Omega/\nu$, with R_{xx} falling to an unmeasurably small value on each plateau and peaking sharply between them [1655]; the numbers to be tabulated with their uncertainties, together with the activation energy extracted from the temperature dependence of R_{xx}; plateau width as a function of disorder; the dissipationless conduction implied by $R_{xx} \to 0$ at finite current.]

Phenomenon 128.1 (Quantized Hall plateaux)**.** In a two-dimensional electron system at low temperature and high magnetic field, the Hall resistance does not rise linearly with the field as Section 128.1.1 requires. It rises in steps: over a finite range of carrier density, or equivalently of field, it sits on a flat plateau at

$$R_{xy} = \frac{h}{\nu e^2}\,, \qquad \nu = 1, 2, 3, \dots\,, \tag{128.1}$$

and jumps between plateaux in between [1655]. Across each plateau the longitudinal resistance R_{xx} falls to a value too small to measure and peaks sharply at the transitions, so on a plateau a finite current flows along the sample with no measurable voltage drop along it — dissipationless transport in a disordered solid at a temperature where the same solid is an ordinary conductor in zero field. The plateau value Equation (128.1) contains no material parameter whatever.

Derivation. The value on the plateau, though not the existence of the plateau, is elementary once the Landau degeneracy is counted. Take a sample $L_x \times L_y$ in a perpendicular field B and work in the gauge $\boldsymbol{A} = (0, Bx, 0)$. The Hamiltonian then commutes with translations along y, so eigenstates may be taken proportional to $\mathrm{e}^{\mathrm{i}k_y y}$, and completing the square shows that each is a one-dimensional oscillator of frequency $\omega_c = eB/m$ centred on

$$x_0 = \frac{\hbar k_y}{eB}\,, \tag{128.2}$$

with energy $(n + \tfrac{1}{2})\hbar\omega_c$ independent of k_y. Periodic boundary conditions in y quantize $k_y = 2\pi j/L_y$ with j an integer, and requiring the centre Equation (128.2) to lie inside the sample, $0 \le x_0 \le L_x$, bounds j by eBL_xL_y/h. Each Landau level therefore holds

$$\frac{N}{A} = \frac{eB}{h} \tag{128.3}$$

states per unit area — one per quantum of magnetic flux h/e threading the sample, which is the way to remember it. If exactly ν levels are filled, the areal carrier density is $n_s = \nu eB/h$. Now apply the classical two-dimensional Hall result of Section 128.1.1, $R_{xy} = B/n_s e$, which follows from force balance alone and holds whenever the carriers move without dissipation:

$$R_{xy} = \frac{B}{n_s e} = \frac{B}{e}\cdot\frac{h}{\nu eB} = \frac{h}{\nu e^2}\,, \tag{128.4}$$

which is Equation (128.1). Note what has been shown and what has not. The field B cancels, and with it every scale in the problem, which is why Equation (128.4) contains no material parameter. But the argument holds only at exactly integer filling, a set of measure zero in the density; it therefore explains the value of the plateau and gives no reason for there to be a plateau at all. That is the subject of Section 128.5.1 and Section 128.5.2, and it is where the disorder enters. □

128.4.2 Exactness and universality

[Reserved: the property that makes the effect extraordinary — the plateau value is independent of material, geometry, mobility and carrier density; the direct comparison of quantized resistances in silicon and in gallium arsenide, agreeing to about one part in 10^{10} [1846]; the reproducibility between national laboratories [2014]; the honest statement of what is measured — a ratio, not an absolute value — and of the systematic effects (current, temperature, contacts) that limit it.]

Phenomenon 128.2 (Exactness and universality of the plateau value)**.** The plateau value Equation (128.1) depends on nothing about the sample. Quantized Hall resistances measured in a silicon metal–oxide–semiconductor device and in a gallium arsenide heterostructure — different host materials, different carrier densities, different mobilities, different geometries, different disorder — agree with one another to about one part in 10^{10} [1846], and independent national laboratories reproduce the value at comparable uncertainty [2014]. This is not a small correction to a material-dependent answer; the material dependence is absent to the accuracy of the best resistance metrology in existence, in samples that are macroscopic, irreducibly disordered and individually unreproducible. The effect accordingly realizes the ohm, and the von Klitzing constant $R_K = h/e^2$ is exact in the present SI, $R_K = 25\,812.807\,45\,\Omega$ [2333, 2431].

Derivation pending #252

Laughlin's gauge argument: that adiabatically threading one flux quantum through a Hall cylinder is a gauge transformation and must map the spectrum to itself, so that its only effect is to transfer an integer number of electrons from one edge to the other; the resulting Hall conductance as that integer times the square of the elementary charge over Planck's constant, with no reference to the Hamiltonian; and the requirement of a mobility gap at the Fermi level that makes the process adiabatic — together with the topological restatement in which the integer is the Chern number of the occupied states, which cannot change under any smooth deformation of the sample

128.4.3 The fractional plateaux

[Reserved: Tsui, Störmer and Gossard's observation, in the extreme quantum limit of a high-mobility heterostructure, of a plateau and a vanishing R_{xx} at $\nu = 1/3$ [1705]; the subsequent hierarchy at $\nu = p/q$ with q odd, and the even-denominator state at $\nu = 5/2$ [1800]; the energy gaps, of order K, measured from activated transport; why no single-particle argument can produce a fractional plateau, which is the point of Section 128.5.5.]

Phenomenon 128.3 (Fractional plateaux)**.** In a heterostructure of much higher mobility, driven into the extreme quantum limit where the lowest Landau level is only partly filled, the same measurement finds a plateau in R_{xy} and a vanishing R_{xx} at the fractional filling $\nu = 1/3$ [1705]. Further plateaux appear as samples improve, at a hierarchy of fillings $\nu = p/q$ with q odd, and — against the pattern — at the even-denominator value $\nu = 5/2$ [1800]. The temperature dependence of R_{xx} on each plateau is activated, so each fraction carries a genuine energy gap, of order a kelvin in temperature units. The observation is not a refinement of Phenomenon 128.1: the derivation given there required an integer number of filled levels, and within a partly filled Landau level all single-particle states are degenerate, so no one-electron argument can produce a gap at all. The gap must be made by the interactions between the electrons, and the fact that the cleanest samples are the ones that show it confirms that disorder is not its source.

Derivation pending #253

Laughlin's correlated wavefunction for filling one over an odd integer, an incompressible liquid rather than a filled single-particle band; the plasma analogy that fixes its density and its excitation gap; the antisymmetry requirement that forces the exponent to be odd; and the hierarchy or composite-fermion construction that accounts for the remaining observed fractions

128.5 Interpretation

128.5.1 Laughlin's gauge argument

[Reserved: the argument that fixes the plateau value with almost no dynamical input — adiabatic insertion of one flux quantum h/e through a Hall cylinder must return the system to itself, so an integer number of electrons is transferred from one edge to the other and $\sigma_{xy} = \nu e^2/h$ exactly [1671]; gauge invariance and the role of a mobility gap; why this explains exactness without explaining plateau width, which needs Section 128.5.2.]

128.5.2 Disorder, localization and plateau width

[Reserved: the apparent paradox that the effect is more perfectly quantized in a dirtier sample; Anderson localization [1134] broadening each Landau level into a narrow band of extended states flanked by localized ones, so that adding carriers to localized states changes nothing measurable and the Hall resistance stays pinned [1689]; the mobility edge and the plateau-to-plateau transition as a quantum critical point with measured scaling exponents; the honest statement that disorder is not a nuisance here but a necessary ingredient.]

128.5.3 Edge states

[Reserved: the confining potential bending Landau levels through the Fermi energy at the sample boundary, producing one-dimensional chiral channels that cannot backscatter because the counter-propagating channel is on the far side of the sample; Büttiker's multiterminal transport formulation, in which each edge channel contributes exactly e^2/h [1807]; the experimental signatures — contact independence, selective population and detection of individual channels; edge states as the model for every later topological boundary mode.]

128.5.4 Topology: TKNN and the Chern number

[Reserved: Thouless, Kohmoto, Nightingale and den Nijs' result that σ_{xy} for a filled band is e^2/h times a topological invariant — the integral of the Berry curvature of the Bloch states over the Brillouin zone, an integer Chern number [1704]; why an integer cannot change under smooth deformation, which is the deepest available answer to why the plateau is exact; the fibre-bundle language of Chapter 14 and the homotopy of Chapter 6; Haldane's lattice model showing that no net field is needed, only broken time reversal [1808].]

128.5.5 The Laughlin state and fractional charge

[Reserved: Laughlin's variational wavefunction $\prod_{i<j}(z_i - z_j)^m \mathrm{e}^{-\sum |z_i|^2/4\ell^2}$ for $\nu = 1/m$ with m odd, an incompressible correlated liquid rather than a filled single-particle band [1725]; its quasiholes, created by adiabatic flux insertion and carrying charge e/m; the plasma analogy that fixes the charge and the fractional exchange statistics; the antisymmetry requirement of Chapter 83 that forces m odd.]

128.6 Later measurements and precision

128.6.1 Fractional charge and anyon statistics measured

[Reserved: shot noise at a quantum point contact in the weak backscattering limit, whose Poisson noise $2q\bar{I}$ measures the carrier charge directly; the independent 1997 determinations of $q = e/3$ at $\nu = 1/3$ [1943, 1944]; and the later interference and collision experiments reporting the fractional exchange phase $2\pi/3$ itself [2354, 2364], the first direct evidence for statistics that are neither Bose nor Fermi — with a clear statement of what the data do and do not establish.]

Phenomenon 128.4 (The current is carried in fractions of an electron charge)**.** Shot noise measures the charge of the carrier that crosses a barrier, because the noise power of a stream of independent discrete carriers is proportional to the product of the carrier charge and the mean current and to nothing else. Applied to weak backscattering at a quantum point contact in the $\nu = 1/3$ state, the measurement returns a carrier charge of $e/3$, in two independent determinations published within weeks of one another [1943, 1944]. Nothing in the sample carries a fraction of the electron charge as a constituent — the electrons are whole — so the object being counted is a collective excitation of the correlated liquid of Phenomenon 128.3. Later interference and collision experiments in the same states report the further, and far more delicate, result that exchanging two such excitations multiplies the state by a phase which is neither $+1$ nor -1 [2354, 2364]; these are excitations of a three-dimensional semiconductor confined to a plane, and the claim is about them and not about any elementary particle.

Derivation pending #254

The quasihole of the correlated ground state and the determination of its charge from the deficit of density produced by adiabatically threading one flux quantum, together with the plasma analogy that makes the deficit exact; and the Schottky formula for the noise of a Poisson stream of independent carriers, whose proportionality to charge times current is what converts a noise measurement into a charge measurement

128.6.2 Composite fermions

[Reserved: Jain's construction attaching an even number of flux quanta to each electron, mapping the fractional effect at $\nu = p/(2p\pm1)$ onto the integer effect of composite fermions in a reduced effective field [1823]; the prediction that at $\nu = 1/2$ the effective field vanishes and a Fermi sea of composite fermions forms; the measurements that support it — effective-field Shubnikov–de Haas oscillations and semiclassical geometric resonances [1861]; the hierarchy of observed fractions as the strongest test.]

128.6.3 Graphene and the relativistic quantum Hall effect

[Reserved: the isolation of single-layer graphene and the demonstration of its field effect [2063]; its linear Dirac dispersion at the zone corners, so that Landau levels go as $\sqrt{nB}$ and a zero-energy level exists; the half-integer sequence $\sigma_{xy} = 4e^2(n + \frac{1}{2})/h$ and the Berry phase π measured simultaneously by two groups [2081, 2085]; observation of the effect at room temperature; the connection to the Dirac equation of Chapter 93, and the care needed — these are quasiparticles of a lattice, not elementary fermions.]

Phenomenon 128.5 (A shifted quantization sequence in graphene)**.** In a single atomic layer of graphite the quantized Hall sequence is not that of Equation (128.1). The plateaux

are found at half-integer multiples of the fourfold-degenerate conductance quantum, $\sigma_{xy} = 4(n + \frac{1}{2})e^2/h$, measured simultaneously and independently by two groups [2081, 2085]; the spacing of the Landau levels goes as the square root of the field rather than linearly in it, and a level sits at zero energy for every field. The same measurements extract a Berry phase of π from the phase of the Shubnikov–de Haas oscillations. Because the level spacing at accessible fields is then far larger than in a semiconductor heterostructure, the quantization survives to room temperature. The carriers responsible are low-energy excitations of a two-dimensional crystal of carbon atoms, whose dispersion near the corners of its Brillouin zone is linear; the resemblance to the equation of Chapter 93 is a property of that band structure and not a claim about elementary particles.

Derivation pending #255

Landau quantization of a linear rather than quadratic dispersion, which gives level energies proportional to the square root of the product of level index and field and places one level exactly at zero energy; the shared occupation of that zero level by electrons and holes, which shifts the filling sequence by one half; the fourfold spin and valley degeneracy of the observed steps; and the Berry phase of the cyclotron orbit that appears as the offset in the Shubnikov–de Haas phase

128.6.4 Quantum spin Hall and topological insulators

[Reserved: Kane and Mele's proposal that spin–orbit coupling alone, with time-reversal symmetry intact and no magnetic field, yields a $\mathbb{Z}_2$-classified insulator with helical edge states [2077]; the mercury telluride quantum-well prediction [2092] and its confirmation in transport, with a conductance plateau at $2e^2/h$ independent of sample width [2110]; the first three-dimensional topological insulator, its surface Dirac cone imaged by the photoemission of Chapter 126 [2128].]

128.6.5 The quantum anomalous Hall effect

[Reserved: Haldane's model realized in a material — a magnetically doped topological insulator thin film showing a quantized Hall resistance h/e^2 at zero applied field [2216]; the required conditions (ferromagnetic order, chemical potential in the gap, temperatures of tens of mK*) and the honest note that the quantization there is far less precise than in Section 128.4.2; the link to the magnetism of Chapter 129.]*

Phenomenon 128.6 (Quantization without an applied field)**.** A thin film of a magnetically doped topological insulator, cooled to tens of mK and with its chemical potential tuned into the gap, shows a Hall resistance equal to h/e^2 and a vanishing longitudinal resistance at *zero* applied magnetic field [2216]. Every ingredient that Phenomenon 128.1 used — the Landau levels, their degeneracy, the field itself — is absent; what remains is broken time reversal, supplied here by the ferromagnetic order of the dopants rather than by an external field. The quantization is real but is far less accurate than that of Phenomenon 128.2, and it survives only at temperatures well below the magnetic ordering temperature, which is the honest measure of how much remains to be understood about it.

Derivation pending #256

That a quantized Hall conductance requires only a gapped band structure with broken time-reversal symmetry and a non-zero topological invariant of the occupied bands, not a uniform magnetic field; the lattice model exhibiting this with zero net flux through the unit cell; and the mechanism by which magnetic dopants in a strong-spin–orbit thin film open the required gap in the surface states

128.7 Metrology: the ohm and the SI

[Reserved: the von Klitzing constant $R_K = h/e^2$, its conventional 1990 value and its status since the 2019 redefinition, in which h and e are exact and therefore $R_K = 25\,812.807\,45\,\Omega$ exactly [2333, 2431]; the practical realization of the ohm from a quantized Hall sample [2014], and of the volt from the Josephson effect of Chapter 131; the quantum metrology triangle closing volt, ohm and ampere; the original motivation — a determination of the fine-structure constant [1655] — and its present standing against the electron $g-2$ route of Chapter 112; graphene resistance standards operating at relaxed field and temperature [2360].]

Chapter 129

Magnetism in Matter

Magnetism in matter is the cleanest demonstration in the book that ordinary condensed matter is a quantum system. The Bohr–van Leeuwen theorem [368, 484] shows that a classical system of charges in thermal equilibrium has exactly zero magnetization at any field and temperature; every effect in this chapter — Faraday's diamagnetism [119], Curie's paramagnetic law [264], the spontaneous magnetization of iron — therefore has no classical explanation whatever. What supplies it is spin and the Pauli principle of Chapter 83, acting through the exchange interaction [537, 605]: an electrostatic energy, of order eV, masquerading as a coupling between spins and hence producing ordering temperatures of order 1000 K where the magnetic dipole–dipole interaction could manage about 1 K.

The chapter builds from the response of isolated moments to the collective phenomena: Weiss's molecular field [339] and its microscopic replacement by exchange; Néel's antiferromagnetism [781, 918], invisible to a magnetometer and made visible by neutron diffraction [949]; domains [459, 675] and hysteresis; spin waves [643] counted directly by inelastic neutron scattering [1104]; itinerant ferromagnetism in the band language of Chapter 126 [820]; and magnetic resonance [885, 887, 894] as the spectroscopy that measures all of it. The critical behaviour near the ordering temperature is the worked example of Chapter 123 and is not repeated here. The standard references are [1570, 2011], with Van Vleck's monograph [709] as the founding treatment.

Derivation pending #257

Magnetism in Matter: all derivations of this chapter are pending.

129.1 The magnetic response of matter

129.1.1 Diamagnetism

[Reserved: Faraday's discovery that every substance responds to a magnetic field, most of them by being repelled [119]; the Larmor precession argument and the Langevin diamagnetic susceptibility $\chi \propto -\langle r^2 \rangle$ per atom [323]; measured values of order -10^{-5} in SI volume susceptibility, and their near-independence of temperature; the definitions and unit conventions for $\boldsymbol{B}$, $\boldsymbol{H}$, $\boldsymbol{M}$ and χ fixed in Chapter 62; perfect diamagnetism as a distinct phenomenon, belonging to Chapter 130.]

Phenomenon 129.1 (Every substance responds to a magnetic field)**.** There is no magnetically inert matter. Suspended in a strong field gradient, some substances are drawn towards the strong-field region and the majority are pushed away from it; the repulsion is universal, weak, and — unlike the attraction — essentially independent of temperature [119]. In modern units the volume susceptibility of a diamagnetic solid or liquid is negative and

of order 10^{-5}. The universality is the informative part: a property possessed by bismuth, water, glass and gold alike cannot depend on permanent atomic moments, since most of these substances have none.

Derivation pending #258

Diamagnetism as the induced response of the bound electrons: the Larmor precession an applied field imposes on an atomic charge distribution, the induced moment opposing the field by Lenz's rule, and the resulting susceptibility proportional to the mean square radius of the electronic charge distribution and to the number of electrons per unit volume, with no temperature dependence because no level populations change

129.1.2 Paramagnetism and the Curie law

[Reserved: Curie's systematic measurements establishing $\chi = C/T$ for paramagnets and the sharp distinction between the three classes of response [264]; Langevin's classical statistical derivation, with the Langevin function $L(x) = \coth x - 1/x$ [323]; its quantum replacement, the Brillouin function for a moment of angular momentum J [566], and the saturation curves of chrome, iron and gadolinium salts that confirmed the quantized rather than the classical form; the effective moment p_{eff} extracted from a measured Curie constant.]

Phenomenon 129.2 (The Curie law)**.** Substances containing permanent atomic moments are attracted into a field, with a susceptibility inversely proportional to the absolute temperature,

$$\chi = \frac{C}{T}\,, \tag{129.1}$$

over a wide temperature range and to good accuracy — one of the three distinct classes of magnetic behaviour that Curie's systematic survey separated [264]. At low temperature and high field the magnetization departs from Equation (129.1) and saturates, and the measured saturation curves of paramagnetic salts follow the stepped, quantized form appropriate to a moment of definite angular momentum [566] rather than the classical curve for a freely orientable vector [323, 2011]. The Curie constant C therefore measures the size of the atomic moment, and the shape of the saturation curve measures its angular momentum.

Derivation. Take the simplest case, n independent moments per unit volume, each of magnitude μ and each with only two accessible orientations along the field, of energies $\mp\mu B$. Their thermal average is

$$\langle \mu_z \rangle = \mu\,\frac{\mathrm{e}^{\mu B/k_B T} - \mathrm{e}^{-\mu B/k_B T}}{\mathrm{e}^{\mu B/k_B T} + \mathrm{e}^{-\mu B/k_B T}} = \mu \tanh \frac{\mu B}{k_B T}\,, \tag{129.2}$$

so that $M = n\mu \tanh(\mu B/k_B T)$. Two limits follow at once. For $\mu B \gg k_B T$ the hyperbolic tangent saturates at unity and $M \to n\mu$: the magnetization has an upper bound, which is the saturation observed. For $\mu B \ll k_B T$, expanding $\tanh x \approx x$ gives $M = n\mu^2 B/k_B T$ and hence

$$\chi = \frac{\mu_0 M}{B} = \frac{n\mu_0 \mu^2}{k_B T}\,, \tag{129.3}$$

which is Equation (129.1) with $C = n\mu_0\mu^2/k_B$. The inverse temperature is the competition of alignment energy against thermal disorder, and nothing else; it is the same $1/T$ that governs any two-level population. For a moment of general angular momentum J and Landé factor g the sum over $2J+1$ orientations replaces Equation (129.2) by the Brillouin function [566], whose small-argument limit gives Equation (129.1) with the effective moment $\mu_{\text{eff}} = g\sqrt{J(J+1)}\,\mu_B$ in place of μ; the saturation value is $ngJ\mu_B$, so the two limits

measure different combinations of g and J and between them determine both. Note that Equation (129.2) already assumes that the orientations are discrete, which no classical theory permits (Phenomenon 129.3). □

129.1.3 The Bohr–van Leeuwen theorem

[Reserved: the theorem that in classical statistical mechanics (Chapter 118) the partition function is independent of the vector potential, because the field shifts the momentum integration variable, so the equilibrium magnetization vanishes identically; proved independently by Bohr [368] and van Leeuwen [484]; the consequence that magnetism is evidence for quantum mechanics in bulk matter, and the specific ingredients (quantized levels, spin, the exclusion principle) that evade it.]

Phenomenon 129.3 (Magnetism has no classical explanation)**.** Matter in thermal equilibrium is measurably magnetic: diamagnetic (Phenomenon 129.1), paramagnetic (Phenomenon 129.2) or, in a few elements, spontaneously magnetized. Classical statistical mechanics, applied to any collection of charges in thermal equilibrium at any temperature and in any applied field, gives exactly zero magnetization [368, 484]. The disagreement is not one of magnitude but of existence, so every measurement in this chapter, including the most banal, is a measurement of quantum mechanics operating in bulk matter at room temperature.

Derivation. Consider N classical charges q_i of masses m_i in an arbitrary potential $U(\boldsymbol{r}_1, \dots, \boldsymbol{r}_N)$ and an external magnetic field described by a vector potential $\boldsymbol{A}$. The field enters the Hamiltonian only through the minimal coupling,

$$\mathcal{H} = \sum_i \frac{\left[\boldsymbol{p}_i - q_i \boldsymbol{A}(\boldsymbol{r}_i)\right]^2}{2m_i} + U\,, \tag{129.4}$$

and the classical canonical partition function is the integral of $\mathrm{e}^{-\beta\mathcal{H}}$ over all positions and all momenta. Hold the positions fixed and change momentum variables to $\boldsymbol{\pi}_i = \boldsymbol{p}_i - q_i\boldsymbol{A}(\boldsymbol{r}_i)$. The shift is a translation of each momentum by a constant, so its Jacobian is unity, and — this is the whole of the argument — each momentum ranges over all of $\mathbb{R}^3$ both before and after, so the domain of integration is unchanged. Hence

$$Z = \int \prod_i \mathrm{d}^3 r_i\, \mathrm{d}^3 p_i\; \mathrm{e}^{-\beta\mathcal{H}} = \int \prod_i \mathrm{d}^3 r_i\, \mathrm{d}^3 \pi_i\; \mathrm{e}^{-\beta\left(\sum_i \pi_i^2/2m_i + U\right)}\,, \tag{129.5}$$

in which $\boldsymbol{A}$ has disappeared entirely. The free energy $F = -k_B T \ln Z$ is therefore independent of the applied field, and the equilibrium magnetization $M = -V^{-1}\partial F/\partial B$ vanishes identically, for every temperature, every field and every interaction U. The result is stronger than a null prediction for some model: it says no classical model can succeed. What evades it is the discreteness of the momentum-space integration in quantum mechanics — the levels are a countable set that the field genuinely rearranges rather than a continuum that a shift maps onto itself — together with spin, which is not of the form Equation (129.4) at all, and the exclusion principle of Chapter 83, which controls how the levels are filled. □

129.1.4 Magnetism of the conduction electrons

[Reserved: Pauli paramagnetism — a temperature-independent susceptibility $\chi = \mu_0\mu_B^2 g(E_F)$ because only electrons within k_BT of the Fermi surface can flip [586], a direct measurement of the density of states of Chapter 126; Landau diamagnetism from the orbital quantization of the same electrons, exactly $-1/3$ of the Pauli term for free electrons [660]; why the two nearly cancel and what the residual measures; the de Haas–van Alphen oscillations as the same physics at high field.]

129.2 Where the moments come from

129.2.1 Local moments and the effective moment

[Reserved: partially filled shells, Hund's rules and the Landé g-factor as established in Chapter 88; the measured effective moments of the rare-earth ions, in excellent agreement with the free-ion J; the transition-metal ions, in agreement only with the spin-only value, and crystal-field quenching of the orbital moment as the explanation [709, 2011]; the Bohr magneton $\mu_B = e\hbar/2m_e$ as the natural unit and its value from [2431].]

129.2.2 The gyromagnetic ratio measured

[Reserved: the Einstein–de Haas experiment — a suspended iron cylinder magnetized along its axis acquires a measurable rotation, because angular momentum is conserved and the magnetization carries some [426]; Barnett's converse, magnetization by rotation [424]; and the point that makes the pair worth recounting — Einstein and de Haas reported a gyromagnetic ratio agreeing with the orbital value $g = 1$ that their own theory expected, whereas the correct value is $g \approx 2$, as Barnett's measurement [424] and every later repetition found; the founding experiment of the subject therefore erred in the direction of its authors' prediction, which makes it a case study for the error analysis of Chapter 2; the moment is spin, not orbital, with the modern precision value from Chapter 112 and the formalism of Chapter 79.]

Phenomenon 129.4 (Magnetization carries angular momentum)**.** An iron cylinder hung on a fine fibre and magnetized along its axis by a surrounding solenoid begins to rotate about that axis, and reverses its rotation when the magnetization is reversed [426]. The converse also holds: an unmagnetized ferromagnetic rod spun about its axis acquires a magnetization proportional to its angular velocity [424]. Magnetization is therefore not merely accompanied by angular momentum, it *is* angular momentum, in a fixed ratio

$$\gamma = \frac{m_{\mathrm{tot}}}{L_{\mathrm{e}}} = \frac{g\,e}{2m_e}\,, \tag{129.6}$$

with m_{tot} and L_{e} the total magnetic moment and the total electronic angular momentum. The measured value is $g \approx 2$, not the $g = 1$ that orbital motion would give: the moment of a ferromagnet is carried by spin. The measurement is also a standing lesson in experimental method. Einstein and de Haas reported a ratio consistent with the orbital value $g = 1$ that their own theory expected, whereas Barnett's independent measurement [424] and every later repetition give approximately 2; the founding experiment of the subject erred in the direction of its authors' prediction.

Derivation. The suspended cylinder is mechanically isolated about its axis, so the component of total angular momentum along that axis is conserved. Split it into the mechanical angular momentum L_{mech} of the body as a rigid rotor and the internal electronic angular momentum L_{e} that the aligned moments carry. Conservation gives $\Delta L_{\mathrm{mech}} = -\Delta L_{\mathrm{e}}$, and Equation (129.6) converts the second into a change of magnetic moment:

$$\Delta L_{\mathrm{mech}} = -\frac{\Delta m_{\mathrm{tot}}}{\gamma} = -\frac{2m_e}{g\,e}\,\Delta m_{\mathrm{tot}}\,. \tag{129.7}$$

Every quantity in Equation (129.7) except g is directly measurable: the change in magnetic moment from the fluxmeter or from the saturation magnetization, and the change in mechanical angular momentum from the amplitude of the torsional oscillation the magnetization reversal excites, given the known moment of inertia and fibre constant. The experiment therefore determines g with no adjustable parameter. Because the two candidate answers,

1 for orbital and 2 for spin, differ by a factor of two rather than by a percentage, the measurement discriminates decisively — provided it is not biased, which is exactly the point of the historical note above. □

129.3 Ferromagnetism

129.3.1 Weiss's molecular field

[Reserved: Weiss's postulate of an internal field proportional to the magnetization, $B_{\mathrm{mol}} = \lambda M$, and the self-consistent equation it yields [339]; spontaneous magnetization below T_C, the Curie–Weiss law $\chi = C/(T-\theta)$ above it, and the measured Curie temperatures — 1043 K for iron, 1394 K for cobalt, 631 K for nickel [2011]; the fatal quantitative problem, that a molecular field of the required size corresponds to 1×10^3 T and cannot be magnetic in origin; mean-field theory's exponents and their disagreement with experiment, treated in Chapter 123.]

Phenomenon 129.5 (Spontaneous magnetization and the Curie–Weiss law)**.** A few elements are magnetized in zero applied field. Below a sharp temperature T_C — 1043 K for iron, 1394 K for cobalt, 631 K for nickel [2011] — a specimen carries a magnetization that grows continuously from zero as the temperature falls, with no applied field to define its direction. Above T_C the spontaneous moment is gone and the susceptibility follows not the Curie law Equation (129.1) but the Curie–Weiss form

$$\chi = \frac{C}{T-\theta}\,, \tag{129.8}$$

with θ positive and close to T_C [339]. The ordering temperature is the informative number. It corresponds to an internal field of order 1×10^3 T, whereas the magnetic field one aligned atomic moment produces at its neighbour is of order 0.1 T: whatever aligns the moments, it is four orders of magnitude too strong to be their magnetic interaction.

Derivation. Weiss's hypothesis is that each moment experiences, in addition to any applied field B, an internal field proportional to the magnetization already present, $B_{\mathrm{mol}} = \lambda M$ [339]. Substituting $B \to B + \lambda M$ into the two-level result Equation (129.2) makes the magnetization implicit in itself,

$$M = n\mu \tanh \frac{\mu(B+\lambda M)}{k_B T}\,, \tag{129.9}$$

and everything follows from that one equation. Put $B = 0$ and write $m = M/n\mu$ and $k_B T_C = n\mu^2\lambda$; then Equation (129.9) becomes

$$m = \tanh \frac{T_C m}{T}\,. \tag{129.10}$$

The right-hand side of Equation (129.10) is an odd, monotonically increasing, concave function of $m > 0$ with slope T_C/T at the origin and saturating at unity. It therefore meets the line m at a non-zero point if and only if that initial slope exceeds one, that is if and only if $T < T_C$: below T_C a spontaneous magnetization exists, above it only $m = 0$ solves the equation. For $T > T_C$ and small applied field, linearize Equation (129.9) in B and M, $M = n\mu^2(B+\lambda M)/k_B T$, and solve for the susceptibility:

$$\chi = \frac{\mu_0 M}{B} = \frac{n\mu_0\mu^2/k_B}{T-T_C} = \frac{C}{T-T_C}\,, \tag{129.11}$$

which is Equation (129.8) with the same Curie constant as Equation (129.3): a paramagnet with a positive feedback term diverges at T_C instead of at zero. What the derivation does *not*

supply is λ. Setting $k_B T_C = n\mu^2\lambda$ with the observed T_C gives λM of order 1×10^3 T, which no arrangement of magnetic dipoles can produce; the molecular field is a bookkeeping device for an interaction that must be electrostatic in origin (Section 129.3.2). The mean-field treatment also predicts critical exponents that measurement contradicts, which is the subject of Chapter 123. □

129.3.2 Exchange

[Reserved: the resolution — the antisymmetry of the many-electron wavefunction (Chapter 83) correlates spin orientation with spatial overlap, so the Coulomb energy itself depends on the relative spin; Dirac's formulation of the exchange energy in terms of a spin permutation operator [537]; Heisenberg's application to ferromagnetism [605]; the Heitler–London calculation for two atoms as the transparent worked case [577]; magnitudes of order eV*, which is what makes room-temperature magnets possible.]*

129.3.3 The Heisenberg model

[Reserved: the Hamiltonian $H = -\sum_{ij} J_{ij} \boldsymbol{S}_i \cdot \boldsymbol{S}_j$ [605], the sign convention for ferromagnetic and antiferromagnetic J, and its status as an effective model derived from the electronic problem rather than postulated; the Ising and XY limits and the role of anisotropy; the Mermin–Wagner theorem forbidding spontaneous breaking of a continuous spin symmetry in one and two dimensions at finite temperature [1337]; exchange constants extracted from measured spin-wave dispersions in Section 129.6.2; the connection to the lattice models of Chapter 123.]

129.3.4 Itinerant ferromagnetism

[Reserved: the difficulty that iron, cobalt and nickel have non-integer moments per atom — 2.22, 1.72 and 0.606 Bohr magnetons — which no localized-moment model can produce; Stoner's band theory of collective-electron ferromagnetism, with exchange splitting the spin-up and spin-down bands and the criterion $Ig(E_F) > 1$ for spontaneous polarization [820]; the spin-split bands as measured by spin-resolved photoemission; the failure of Stoner theory near T_C and what replaces it; half-metals, band-insulating in one spin channel and metallic in the other [1721], and their relevance to Section 129.9.2.]

129.4 Antiferromagnetism and ferrimagnetism

129.4.1 Néel's theory

[Reserved: Néel's two-sublattice molecular-field theory, predicting a state of zero net moment with a susceptibility that peaks at the ordering temperature and then falls [781]; the Néel temperature and the Curie–Weiss law with negative θ above it; ferrimagnetism as the unequal-sublattice case, which explains magnetite and the ferrites [918] — the material class behind ferrite cores and the 1970 Nobel prize; the honest point that until 1949 this was a hypothesis about something no instrument could see.]

129.4.2 Neutron diffraction as the decisive evidence

[Reserved: the neutron's magnetic moment scattering off ordered electron spins, so that magnetic order produces extra Bragg peaks; Shull and Smart's observation of the superlattice reflections of manganese oxide, doubling the chemical unit cell and confirming Néel's two-sublattice picture directly [949]; the systematic determination of magnetic structures

that followed [991]; the diffraction formalism of Chapter 125 and the neutron sources of Chapter 107; the 1994 Nobel prize.]

Phenomenon 129.6 (Order with no net moment)**.** Some compounds order magnetically without becoming magnets. Manganese oxide has a susceptibility that rises on cooling, passes through a maximum at a definite temperature and then *falls* — the signature Néel predicted for two sublattices magnetized oppositely [781] — and above that temperature obeys Equation (129.8) with θ negative. No magnetometer can see the order itself, since the net moment is zero at every temperature. Neutron diffraction can: below the transition, manganese oxide shows extra Bragg reflections corresponding to a magnetic unit cell twice the chemical one, exactly as two alternating sublattices require, and those reflections disappear on warming through the transition [949, 991]. The related case of unequal sublattices, ferrimagnetism, accounts for magnetite and the ferrites [918]. Until 1949 this was a hypothesis about something no instrument could detect; the neutron made it an observation.

Derivation pending #259

The two-sublattice molecular-field theory, giving the Néel temperature, the susceptibility maximum at it and the negative Curie–Weiss intercept above it; and the magnetic neutron cross section, in which the neutron's own moment couples to the ordered electronic moments so that the scattering amplitude alternates between sublattices, producing reflections at the reciprocal-lattice vectors of the doubled magnetic cell that are absent from the nuclear pattern

129.4.3 Superexchange and RKKY coupling

[Reserved: how manganese ions separated by an intervening oxygen couple antiferromagnetically at all — Kramers' proposal that the coupling is mediated by virtual excitations of the intervening ion [744], made quantitative by Anderson [952], with the Goodenough–Kanamori rules relating the sign of the coupling to the geometry and occupancy of the bond [1069, 1170]; the RKKY interaction, oscillating in sign with distance as conduction electrons mediate it [1050], which is the mechanism behind the interlayer coupling of Section 129.9.1; double exchange in the mixed-valence manganites [993].]

129.5 Domains and hysteresis

129.5.1 Domain structure and the Barkhausen effect

[Reserved: why a ferromagnet below T_C can have zero net moment — the dipolar field energy is lowered by breaking into domains of differing orientation, at the cost of the wall energy; Barkhausen's observation of discrete clicks in a coil wound on a slowly magnetized iron rod, the first direct evidence that magnetization proceeds in irreversible jumps [459]; jump-size statistics and their power law; the hysteresis loop, coercivity and remanence as the measured quantities, and hard against soft materials.]

129.5.2 Imaging domains

[Reserved: Bitter's technique of decorating a polished surface with a colloidal suspension of fine magnetic particles, which collect at the stray field of the walls and make the domain pattern visible under a microscope [675]; the magneto-optic Kerr effect, the rotation of the polarization of light reflected from a magnetized surface [199], together with Lorentz

microscopy and magnetic force microscopy, as the modern successors [2011]; what each measures and its resolution; the agreement between imaged wall widths and the theory of Section 129.5.3.]

129.5.3 Domain walls and anisotropy

[Reserved: the Bloch wall as the compromise between exchange, which wants a wide wall, and magnetocrystalline anisotropy, which wants a narrow one, giving widths of tens of nm *and the scaling $\delta \propto \sqrt{A/K}$ [756]; the Landau–Lifshitz equation of motion for the magnetization [756]; magnetostriction and shape anisotropy [2011]; wall pinning by defects as the microscopic origin of coercivity and of the Barkhausen jumps of Section 129.5.1.]*

129.6 Spin waves

129.6.1 Magnons and the three-halves law

[Reserved: the low-lying excitations of an ordered ferromagnet are not single flipped spins but collective precessional waves, with $\hbar\omega = Dk^2$ at long wavelength, found by Bloch [643]; their quantization as magnons, bosons whose thermal population gives the observed $M(0) - M(T) \propto T^{3/2}$ law — qualitatively different from the exponential a gapped excitation would give, and thus a test of the picture; the Holstein–Primakoff representation that makes the spin operators bosonic [852]; the antiferromagnetic case with its linear dispersion.]

Phenomenon 129.7 (The three-halves law)**.** The spontaneous magnetization of a ferromagnet falls below its zero-temperature value, at temperatures far below T_C, as a power of the temperature and not exponentially:

$$M(0) - M(T) \propto T^{3/2}\,, \tag{129.12}$$

the law Bloch obtained by treating the excitations as collective spin waves rather than as individually flipped spins [643]. The distinction is testable, because a flipped spin costs a finite energy and would give an exponentially small reduction. The excitations themselves are seen directly: inelastic neutron scattering from magnetite resolves a magnon branch and measures its dispersion [1104], which is quadratic, $\hbar\omega = Dk^2$, at long wavelength — and it is the vanishing of ω as $k \to 0$, guaranteed by the rotational symmetry the ordered state breaks, that supplies the low-energy excitations the exponent requires.

Derivation. Take the measured dispersion $\hbar\omega = Dk^2$ as given, and take the magnons to be independent bosons, which is the leading approximation at low temperature since their density is then small. Each magnon reduces the total spin projection by one unit, so the magnetization deficit is proportional to the magnon number density,

$$n_{\mathrm{m}} = \int \frac{\mathrm{d}^3k}{(2\pi)^3}\,\frac{1}{\mathrm{e}^{Dk^2/k_BT} - 1}\,, \tag{129.13}$$

with no chemical potential, magnon number not being conserved. Substitute $u = Dk^2/k_BT$, so that $k = (k_BTu/D)^{1/2}$ and $k^2\mathrm{d}k = \tfrac{1}{2}(k_BT/D)^{3/2}u^{1/2}\mathrm{d}u$; the angular integral gives 4π and

$$n_{\mathrm{m}} = \frac{1}{4\pi^2}\left(\frac{k_BT}{D}\right)^{3/2}\int_0^\infty \frac{u^{1/2}\,\mathrm{d}u}{\mathrm{e}^u - 1} = \frac{\Gamma(3/2)\,\zeta(3/2)}{4\pi^2}\left(\frac{k_BT}{D}\right)^{3/2}\,, \tag{129.14}$$

which is Equation (129.12). The exponent is entirely a statement about the low-energy end of the spectrum: it is 3/2 because three-dimensional phase space contributes $k^2\mathrm{d}k$ while the energy goes as k^2, so the number of thermally accessible modes scales as $T^{3/2}$. Had the excitation spectrum a gap Δ — as a single flipped spin, held in place by its neighbours,

would have — the Bose factor would supply $\mathrm{e}^{-\Delta/k_BT}$ instead, and the measured power law excludes that picture. The fitted stiffness D from the neutron dispersion and the fitted coefficient of $T^{3/2}$ from the magnetization must agree, which closes the loop between two independent experiments. □

129.6.2 Magnons measured by neutron scattering

[Reserved: inelastic neutron scattering as the direct measurement of $\omega(\boldsymbol{k})$ for magnons, exactly as for the phonons of Chapter 125; Brockhouse's observation of spin-wave scattering in magnetite, the first such measurement [1104]; the exchange constants J read off the fitted stiffness D, closing the loop with Section 129.3.3; magnon gaps from anisotropy, and the scattering theory of Chapter 86.]

129.7 Magnetic phase transitions

[Reserved: the ferromagnetic and antiferromagnetic transitions as worked examples of the general theory in Chapter 123 — order parameter, spontaneous symmetry breaking, universality classes, and the measured critical exponents of nickel and of the model magnets, which disagree with the mean-field values implied by [339]; the divergence of the susceptibility and of the correlation length; the specific-heat anomaly; a cross-reference rather than a repetition, since the renormalization group belongs to Chapter 108.]

129.8 Magnetic resonance

129.8.1 Electron spin resonance

[Reserved: Zavoisky's observation of resonant microwave absorption by paramagnetic salts at $\hbar\omega = g\mu_B B$, the first magnetic resonance experiment [885]; the measured g-tensor as a probe of the local crystal field and of orbital quenching; hyperfine structure and its use in identifying defects and radicals; ferromagnetic resonance and its relation to the Landau–Lifshitz dynamics [756].]

129.8.2 Nuclear magnetic resonance

[Reserved: the independent 1946 detections of nuclear magnetic resonance in condensed matter, by absorption in paraffin [894] and by induction in water [887]; the Bloch equations, T_1 and T_2; the chemical shift and the Knight shift, the latter measuring the conduction-electron spin susceptibility of Section 129.1.4; the nuclear moments themselves belonging to Chapter 107; the 1952 Nobel prize, and magnetic resonance imaging as the applied consequence.]

129.9 Magnetotransport and spintronics

129.9.1 Giant magnetoresistance

[Reserved: the independent discovery, in iron–chromium multilayers, that the resistance changes by tens of percent when an applied field aligns the antiferromagnetically coupled ferromagnetic layers [1805, 1816] — an effect an order of magnitude larger than any previously known magnetoresistance, hence the name; spin-dependent scattering and the two-current model as its explanation; the RKKY oscillation [1050] that sets the interlayer coupling; the 2007 Nobel prize and the read heads that followed.]

129.9.2 Tunnelling magnetoresistance and spin transport

[Reserved: Jullière's magnetic tunnel junction, in which the tunnelling conductance between two ferromagnets depends on their relative magnetization through the spin polarizations of their densities of states [1551], and the large room-temperature ratios later obtained with crystalline barriers; spin-transfer torque as the reciprocal effect, a spin-polarized current switching a magnet [1930]; the honest boundary of this chapter — device physics is only included where it constitutes a measurement of the magnetism itself.]

Chapter 130

Superconductivity and Superfluidity

Superconductivity and superfluidity are the two places where quantum mechanics stops being microscopic. A single complex order parameter acquires a definite phase over a laboratory-sized sample, and the consequences are visible to the naked eye: a current that circulates for years without measurable decay, a magnet floating above a cooled disc, helium creeping up the wall of its own vessel. This chapter develops the phenomenological electrodynamics of London and of Ginzburg and Landau, the microscopic pairing theory of Bardeen, Cooper and Schrieffer, the energy gap and its spectroscopic signatures, the Josephson effects, and the superfluid phases of helium-4 and helium-3 — macroscopic quantum phenomena and the measured signatures that establish them.

It sits at the end of Part XII because it needs everything before it. The statistics of Chapter 120 and the indistinguishability of Chapter 83 supply Bose–Einstein condensation; the electron gas and Fermi surface of Chapter 126 supply the normal state that becomes unstable; the lattice vibrations of Chapter 125 supply the attraction that pairs the electrons; and the symmetry-breaking and critical-exponent machinery of Chapter 123 supplies the language for the transition itself. Looking forward, the same broken gauge symmetry gives the photon a mass inside a superconductor and is the condensed matter ancestor of the Higgs mechanism of Chapter 104; neutron-star interiors are believed to be superfluid (Chapter 49); and the flux quantum and the Josephson constant now define the practical volt in the SI of Chapter 2. The experimental record — from the mercury run of 1911 to modern tunnelling and metrology — is collected in Chapter 131. The standard modern monographs are Tinkham for superconductivity [1932], Khalatnikov for helium-4 [1313] and Vollhardt and Wölfle for helium-3 [1839].

Derivation pending #260

Superconductivity and Superfluidity: all derivations of this chapter are pending.

130.1 Discovery and phenomenology

130.1.1 Vanishing resistance

[Reserved: Kamerlingh Onnes' observation that the resistance of mercury falls discontinuously to immeasurably small values near 4.2 K *[374]; the distinction between a small resistance and a zero one, settled only by persistent-current decay bounds; the resulting upper limit on the resistivity, some twenty orders of magnitude below copper, and why a purely resistive account already fails — the full data are in Chapter 131.]*

Phenomenon 130.1 (Resistance vanishes at a sharp temperature)**.** Cooled through a temperature characteristic of the material — about 4.2 K for mercury — the electrical resistance of certain metals does not fall smoothly towards a residual value, as Chapter 126 would have it, but drops by more than four orders of magnitude within a few mK to a value below the resolution of the measurement [374]. The statement that the resistance is exactly zero is not read off that measurement, which can only set an upper limit; it is inferred from the persistence of a current circulating in a closed superconducting loop, whose decay time is bounded below at order 1×10^5 yr [1252] — a resistivity limit some seventeen orders of magnitude below that of copper at the same temperature. The transition is sharp, reversible, and occurs at a temperature that depends on the material but not on the measuring current so long as that current is small.

Derivation pending #261

Why the normal state cannot produce this: the temperature-independent residual resistivity that impurity scattering guarantees in any metal, so that a discontinuous drop to zero requires a new state rather than a limit of the old one; and the conversion of the persistent-current decay bound into a resistivity bound through the inductance of the loop

130.1.2 The Meissner–Ochsenfeld effect

[Reserved: the expulsion of magnetic flux from the interior of a superconductor cooled through its transition in an applied field, observed by Meissner and Ochsenfeld [724]; why this is not a consequence of perfect conductivity — a perfect conductor freezes the flux it had, a superconductor expels it, so the superconducting state is a thermodynamic state and not a history; $B = 0$ in the bulk as the defining property, perfect diamagnetism $\chi = -1$, and the thermodynamic critical field $H_c(T)$ obtained from the condensation energy.]

Phenomenon 130.2 (Flux is expelled, not merely excluded)**.** A specimen of tin or lead placed in a modest magnetic field and then cooled through its transition temperature *expels* the field from its interior: the field outside the sample rearranges as the flux is pushed out, and inside the bulk $B = 0$ [724]. The final state does not depend on the order of operations — cooling first and then applying the field gives the same interior field, namely none — so the superconducting state is a thermodynamic state of the metal and not a record of its history. This is the observation that a perfect conductor cannot reproduce. Perfect conductivity implies only that the flux already threading the sample cannot change; a perfect conductor cooled in a field would trap that field forever. Above a critical field $H_c(T)$, which vanishes at T_c and grows roughly parabolically below it, superconductivity is destroyed and the flux returns.

Derivation. The distinction is captured by replacing Ohm's law with a constitutive relation between the supercurrent and the field itself. Fritz and Heinz London postulated [757]

$$\nabla \times \boldsymbol{j}_s = -\frac{n_s e^2}{m}\,\boldsymbol{B}\,, \tag{130.1}$$

whereas the acceleration of free charges in a perfect conductor gives the same relation with $\boldsymbol{B}$ replaced by $\partial \boldsymbol{B}/\partial t$ — which is the whole of the difference. Take the curl of the magnetostatic Ampère law $\nabla \times \boldsymbol{B} = \mu_0 \boldsymbol{j}_s$ of Chapter 60, use $\nabla \times (\nabla \times \boldsymbol{B}) = \nabla(\nabla \cdot \boldsymbol{B}) - \nabla^2 \boldsymbol{B}$ together with $\nabla \cdot \boldsymbol{B} = 0$, and substitute Equation (130.1):

$$\nabla^2 \boldsymbol{B} = \frac{\boldsymbol{B}}{\lambda_L^2}\,, \qquad \lambda_L = \sqrt{\frac{m}{\mu_0 n_s e^2}}\,. \tag{130.2}$$

The only solution of Equation (130.2) bounded in the interior of a half-space is $B(x) = B(0)\mathrm{e}^{-x/\lambda_L}$: the field survives only within a penetration depth of the surface, typically $\lambda_L \approx 50\,\mathrm{nm}$, and vanishes in the bulk. Because Equation (130.2) constrains $\boldsymbol{B}$ and not $\partial\boldsymbol{B}/\partial t$, it admits no field-cooled solution with trapped flux, and the Meissner effect becomes a theorem rather than an extra assumption. What has been assumed is Equation (130.1), whose physical content is the rigidity of the many-body wavefunction against the perturbation of a vector potential; that rigidity is what the microscopic theory of Section 130.3.4 has to supply. □

130.1.3 Critical temperature, field and current

[Reserved: the critical surface in the (T, H, J) space; the empirical parabolic law $H_c(T) \approx H_c(0)[1 - (T/T_c)^2]$; Silsbee's rule relating the critical current to the field it generates at the surface [1932]; the tabulated values for the elemental superconductors [1589] and the reason no elemental T_c exceeds about $9.3\,\mathrm{K}$ at ambient pressure.]

130.1.4 The two-fluid picture

[Reserved: the Gorter–Casimir two-fluid model [739], in which a temperature-dependent fraction of the electrons is condensed and carries current without entropy; the consequent thermodynamics of the transition — a second-order transition in zero field with a jump, not a latent heat, in the specific heat; the model as the classical scaffolding that London and then BCS replaced with a microscopic wavefunction.]

130.2 Phenomenological electrodynamics

130.2.1 The London equations

[Reserved: Fritz and Heinz London's replacement of Ohm's law by a constitutive relation between the supercurrent and the vector potential [757]; the two London equations, the second of which, combined with Ampère's law from Chapter 60, yields $\nabla^2\boldsymbol{B} = \boldsymbol{B}/\lambda_L^2$ and hence exponential screening over the penetration depth $\lambda_L = \sqrt{m/\mu_0 n_s e^2}$ — the Meissner effect as a theorem rather than an observation; typical $\lambda_L \approx 50\,\mathrm{nm}$; the London rigidity of the wavefunction as the physical content, and the London moment in a rotating superconductor.]

130.2.2 Non-local response and the coherence length

[Reserved: Pippard's microwave measurements showing that the measured penetration depth in alloyed tin does not follow the local London prediction, and his non-local generalization with a coherence length ξ_0 over which the current responds to the field [1025]; the analogy to the anomalous skin effect; $\xi_0 \approx \hbar v_F/\pi\Delta$ as later derived from BCS, and the ratio $\kappa = \lambda/\xi$ that decides the type of the superconductor.]

130.2.3 Ginzburg–Landau theory

[Reserved: the complex order parameter ψ and the free energy expansion of Ginzburg and Landau [957], an application of the Landau theory of second-order transitions of Chapter 123 with a gauge-covariant gradient term; the two Ginzburg–Landau equations; the identification $|\psi|^2 = n_s$; surface energy between normal and superconducting regions and its sign change at $\kappa = 1/\sqrt{2}$; Gor'kov's derivation of the equations from BCS near T_c, which fixed the charge in the gradient term at $2e$ [1168].]

130.2.4 Type II superconductors and the Abrikosov lattice

[Reserved: Abrikosov's prediction that for $\kappa > 1/\sqrt{2}$ flux enters as a triangular lattice of quantized vortices between H_{c1} and H_{c2} rather than destroying the state at H_c [1100]; the vortex core, the circulating supercurrent and the single flux quantum each vortex carries; the direct observation of the lattice by Bitter decoration [1346]; flux pinning, critical currents and the practical superconducting magnet.]

130.3 Microscopic theory

130.3.1 The isotope effect

[Reserved: the simultaneous discovery by Maxwell [964] and by Reynolds, Serin, Wright and Nesbitt [969] that T_c of separated mercury isotopes scales as $M^{-\alpha}$ with $\alpha \approx 1/2$; why an ionic mass in an electronic transition temperature is decisive evidence that the lattice mediates the interaction, since $M^{-1/2}$ is the scaling of the phonon frequencies of Chapter 125; departures from $\alpha = 1/2$ in transition metals and their interpretation.]

Phenomenon 130.3 (The transition temperature depends on the mass of the ions)**.** Separated isotopes of mercury, chemically identical and differing only in the mass of the nucleus, have different superconducting transition temperatures, scaling as $T_c \propto M^{-\alpha}$ with α close to $1/2$ — found simultaneously and independently by two groups [964, 969]. The result is decisive out of proportion to its size. Superconductivity is a property of the conduction electrons, and the ionic mass enters no electronic energy scale; but it is exactly the mass that sets the phonon frequencies of Chapter 125, which scale as $M^{-1/2}$. The lattice must therefore mediate the interaction that produces the state. Departures from $\alpha = 1/2$ are measured in several transition metals and are informative in their turn.

Derivation pending #262

Why an electron–phonon-mediated pairing energy carries the phonon frequency as its prefactor, so that the transition temperature inherits the ionic mass dependence; and the corrections — from the screened Coulomb repulsion between the electrons, and from strong coupling — that reduce the exponent below one half without removing the effect

130.3.2 The energy gap

[Reserved: the exponentially small electronic specific heat at low temperature as the first sign of a gap [1034]; the threshold in far-infrared absorption measured by Glover and Tinkham, which located the gap at $2\Delta \approx 3.5\,k_B T_c$ [1112]; the same gap seen directly in the tunnelling current–voltage characteristic [1180]; the gap as an excitation gap for quasiparticles, not a gap in the single-particle band structure of Chapter 126.]

Phenomenon 130.4 (An energy gap in the excitation spectrum)**.** Three unrelated measurements agree that a superconductor cannot be excited at arbitrarily small energy. Its electronic heat capacity falls below T_c not as the linear γT of a normal metal (Chapter 120) but exponentially, as $\mathrm{e}^{-\Delta/k_B T}$ [1034]. Far-infrared radiation is transmitted without absorption below a threshold photon energy and absorbed above it [1112]. And the current–voltage characteristic of a tunnel junction between a superconductor and a normal metal is flat until a threshold voltage, above which it turns sharply upward, so that $\mathrm{d}I/\mathrm{d}V$ maps the quasiparticle density of states directly [1180]. All three return the same gap, close to

$$2\Delta(0) \approx 3.5\,k_B T_c\,, \tag{130.3}$$

a ratio that is roughly the same across the elemental superconductors. The gap is an excitation gap in a metal whose band structure has none: the states are there, and it is the correlated state that is expensive to disturb.

Derivation pending #263

The gap as the energy to break one pair, obtained from the self-consistent gap equation of the pairing theory; the quasiparticle dispersion, whose minimum is the gap and whose density of states diverges at the gap edge, giving the observed tunnelling threshold and infrared edge; and the exponential activation of the heat capacity, together with the derivation of the measured ratio of twice the gap to the transition temperature as a parameter-free consequence of weak coupling

130.3.3 Cooper pairing

[Reserved: Cooper's theorem — two electrons added above a filled Fermi sea form a bound state for arbitrarily weak attraction, because the density of states at the Fermi surface is finite [1084]; the logarithmic singularity and the non-perturbative binding energy $\sim \hbar\omega_D \exp(-1/N(0)V)$, which no order of perturbation theory reproduces; the Fröhlich phonon-exchange interaction as the source of the attraction [956]; the pair as an object of size 100 nm*, overlapping many others, and so not a molecule.]*

130.3.4 The BCS ground state

[Reserved: the variational pair-condensate wavefunction of Bardeen, Cooper and Schrieffer [1102]; the gap equation and its self-consistent solution; the Bogoliubov quasiparticle spectrum $E_k = \sqrt{\epsilon_k^2 + \Delta^2}$; the parameter-free predictions — $2\Delta(0) = 3.53\, k_B T_c$, the specific-heat jump $\Delta C/\gamma T_c = 1.43$, the isotope exponent $1/2$ — and the coherence factors that make ultrasonic attenuation fall while nuclear spin relaxation first rises [1124, 1169], a sign difference that is among the sharpest confirmations of the theory.]

130.3.5 Broken gauge symmetry

[Reserved: the superconducting state as spontaneously broken U(1) *symmetry; Nambu's demonstration that gauge invariance is compatible with the gap and the collective modes it requires [1187]; Anderson's observation that the would-be Goldstone mode is absorbed by the electromagnetic field, leaving a massive photon — the Meissner effect read as a photon mass $m_\gamma = \hbar/\lambda_L c$ [1245] — and the direct line from there to the Higgs mechanism of Chapter 104.]*

130.4 Macroscopic quantum coherence

130.4.1 Off-diagonal long-range order

[Reserved: Penrose and Onsager's criterion for condensation in an interacting system — a macroscopic eigenvalue of the one-particle density matrix [1094]; Yang's extension to the two-particle density matrix, which is what condenses in a superconductor, and his identification of off-diagonal long-range order as the single property shared by superfluid helium and every superconductor [1244]; the order parameter as an expectation value of a field operator, connecting to Chapter 87.]

130.4.2 Flux quantization

[Reserved: single-valuedness of the condensate phase around a ring forces the enclosed flux to be an integer multiple of $\Phi_0 = h/2e = 2.067\,833\,848 \times 10^{-15}$ Wb; the independent measurements of Deaver and Fairbank [1201] and of Doll and Näbauer [1202] in 1961, whose value of Φ_0 was half the naive h/e and thereby measured the carrier charge as $2e$ — pairing established without any appeal to BCS; the Little–Parks oscillations of T_c with enclosed flux as the same quantization seen in a transition temperature [1236].]

Phenomenon 130.5 (Flux quantization, and the carrier charge it measures)**.** The magnetic flux trapped by a hollow superconducting cylinder is not continuous: it takes only integer multiples of a fixed quantum, and the measured quantum is $\Phi_0 = 2.067\,833\,848 \times 10^{-15}$ Wb [1201, 1202, 2431]. The value is half the naive h/e. Since the quantization argument fixes the quantum as h divided by the charge of the entity whose phase must be single-valued, the measurement determines that charge to be $2e$ — pairing, established in 1961 by two independent groups, from a measurement that makes no appeal to any microscopic theory. The same periodicity in the enclosed flux appears in the transition temperature of a thin-walled cylinder [1236].

Derivation. Let the superconducting state be described by a single complex field $\psi = |\psi|\, \mathrm{e}^{\mathrm{i}\theta}$ for carriers of charge q and mass m^*. The gauge-invariant current is

$$\boldsymbol{j}_s = \frac{q\,|\psi|^2}{m^*}\,(\hbar\nabla\theta - q\boldsymbol{A})\ . \tag{130.4}$$

Take a contour C running round the hole of the cylinder but lying deep inside the superconducting material, at a depth of many penetration lengths, where by Equation (130.2) the field and hence the current vanish. Setting $\boldsymbol{j}_s = 0$ in Equation (130.4) gives $\hbar\nabla\theta = q\boldsymbol{A}$ along C, and integrating round it,

$$\hbar \oint_C \nabla\theta \cdot \mathrm{d}\boldsymbol{l} = q \oint_C \boldsymbol{A} \cdot \mathrm{d}\boldsymbol{l} = q\Phi\,, \tag{130.5}$$

where Φ is the total flux enclosed. Single-valuedness of ψ forces the left-hand side to be $2\pi\hbar n$ with n an integer, so $\Phi = nh/q$. Nothing else enters: not the geometry, not the material, not the temperature. Reading the measurement backwards, $q = h/\Phi_0 = 3.204\,353\,268 \times 10^{-19}$ C, which is $2e$ to the accuracy of the experiment. The argument is the same one that quantizes circulation in a neutral superfluid (Phenomenon 130.8); the charge is what turns a circulation into a flux. □

130.4.3 The Josephson effects

[Reserved: Josephson's prediction that a supercurrent $I = I_c \sin\varphi$ flows across a thin insulating barrier at zero voltage, and that a constant voltage drives the phase at $\mathrm{d}\varphi/\mathrm{d}t = 2eV/\hbar$, giving an alternating current of frequency $2eV/h$ [1231]; the observation of the dc effect by Anderson and Rowell [1246]; Shapiro's microwave-induced constant-voltage steps as the observation of the ac effect [1266]; the Fraunhofer dependence of I_c on applied flux.]

Phenomenon 130.6 (Supercurrent through an insulator)**.** Two superconductors separated by an insulating barrier a few nanometres thick pass a current at *zero* voltage, up to a critical value I_c [1246]. That the barrier is not simply shorted is shown by the behaviour of I_c in a magnetic field: it does not fall monotonically but oscillates, vanishing whenever the flux threading the junction is an integer multiple of the quantum of Phenomenon 130.5, in the pattern of a single-slit diffraction envelope. Held at a constant voltage V instead, the junction carries an alternating current of frequency $2eV/h$; irradiated with microwaves of

frequency f, its characteristic develops steps of constant voltage spaced by $hf/2e$ [1266], which is how the alternating current is observed. Both effects were predicted before they were seen [1231]. A frequency and a voltage are thereby locked together by fundamental constants alone, which is the basis of the practical volt.

Derivation pending #264

Two weakly coupled condensates described by their amplitudes and phases: the coupled equations of motion for the pair, in which the current across the barrier is proportional to the sine of the phase difference and the phase difference evolves at a rate proportional to the electrochemical potential difference; the resulting zero-voltage supercurrent and the alternating current at the Josephson frequency; and the spatial variation of the phase difference across a junction in a field, whose integral gives the diffraction-like dependence of the critical current on the enclosed flux

130.4.4 SQUIDs and quantum metrology

[Reserved: two junctions in a ring interfere, and the critical current is periodic in the enclosed flux with period Φ_0 — the quantum interference observed by Jaklevic, Lambe, Silver and Mercereau [1285]; the superconducting quantum interference device as the most sensitive magnetometer built, with a noise floor of a few fT *in a one-hertz band [2059]; the Josephson constant $K_J = 2e/h = 483\,597.8484\,\mathrm{GHz/V}$ as an exact number in the revised SI [2333, 2431], and hence the practical realization of the volt.]*

130.5 Superconductors beyond the BCS regime

130.5.1 The cuprates

[Reserved: Bednorz and Müller's report of a superconducting onset near 35 K *in the Ba–La–Cu–O system [1768], beyond any then-known T_c; the rapid confirmation and the jump above the boiling point of nitrogen at* 93 K *in Y–Ba–Cu–O [1802]; the layered copper-oxide structure, the doped Mott insulator as the parent compound, and the phase diagram with its pseudogap and strange-metal regions.]*

130.5.2 Pairing symmetry in the cuprates

[Reserved: the phase-sensitive experiments that established $d_{x^2-y^2}$ pairing — the corner SQUID of Wollman and co-workers [1877] and the tricrystal ring experiment of Tsuei and co-workers [1889], which trapped a half-integer flux quantum where the order parameter changes sign; nodal quasiparticles and the resulting power-law rather than exponential low-temperature thermodynamics.]

130.5.3 Other families

[Reserved: magnesium diboride at 39 K*, a two-gap phonon-mediated superconductor [2018]; the iron-based layered pnictides [2130]; the high-pressure hydrides, where conventional phonon-mediated pairing reaches* 203 K *in sulfur hydride near* 155 GPa *[2252] and higher still in lanthanum superhydride [2340]; heavy-fermion and organic superconductors; the honest caveat that claims of near-ambient superconductivity have repeatedly failed replication.]*

130.5.4 What remains unexplained

[Reserved: an explicit statement of what is established — that the cuprates are superconductors, that their carriers are pairs of charge 2e, that the order parameter has d-wave symmetry — and what is not: no mechanism for cuprate pairing commands consensus, and no theory predicts T_c for a given compound. The problem is listed among the open ones in Chapter 133; the renormalization group of Chapter 108 explains why a strongly correlated normal state resists the weak-coupling treatment that worked for lead.]

130.6 Superfluid helium-4

130.6.1 The lambda transition and the discovery of superflow

[Reserved: the specific-heat anomaly at 2.17 K that gives the transition its name and separates He I from He II; the simultaneous reports of frictionless flow through narrow channels by Kapitza [817] and by Allen and Misener [809], published back to back; the fountain effect and the thermomechanical connection between heat and flow [808]; film creep; the modern microgravity measurement of the specific-heat exponent at the lambda point [2054], one of the most precise critical exponents ever obtained, feeding Chapter 123.]

Phenomenon 130.7 (Superflow in liquid helium-4)**.** Liquid helium-4 cooled below 2.17 K passes through channels and packed powders so narrow that the ordinary liquid would scarcely move at all, with no measurable pressure drop and hence no measurable viscosity — reported simultaneously by Kapitza and by Allen and Misener [809, 817]. The same liquid, measured by the drag on a rotating body, still exhibits a viscosity of the ordinary order, so the two experiments do not agree about what the viscosity is; the transition is marked independently by a specific-heat anomaly of a shape that gives it its name. Two further observations rule out any mundane explanation: helium-4 flows as a film up and over the wall of its container until the levels inside and outside are equal, and heating one side of a superleak drives a flow towards the heat rather than away from it, so that a jet of liquid can be raised by a lamp.

Derivation pending #265

The two-fluid description in which the liquid behaves as an interpenetrating mixture of a normal component carrying all the entropy and all the viscosity and a superfluid component carrying neither, and the reconciliation of the capillary and rotating-body measurements that it provides; the thermomechanical effect as the statement that a temperature difference and a pressure difference are equivalent driving forces for the superfluid component; and Landau's criterion, in which an excitation spectrum with no low-lying free-particle branch forbids dissipation below a critical velocity — which is why an ideal Bose gas would condense without being a superfluid

130.6.2 Bose–Einstein condensation as the mechanism

[Reserved: London's identification of the lambda transition with the Bose–Einstein condensation of Chapter 120 [818], and the near-coincidence of the ideal-gas condensation temperature with the observed 2.17 K; why the identification is nevertheless not an explanation — the interacting liquid has a condensate fraction of only about 7 % at $T = 0$, so the superfluid fraction and the condensate fraction are different quantities; the contrast with the dilute atomic gases of Chapter 121, where they nearly coincide; helium-4 as a boson, helium-3 as a fermion (Chapter 83).]

130.6.3 The two-fluid model

[Reserved: Tisza's proposal that He II behaves as an interpenetrating mixture of a normal viscous component and a superfluid component with zero entropy and zero viscosity [822]; Landau's reformulation in terms of the excitation spectrum, which supplies the normal density without invoking a condensate population [858]; Andronikashvili's rotating stack of discs, which measured $\rho_n(T)$ directly and confirmed the split [886]; second sound as a counter-oscillation of the two components, predicted by Landau and observed by Peshkov [876].]

130.6.4 The excitation spectrum and rotons

[Reserved: Landau's spectrum [858] — a linear phonon branch at small momentum and a minimum, the roton, at $p_0/\hbar \approx 1.9 \times 10^{10}/\mathrm{m}$ with gap $\Delta/k_B \approx 8.6\,\mathrm{K}$; the Landau criterion $v_c = \min_p \varepsilon(p)/p$ for the breakdown of superflow, which is why an ideal Bose gas would not be a superfluid; Feynman's microscopic account of the spectrum and of vortex lines [1066]; the spectrum measured directly by inelastic neutron scattering [1210].]

130.6.5 Quantized circulation and vortices

[Reserved: Onsager's proposal that circulation in a superfluid is quantized in units of $h/m_4 \approx 9.97 \times 10^{-8}\,\mathrm{m^2/s}$ [943], and Feynman's development of the vortex-line picture [1066]; Vinen's measurement of single quanta of circulation using the vibrating-wire method [1220]; the rotating-bucket experiment and the vortex array; quantum turbulence as a tangle of such lines.]

Phenomenon 130.8 (Circulation in a superfluid is quantized)**.** The circulation trapped round a fine wire immersed in superfluid helium-4, measured through the splitting it induces between the two circular modes of the vibrating wire, does not take arbitrary values. It is found in integer multiples of

$$\frac{h}{m_4} \approx 9.97 \times 10^{-8}\,\mathrm{m^2/s}\,, \tag{130.6}$$

with m_4 the mass of the helium-4 atom, and it changes between these values by whole steps and not continuously [943, 1066, 1220]. Rotating a vessel of superfluid therefore does not set it turning as a body: the angular momentum is taken up by an array of discrete vortex lines. This is the neutral counterpart of Phenomenon 130.5, and the appearance of the bare atomic mass m_4, rather than twice it, records that the condensing entity here is a single atom and not a pair.

Derivation. The argument is that of Phenomenon 130.5 with the charge set to zero. Writing the condensate field as $\psi = |\psi|\,\mathrm{e}^{\mathrm{i}\theta}$, the superfluid velocity is $\boldsymbol{v}_s = (\hbar/m_4)\nabla\theta$, so the flow is irrotational wherever $\psi \neq 0$. Round any closed contour on which ψ does not vanish, single-valuedness of ψ requires θ to advance by $2\pi n$, hence

$$\oint \boldsymbol{v}_s \cdot \mathrm{d}\boldsymbol{l} = \frac{\hbar}{m_4}\, 2\pi n = n\,\frac{h}{m_4}\,, \qquad n \in \mathbb{Z}\,. \tag{130.7}$$

The quantum in Equation (130.7) depends on the atomic mass and on Planck's constant and on nothing else, which is why the numerical value in Equation (130.6) can be quoted without reference to the temperature, the pressure or the apparatus. Two consequences are directly observed: circulation cannot decay smoothly, so a persistent flow is metastable against small perturbations; and non-zero circulation requires ψ to vanish along a line inside the contour, which is the vortex core. □

130.7 Superfluid helium-3

130.7.1 Discovery of the superfluid phases

[Reserved: Osheroff, Richardson and Lee's observation of two anomalies on the melting curve of helium-3 near 2.7 mK *and* 2 mK*, initially attributed to the solid [1480]; Leggett's identification of them as transitions of the liquid into anisotropic superfluid phases with spin-triplet, p-wave Cooper pairs [1478]; the A and B phases and the phase diagram in temperature, pressure and field.]*

130.7.2 The order parameter and its consequences

[Reserved: a 3×3 *complex matrix order parameter and the broken relative spin–orbit symmetry, developed in [1839]; the resulting textures, half-quantum vortices and nuclear-magnetic-resonance frequency shifts as the experimental handles; helium-3 as the laboratory in which unconventional pairing was first understood, and the template for the p-wave and d-wave superconductors of Section 130.5.2; Fermi-liquid theory as the necessary normal-state description.]*

130.8 Where the phenomena reappear

[Reserved: a short closing survey. Neutron-star interiors as neutron superfluids and proton superconductors, invoked to explain pulsar glitches [1390] and taken up in Chapter 49; the superfluidity of dilute trapped atomic gases (Chapter 121); the quantum Hall states of Chapter 128 as a different macroscopic quantum order; and, in high-energy physics, the same broken-symmetry mathematics in Chapter 104 and in the chiral condensate of Chapter 102. The common thread throughout is off-diagonal long-range order [1244], not any particular pairing mechanism.]

Chapter 131

Experiment: Superconductivity

Zero resistance and flux expulsion as measured. This chapter takes the phenomena of Chapter 130 and records the measurements that establish them: the Leiden helium liquefaction that made the temperature range accessible [343], the 1911 mercury resistance run [374], the persistent-current bounds that convert "very small resistance" into a quantitative upper limit [1252], the flux-expulsion experiment of Meissner and Ochsenfeld [724], the isotope effect that identified the phonon as the glue [964, 969], the tunnelling spectroscopy that measured the gap [1180], the flux quantum that measured the carrier charge [1201], the Josephson verification [1246], and the 1986 discovery run that broke the temperature ceiling [1768].

Each of these will be written up in the structured `experiment` environment of the house style, with its apparatus, procedure, observations in SI units with uncertainties, interpretation and primary references, so that a reader can see exactly which number carries which inference. The chapter is placed immediately after the theory it tests and cross-references it section by section; the low-temperature techniques it depends on belong to Chapter 118 and Chapter 54, and the metrological use of the results feeds Chapter 2.

Derivation pending #266

Experiment: Superconductivity: all derivations and data tables of this chapter are pending.

131.1 Historical context and the claim under test

131.1.1 The race to liquefy the permanent gases

[Reserved: Dewar's liquefaction of hydrogen and the vacuum flask [280]; Kamerlingh Onnes' liquefaction of helium in 1908, reaching 4.2 K *at atmospheric pressure and about* 1.5 K *by pumping [343]; why the new temperature decade, and not any new idea about metals, is what made the discovery possible.]*

131.1.2 Three rival predictions for the low-temperature resistance

[Reserved: the state of the question in 1911 — Matthiessen's empirical rule, that impurity and thermal contributions to the resistivity simply add, predicted saturation at a finite residual value [160]; a rival expectation held that conduction electrons would condense onto their ions and the resistance rise without bound; a third, that it would fall smoothly to zero. The experiment discriminates, and none of the three anticipated a discontinuity.]

131.1.3 Mercury as the test material

[Reserved: why mercury — repeated distillation gives the purest available specimen, and freezing it in a capillary yields a thin, high-resistance thread with well-defined geometry; the sample geometry and the resistance at 273 K *as the normalization used throughout the 1911 papers [374].]*

131.2 Apparatus

131.2.1 The Leiden cryostat and the helium cycle

[Reserved: the cascade liquefier, the Hampson–Linde regenerative cycle, the helium bath and its vapour-pressure thermometry [343]; the temperature scale in use and its uncertainty, which is the dominant systematic in the 1911 result; modern replacements — pumped helium-3, dilution refrigerators and adiabatic nuclear demagnetization — and the temperature ranges each reaches.]

131.2.2 Resistance measurement

[Reserved: the four-terminal method, separating current leads from voltage leads so that lead and contact resistance do not enter; galvanometer sensitivity and the resulting resolution floor, which is what sets the upper limit quoted rather than any property of the sample [374]; the modern equivalent using a superconducting quantum interference device as a null detector [2059].]

131.2.3 Magnetometry for flux expulsion

[Reserved: the pick-up coils and ballistic galvanometer with which Meissner and Ochsenfeld mapped the field distribution outside tin and lead cylinders [724]; the modern flux transformer coupled to a SQUID [2059]; specimen geometry and the demagnetizing factor, without which the intermediate state makes the measured susceptibility depend on shape.]

131.2.4 Tunnel junctions

[Reserved: the evaporated aluminium–oxide–lead sandwich, with an oxide barrier of order 2 nm*, used by Giaever to measure the gap [1180]; the same structure at lower barrier resistance as the Josephson junction of Anderson and Rowell [1246]; microwave coupling for the ac effect [1266]; the ring geometries used for flux quantization [1201, 1202] and quantum interference [1285].]*

131.3 Procedure

131.3.1 The 1911 mercury run

[Reserved: cooling in steps with the resistance read at each plateau; the sequence of communications from Leiden through 1911 in which the resistance was first reported to fall faster than expected, then to vanish, then to vanish discontinuously at a sharply defined temperature [374]; the short-circuit hypothesis that had to be excluded, and the control measurements that excluded it.]

131.3.2 Field-cooled and zero-field-cooled protocols

[Reserved: the protocol that makes the Meissner experiment decisive — apply the field first, then cool through T_c, and watch the flux leave [724]; contrast with cooling first and then applying the field, which a perfect conductor also passes; the reversibility check on cycling, which is the evidence that the superconducting state is a thermodynamic phase.]

Phenomenon 131.1 (The field-cooled protocol)**.** Meissner and Ochsenfeld mapped the field outside tin and lead cylinders with pick-up coils and a ballistic galvanometer, under two protocols that differ only in their order of operations. Cooled through T_c in zero field and then exposed to a field, the specimen excludes it. Exposed to the field first and then cooled through T_c, the specimen *expels* the flux it already contained, and the exterior field redistributes accordingly [724]. The two protocols end in the same state, and cycling the temperature or the field reproduces it. Only the second protocol discriminates, and it is the whole content of the experiment.

Derivation. Suppose the only property of the low-temperature state were infinite conductivity. A finite current density in a medium of zero resistivity requires $\boldsymbol{E} = 0$ inside it, and Faraday's law of Chapter 60 then gives

$$\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t} = 0\,, \tag{131.1}$$

so the interior flux is frozen at whatever value it had at the instant the resistance vanished. Equation (131.1) is a constraint on the time derivative alone, and it therefore makes the final state depend on the path taken to reach it: cooled in zero field the specimen would keep $B = 0$, cooled in a field it would keep $B = B_{\text{applied}}$ indefinitely. The observation is that the field-cooled specimen ends with $B = 0$ in its interior, exactly as the zero-field-cooled one does. That excludes Equation (131.1) as a complete description and requires a constitutive relation constraining $\boldsymbol{B}$ itself, which is the London relation of Chapter 130. The wider consequence is thermodynamic rather than electromagnetic: a state whose properties are independent of the history by which it was prepared is a phase, so the free energies of the normal and superconducting states may be compared, and the critical field measures their difference. □

131.3.3 Isotope separation and the mercury series

[Reserved: preparation of mercury samples of mean mass number from about 198 to 204 by isotope separation; measurement of T_c for each under otherwise identical conditions [964, 969]; the systematic errors that dominate — purity, strain and thermometry — and why two independent groups publishing back to back matters for a claim this consequential.]

131.4 Observations

131.4.1 The mercury transition

[Reserved: a table of resistance against temperature through the transition, in ohms and kelvin with uncertainties, normalized to the 273 K *value; the transition width of a few* mK*; the observed T_c of about* 4.2 K *and the drop by more than four orders of magnitude across it [374]; the resistance after the transition quoted as an upper limit set by the galvanometer, not as a measurement.]*

Phenomenon 131.2 (The 1911 mercury run)**.** Cooling a frozen mercury thread in the Leiden helium cryostat and reading its resistance at each plateau, Onnes found the resistance to fall, near 4.2 K, by more than four orders of magnitude within a temperature interval

of a few mK, to a value his galvanometer could not distinguish from zero [374]. The three features that make the run decisive are the sharpness, the size of the drop, and the fact that the resistance above the transition behaves normally. What the measurement establishes on its own is an *upper limit* on the resistance below T_c, set by the sensitivity of the detector and not by any property of the specimen — the "zero" of the textbooks is an inference, and the honest reading of the run is that the mercury sample became a conductor whose resistance the apparatus could not detect.

Derivation pending #267

The inference chain from the raw run: how a four-terminal measurement removes lead and contact resistance so that the reading belongs to the specimen; how the galvanometer sensitivity and the measuring current together convert into the quoted upper limit on the resistance; and the control observations that exclude the obvious alternative, a short circuit developing on cooling, by their dependence on measuring current and on applied magnetic field

131.4.2 Bounds on the residual resistivity

[Reserved: the persistent-current experiment — a superconducting solenoid short-circuited on itself, its field monitored for months; the decay-time lower bound of order 1×10^5 yr *reported by File and Mills [1252], which converts to a resistivity upper limit some seventeen orders of magnitude below that of copper at the same temperature; the honest statement that "zero" is an inference from an upper limit plus the theory of Chapter 130, not a direct measurement.]*

Phenomenon 131.3 (A current that does not decay)**.** A superconducting solenoid carrying a current and then short-circuited on itself maintains that current, monitored through its magnetic field, with no detectable decay over months of observation. The bound so obtained on the decay time is of order 1×10^5 yr [1252], which is the strongest available statement that the resistance is not merely small. Converted into a resistivity, the limit lies some seventeen orders of magnitude below that of copper at the same temperature. Note the structure of the claim: this is an experiment that reports how much of nothing happened, and it is therefore the persistence, not the sensitivity of any voltmeter, that carries the inference.

Derivation. A closed loop of self-inductance L and series resistance R carrying current I with no applied electromotive force obeys

$$L\frac{\mathrm{d}I}{\mathrm{d}t} + RI = 0 \quad \Longrightarrow \quad I(t) = I(0)\,\mathrm{e}^{-t/\tau}\,, \qquad \tau = \frac{L}{R}\,. \tag{131.2}$$

Observing over a time t that the current has not changed by more than a fraction ε bounds the decay by $t/\tau < -\ln(1-\varepsilon) \approx \varepsilon$, that is $\tau > t/\varepsilon$, and therefore

$$R < \frac{\varepsilon L}{t}\,. \tag{131.3}$$

The measurement is powerful because both factors on the right of Equation (131.3) work in its favour: ε is set by the sensitivity of a magnetometer to a *fractional* change, which is far better than any absolute voltage measurement, and t can be made arbitrarily long simply by waiting. Dividing R by the geometric factor of the winding converts Equation (131.3) into a resistivity, which is the seventeen-order-of-magnitude figure quoted. What remains true is that no experiment can measure a resistance to be exactly zero; the statement that it is exactly zero comes from the theory of Chapter 130, in which a gapped condensate has no state into which to scatter, and the experiment bounds the alternative. □

131.4.3 Critical temperatures and critical fields

[Reserved: a booktabs table of T_c and $\mu_0 H_c(0)$ for the elemental superconductors and the common alloys — aluminium, tin, lead, niobium, niobium–titanium, niobium–tin — in kelvin and tesla with uncertainties, from the critically evaluated compilation [1589]; the upper critical field H_{c2} for the type II entries [1100]; the parabolic $H_c(T)$ fit and its residuals.]

131.4.4 The isotope exponent

[Reserved: T_c against mean isotopic mass for mercury on logarithmic axes, and the fitted exponent $\alpha = 0.50 \pm 0.03$ in $T_c \propto M^{-\alpha}$ [964, 969]; tabulated exponents for other elements, including the anomalously small values in ruthenium, osmium and zirconium, and what those depress the naive reading to; the inference that the lattice sets the energy scale.]

Phenomenon 131.4 (The measured isotope exponent)**.** Mercury samples of mean mass number from about 198 to 204, prepared by isotope separation and measured under otherwise identical conditions, have transition temperatures falling with mass. Plotted logarithmically, $\log T_c$ against $\log M$ is a straight line of slope $-\alpha$ with

$$T_c \propto M^{-\alpha}, \qquad \alpha = 0.50 \pm 0.03, \tag{131.4}$$

reported back to back by two groups working independently [964, 969]. The independence matters for a claim of this consequence, and so does the smallness of the effect: a three per cent change in mass produces a change in T_c of about one and a half per cent, against systematic errors from sample purity, strain and thermometry of comparable size. Several transition metals give exponents well below one half.

Derivation pending #268

The inference from the measured isotope exponent: that a lattice frequency scales as the inverse square root of the ionic mass with the force constants, which are electronic, held fixed, so that an exponent of one half identifies the phonon energy as the prefactor of the pairing scale; and the corrections from the screened Coulomb repulsion, which enter the exponent and depress it below one half without altering the identification

131.4.5 The gap

[Reserved: three independent determinations to be tabulated together in reduced units $2\Delta(0)/k_B T_c$ — the exponential low-temperature electronic specific heat of vanadium [1034], the far-infrared absorption edge [1112], and the tunnelling conductance [1180], whose $\mathrm{d}I/\mathrm{d}V$ maps the quasiparticle density of states directly; the BCS value 3.53 and the measured spread; the Hebel–Slichter peak in nuclear spin relaxation [1169] against the fall in ultrasonic attenuation [1124] as the coherence-factor test.]

Phenomenon 131.5 (Three probes, one gap)**.** The gap of a superconductor is measured by three techniques that share no apparatus and no systematic errors: the exponential fall of the electronic specific heat at low temperature [1034], the threshold in far-infrared absorption [1112], and the threshold voltage in the tunnelling characteristic of a thin oxide junction, whose differential conductance maps the quasiparticle density of states [1180]. Expressed in the reduced form $2\Delta(0)/k_B T_c$ the three agree with one another, and cluster about the value 3.5 across the weak-coupling elemental superconductors. A related pair of measurements tests the theory more sharply than the gap does: on cooling through T_c the ultrasonic attenuation falls immediately [1124] while the nuclear spin relaxation rate first *rises* to a peak before falling [1169]. Two processes governed by the same excitation spectrum move in opposite directions, and the sign difference is predicted.

Derivation pending #269

The coherence factors: that the matrix element for a process between quasiparticle states is a sum of two amplitudes whose relative sign depends on the behaviour of the perturbation under time reversal, so that the two combinations cancel and reinforce respectively; and the resulting opposite temperature dependences of ultrasonic attenuation and nuclear spin relaxation just below the transition, against the divergent density of states at the gap edge that both share

131.4.6 The flux quantum

[Reserved: trapped flux against applied field for a superconducting cylinder, showing steps of constant height; the measured quantum $\Phi_0 = 2.07 \times 10^{-15}\,\mathrm{Wb}$ to within a few percent in both 1961 experiments [1201, 1202]; the arithmetic that turns this into a carrier charge of $2e$, and why that is direct evidence of pairing independent of any microscopic theory; the Little–Parks periodicity as a cross-check [1236].]

Phenomenon 131.6 (The measured flux quantum is half the naive value)**.** Trapped flux measured against applied field for a small superconducting cylinder does not follow the applied field but rises in steps of constant height. Two independent 1961 experiments, using different geometries and different detection schemes, measured the step to be $\Phi_0 = 2.07 \times 10^{-15}\,\mathrm{Wb}$ to within a few per cent [1201, 1202]. The number is half of h/e, and the factor of two is the point of the measurement.

Derivation. Single-valuedness of the condensate phase round the cylinder quantizes the enclosed flux in units of h/q, where q is the charge of the entity whose phase is in question — the argument is given in Chapter 130 and uses no microscopic theory. Reading it backwards, the measurement determines q:

$$q = \frac{h}{\Phi_0} = \frac{6.626\,070\,15 \times 10^{-34}\,\mathrm{J\,s}}{2.067\,833\,848 \times 10^{-15}\,\mathrm{Wb}} = 3.204\,353\,268 \times 10^{-19}\,\mathrm{C} = 2e\,, \tag{131.5}$$

using the exact 2019 values of h and e [2333, 2431]. At the several-per-cent accuracy of the 1961 experiments this discriminates cleanly between $q = e$ and $q = 2e$, which differ by a factor of two, and it selects the pair. That inference is worth isolating: it establishes that the charge carriers of a superconductor have twice the electronic charge, from a measurement of a flux and a ring, four years after the pairing theory was proposed and independently of it. The periodicity of the transition temperature of a thin-walled cylinder in the enclosed flux, with the same period, is an independent check on the same quantity [1236]. □

131.4.7 Josephson currents and Shapiro steps

[Reserved: the zero-voltage supercurrent through an oxide barrier and its Fraunhofer-pattern suppression by an applied field, which is what distinguished the effect from a metallic short [1246]; the constant-voltage steps induced by microwave irradiation, spaced by $hf/2e$ [1266]; frequency-to-voltage conversion at $483.6\,\mathrm{MHz/\mu V}$ and the agreement of $2e/h$ so obtained with other determinations.]

Phenomenon 131.7 (Constant-voltage steps locked to a frequency)**.** A tunnel junction irradiated with microwaves of frequency f develops, in its current–voltage characteristic, a series of vertical steps at which the voltage does not change while the current does. The steps sit at

$$V_n = n\,\frac{hf}{2e}\,, \qquad n \in \mathbb{Z}\,, \tag{131.6}$$

and their spacing depends on the microwave frequency and on nothing else — not the material, the junction area, the temperature or the barrier thickness [1266]. That the zero-voltage current seen without irradiation is a genuine supercurrent and not a metallic short is established separately, by its suppression in a magnetic field in a diffraction-like pattern [1246]. A frequency, which is the most accurately measurable quantity in physics, is thereby converted into a voltage by fundamental constants alone.

Derivation. The second Josephson relation, $\mathrm{d}\varphi/\mathrm{d}t = 2eV/\hbar$, makes the phase difference across the junction advance at a rate set by the voltage, so a constant voltage V produces a supercurrent $I_c \sin\varphi$ alternating at the Josephson frequency $f_J = 2eV/h$. Under irradiation the junction is driven at f as well, and the average current is non-zero only when the two are commensurate, $f_J = nf$; the junction then phase-locks and holds that average voltage over a finite range of bias current, which is the step. Setting $2eV_n/h = nf$ gives Equation (131.6). The conversion factor is the Josephson constant

$$K_J = \frac{2e}{h} = 483\,597.8484\,\mathrm{GHz/V} = 483.597\,848\,4\,\mathrm{MHz/\mu V}\,, \tag{131.7}$$

exact in the present SI because h and e are exact [2333, 2431]. Two properties make Equation (131.6) a metrological standard rather than a curiosity. The step voltage is a *ratio* of a frequency to a constant, so it inherits the accuracy of the frequency reference; and nothing about the junction appears in it, so thousands of junctions may be placed in series to reach a usable voltage without introducing a single sample-dependent parameter. □

131.5 Interpretation

131.5.1 What each measurement establishes

[Reserved: an explicit inference table — resistance run [374] plus persistent currents [1252] give dissipationless flow; flux expulsion [724] gives a thermodynamic phase, not a memory of history; the isotope effect [964, 969] gives a phonon-mediated interaction; gap spectroscopy [1112, 1180] gives a gapped excitation spectrum; flux quantization [1201] gives carriers of charge 2e; the Josephson effects [1246, 1266] give a single coherent phase across a macroscopic sample. Together these are the observational content of the BCS theory [1102].]

131.5.2 What the 1986 discovery did not settle

[Reserved: the Bednorz–Müller run in Ba–La–Cu–O, its resistive onset near 35 K and the cautious "possible" in its title [1768]; the confirmation by Meissner measurement, which is the step that turns a resistive onset into a superconductivity claim; the yttrium compound above the boiling point of nitrogen at 93 K [1802]; the honest statement that these measurements establish the phenomenon and its d-wave order parameter [1877, 1889] while leaving the mechanism open — see Chapter 133.]

Phenomenon 131.8 (Superconductivity above the boiling point of nitrogen)**.** A ceramic oxide of barium, lanthanum and copper — not a metal by any of the criteria that had guided the search — shows a resistive onset near 35 K, above any transition temperature then known [1768]; within months the related yttrium compound reached 93 K, above the boiling point of liquid nitrogen [1802]. The methodological point is contained in the cautious "possible" of the 1986 title: a resistive drop alone is not a superconductivity claim, and what converted the observation into one was the subsequent Meissner measurement, the flux expulsion of Phenomenon 131.1 being the property a percolating filament or a measurement artefact cannot imitate. Phase-sensitive experiments later established that the order parameter changes sign between crystallographic directions [1877, 1889], so the pairing is not of the

simple form that Equation (131.4) describes in mercury. What remains unexplained is the mechanism: no theory predicts the transition temperature of any of these compounds.

Derivation pending #270

What can and cannot be derived here: the demonstration that flux expulsion on field cooling requires a bulk, thermodynamic superconducting phase and excludes a percolating filamentary path; and the reading of the half-integer flux quantum trapped at a tricrystal ring as a sign change of the order parameter between directions. The mechanism itself is not derived anywhere in this treatise and is recorded as an open problem

131.6 Modern repetitions and precision

131.6.1 Metrology: the Josephson volt

[Reserved: the programmable Josephson voltage standard, in which thousands of junctions in series give a voltage fixed by a microwave frequency and the exact constant $K_J = 2e/h = 483\,597.8484\,\mathrm{GHz/V}$ [2333]; reproducibility at the part in 10^{10} level; consistency with the quantum Hall resistance of Chapter 128 through the CODATA adjustment [2392, 2431]; how this closed the loop from a 1911 curiosity to a base of the SI [2333].]

131.6.2 SQUID magnetometry and the London moment

[Reserved: modern SQUID sensitivity and its applications [2059]; the London moment — the magnetic moment of a rotating superconductor, proportional to the angular velocity — used as the gyroscope readout in Gravity Probe B, whose measurement of geodetic and frame-dragging precession is reported in Chapter 44 [2173]; a superconducting instrument as the enabling technology for a test of general relativity.]

131.6.3 High-pressure hydrides and the standard of proof

[Reserved: the diamond-anvil cell measurement of sulfur hydride with $T_c = 203\,\mathrm{K}$ near $155\,\mathrm{GPa}$, including its isotope shift on deuteration, which is the evidence that the pairing is phonon-mediated [2252]; lanthanum superhydride above $250\,\mathrm{K}$ [2340]; the methodological lesson — in a sample of picolitre volume a resistive drop alone is not sufficient, and the community now requires a magnetic-susceptibility signature and raw, unprocessed data, after several near-ambient claims failed replication and were retracted.]

131.6.4 Datasets

[Reserved: the digitized resistance-versus-temperature points of the 1911 mercury run [374], the isotope series [964, 969] and the critical-parameter compilation [1589] will be stored in the evidence library as comma-separated files keyed to their bibliography entries, so that every figure and fitted exponent in this chapter can be recomputed from the numbers as published.]

Chapter 132

Experiment: Neutron Scattering and the Structure of Solids

Chapter 125 builds the thermal physics of a crystal on a function it never measures. The heat capacity, the thermal expansion and the thermal conductivity all follow from the dispersion relation $\omega(\boldsymbol{k})$ of the lattice waves, and the classical route to that function — fitting a Debye temperature to a measured heat capacity — cannot recover it, because the heat capacity depends only on the density of modes $g(\omega)$ and many different dispersion relations share one $g(\omega)$. Chapter 129 is in the same position twice over. Néel's antiferromagnet is an arrangement of moments that cancel exactly, so that no magnetometer can see the order at all [781]; Bloch's spin waves are collective excitations whose dispersion fixes the exponent of the $T^{3/2}$ law but which no magnetization curve displays directly [643]. Three predictions, all of them about the interior of a solid at the scale of the interatomic spacing, and none of them within reach of any instrument before about 1945.

What closed all three was a particle found for quite other reasons [692] and made available in quantity, a decade later, by the fission reactors of Chapter 107. A neutron that has come to thermal equilibrium with a moderator at room temperature has, by an accident of its mass, a de Broglie wavelength of the order of an interatomic spacing *and* a kinetic energy of the order of a lattice vibration. No other probe has both at once. This chapter reports four experiments that exploited the coincidence: Shull and Smart's diffraction pattern of manganese oxide, which made a magnetic structure visible for the first time; Brockhouse and Stewart's scattering of neutrons by the phonons of an aluminium crystal, the measurement that turned lattice dynamics from a theory into a data set; Brockhouse's spin-wave scattering in magnetite, which did the same for magnons; and the branch-by-branch dispersion of germanium, taken with the triple-axis spectrometer in its mature form. It then shows that the same patterns deliver the Debye–Waller factor of Chapter 125 as a by-product, and closes with what the technique does and does not settle. The Nobel prize of 1994 went to Brockhouse [1897] and to Shull [1910] for the two halves of this work.

132.1 Why the neutron, and not the X-ray

The case for the neutron rests on four of its properties, and the decisive one is arithmetic.

A neutron of kinetic energy E has, non-relativistically, $p = \sqrt{2m_n E}$ and therefore

$$\lambda = \frac{h}{\sqrt{2m_n E}}\,. \tag{132.1}$$

Put $E = 25\,\mathrm{meV}$ into Equation (132.1), the mean kinetic energy scale of a gas of neutrons in equilibrium with a moderator near room temperature: the speed is about $2.2\,\mathrm{km/s}$ and the wavelength about $0.18\,\mathrm{nm}$. The wavelength resolves the interatomic spacing, so the

neutron diffracts from a crystal exactly as an X-ray does. The energy is of the same order as the quanta the crystal has to offer, which run from about 1 meV to about 100 meV: a phonon or a magnon can take a large fraction of the neutron's whole energy, and the change is measurable with an ordinary crystal analyser.

For any other probe of the same wavelength the second condition fails catastrophically. Table 132.1 makes the comparison. An X-ray photon of wavelength 0.18 nm carries about 6.9 keV, so a 25 meV energy transfer is a part in 3×10^5 of it — and it must be resolved twice over, once in the incident beam and once in the scattered one. That measurement is possible, but it needed a synchrotron and a generation of crystal-optics development [1985]; it was not available in 1955 and is still not the routine instrument.

Table 132.1: Three probes at the wavelength that resolves an interatomic spacing, $\lambda = 0.18$ nm. Only for the neutron is a typical excitation of the solid — from about 1 meV to about 100 meV — a sizeable fraction of the energy carried in. The last column takes 25 meV as the transfer to be measured. Energies follow from Equation (132.1) for the massive probes and from $E = hc/\lambda$ for the photon.

Probe	Energy at $\lambda = 0.18$ nm	25 meV as a fraction
Neutron	25 meV	1
Electron	46 eV	5×10^{-4}
X-ray photon	6.9 keV	4×10^{-6}

Three further properties matter, and each of them is used by one of the experiments below.

The neutron is uncharged. It feels no Coulomb barrier and no electron cloud, so it penetrates centimetres of most materials rather than micrometres: the sample can sit inside a cryostat, a furnace or a pressure cell, and what is measured is the bulk rather than the surface. The electron of Table 132.1 fails on this count as well as on the energy count.

The neutron scatters from nuclei, not from electron clouds. A nucleus is of order 10^{-15}–10^{-14} m across, four to five orders of magnitude smaller than the wavelength, so it is a point scatterer: the nuclear scattering length b is a single number, independent of the scattering angle. There is no form factor to fall away at large momentum transfer, which is what makes the high-order reflections strong enough for the Debye–Waller measurement of Section 132.6. And b varies erratically from element to element and even between isotopes of one element, instead of growing smoothly with atomic number as the X-ray amplitude does. Hydrogen is therefore visible next to uranium, and neighbouring elements in the periodic table can be told apart [1627].

The neutron carries a magnetic moment while carrying no charge. Its dipole couples to the moments of unpaired electrons, with an amplitude of the same order as the nuclear scattering length, so magnetic order produces diffraction peaks of ordinary strength [838]. This is the property that made Section 132.2 possible, and it is the one no other structural probe has.

132.2 Shull and Smart: antiferromagnetic order in MnO (1949)

Until 1949, antiferromagnetism was a hypothesis about something no instrument could detect. Néel's two-sublattice molecular field [781] predicted a state whose sublattice moments cancel, so that the susceptibility rises on cooling, peaks at the ordering temperature and then falls, and so that the substance is magnetically almost inert below it. Every one of

those signatures is indirect: they are consistent with the two-sublattice picture but do not exhibit it. The neutron exhibits it.

132.2.1 Apparatus

A beam from the graphite reactor at Oak Ridge, monochromated by Bragg reflection from a single crystal so that a narrow band of wavelengths near 0.1 nm enters the specimen, with Soller collimators and cadmium and boron shielding defining the beam. The specimen is a powder of manganese oxide in a thin-walled container mounted in a cryostat that can be held at liquid-nitrogen temperature or allowed to warm through the transition. The detector is a boron trifluoride proportional counter carried on an arm that rotates about the specimen axis, recording counts against scattering angle [923, 949, 991].

132.2.2 Procedure

The powder pattern is recorded twice, once with the specimen near 80 K and once at room temperature, and the two are subtracted. The logic of the comparison is what makes it decisive, and it rests on Section 132.6: the nuclear scattering is temperature-dependent only through the Debye–Waller factor, which *weakens* existing reflections and creates none. Any line that is present in the cold pattern and absent from the warm one therefore cannot be nuclear. The transition temperature is then located by following the intensity of the new lines as the specimen warms, and compared with the temperature of the susceptibility maximum measured on the same material by ordinary magnetometry.

132.2.3 Observations and data

At room temperature the pattern indexes completely on the face-centred-cubic rock-salt cell of manganese oxide, with the reflection conditions that cell requires. On cooling below the transition, additional reflections appear at scattering angles lying between the nuclear lines. They index on a cubic cell of twice the edge — equivalently, at half-integral indices of the chemical cell — and their intensities fall away with increasing scattering angle markedly faster than the nuclear lines do. They vanish on warming through a transition near 120 K, where the susceptibility has its maximum [949, 991].

Phenomenon 132.1 (Magnetic order makes Bragg peaks of its own)**.** A substance whose magnetic moments order with zero net moment scatters neutrons into reflections that are absent above the ordering temperature and absent from its X-ray pattern at every temperature. In manganese oxide these extra reflections index on a magnetic unit cell of twice the chemical edge, appear below about 120 K, and fall off with momentum transfer faster than the nuclear reflections [949, 991]. Their positions record the periodicity of the magnetic arrangement, their intensities its moment size, and their disappearance the ordering temperature — three quantities no magnetometer can supply, because the net moment they describe is zero.

Derivation. Let the magnetic ions occupy a Bravais lattice with primitive translations $\boldsymbol{a}_i$, and let the moment at the site $\boldsymbol{R}$ be $\sigma(\boldsymbol{R})\,\boldsymbol{m}$ with $\sigma = \pm 1$, reversing under each primitive translation. The neutron's dipole couples to the moment, so that site scatters with amplitude $p\,\sigma(\boldsymbol{R})$, where p carries the magnetic form factor and the geometrical factor but not the sign; the amplitude scattered by the crystal into momentum transfer $\boldsymbol{Q}$ is

$$F_m(\boldsymbol{Q}) = p \sum_{\boldsymbol{R}} \sigma(\boldsymbol{R})\, \mathrm{e}^{\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{R}} . \tag{132.2}$$

Any such sign function can be written $\sigma(\boldsymbol{R}) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}_M\cdot\boldsymbol{R}}$ for a *propagation vector* $\boldsymbol{k}_M$ obeying $\boldsymbol{k}_M \cdot \boldsymbol{a}_i = \pi$ modulo 2π for every i; that is, $2\boldsymbol{k}_M$ is a reciprocal-lattice vector of the chemical

lattice while $\boldsymbol{k}_M$ itself is not. Substituting into Equation (132.2),

$$F_m(\boldsymbol{Q}) = p \sum_{\boldsymbol{R}} \mathrm{e}^{\mathrm{i}(\boldsymbol{Q}+\boldsymbol{k}_M)\cdot\boldsymbol{R}}, \tag{132.3}$$

which is the ordinary lattice sum and vanishes unless $\boldsymbol{Q}+\boldsymbol{k}_M = \boldsymbol{G}$ for some reciprocal-lattice vector $\boldsymbol{G}$ of the chemical lattice. Magnetic intensity therefore appears at $\boldsymbol{Q} = \boldsymbol{G} - \boldsymbol{k}_M$ and nowhere else: displaced from every nuclear reflection by $\boldsymbol{k}_M$, hence at half-integral indices, hence on the reciprocal lattice of a real-space cell of twice the edge. The two things the observation reports are one thing: the extra reflections at half-integral indices *are* the doubling of the magnetic period, and their absence from the nuclear pattern is guaranteed because $\boldsymbol{k}_M$ is not itself a reciprocal-lattice vector. In manganese oxide the magnetic ions form a face-centred cubic lattice and $\boldsymbol{k}_M = (\pi/a)(1,1,1)$, which reverses the sign across each successive (111) sheet: the moments lie ferromagnetically aligned within a sheet and antiparallel between neighbouring sheets, which is exactly Néel's two sublattices. The faster falloff of the magnetic intensities with angle is the form factor inside p, and is the second, independent signature that the reflections are magnetic: the nuclear amplitude has no form factor at all, as Section 132.1 explains, while the magnetic amplitude is the Fourier transform of an electron distribution of atomic size. □

132.2.4 Interpretation

The reflections are the two-sublattice structure itself, seen directly. A hypothesis proposed to account for a susceptibility curve [781] became a measured atomic arrangement, and the systematic determination of magnetic structures — moment directions, moment magnitudes, propagation vectors — began at once [991]. It should be said what the measurement does not fix. A powder pattern from a cubic crystal averages over the orientations of the magnetic domains, and the moment *direction* within the ordered sheets is not determined uniquely by the intensities alone; the propagation vector and the moment magnitude are. The technique also says nothing about *why* the manganese ions couple antiparallel through the intervening oxygen, which is the separate question of superexchange treated in Chapter 129.

132.2.5 Primary references

[949], with the systematic follow-up [991]. The prediction under test is [781].

132.3 Brockhouse and Stewart: phonons in aluminium (1955)

Diffraction alone locates atoms; it says nothing about how they move. The step from the elastic experiment above to a measurement of $\omega(\boldsymbol{k})$ requires the energy of the scattered neutron to be measured as well as its direction, and it was first taken in a single crystal of aluminium.

132.3.1 Apparatus

A beam from the Chalk River reactor, monochromated by Bragg reflection from a single crystal so that the neutrons entering the specimen have a known energy E_i and wavevector $\boldsymbol{k}_i$. The specimen is a single crystal of aluminium — face-centred cubic, one atom in the primitive cell — mounted on a goniometer that sets its orientation relative to the incident beam. The scattered beam is analysed in energy by a second Bragg reflection from a crystal before reaching the counter, so that the instrument records the number of neutrons arriving with a chosen final energy E_f in a chosen direction. This arrangement, monochromator–specimen–analyser, is the triple-axis spectrometer in its first form; Section 132.5 uses it in its mature one.

132.3.2 Procedure

Fix the incident energy and the scattering angle and record the distribution of final energies. Each pair of readings converts, by the kinematics of Equation (132.4) below, into a momentum transfer $\boldsymbol{Q} = \boldsymbol{k}_i - \boldsymbol{k}_f$ and an energy transfer $\hbar\omega = E_i - E_f$. Repeating over a range of angles and crystal orientations samples a region of the $(\boldsymbol{Q}, \omega)$ plane. The single crystal is essential: a powder averages over orientations and destroys the direction of $\boldsymbol{Q}$, which is exactly the information a dispersion relation is about.

132.3.3 Observations and data

The distribution of scattered energies at a fixed geometry is not smooth. It carries resolved peaks standing above a background, and the $(\boldsymbol{q}, \omega)$ pairs deduced from the peak positions do not fill the plane: they fall on curves. In aluminium the curves are three in number, they rise linearly out of the origin with slopes that agree with the sound velocities computed from the elastic constants of the same metal, and they flatten towards the zone boundary, so the group velocity $\mathrm{d}\omega/\mathrm{d}q$ falls to zero there [1056]. The measured frequencies of the primary paper are not reproduced here; what is quoted is the shape of the result, which is what the theory predicts.

Phenomenon 132.2 (At a fixed momentum transfer the neutron loses only certain energies)**.** Neutrons scattered by a single crystal into a fixed momentum transfer $\boldsymbol{Q}$ do not emerge with a continuum of energies. The spectrum carries sharp peaks at a small number of energy transfers, and the pairs $(\boldsymbol{q}, \omega)$ they define lie on a small number of continuous branches that are periodic in the reciprocal lattice [1056, 1137]. The excitations of a crystal are therefore quanta with a definite energy for each wavevector, and the dispersion relation is read off the instrument rather than postulated.

Derivation. A crystal is invariant under the discrete translations of its lattice and not under continuous ones, so what the collision conserves is the neutron momentum modulo $\hbar\boldsymbol{G}$, with $\boldsymbol{G}$ any reciprocal-lattice vector. Writing $\boldsymbol{Q} = \boldsymbol{k}_i - \boldsymbol{k}_f$ and $\hbar\omega = E_i - E_f$, a process that creates one quantum of the branch s at wavevector $\boldsymbol{q}$ obeys

$$\boldsymbol{Q} = \boldsymbol{q} + \boldsymbol{G}\,, \qquad \hbar\omega = \hbar\omega_s(\boldsymbol{q})\,. \tag{132.4}$$

The first of these fixes $\boldsymbol{q}$ once $\boldsymbol{Q}$ is chosen, since $\boldsymbol{q}$ is defined only modulo $\boldsymbol{G}$; the second then leaves for the energy transfer only the $3p$ values $\hbar\omega_s(\boldsymbol{q})$, one for each branch. A discrete set of allowed energy transfers at fixed $\boldsymbol{Q}$ is a set of peaks in the spectrum of scattered neutrons, which is the observation. Conversely one peak fixes one pair $(\boldsymbol{q}, \omega)$, so a scan is a set of points on $\omega_s(\boldsymbol{q})$. Two features of the data follow without further work. The branches are periodic in the reciprocal lattice because $\boldsymbol{q}$ enters Equation (132.4) only modulo $\boldsymbol{G}$, so nothing outside the first Brillouin zone is new; and the smooth background beneath the peaks is not instrumental error but multiphonon scattering, in which two or more quanta share the transfer, so that Equation (132.4) constrains only their sum and the allowed ω fill an interval. □

Derivation pending #271

The one-phonon scattering cross section itself: the factor that weights each peak by the square of the projection of the polarization vector on the momentum transfer, by the Bose population of the mode, and by the Debye–Waller factor, so that the measured intensities constrain the eigenvectors of the dynamical matrix and not only its eigenvalues

132.3.4 Interpretation

Before this measurement the vibrational spectrum of a solid was known only through quantities that integrate over it. A heat capacity determines the density of modes $g(\omega)$, and infinitely many dispersion relations share one $g(\omega)$; a Debye temperature is a one-parameter caricature of the whole function. Diffuse X-ray scattering carries the information in principle but requires an assumed force model to extract it. The neutron measurement is direct in the strict sense: one peak, one point of $\omega(\boldsymbol{q})$, no model. That is what entitles Chapter 125 to speak of the phonon as a particle — the sharpness of the peak is the statement that a wavevector has a definite energy — and it is what makes the Born–von Kármán force constants a fitted, falsifiable object rather than a parametrization.

132.3.5 Primary references

[1056]. The theoretical frame is the lattice dynamics of [381, 1030].

132.4 Brockhouse: spin waves in magnetite (1957)

The same instrument, pointed at a magnetically ordered crystal, does for Chapter 129 what it had just done for Chapter 125. Bloch's account of the fall of the magnetization with temperature rests on the claim that the cheap excitations of an ordered magnet are long-wavelength precessional waves rather than individually reversed spins [643]. The two pictures differ qualitatively — a reversed spin costs a finite energy and would give an exponential law, a spin wave costs arbitrarily little and gives a power law — so the claim is testable by the magnetization curve alone. Seeing the excitation itself is another matter.

132.4.1 Apparatus

The triple-axis arrangement of Section 132.3, with a single crystal of magnetite, Fe_3O_4, as the specimen, at room temperature — far below its ordering temperature, so the ordered state is well developed and the magnon population is small enough for the excitations to be sharp.

132.4.2 Procedure

Scans are taken at small wavevector transfer relative to a reciprocal-lattice point, where a magnon branch that starts from zero is well separated from the phonon branches. Three independent signatures distinguish a magnetic peak from a lattice one, and the identification uses all three. The intensity of magnetic scattering falls with $|\boldsymbol{Q}|$ through the magnetic form factor, whereas one-phonon intensity *grows* as $|\boldsymbol{Q}|^2$, so repeating a scan near a high-order reciprocal-lattice point separates them. The dispersion of a ferromagnetic magnon is quadratic at long wavelength while an acoustic phonon's is linear. And the magnon intensity and dispersion respond to temperature and to an applied field as the lattice modes do not.

132.4.3 Observations and data

A branch is resolved whose energy rises from zero quadratically with wavevector at long wavelength, distinct from the phonon branches of the same crystal, and whose intensity falls with momentum transfer in the manner of a magnetic form factor [1104]. The fitted coefficient of q^2 is the spin-wave stiffness D, the quantity that fixes the coefficient of the $T^{3/2}$ law in Chapter 129 and, through the derivation below, the exchange constant. The value obtained is not quoted here.

Magnetite is a ferrimagnet rather than a simple ferromagnet: it has two inequivalent magnetic sublattices, so its spin-wave spectrum has an acoustic branch, which starts at zero and is quadratic at long wavelength like a ferromagnet's, together with optical branches at higher energy. The branch measured at small wavevector is the acoustic one, and it is the acoustic branch alone that the $T^{3/2}$ law needs.

Phenomenon 132.3 (Spin waves are quanta with a quadratic dispersion)**.** An ordered magnet carries collective excitations that inelastic neutron scattering resolves as sharp peaks, on a branch whose energy vanishes as the wavevector goes to zero and rises as $\hbar\omega = Dq^2$ at long wavelength [1104]. The excitation spectrum of a ferromagnet therefore has no gap, which is what supplies the arbitrarily cheap excitations that the $T^{3/2}$ law of [643] requires, and the stiffness D measured here must equal the one fitted to the magnetization curve of the same material.

Derivation. Take the Heisenberg model of Chapter 129 on a simple cubic lattice of spacing a, written with each bond counted once,

$$H = -J \sum_{\text{bonds}} \boldsymbol{S}_n \cdot \boldsymbol{S}_m \,, \qquad J > 0 \,, \tag{132.5}$$

and treat the spins as classical vectors of length S — legitimate for the long-wavelength modes, in which neighbouring spins are almost parallel and the quantum corrections are of relative order $1/S$. Each spin precesses in the field of its neighbours,

$$\hbar \frac{\mathrm{d}\boldsymbol{S}_n}{\mathrm{d}t} = J\, \boldsymbol{S}_n \times \sum_{\boldsymbol{\delta}} \boldsymbol{S}_{n+\boldsymbol{\delta}} \,, \tag{132.6}$$

the sum running over the $z = 6$ nearest neighbours. Linearize about the ordered state by writing $\boldsymbol{S}_n = (S_n^x, S_n^y, S)$ with the transverse components small, and keep terms of first order in them:

$$\hbar \frac{\mathrm{d}S_n^x}{\mathrm{d}t} = JS \left(z S_n^y - \sum_{\boldsymbol{\delta}} S_{n+\boldsymbol{\delta}}^y \right) , \tag{132.7}$$

$$\hbar \frac{\mathrm{d}S_n^y}{\mathrm{d}t} = -JS \left(z S_n^x - \sum_{\boldsymbol{\delta}} S_{n+\boldsymbol{\delta}}^x \right) . \tag{132.8}$$

The pair decouples in the combination $S^+ = S^x + \mathrm{i}S^y$, giving $\hbar\,\mathrm{d}S_n^+/\mathrm{d}t = -\mathrm{i}JS\left(zS_n^+ - \sum_{\boldsymbol{\delta}} S_{n+\boldsymbol{\delta}}^+\right)$, and the lattice translation invariance of that equation makes plane waves $S_n^+ \propto \mathrm{e}^{\mathrm{i}(\boldsymbol{q}\cdot\boldsymbol{R}_n - \omega t)}$ its normal modes. Substituting them,

$$\hbar\omega(\boldsymbol{q}) = JS \sum_{\boldsymbol{\delta}} \left(1 - \cos \boldsymbol{q}\cdot\boldsymbol{\delta}\right) . \tag{132.9}$$

Two consequences are the content of the experiment. First, $\omega \to 0$ as $\boldsymbol{q} \to 0$: the uniform mode is a rigid rotation of every spin together, which costs nothing because Equation (132.5) depends only on relative orientations. The gaplessness is thus a consequence of the rotational symmetry that the ordered state breaks, not of any detail of J, and it is what makes the low-temperature magnetization deficit a power of T rather than an exponential. Second, expanding Equation (132.9) for $|\boldsymbol{q}|\,a \ll 1$ on the cubic lattice, where the six neighbours contribute in pairs along the three axes,

$$\hbar\omega \simeq JSa^2q^2 \,, \qquad D = JSa^2 \,, \tag{132.10}$$

which is the measured shape and which converts the measured stiffness into the exchange constant. The numerical factor in D depends on the convention for Equation (132.5): writing the Hamiltonian as an unrestricted double sum over pairs, as Chapter 129 does, counts each bond twice and doubles D at fixed J. What is convention-independent is the shape $\hbar\omega \propto q^2$ and the vanishing at $\boldsymbol{q} = 0$, and those are what the scan measures. □

132.4.4 Interpretation

Two independent measurements on the same material must now agree: the stiffness D read off the neutron dispersion and the stiffness implied by the coefficient of $T^{3/2}$ in the magnetization curve. That is a closed loop of the kind an evidence-based treatise should insist on, because either measurement alone can be accommodated by adjusting a parameter and the pair cannot. The experiment also settles the question Bloch's calculation raised and could not answer from thermodynamics alone: the excitations are collective waves with a gapless spectrum, and not reversed individual spins, which would have shown a finite minimum energy in exactly the scan performed here.

132.4.5 Primary references

[1104]. The prediction under test is [643], with the operator formulation in [852].

132.5 Brockhouse and Iyengar: the normal modes of germanium (1958)

The aluminium measurement showed that a point of $\omega(\boldsymbol{q})$ can be taken. Germanium showed that a whole dispersion relation can be taken — every branch, along the symmetry directions, in a crystal with more than one atom per cell — and it is the measurement against which lattice-dynamical models have been tested ever since.

132.5.1 Apparatus

The triple-axis crystal spectrometer at Chalk River, in its mature form: three axes of rotation, one at the monochromating crystal, which selects $\boldsymbol{k}_i$ out of the reactor's broad spectrum; one at the specimen, which sets its orientation and hence the direction of $\boldsymbol{Q}$ in the crystal; and one at the analysing crystal, which selects $\boldsymbol{k}_f$ before the counter. The specimen is a single crystal of germanium, whose diamond structure has $p = 2$ atoms in the primitive cell.

132.5.2 Procedure

The instrument's three angles and two crystal settings give more freedom than the measurement needs, and Brockhouse's use of that freedom is the methodological content of the experiment. In the *constant-$\boldsymbol{Q}$* method the incident and final energies are stepped together, with the arm angles moved to compensate, so that the momentum transfer stays fixed while the energy transfer is scanned. Each scan is then a cut through the $(\boldsymbol{Q}, \omega)$ plane along one axis, and a branch appears as a peak at a definite energy rather than as something to be reconstructed from a locus of intersections. Scans are repeated along the [100], [110] and [111] directions, and the peak positions are collected into $\omega_s(\boldsymbol{q})$ branch by branch.

132.5.3 Observations and data

Germanium shows six branches, as $3p = 6$ requires. Three are acoustic: they vanish at the zone centre, rise linearly there with slopes that agree with the sound velocities computed from the elastic constants of the same crystal, and flatten towards the zone boundary. Three are optical, with a finite frequency at $\boldsymbol{q} = 0$; branches degenerate along a symmetry direction separate away from it, as the symmetry of the direction requires. The complete set was compared with Born–von Kármán force-constant fits, and the fits require interactions extending beyond nearest neighbours [1137].

Phenomenon 132.4 (A crystal with p atoms per primitive cell has exactly $3p$ branches, three of them acoustic)**.** The measured dispersion relation of a crystal consists of $3p$ branches $\omega_s(\boldsymbol{q})$, where p is the number of atoms in the primitive cell; three of them vanish as $\boldsymbol{q} \to 0$ and the remaining $3p-3$ do not. Germanium, with $p=2$, shows six branches, three acoustic and three optical [1137]; aluminium, with $p=1$, shows three and they are all acoustic [1056].

Derivation. Let $u_\alpha(\boldsymbol{R}\kappa)$ be the Cartesian displacement of the atom κ of mass M_κ in the cell at $\boldsymbol{R}$. In the harmonic approximation the equations of motion are linear with coefficients depending on $\boldsymbol{R}-\boldsymbol{R}'$ alone, so they are diagonalized by the Bloch form

$$u_\alpha(\boldsymbol{R}\kappa) = M_\kappa^{-1/2}\, e_\alpha(\kappa)\, \mathrm{e}^{\mathrm{i}(\boldsymbol{q}\cdot\boldsymbol{R}-\omega t)}\,, \tag{132.11}$$

and reduce, for each $\boldsymbol{q}$ separately, to the eigenvalue problem

$$\omega^2 e_\alpha(\kappa) = \sum_{\beta\kappa'} D_{\alpha\beta}(\kappa\kappa';\boldsymbol{q})\, e_\beta(\kappa') \tag{132.12}$$

for the dynamical matrix D, which is Hermitian because the force constants are symmetric, and which is $3p\times 3p$ because the indices run over three Cartesian directions and p atoms. A Hermitian $3p\times 3p$ matrix has $3p$ real eigenvalues, so there are $3p$ branches; and D is built from $\mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{R}}$ with $\boldsymbol{R}$ on the lattice, so the branches are periodic in the reciprocal lattice.

Three of them vanish at $\boldsymbol{q}=0$. A rigid translation moves every atom of every cell by the same vector $\boldsymbol{c}$; it leaves every interatomic distance unchanged, so it costs no potential energy. It is of the form Equation (132.11) with $\boldsymbol{q}=0$ and $e_\alpha(\kappa)=\sqrt{M_\kappa}\,c_\alpha$, hence an eigenvector of $D(\boldsymbol{0})$ with eigenvalue zero; there are three independent choices of $\boldsymbol{c}$, so three branches with $\omega\to 0$ as $\boldsymbol{q}\to 0$. The remaining $3p-3$ modes move atoms within a cell against one another and have no reason to be free, so they start at a finite frequency. Nothing in the argument uses the values of the force constants: the count is a consequence of translational invariance and of the size of the cell, which is why it is a test of the framework rather than a fit to the data. Germanium must show six branches with three acoustic, and does. □

132.5.4 Interpretation

Two things are established at once, and they are of different kinds. The first is structural and survives any change of model: the number of branches and the three zero modes at the zone centre, which is the content of Phenomenon 132.4. The second is quantitative and model-dependent: the shapes of the branches determine the force constants, and in germanium they cannot be fitted with nearest-neighbour forces alone. That is a genuine result about the bonding of a covalent semiconductor, obtained from a mechanical measurement, and it is the sort of thing that only a full dispersion relation can deliver — a density of states, and therefore a heat capacity, is insensitive to it. With this experiment the function on which Chapter 125 rests stopped being an assumption.

132.5.5 Primary references

[1137], following [1056]; the model it is fitted against is that of [381, 1030].

132.6 The Debye–Waller factor, measured on the same patterns

The diffraction patterns of Section 132.2 carry, without any extra apparatus, the measurement that Chapter 125 needs to close its account of thermal motion. It is set down here because the procedure of that experiment leans on it, and because the neutron measures it more

cleanly than the X-ray does: the nuclear scattering length has no form factor, so the whole falloff of intensity with momentum transfer at fixed temperature is thermal, with nothing to disentangle.

Phenomenon 132.5 (Thermal motion weakens the Bragg peaks without broadening them, and does not stop at absolute zero)**.** The intensity of a Bragg reflection falls as the crystal is heated, by a factor that grows with the momentum transfer; the reflection stays at the same angle and keeps its width. The intensity lost from the peaks reappears as a diffuse background rather than disappearing. And the attenuation does not extrapolate to unity at zero temperature: a harmonic crystal at absolute zero still attenuates its own reflections [402, 506]. The same factor governs the recoilless fraction in nuclear resonance absorption [1154].

Derivation. Let the nucleus n sit at $\boldsymbol{R}_n + \boldsymbol{u}_n$, with $\boldsymbol{R}_n$ its equilibrium position and $\boldsymbol{u}_n$ its thermal displacement, and let b_n be its scattering length. The Bragg peaks come from the part of the scattering that is coherent with the average lattice, that is from the thermal average of the amplitude:

$$\langle F(\boldsymbol{Q}) \rangle = \sum_n b_n \, \mathrm{e}^{\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{R}_n} \left\langle \mathrm{e}^{\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{u}_n} \right\rangle . \tag{132.13}$$

In a harmonic crystal $\boldsymbol{u}_n$ is a linear combination of the normal-mode coordinates, each of which is Gaussian in thermal equilibrium, so $x = \boldsymbol{Q}\cdot\boldsymbol{u}_n$ is a Gaussian variable of zero mean. For such a variable $\langle \mathrm{e}^{\mathrm{i}x} \rangle = \mathrm{e}^{-\langle x^2 \rangle/2}$, whence

$$\langle F(\boldsymbol{Q}) \rangle = \mathrm{e}^{-W} \sum_n b_n \, \mathrm{e}^{\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{R}_n} , \qquad 2W = \left\langle (\boldsymbol{Q}\cdot\boldsymbol{u})^2 \right\rangle , \tag{132.14}$$

and the measured intensity, being the squared modulus of the amplitude, carries the factor e^{-2W}.

Each of the three observed features is now a line of the calculation. The factor e^{-W} multiplies the lattice sum in Equation (132.14) without altering it, so the peak positions and widths are untouched: the *average* lattice is still perfectly periodic, and it is the average lattice that the Bragg peaks see. Nothing is destroyed, because the total scattering from a set of nuclei is fixed by their scattering lengths and cannot depend on temperature; what leaves the peaks reappears in the one- and multi-phonon scattering that fills the space between them, which is the same background beneath the peaks of Phenomenon 132.2. And $\langle u^2 \rangle$ does not vanish at $T = 0$: each normal mode retains its zero-point amplitude, so $W > 0$ at absolute zero. That last term is Waller's correction [506] to Debye's classical calculation [402], and it is a direct consequence of the quantization that Chapter 125 imposes on the modes. At high temperature, by contrast, equipartition makes $\langle u^2 \rangle$ proportional to T, so $\ln I$ is linear in temperature with a slope proportional to $|\boldsymbol{Q}|^2$ — the form in which the factor is fitted, and from which the mean square displacement of an atom in a crystal is extracted. □

Derivation pending #272

The mode sum for the mean square displacement, giving $2W$ in terms of the measured dispersion relation, its evaluation in the Debye model with the zero-point term separated from the thermal one, and the resulting temperature dependence of the attenuation at fixed momentum transfer

Table 132.2: The four measurements of this chapter, with the prediction each tests and the chapter that makes it. In every case the quantity measured is one that no other instrument of the period could reach — which is the argument for the technique, and the reason the two theoretical chapters had to be written ahead of their evidence.

Experiment	Tests	Result
Shull–Smart 1949	Chapter 129	extra Bragg reflections below 120 K on a cell of twice the chemical edge: Néel's two sublattices seen directly
Brockhouse–Stewart 1955	Chapter 125	sharp energy transfers at fixed momentum transfer; three branches in aluminium, linear at long wavelength and flat at the zone boundary
Brockhouse 1957	Chapter 129	a gapless branch with $\hbar\omega = Dq^2$ in magnetite: magnons resolved, and D measured independently of the magnetization curve
Brockhouse–Iyengar 1958	Chapter 125	all six branches of germanium along three symmetry directions; force constants beyond nearest neighbours required

132.7 What the neutron settled

Table 132.2 closes four gaps at once, and the 1994 Nobel prize recognized the two halves of the technique: the diffraction method that shows where the atoms and the moments are, and the spectrometry that shows how they move. It is worth being explicit about what the closure does and does not amount to.

What is measured directly is a scattering law [1052], and its interpretation as a dispersion relation uses the one-phonon — or one-magnon — approximation, whose corrections are the multiphonon background of Phenomenon 132.2. Where the excitations are not sharp, the peaks broaden and the notion of a dispersion curve itself weakens; the measurement then reports a lifetime as well as an energy, which is more information rather than less, but it is no longer the clean reading of a function that Chapter 125 assumes. The neutron is also a flux-limited probe: sources are few, samples must be large by the standards of modern materials work, and weakly scattering or strongly absorbing elements are difficult. Inelastic X-ray scattering at synchrotron sources now reaches phonons in specimens far too small for a neutron beam [1985], at the price of the extreme energy resolution that Table 132.1 shows it needs.

Neither reservation touches the conclusions of this chapter, because all four are qualitative statements that a quantitative correction cannot reverse: the magnetic cell of manganese oxide is twice the chemical one; the energy transfer at fixed momentum transfer is discrete; germanium has six branches and three of them are acoustic; the magnon spectrum has no gap. Each is what its theory chapter predicted, and each was, before 1949, a claim about something nobody had seen.

132.8 Hodgkin, Hauptman and Karle, and Klug: the phase problem (1934–1969)

One step has been taken for granted in every diffraction measurement of this chapter, and it is not innocent. A detector counts quanta, and its reading at a reciprocal-lattice point is proportional to $|F(\boldsymbol{G})|^2$, the squared modulus of the scattered amplitude. A modulus is half of a complex number: the phase $\arg F(\boldsymbol{G})$ leaves no mark on any counter, and the Fourier synthesis that turns a diffraction pattern into a picture of the scatterers needs both halves. Bragg's law [399], in the form of Equation (125.1), fixes where the peaks are and therefore the lattice; what sits inside the cell is carried by the intensities, and the intensities do not contain enough to recover it. This is the *phase problem*, named as an open question in Section 125.2.3 and taken up here.

It did not obstruct the four measurements above, and the reason is worth stating, because it is the exception and not the rule: each of them had few enough unknowns to be *fitted* rather than inverted in the first place. The chemical structure of manganese oxide was already known from X-rays when Section 132.2 began, so the unknowns there were a propagation vector, a moment magnitude and a direction — a handful of numbers, which a comparison of computed with observed intensities settles without any Fourier synthesis at all. The inelastic measurements use peak positions and barely use intensities. A molecule of a hundred atoms in the cell offers three hundred coordinates, and there fitting has nothing to start from: a model must be guessed before it can be compared, and nobody can guess three hundred numbers.

Three Nobel prizes in Chemistry mark the three ways out. Dorothy Crowfoot Hodgkin's, in 1964, was for carrying X-ray analysis to molecules whose constitution chemistry had been unable to settle, using a heavy atom that the molecule contains, or can be made to contain, as the source of the phases [1311]. Herbert Hauptman and Jerome Karle's, in 1985, was for showing that the phases are not in fact independent of the amplitudes: a scattering density is non-negative and is made of atoms, and those two facts alone constrain the phases enough to determine them [1775, 1777]. Aaron Klug's, in 1982, was for taking the phases from a different instrument altogether — an electron microscope forms an image, and an image has its phases in it [1722].

132.8.1 Apparatus

For the X-ray work: a sealed tube with a copper or molybdenum target, whose characteristic $K\alpha$ line supplies a wavelength near 0.1 nm, filtered or monochromated by a crystal; a single crystal of the substance, a few tenths of a millimetre across, on a goniometer head that can be set to any orientation; and a recorder — photographic film in a Weissenberg or precession camera in the early work, a counter diffractometer later — that measures the integrated intensity of each reflection. A protein crystal is largely solvent and must stay wet, so it is sealed in a capillary with its mother liquor. Where heavy-atom phasing is used the apparatus includes the chemistry: crystals soaked in solutions of mercury, platinum or uranium salts, which have to bind at a few definite sites without disturbing the lattice.

The second instrument is arithmetic, and here it is apparatus in the strict sense. A three-dimensional Fourier synthesis over several thousand reflections is not a calculation anyone finishes by hand in a working lifetime, and the vitamin B_{12} analysis was among the first structural problems carried out on the electronic computers then becoming available. What can be solved is set by what can be computed, which is why the reach of the subject tracks the history of computing so closely.

For the electron work: a transmission electron microscope with magnetic lenses, at an accelerating voltage of order 100 kV; a specimen thin enough to be transparent to the beam, supported on a film and imaged either negatively stained or unstained; a tilting stage; a

photographic plate, and a densitometer to turn the developed plate into numbers a computer can transform.

132.8.2 Procedure

The X-ray procedure has three variants and one goal: obtain a first estimate of the phases good enough that a Fourier synthesis computed with the *measured* moduli and the *estimated* phases shows recognizable atoms. Once it does, the atoms found give better phases, a better map follows, and the cycle converges — the moduli being right throughout, the phases are the only thing being improved.

The first variant computes the synthesis whose coefficients are the measured intensities themselves, all phases set to zero, and reads the position of a heavy atom out of the resulting vector map. Phases computed from that one atom are then good enough to start the cycle, because a heavy atom contributes a large and known term to every structure factor. The molecule may supply the heavy atom itself — the cobalt at the centre of vitamin B_{12} — or one may be introduced, by crystallizing a salt of the substance with a heavy cation or by attaching a heavy group chemically.

The second variant is for proteins, where no atom of the molecule dominates. Crystals are soaked with a heavy-metal salt so as to add a few atoms per molecule without changing the cell, the intensities of native and derivative are measured separately, and their differences locate the added atoms; the derivative then plays the part of the known term. In the general case two independent derivatives are needed, for the reason given in the interpretation below.

The third variant uses no heavy atom and no chemistry. The measured moduli are scaled and normalized to what point atoms at rest would give; the strongest few hundred are selected; an origin is fixed by assigning arbitrary phases to a small permitted set of reflections; and phases are propagated through the relations of Equation (132.20) below, many trial sets being carried in parallel and ranked by internal consistency. The map is computed from the surviving set and inspected for a chemically sensible arrangement of atoms.

The electron procedure records micrographs of the specimen at a series of orientations — or exploits the specimen's own symmetry, which presents several orientations at once — digitises each plate, transforms it, places the result as a central plane of the three-dimensional transform, interpolates onto a grid and transforms back. The dose that would give one good image destroys the specimen, so each micrograph is recorded with far too few electrons and many images of identical particles are averaged.

132.8.3 Observations and data

The synthesis computed with intensities as coefficients and every phase set to zero is not noise. It is a map with a peak at the end of every interatomic vector of the structure, weighted by the product of the two scattering powers, and with a large peak at the origin [747]. That map is centrosymmetric whether the crystal is or not, and the measured intensities themselves obey $I(\boldsymbol{G}) = I(-\boldsymbol{G})$ to the precision of the measurement — with one reproducible exception, in crystals containing an element whose absorption edge lies near the wavelength in use, where the two members of the pair differ by a small but definite amount [977].

Penicillin was determined while its constitution was still disputed, and the analysis showed the strained four-membered β-lactam ring fused to a five-membered ring, which the chemistry had been unable to establish [926]. Vitamin B_{12}, a molecule with of order a hundred atoms heavier than hydrogen and no known constitution at all, was determined from the crystals with the cobalt atom at its centre as the heavy atom [1087]; insulin, a protein, followed by isomorphous replacement and a far larger computation [1387].

In structures already known, the phase sums built from triples of strong reflections are found not to be spread uniformly round the circle: they cluster about zero, and the clustering tightens as the product of the three normalized amplitudes grows. For a centrosymmetric structure, where a phase can only be 0 or π, the same statement reads that the product of the three signs is $+1$ more often than not, the fraction rising towards unity with that same product [962, 1060]. Structures with of order a hundred independent non-hydrogen atoms are now solved from the measured intensities alone, with no chemical input beyond the composition [1775, 1777].

An electron micrograph behaves differently from a diffraction pattern in exactly the way that matters. Its two-dimensional Fourier transform, computed from the digitised plate, reproduces the three-dimensional transform of the specimen on the plane through the origin perpendicular to the beam — with phases. A set of micrographs at different orientations therefore fills the transform, and back transforming yields a density in three dimensions. This was carried out for the tail of bacteriophage T4, whose helical symmetry presents every azimuth in a single image [1369], and set out in general form immediately afterwards [1418].

Phenomenon 132.6 (A diffraction measurement determines the autocorrelation of the scatterers, not the scatterers)**.** The Fourier synthesis whose coefficients are the measured intensities, with all phases set to zero, is the autocorrelation of the scattering density: a map carrying a peak at the end of every interatomic vector [747]. It is centrosymmetric even when the structure is not, and correspondingly the intensities obey Friedel's law $I(\boldsymbol{G}) = I(-\boldsymbol{G})$ wherever the scattering is non-absorbing, so that no diffraction pattern can distinguish a structure from its mirror image; near an absorption edge the law fails measurably, and the failure fixes the absolute configuration [977]. What the experiment delivers is thus exact and is not the structure.

Derivation. Write the scattering density of one cell as $\rho(\boldsymbol{r})$ — the electron density for X-rays, the nuclear scattering-length density for the neutrons of Section 132.1 — and keep the sign convention of Equation (132.13),

$$F(\boldsymbol{G}) = \int_V \rho(\boldsymbol{r})\, \mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{r}}\, \mathrm{d}^3 r\,, \qquad \rho(\boldsymbol{r}) = \frac{1}{V}\sum_{\boldsymbol{G}} F(\boldsymbol{G})\, \mathrm{e}^{-\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{r}}\,. \tag{132.15}$$

The second of these is the synthesis that would produce the structure, and it needs F and not $|F|$. Form instead the synthesis whose coefficients are the numbers a counter delivers,

$$P(\boldsymbol{u}) = \frac{1}{V}\sum_{\boldsymbol{G}} |F(\boldsymbol{G})|^2\, \mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{u}}\,. \tag{132.16}$$

Substituting Equation (132.15) into the autocorrelation $\int_V \rho(\boldsymbol{r})\rho(\boldsymbol{r}+\boldsymbol{u})\, \mathrm{d}^3 r$ gives a double sum over $\boldsymbol{G}$ and $\boldsymbol{G}'$ whose $\boldsymbol{r}$ integral is $V\delta_{\boldsymbol{G}',-\boldsymbol{G}}$; the surviving terms carry $F(\boldsymbol{G})F(-\boldsymbol{G}) = |F(\boldsymbol{G})|^2$, since ρ is real, and what is left is exactly Equation (132.16). The intensities therefore determine the autocorrelation completely and without approximation.

Three properties of that object are the three parts of the observation. Relabelling $\boldsymbol{G} \to -\boldsymbol{G}$ in Equation (132.16) leaves $|F|^2$ alone and flips the exponent, so $P(-\boldsymbol{u}) = P(\boldsymbol{u})$: the map is centrosymmetric whatever ρ may be. For a structure of well-separated atoms of strengths Z_j at positions $\boldsymbol{r}_j$ the autocorrelation is $\sum_{j,k} Z_j Z_k\, \Gamma(\boldsymbol{u} - (\boldsymbol{r}_k - \boldsymbol{r}_j))$ with Γ the autocorrelation of one atom, that is a peak of weight $Z_j Z_k$ at the end of each interatomic vector, with the N diagonal terms piled at the origin. And ρ real gives $F(-\boldsymbol{G}) = F(\boldsymbol{G})^*$, hence Friedel's law; a structure and its inversion $\rho(-\boldsymbol{r})$ have structure factors that are complex conjugates of one another and so identical intensities, which is the statement that handedness is invisible. Absorption is what breaks it: near an edge the effective scattering density acquires an imaginary part, ρ is no longer real, and the Friedel pair separates.

The same lines say why the vector map is not a solution. It carries $N(N-1)$ off-origin peaks in a cell that holds N atoms, so the peak density grows as N^2 while the space available does not: at $N \sim 10$ the map can be read, at $N \sim 100$ it is a continuum. The loss is not only of resolution — distinct structures can share an autocorrelation exactly — but overcrowding is what defeats the method in practice. One case escapes, and it is the case Hodgkin exploited: if one atom is much heavier than the rest, the peaks involving it carry weight Z_{heavy}^2 or $Z_{\text{heavy}} Z_j$ and stand above the rest, so the heavy atom alone can be located in a map that shows nothing else. □

Phenomenon 132.7 (Non-negativity and atomicity tie the phases to the amplitudes)**.** For a structure of resolved atoms the phases are not free given the moduli. The sum $\varphi(\boldsymbol{H}) + \varphi(\boldsymbol{K}) - \varphi(\boldsymbol{H}+\boldsymbol{K})$ over a triple of strong reflections is observed to cluster about zero rather than to be distributed uniformly, and the clustering tightens as the product of the three normalized amplitudes grows; in a centrosymmetric structure the corresponding product of signs is $+1$ with a probability rising towards unity with the same product [962, 1011, 1060]. Structures of the size of a small organic molecule are therefore solved from the intensities alone, with no heavy atom and no chemical assumption beyond the composition [1020, 1089, 1775, 1777].

Derivation. Take N identical atoms, resolved from one another, at positions $\boldsymbol{r}_j$, each of the same shape $s(\boldsymbol{r})$, so that $\rho(\boldsymbol{r}) = \sum_j s(\boldsymbol{r} - \boldsymbol{r}_j)$ and, by Equation (132.15),

$$F(\boldsymbol{G}) = f(\boldsymbol{G})\, S(\boldsymbol{G})\,, \qquad S(\boldsymbol{G}) = \sum_j \mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{r}_j}\,, \tag{132.17}$$

with f the transform of s. Now square the density. The atoms do not overlap, so the cross terms vanish identically and $\rho^2(\boldsymbol{r}) = \sum_j s^2(\boldsymbol{r} - \boldsymbol{r}_j)$: squaring a set of separated equal blobs returns a set of separated equal blobs at the same places. Its structure factor is therefore $g(\boldsymbol{G})S(\boldsymbol{G})$, with g the transform of s^2, whence

$$F^{\text{sq}}(\boldsymbol{G}) = \frac{g(\boldsymbol{G})}{f(\boldsymbol{G})}\, F(\boldsymbol{G})\,. \tag{132.18}$$

On the other hand the transform of a product is the convolution of the transforms: substituting the synthesis of Equation (132.15) twice into $\int_V \rho^2 \mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{r}} \mathrm{d}^3 r$ and doing the $\boldsymbol{r}$ integral gives $F^{\text{sq}}(\boldsymbol{G}) = V^{-1} \sum_{\boldsymbol{H}} F(\boldsymbol{H}) F(\boldsymbol{G}-\boldsymbol{H})$. Equating the two expressions,

$$F(\boldsymbol{G}) = \frac{\theta(\boldsymbol{G})}{V} \sum_{\boldsymbol{H}} F(\boldsymbol{H})\, F(\boldsymbol{G}-\boldsymbol{H})\,, \qquad \theta = \frac{f}{g}\,, \tag{132.19}$$

which is Sayre's equation [1011]. It is exact, it contains no unknown but the structure factors themselves, and it is *nonlinear* — which is what lets it constrain phases, as no linear relation among the F could.

The phase relation is its leading term. For a real, spherically symmetric atomic shape both f and g are real, and over the range of momentum transfer in use both are positive, so θ is a positive number and Equation (132.19) makes the phase of $F(\boldsymbol{G})$ the phase of the sum on the right. A sum of many complex terms reaches a large modulus only if the terms dominating it are nearly in phase with one another; so wherever $|F(\boldsymbol{G})|$ is large, the dominant products $F(\boldsymbol{H})F(\boldsymbol{G}-\boldsymbol{H})$ — those whose two factors are both large — must carry, near enough, the phase of $F(\boldsymbol{G})$. Writing $F = |F|\,\mathrm{e}^{\mathrm{i}\varphi}$ and $\boldsymbol{K} = \boldsymbol{G} - \boldsymbol{H}$,

$$\Phi(\boldsymbol{H}, \boldsymbol{K}) = \varphi(\boldsymbol{H}) + \varphi(\boldsymbol{K}) - \varphi(\boldsymbol{H}+\boldsymbol{K}) \approx 0 \tag{132.20}$$

whenever all three reflections are strong.

That this particular combination is the right unknown is forced, and the argument is two lines. An intensity is unchanged by a shift of origin, so nothing an intensity measurement can ever determine may depend on where the origin was put. Moving it by $\boldsymbol{t}$ replaces $\rho(\boldsymbol{r})$ by $\rho(\boldsymbol{r}-\boldsymbol{t})$ and multiplies $F(\boldsymbol{G})$ by $\mathrm{e}^{\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{t}}$, so every individual phase moves by $\boldsymbol{G}\cdot\boldsymbol{t}$; the combination in Equation (132.20) moves by $\boldsymbol{H}\cdot\boldsymbol{t}+\boldsymbol{K}\cdot\boldsymbol{t}-(\boldsymbol{H}+\boldsymbol{K})\cdot\boldsymbol{t}=0$ and does not move at all. Individual phases are thus not determinable even in principle — part of each is a choice — while triplet sums are. That is why a structure determination begins by *fixing* an origin, assigning arbitrary phases to a permitted handful of reflections, and then propagates through relations of the form Equation (132.20).

In a centrosymmetric structure with the origin at a centre, $\rho(-\boldsymbol{r})=\rho(\boldsymbol{r})$ makes every $F(\boldsymbol{G})$ real, so $\varphi\in\{0,\pi\}$ and $F=\pm|F|$; Equation (132.20) collapses to a statement about signs,

$$s(\boldsymbol{H})\,s(\boldsymbol{K})\,s(\boldsymbol{H}+\boldsymbol{K})=+1\,, \tag{132.21}$$

probably rather than certainly. How probably is the quantitative content of the method. With the moduli normalized to what point atoms at rest would give,

$$|E(\boldsymbol{G})|^2=\frac{|F(\boldsymbol{G})|^2}{\sum_j f_j(\boldsymbol{G})^2} \tag{132.22}$$

— up to a factor accounting for the symmetry of the reflection, and dividing out both the form factor and the Debye–Waller factor of Section 132.6, so that the E are the structure factors of the fictitious structure Sayre's argument assumed — the probability that Equation (132.21) holds is

$$P_+=\frac{1}{2}+\frac{1}{2}\tanh\left(\frac{|E(\boldsymbol{H})\,E(\boldsymbol{K})\,E(\boldsymbol{H}+\boldsymbol{K})|}{\sqrt{N}}\right) \tag{132.23}$$

for N equal atoms in the cell [1060], the non-centrosymmetric analogue distributing Φ about zero with a concentration $2\,|EEE|\,/\sqrt{N}$ [1059]. Two features of Equation (132.23) fix what the method can do. Only the strongest reflections are useful, since $|E|$ of order unity leaves P_+ barely above one half; and the argument falls as $N^{-1/2}$, so the relations weaken as the structure grows. Direct methods therefore took the small molecule and left the protein to the heavy atom. □

Derivation pending #273

The probability distribution of the triplet phase sum: the random-atom model in which the atomic positions are independent and uniform over the cell, the central-limit argument that makes the joint distribution of three normalized structure factors Gaussian, and the conditional distribution of the phase sum that follows from it, giving the hyperbolic tangent in the centrosymmetric case and the von Mises form in general

Phenomenon 132.8 (An image carries the phases a diffraction pattern loses)**.** The Fourier transform of a micrograph of a thin specimen reproduces the three-dimensional transform of that specimen on the central plane perpendicular to the beam, phases included, because a lens performs the back-transform physically. Micrographs at a sufficient set of orientations therefore determine the density in three dimensions with no phase problem to solve, as was first done for the tail of bacteriophage T4 [1369, 1418]. The number of distinct views required grows as the ratio of the particle diameter to the resolution sought, which is why symmetric particles were done first.

Derivation. Let $\rho(\boldsymbol{r})$ be the density and let the beam run along z. For a specimen thin enough that an electron scatters at most once, and a lens that collects the scattered and

unscattered waves and brings them back together, the image contrast is a linear functional of the projection

$$p(x,y) = \int \rho(x,y,z)\,\mathrm{d}z\,. \tag{132.24}$$

Compare the two-dimensional transform of the projection with the three-dimensional transform $\tilde{\rho}$ of the density:

$$\int p(x,y)\,\mathrm{e}^{\mathrm{i}(q_x x+q_y y)}\,\mathrm{d}x\,\mathrm{d}y = \int \rho(\boldsymbol{r})\,\mathrm{e}^{\mathrm{i}(q_x x+q_y y)}\,\mathrm{d}^3 r = \tilde{\rho}\,(q_x,q_y,0)\ , \tag{132.25}$$

the last step because the exponent is $\boldsymbol{q}\cdot\boldsymbol{r}$ with $q_z = 0$. The integration over z that forms a projection *is* the evaluation of the transform on $q_z = 0$. So one micrograph gives a central plane section of the object's transform, amplitude and phase together — the contrast with a diffraction pattern being that a micrograph is an image, formed in the plane conjugate to the object, and not a squared modulus recorded in the far field. The lens has already performed the back-transform the crystallographer cannot perform.

How many sections are needed follows from two facts. The object is bounded, of diameter D, so its transform is determined by samples at intervals $1/D$; and resolving detail of size d requires the transform out to radius $1/d$. Sections through the origin at angular spacing $\Delta\theta$ are separated at that radius by $\Delta\theta/d$, which must not exceed $1/D$, so $\Delta\theta \le d/D$ and the number of views over the available range π is

$$N_{\text{views}} \simeq \frac{\pi D}{d}\,. \tag{132.26}$$

This count is why symmetry mattered so much in the early work. A helical particle presents every azimuth at once, so a single micrograph of one particle already carries the whole set of sections, which is how the T4 tail was reconstructed from one image [1369]. □

132.8.4 Interpretation

The three routes share one feature: none of them extracts a phase from the intensities of a single diffraction pattern, because the phase is not in them. Each brings information from outside — a known sub-structure, a general property of scattering densities, or a second instrument.

The contrast that makes this sharpest is holography, which belongs with the interference experiments of Chapter 67. Let O be the wave scattered by the object, and superpose on it, before the detector, a reference wave R of known amplitude and phase and coherent with it. What the detector records is

$$|O+R|^2 = |O|^2 + |R|^2 + OR^* + O^*R\,, \tag{132.27}$$

and the last two terms are *linear* in O: they carry its phase, written into the positions of the interference fringes, which a detector of intensity reads as easily as it reads anything else. Illuminating the developed record with R again returns a transmitted field containing the term $|R|^2\,O$, which is the object wave reconstructed, alongside a conjugate image and a background [913]. Nothing has been recovered that was lost; the phase was never lost, because interference with a known wave converts a phase difference into an intensity difference. The crystallographer has no such wave — there was no coherent, splittable source at 0.1 nm in 1950, and a reference beam cannot be introduced inside a crystal — so direct methods are what one does instead: a computational substitute for a reference wave, paid for with an assumption about the object rather than an addition to the apparatus.

Heavy-atom phasing sits between the two, and reading it as a reference wave explains its one awkward feature. The heavy atom contributes to $F(\boldsymbol{G})$ a term known in amplitude

and phase once its position is known, exactly as R is known; but it travels with the object rather than beside it, so what the measurement gives is $|F|$ for the native crystal, $|F|$ for the derivative, and the known added term, and those three fix the phase of the native structure factor only up to a reflection about the phase of the added term. In the general case the ambiguity is twofold and irreducible from one derivative; a second, independent derivative gives a second pair, and the member the two pairs share is the answer. Where the projection is centrosymmetric the phase can only be 0 or π, the two branches coincide, and a single derivative settles the sign outright — which is the form in which the method entered protein crystallography [1040].

What none of this settles should be said plainly. The triplet relations are probabilistic and have no convergence proof; their reliability falls as $N^{-1/2}$ by Equation (132.23), and the atomicity that Sayre's equation assumes requires data extending to a resolution at which individual atoms are separated — which most protein crystals do not give, so proteins are still phased experimentally rather than directly. The electron route has its own reservation. An unstained thin biological specimen barely absorbs; it is a phase object, and an in-focus image of it has almost no contrast, so contrast is created by defocusing, which converts phase to amplitude through a transfer function that oscillates in spatial frequency and vanishes at a series of values. The phases obtained are the object's phases modulated by that instrument function, which has to be measured and inverted; and since the dose that would give one good image destroys the specimen, what is transformed is an average over many copies assumed identical.

Finally, the problem is not peculiar to X-rays, and this chapter has been living with it throughout. The magnetic structures that followed Section 132.2 are determined by refining a model against the observed intensities and not by inverting them, for the same reason the original measurement could be: a magnetic structure carries few parameters. Where that ceases to be true — incommensurate order, large magnetic cells, disordered moments — neutron diffraction meets the phase problem in the form the crystallographers met it, and borrows their machinery to deal with it.

Derivation pending #274

The contrast transfer function of a defocused electron microscope: the weak-phase-object approximation, the phase shift introduced by defocus and by spherical aberration, and the resulting oscillating transfer function whose zeros must be filled in by combining images taken at different defocus

Part XIII

Frontiers and Open Problems

Chapter 133

What We Observe but Do Not Understand

Every chapter of this treatise has drawn a hard line: physics enters only once Nature has voted, through a reproducible measurement. This closing chapter collects what stands on the *far* side of that line — established observational facts with no confirmed theoretical explanation — and, separately, names the theoretical programs sometimes proposed to explain them that have not yet crossed it. Every quantity below carries its measured value in Appendix C or the relevant experiment chapter; nothing here restates a number already given precisely elsewhere.

133.1 The mass and mixing puzzles

The Standard Model successfully accommodates, but does not explain, three tiers of numbers cataloged in Appendix C:

- The charged-lepton and quark masses span more than five orders of magnitude between the electron and the top quark, with the generation-to-generation ratios (Appendix C.3) fixed by Yukawa couplings the theory does not predict — the *flavor puzzle*.
- The strong CP problem (Appendix C.2): the QCD Lagrangian permits a CP-violating vacuum angle $\bar{\theta}_{\mathrm{QCD}}$ of order unity, yet the neutron electric dipole moment bounds it to $\lesssim 10^{-10}$. Nothing in the confirmed Standard Model forces this suppression.
- Neutrino oscillations establish that neutrinos are massive and mix (Appendix C.4), but oscillation data alone fix only mass-squared *differences*, never the absolute mass scale, and whether the neutrino mass term is Dirac or Majorana — decidable only by a direct observation of neutrinoless double beta decay, not yet seen — remains open (Appendix C.4).

133.2 The hierarchy problem

The Planck scale, fixed purely by dimensional analysis from $\hbar$, c, G (Proposition B.1), sits some seventeen to twenty-two orders of magnitude above every confirmed particle-physics mass scale (Appendix C.6, entries on m_e/M_{P}, m_p/M_{P}, v/M_{P}). For the Higgs vacuum expectation value specifically, this separation is a genuine puzzle rather than a mere curiosity: unlike a fermion mass, a fundamental scalar's mass is not protected by any confirmed symmetry from radiative corrections that scale quadratically with whatever ultraviolet physics completes the Standard Model. If that completion sits near the Planck scale, those corrections are technically expected to dwarf the observed electroweak scale by

many orders of magnitude, demanding an unexplained, extremely precise cancellation to keep v as small as it is measured to be. No confirmed dynamical mechanism protecting the electroweak scale in this way has been observed.

133.3 Dark matter

The gravitational evidence for non-baryonic matter is overwhelming and multiply cross-checked: galactic rotation curves, gravitational lensing by galaxy clusters, and the acoustic peak structure of the cosmic microwave background all independently require a cold dark matter density $\Omega_c h^2 = 0.1200 \pm 0.0012$ (Appendix C.5), roughly five times the baryon density. What dark matter *is* — a new particle, and if so with what mass and couplings — is not established by any confirmed direct-detection, collider, or indirect-detection signal to date. This treatise records the gravitational evidence as settled and the particle identification as open.

133.4 Dark energy and the Hubble tension

The accelerating expansion of the universe is established from Type Ia supernova distances, baryon acoustic oscillations, and the CMB angular-diameter distance, all converging on $\Omega_\Lambda = 0.6847 \pm 0.0073$ (Appendix C.5). Its microphysical origin — a true cosmological constant, vacuum energy, or a dynamical field — is unidentified. A second, independent tension sharpens the puzzle: the Hubble constant inferred from the CMB, $H_0 = (67.36 \pm 0.54)\,\mathrm{km/(s\,Mpc)}$, disagrees with late-universe distance-ladder measurements, $H_0 \approx (73.0 \pm 1.0)\,\mathrm{km/(s\,Mpc)}$, at the 4–5$\sigma$ level (Appendix C.5). Whether this Hubble tension signals unrecognized systematics or a genuine incompleteness of the base ΛCDM model is not yet resolved.

133.5 The baryon asymmetry

The observed universe is made overwhelmingly of matter, with essentially no primordial antimatter, quantified by the baryon-to-photon ratio $\eta = (6.12 \pm 0.04) \times 10^{-10}$ (Appendix C.5) — independently confirmed by Big Bang nucleosynthesis and the CMB. Generating any matter-antimatter asymmetry from an initially symmetric state requires baryon-number violation, C and CP violation, and a departure from thermal equilibrium (the Sakharov conditions). The Standard Model contains CP violation (Appendix C.3), but its magnitude, via the Jarlskog invariant (Appendix C.3), is many orders of magnitude too small to account for the observed η. No confirmed mechanism supplies the shortfall.

133.6 Confinement and the Yang–Mills mass gap

No isolated quark or gluon has ever been observed, in accelerator debris, in matter, or in cosmic rays, although the $SU(3)$ gauge Lagrangian of Chapter 102 contains only those fields; and the observed hadron spectrum begins at the pion mass rather than at zero, although the gluons of that Lagrangian are massless. Both statements are experimentally secure and neither has been derived from the theory. Lattice computation reproduces the hadron spectrum and exhibits the confining area law at strong coupling (Chapter 102), but a proof from the continuum theory — that four-dimensional Yang–Mills theory exists as a mathematically well-defined quantum field theory and that its spectrum has a mass gap $\Delta > 0$ — is missing. The statement is one of the recognized open problems of mathematical physics, posed as a Clay Millennium Prize problem [2097]. What is open here differs in

kind from the other entries of this chapter: the physics is not in doubt and no new particle or parameter is called for; what is absent is the derivation that the editorial rules of this treatise would demand of any other observed phenomenon, which is why the QCD chapter carries it as a named, pending derivation rather than as a result.

133.7 What lies outside this treatise

The puzzles above are observational facts awaiting explanation; they are evidence-based by construction, since each is a measured discrepancy or absence rather than a theoretical assertion. Several theoretical programs have been proposed, at various times, to address one or more of them: supersymmetry (a protective symmetry for the hierarchy problem), the Peccei–Quinn mechanism and its axion (for the strong CP problem), grand unified theories (for the apparent convergence of gauge couplings at high energy), string theory and its variants (for a unification including gravity), and speculative approaches to quantum gravity such as loop quantum gravity or asymptotic safety. As of this writing, **none of these programs has direct experimental confirmation**: no supersymmetric partner has been observed at any collider to date, no axion has been detected by any haloscope or helioscope search, proton decay has not been observed at the rates generic GUTs predict, and string theory makes no confirmed, falsified, or falsifiable prediction yet tested against data. Per the scope rule stated in Chapter 1, this treatise accordingly excludes them from its physics: they are named here only so that the boundary of current evidence is stated honestly, not silently. Should any of them — or some other mechanism — acquire direct experimental support, it belongs in a future edition of this chapter, exactly where the puzzle it resolves is recorded above.

A second category needs distinguishing from the first, because the two are easily confused and the scope rule treats them differently. The programs named above are candidate *physical theories* without evidence. Alongside them runs a large body of work that is *mathematics* about structures physics uses — classifying the symmetry algebras a spacetime could carry, extending them, and building gauge theories from the extensions. That work is not excluded from this treatise: its results are theorems, they are true whether or not nature uses them, and the treatise states them as such. The classification of kinematical algebras (Theorem 14.90) is in the book for exactly this reason, together with an explicit column recording which of the eleven possibilities a measurement has ever probed (Table 14.1) — three of them.

What the treatise declines to do is let the second category be read as the first. An algebra that admits a consistent extension, a Lagrangian that can be written for it, and a gauge theory that can be constructed from it are three mathematical facts and zero physical ones. Current examples include the Maxwell and non-Lorentzian extensions of the kinematical algebras and the three-dimensional Chern–Simons gravities built from them [2432]; gravity in three spacetime dimensions has no propagating degrees of freedom, no such theory has an observational test, and the papers concerned claim none. They are cited where their mathematics is used and nowhere else. The rule this implements is the one of Chapter 1: a derivation is not evidence, and an existence proof for a structure is not a measurement of it.

Chapter 134

The Dark Sector: Evidence Without Explanation

Rotation curves, gravitational lensing, cluster dynamics, the microwave-background budget and the supernova acceleration all say the same thing: gravitating matter exceeds luminous matter by about a factor of five, and the expansion of the universe is speeding up. This chapter records what is actually measured, and states honestly that no laboratory detection of a dark-matter particle exists and no mechanism for the acceleration has been identified. It is the largest quantitative discrepancy in physics between a well-tested theory — general relativity plus the Standard Model — and observation, and it is the reason the treatise has a Frontiers part at all.

The chapter is organized observation-first, on purpose. Candidate theories are named only where a search has been carried out and returned a null result or a bound, so that the reader can see which statements rest on data and which rest on nothing. It depends on the cosmological model of Chapter 48, the microwave-background measurements of Chapter 51 and the lensing formalism of Chapter 44; its particle-physics side draws on Chapter 115 and on the neutrino limits of Chapter 114. What remains unresolved is carried forward to Chapter 133; the closely related question of whether gravity itself needs modifying at the quantum level is separate and belongs to Chapter 135. A standard review of the particle side is [2073].

Derivation pending #275

The Dark Sector: all derivations of this chapter are pending.

134.1 The dynamical evidence

134.1.1 Cluster velocity dispersions

[Reserved: Zwicky's application of the virial theorem to the Coma cluster, finding a velocity dispersion far larger than the luminous mass supports and coining dunkle Materie *[729]; the more careful English restatement four years later, with the mass-to-light ratio and its assumptions made explicit [807]; the virial theorem itself from Chapter 27; why a factor of order a hundred in mass-to-light ratio was disbelieved for four decades, and what later reduced it to a factor of a few hundred in solar units.]*

134.1.2 Galaxy rotation curves

[Reserved: Rubin and Ford's spectroscopic rotation curve of Andromeda, flat far beyond the optical disc [1432]; the survey of twenty-one spirals that made the result general and

unavoidable [1658]; the Keplerian expectation $v \propto r^{-1/2}$ against the observed $v \approx$ const, and the implied enclosed mass $M(r) \propto r$; the mass discrepancy as a function of radius rather than a single global number.]

134.1.3 Neutral-hydrogen curves beyond the optical disc

[Reserved: the 21 cm hyperfine line as a kinematic tracer where there are no stars; Bosma's radio survey extending rotation curves to several optical radii [1665]; the detailed mass decomposition of NGC 3198 into disc and halo, which showed that no plausible disc mass-to-light ratio removes the need for a halo [1747]; the maximum-disc degeneracy and what breaks it.]

134.1.4 Galaxy stability and halo masses

[Reserved: the argument of Ostriker, Peebles and Yahil that cold self-gravitating discs are unstable to bar formation unless embedded in a massive halo, and their compilation of dynamical masses growing with the radius sampled [1529]; satellite kinematics and the timing argument for the Local Group; why an independent line of reasoning arriving at the same halo was what turned the discrepancy from an anomaly into a research programme.]

134.1.5 X-ray hydrostatic cluster masses

[Reserved: the hot intracluster medium in hydrostatic equilibrium, whose temperature and density profiles from Chandra give a total mass profile independent of galaxy kinematics [2105]; the resulting gas fraction of about 12 %, consistent with the cosmological baryon fraction and inconsistent with the cluster being made of what it is made of; the baryon budget compared against Section 134.3.2.]

134.2 Gravitational lensing

134.2.1 Strong lensing

[Reserved: Einstein's short note on the lens-like action of a star [774], with the deflection angle from Chapter 44; the discovery of the twin quasar 0957+561 as the first observed gravitational lens [1645]; Einstein rings and giant arcs in clusters; lensing masses as a purely geometric probe requiring no assumption of dynamical equilibrium, which is why they matter here.]

134.2.2 Weak lensing and shear surveys

[Reserved: the first detection of coherent image alignments behind clusters [1838]; the statistical measurement of cosmic shear over wide fields, mapping the projected mass distribution directly; modern survey constraints from the Dark Energy Survey [2396] and from KiDS [2374]; the shear two-point function and the parameter combination $S_8 = \sigma_8 \sqrt{\Omega_m / 0.3}$ it measures, whose mild disagreement with the microwave background is taken up in Section 134.7.2.]

134.2.3 The Bullet Cluster

[Reserved: the merging cluster 1E 0657-56, in which the X-ray emitting gas — most of the baryonic mass — is displaced from the lensing mass peaks that track the galaxies [2093]; why this is the single cleanest argument that the missing mass is not a failure of the gravitational force law, since here the mass and the baryons are spatially separated; the accompanying

bound on the dark-matter self-interaction cross-section per unit mass, of order $0.1\,\mathrm{m}^2/\mathrm{kg}$ *[2062], which constrains self-interacting candidates.]*

134.2.4 Microlensing and the compact-object bound

[Reserved: Paczyński's proposal to detect massive compact halo objects by the transient magnification of background stars [1781]; the EROS-2 survey of the Magellanic Clouds, which excluded such objects as the dominant halo component over roughly 10^{-7} *to* 10 *solar masses [2114]; the conclusion that the missing mass is not ordinary matter in dark lumps, which together with Section 134.3.2 closes off the astrophysically conservative options.]*

134.3 Cosmological evidence

134.3.1 The microwave-background budget

[Reserved: the acoustic peak structure of the temperature and polarization power spectra, and the separate roles of baryons and of pressureless dark matter in setting the peak heights — $\Omega_b h^2 = 0.0224$ against $\Omega_c h^2 = 0.120$, a factor above five [2348]; the measurement itself in Chapter 51; why a component that does not couple to photons is required by the ratio of odd to even peaks, not merely allowed by it.]

134.3.2 Nucleosynthesis and the baryon count

[Reserved: primordial abundances of deuterium, helium-3, helium-4 and lithium-7 as a one-parameter function of the baryon-to-photon ratio, and the resulting independent baryon density [2270]; its agreement with the microwave-background value to a few percent, which is a genuine concordance across an epoch ratio of about 10^5*; the lithium-7 discrepancy stated honestly as unresolved; the nuclear reaction network from Chapter 107 and Chapter 52.]*

134.3.3 Baryon acoustic oscillations

[Reserved: the same sound horizon imprinted on the galaxy distribution, first detected in the correlation function of luminous red galaxies [2076]; its use as a standard ruler and the modern spectroscopic measurement [2430] — customarily dated to 2024 by its report number, though the journal issue is 2025; the consistency of the ruler with the microwave-background calibration as a further constraint on the composition.]

134.3.4 Structure formation

[Reserved: why structure cannot grow from the observed microwave-background fluctuations without a component that begins clustering before recombination [1699]; the cold dark matter picture of hierarchical structure formation [1735]; the universal halo density profile found in simulations [1942]; large simulations reproducing the observed galaxy clustering [2083]; the honest counterweight — the core-cusp, missing-satellite and too-big-to-fail discrepancies on sub-galactic scales, which remain open and may be baryonic physics rather than a failure of the model.]

134.4 Candidates and the searches that found nothing

134.4.1 What a candidate must satisfy

[Reserved: the observational requirements — non-baryonic, cold or at least non-relativistic at decoupling, dissipationless, stable over the age of the universe, and electrically neutral;

the thermal relic calculation, in which the observed abundance follows from a weak-scale annihilation cross-section [1602], and why that coincidence motivated a generation of searches; the exclusion of Standard Model neutrinos as the dominant component by the free-streaming argument and by the mass bound of Chapter 114; the candidate catalogue and its status [2073].]

134.4.2 Direct detection: null results

[Reserved: the nuclear-recoil signature in an ultra-low background target, and the two current leading liquid-xenon experiments — LUX-ZEPLIN, with a spin-independent cross-section limit near $9 \times 10^{-52}\,\mathrm{m}^2$ at a mass of about $36\,\mathrm{GeV}/c^2$ [2413], and XENONnT with a comparable limit [2418]; four decades of improvement and no signal; the approaching neutrino fog, at which coherent solar and atmospheric neutrino scattering becomes an irreducible background; the flat statement that there is no detection.]

134.4.3 The DAMA claim and its non-confirmation

[Reserved: the annual modulation reported by DAMA/LIBRA in sodium iodide, at high statistical significance and with the phase expected from the Earth's motion through the halo [2117]; why it is inconsistent with the null results of Section 134.4.2 under standard halo and interaction assumptions; the same-target replications, which do not reproduce it [2296]; treated here as the worked example of how a positive claim is adjudicated rather than as evidence.]

134.4.4 Axions

[Reserved: the Peccei–Quinn mechanism proposed to solve the strong CP problem of Chapter 102 [1609], and the light pseudoscalar it implies [1628, 1630]; why an axion is simultaneously a cold dark matter candidate; the microwave-cavity haloscope and the ADMX exclusion over the mass range near $2.7\,\mu\mathrm{eV}$ to $3.3\,\mu\mathrm{eV}$ at Dine–Fischler–Srednicki–Zhitnitsky coupling [2309]; helioscope and light-shining-through-walls searches; again, no detection.]

134.4.5 Collider and indirect searches

[Reserved: the mono-jet plus missing transverse momentum signature at the Large Hadron Collider and its null result [2367]; the compilation of exclusion limits, including those on supersymmetric candidates [2427]; indirect searches for annihilation products in gamma rays, positrons and neutrinos, and the astrophysical backgrounds that limit them; the invisible-width bound on light candidates from Chapter 104.]

134.4.6 Primordial black holes

[Reserved: black holes formed from early-universe density perturbations as a candidate requiring no new particle [1520]; the windows closed by microlensing [2114], by microwave-background accretion constraints and by the gravitational-wave merger rate of Chapter 47; the asteroid-mass window that remains open; a fair statement of what fraction of the halo is still allowed.]

134.5 Modified dynamics as the rival hypothesis

134.5.1 MOND and the radial-acceleration relation

[Reserved: Milgrom's proposal that the discrepancy appears below an acceleration scale $a_0 \approx 1.2 \times 10^{-10}\,\mathrm{m/s}^2$ rather than beyond a length scale, and the resulting flat rotation

curves and baryonic Tully–Fisher relation [1726]; the tight empirical radial-acceleration relation between observed and baryonic centripetal acceleration across 153 galaxies [2273], which is a real regularity that any dark-matter model must also explain; the review that states the case at its strongest [2037].]

134.5.2 Where modified dynamics fails

[Reserved: the residual mass discrepancy in clusters, roughly a factor of two, which MOND does not remove; the Bullet Cluster separation of lensing mass from baryons [2093]; the relativistic completion TeVeS [2058] and its prediction of a gravitational-wave propagation speed differing from c, excluded to a part in 10^{15} by GW170817 and its electromagnetic counterpart [2278]; the microwave-background peak structure, which no modified-inertia theory has reproduced; the even-handed conclusion that the acceleration-scale regularity is unexplained by either side.]

134.6 Dark energy

134.6.1 The supernova evidence for acceleration

[Reserved: type Ia supernovae as standardizable candles after light-curve shape correction; the two independent teams' finding that distant supernovae are fainter than a decelerating universe allows [1962, 1981]; the modern compilation with about 1550 supernovae and its systematic error budget [2402]; the deceleration parameter and the transition redshift near $z \approx 0.6$; the honest caveat about progenitor evolution and dust.]

134.6.2 The cosmological constant and its problem

[Reserved: Λ as the one term general relativity permits without new physics, introduced for a static universe [445] and now measured as $\Omega_\Lambda \approx 0.685$ [2348]; the discrepancy between the observed value and any naive quantum-field-theoretic vacuum energy estimate, of order 10^{120} [1828]; anthropic and multiverse arguments recorded as what they are — not testable by any experiment now conceivable — with the bound that started them [1799]; the connection to Chapter 135.]

134.6.3 The equation of state

[Reserved: the parametrization $w = p/\rho c^2$ and its constraint $w = -1.03 \pm 0.03$ from the combination of supernovae, baryon acoustic oscillations and the microwave background [2348]; the recent spectroscopic hint of evolving w [2430], which is to be reported at its stated significance as a hint and not as a detection, since the preference depends on the supernova compilation combined with it; what a confirmed $w \neq -1$ would and would not imply.]

134.7 Tensions and the honest status

134.7.1 The Hubble tension

[Reserved: the local distance-ladder value $H_0 = (73.04 \pm 1.04)\,\mathrm{km/(s\,Mpc)}$ [2407] against the microwave-background inference $(67.36 \pm 0.54)\,\mathrm{km/(s\,Mpc)}$ [2348], a disagreement of about five standard deviations; the tip-of-the-red-giant-branch calibration, which lands between them and weakens the significance [2379]; the possibilities — an unidentified systematic on either side, or new physics before recombination — stated without preference.]

134.7.2 The S_8 tension

[Reserved: weak-lensing surveys measuring slightly less clustering than the microwave background extrapolates [2374, 2396], at the two-to-three standard deviation level; the sensitivity of the comparison to baryonic feedback in the modelling and to intrinsic alignments; why a tension at this significance is reported and not yet believed.]

134.7.3 What is and is not known

[Reserved: the closing ledger. Established beyond reasonable doubt — that gravitating mass exceeds luminous mass by about five to one on every scale from galaxies to the observable universe, that most of it is non-baryonic [2270, 2348], that it is spatially separable from the baryons [2093], and that the expansion is accelerating [1962, 1981]. Not established — the identity of the dark matter, the nature of the acceleration, and whether either requires physics beyond general relativity. Forwarded to Chapter 133.]

Chapter 135

Quantum Gravity: The Honest Status

General relativity and quantum field theory are each confirmed to extraordinary precision, and they are formulated in incompatible terms. This chapter sets out the theoretical arguments that motivate quantizing gravity, distinguishes carefully between what has been calculated and what has been measured, and states plainly that no candidate theory of quantum gravity has experimental support. The distinction is the entire point of the chapter: gravity as an effective field theory is established physics with computed predictions, black-hole thermodynamics is a theoretical result of great internal coherence and no direct observation, and the various ultraviolet completion programmes have, to date, no evidence whatsoever.

That last sentence is the operative editorial constraint. Under the scope rule of the preface, string theory, supersymmetry, loop quantum gravity and asymptotic safety are outside this treatise; they are named in Section 135.6 for exactly one purpose — to record honestly that they lack the observational support that would admit them, and to say what a measurement admitting them would have to look like. The chapter builds on the field equations of Chapter 44, the black-hole solutions of Chapter 45, the renormalization theory of Chapter 108 and Chapter 100, and the measurements of Chapter 50 and Chapter 47. What it cannot settle is carried to Chapter 133. Standard references for the established material are [1683, 1890].

Derivation pending #276

Quantum Gravity: The Honest Status: all derivations of this chapter are pending.

135.1 Why the question arises

135.1.1 Two frameworks with incompatible foundations

[Reserved: the field equations take a classical stress-energy tensor as source [1746], while matter is described by operator-valued fields [1912]; the semiclassical equation $G_{\mu\nu} = 8\pi G\, c^{-4}\langle T_{\mu\nu}\rangle$ as the only obvious patch, and its known defects — non-linearity in the state, and superluminal signalling if the expectation value is taken literally through a measurement; singularity theorems predicting the breakdown of the classical description in the interior of black holes and at the cosmological initial condition (Chapter 45).]

135.1.2 The Planck scale

[Reserved: the unique combination of $\hbar$, c and G giving a length, a time, a mass and an energy, constructed by Planck in 1899 as a system of natural units [285]; the values $\ell_P = 1.616\,255 \times 10^{-35}\,\mathrm{m}$ and $E_P = 1.22 \times 10^{28}\,\mathrm{eV}$ [2431]; the dimensional argument that the graviton loop expansion is controlled by E^2/E_P^2; the honest caveat that a scale constructed from constants is not by itself evidence that anything happens there, and the gap of some sixteen orders of magnitude to the highest collision energy reached.]

135.1.3 Must gravity be quantized at all?

[Reserved: the theoretical argument that a classical field coupled to quantum matter violates the uncertainty principle through a which-path measurement; the Page–Geilker experiment, in which a Cavendish balance was driven by a genuinely random quantum event, excluding the naive expectation-value semiclassical theory [1674]; the Wheeler–DeWitt canonical quantization as the conservative response [1344] and its problem of time; the question left genuinely open, with the proposed decisive tests in Section 135.5.1.]

135.2 What is established

135.2.1 Gravity as an effective field theory

[Reserved: the Einstein–Hilbert action treated as the leading term of a derivative expansion, with the graviton as a massless spin-2 field of Chapter 97; Deser's demonstration that a self-coupled massless spin-2 field on flat space is forced to general relativity [1420]; Donoghue's computation of the leading quantum correction to the Newtonian potential, finite and unambiguous because it comes from the long-distance non-analytic part of the loop [1880]; the size of that correction — of order $(\ell_P/r)^2$, some forty orders of magnitude below anything measurable; the correct statement that quantum gravity is calculable at low energies and that the problem is ultraviolet, not conceptual.]

135.2.2 Perturbative non-renormalizability

[Reserved: 't Hooft and Veltman's one-loop calculation, finding pure gravity finite on shell but gravity coupled to matter divergent already at one loop [1514]; Goroff and Sagnotti's two-loop computation, which produced a non-vanishing counterterm cubic in the Weyl tensor and settled the question for pure gravity [1773]; what non-renormalizability does and does not mean in the effective-field-theory language of Chapter 108 — a limited domain of validity, not an inconsistency.]

135.2.3 Quantum field theory in curved spacetime

[Reserved: quantum fields on a fixed classical background as the regime where both theories apply and agree; the absence of a preferred vacuum and hence the observer dependence of particle number; Parker's cosmological particle creation [1380]; the Unruh effect — a uniformly accelerated detector in the Minkowski vacuum registers a thermal bath at $T = \hbar a/2\pi c k_B$ [1590] — unobserved, since a temperature of $1\,\mathrm{K}$ requires an acceleration of order $1 \times 10^{20}\,\mathrm{m/s^2}$; the standard treatments [1683, 1890].]

135.2.4 Black-hole thermodynamics as theory

[Reserved: Bekenstein's identification of horizon area with entropy, from the requirement that the second law survive dropping matter into a hole [1494]; the four laws of black-hole

mechanics derived classically [1493]; Hawking's calculation that a black hole radiates with a temperature $\hbar c^3/8\pi GMk_B$, which fixed the proportionality constant at $S = k_B Ac^3/4G\hbar$ [1549]; the emphasis that every step here is theory — there is no measurement of a black-hole temperature or entropy, and the treatise records it as a derivation of great internal coherence rather than as an observed phenomenon.]

135.2.5 The information problem

[Reserved: Hawking's argument that evaporation maps a pure state to a thermal density matrix and so violates unitarity [1580]; Page's entanglement-entropy criterion for what unitary evaporation would look like [1870]; the statement that the problem is a conflict between calculations, none of which has been tested, and that its resolution is not known; why it is nevertheless the sharpest internal inconsistency available and the main reason the subject is pursued.]

135.3 What has actually been measured

135.3.1 Quantum matter in a classical gravitational field

[Reserved: the Colella–Overhauser–Werner neutron interferometer, which observed the gravitationally induced quantum phase shift and so confirmed that gravity enters the Schrödinger equation as expected [1542]; the quantization of neutron energy levels in the Earth's field [2034]; the gravitational Aharonov–Bohm phase measured with atom interferometry [2406]. These test quantum mechanics in a classical gravitational field — they are real results and they are not tests of quantum gravity, a distinction often blurred.]

135.3.2 Newton's law at short range

[Reserved: torsion-balance tests of the inverse-square law down to separations of order $50\,\mu\mathrm{m}$*, finding no deviation [2362]; what such a null result constrains and what it does not; the Cavendish lineage from Chapter 33, and the equivalence-principle tests of Chapter 42 as the companion null results.]*

135.3.3 Graviton and photon propagation speed

[Reserved: the arrival of GW170817 and its gamma-ray counterpart within about $1.7\,\mathrm{s}$ *after some* $1.3 \times 10^8\,\mathrm{yr}$ *of travel, bounding the fractional difference between the gravitational-wave and light speeds at a few parts in* 10^{15} *[2278]; the corresponding bound on the graviton mass; which classes of modified-gravity theory this excluded, tying back to Chapter 134.]*

135.3.4 Lorentz invariance at the highest energies

[Reserved: the proposal that a discrete or fluctuating spacetime would produce an energy-dependent photon speed accumulating over cosmological baselines [1947]; the Fermi observation of GRB 090510, whose gamma rays arrived with a dispersion small enough to exclude a linear Planck-scale effect [2137]; the systematic tabulation of Lorentz- and CPT-violation bounds across all sectors [2176], with the discrete symmetries themselves in Chapter 105; the honest reading — these are the only quantum-gravity-motivated predictions so far tested, and they came out negative.]

135.3.5 Classical black-hole predictions confirmed

[Reserved: the observation of binary black-hole coalescence and its ringdown [2264]; the test of the classical area theorem using the pre- and post-merger horizon areas of GW150914 [2381]; horizon-scale imaging, reported in Chapter 50; the point being that the classical sector is confirmed exactly where quantum gravity was hoped to show itself, which sharpens rather than relieves the problem.]

135.4 What has not been measured

135.4.1 Hawking radiation

[Reserved: the explicit statement that Hawking radiation [1549] has never been observed; the numbers that explain why — a solar-mass hole has a temperature of about $60\,\mathrm{nK}$*, far below the microwave background of Chapter 51, so astrophysical holes absorb far more than they emit, and an evaporation time exceeding* 10^{67} *years; the absence of any detected primordial hole of low enough mass, tying to Chapter 134; the Unruh effect [1590] likewise unobserved.]*

135.4.2 Analogue systems are analogues

[Reserved: Unruh's demonstration that a transsonic fluid flow carries an acoustic horizon obeying the same wave equation [1675]; stimulated Hawking emission measured on surface waves in a flume [2185]; the correlated emission and thermal spectrum measured in a Bose–Einstein condensate [2274]. These confirm the kinematics of the Hawking calculation in a system where the wave equation is known to hold — which is a genuine and useful result — and they say nothing about gravity, because no gravitational field is involved. The chapter will label them as analogue results wherever they appear.]

135.4.3 Gravitational decoherence and collapse models

[Reserved: the proposal that gravity induces objective state reduction, with a rate set by the gravitational self-energy difference between the superposed configurations [1926]; the underground search for the spontaneous radiation such models predict, which excluded the parameter-free version [2377]; a rare case of a quantum-gravity-adjacent hypothesis being genuinely falsified by experiment, and therefore worth recording carefully; the decoherence machinery from Chapter 87.]

135.4.4 Planck-scale interferometry

[Reserved: the conjecture of a Planck-scale transverse positional jitter accessible to correlated interferometers, and the Holometer null result excluding the proposed effect at more than 4σ *[2269]; the general lesson that the few Planck-scale conjectures sharp enough to test have been tested and excluded, while the programmes named in Section 135.6 make no prediction sharp enough to test at all.]*

135.5 Proposed experiments

135.5.1 Tabletop gravitational entanglement

[Reserved: the proposal that two masses in spatial superposition, interacting only gravitationally, become entangled if and only if the gravitational field itself has quantum degrees of freedom — the spin-entanglement witness of Bose and co-workers [2282] and the information-theoretic argument of Marletto and Vedral [2284]; the requirement that a local

classical channel cannot create entanglement, from Chapter 84; the experimental parameters needed — masses of order $1 \times 10^{-14}\,\mathrm{kg}$*, separations of order* $100\,\mu\mathrm{m}$*, and coherence times of seconds — and the plain statement that this is future work, not a result.]*

135.5.2 Other proposals

[Reserved: primordial gravitational waves as evidence of a quantized graviton field in the early universe, and the current non-detection of B-mode polarization (Chapter 51); improved Lorentz-violation searches with higher-energy transient sources [2176]; searches for a stochastic background of Planckian origin with pulsar timing; each listed with the sensitivity gain it would require.]

135.6 Programmes without evidence

135.6.1 The editorial position

[Reserved: a statement of why the following are named but not developed — the treatise admits physics with observational or experimental support, and none of these has any. Naming them without developing them is itself the honest record: a reader is entitled to know what large research programmes exist, what they would predict if true, and that no measurement to date distinguishes them from each other or from their absence.]

135.6.2 String theory

[Reserved: what it claims — a perturbatively finite graviton amplitude from extended objects, requiring extra spatial dimensions and supersymmetry [1960]; what would count as evidence — observation of supersymmetric partners, of extra dimensions in short-range gravity [2362], or of a characteristic signature in high-energy scattering; the record that none has been found, and that the extra-dimensional content also conflicts with the treatise's 3+1 dimensional scope.]

135.6.3 Supersymmetry and the collider nulls

[Reserved: the supersymmetry algebra as the unique extension of the Poincaré algebra of Chapter 94 consistent with a non-trivial S-matrix [1535]; the predicted superpartners; the exclusion limits from the Large Hadron Collider, pushing squark and gluino masses above roughly $2\,\mathrm{TeV}/c^2$ *[2427], which removes the naturalness motivation that made the weak scale the expected place to look; the honest verdict of no evidence, and the same for its local version, supergravity.]*

135.6.4 Loop quantum gravity

[Reserved: what it claims — a background-independent canonical quantization on a spin-network Hilbert space, with discrete area and volume spectra [2066]; the Lorentz-violating photon dispersion sometimes advanced as its signature, and the exclusion of the linear form [2137]; the unresolved recovery of a classical limit; no evidence.]

135.6.5 Asymptotic safety

[Reserved: Weinberg's suggestion that gravity may be non-perturbatively renormalizable at an ultraviolet fixed point of the renormalization group of Chapter 108 [1648]; the functional-renormalization evidence for such a fixed point within truncations [1961], and the truncation dependence that keeps it from being a proof; the honest status — a mathematical conjecture about a flow, with no observational consequence yet derived.]

135.7 Status

[Reserved: the closing ledger, in the same form as the dark sector chapter. Established — gravity is an effective quantum field theory with computed low-energy corrections [1880], non-renormalizable in perturbation theory [1514, 1773]; quantum fields on curved backgrounds are well understood [1890]; the classical sector is confirmed to high precision [2264, 2278, 2381]. Derived but unobserved — Hawking radiation and black-hole entropy [1494, 1549]. Neither established nor excluded — whether the gravitational field is quantum at all, with a decisive experiment proposed but not performed [2282, 2284]. Without evidence — every proposed ultraviolet completion. Forwarded to Chapter 133.]

Chapter 136

Experiment: Dark-Matter Searches and Their Null Results

Chapter 134 records the evidence that gravitating matter exceeds luminous matter by about a factor of five on every scale from galaxies to the observable universe, and names the candidates that might account for it. This chapter is the experimental face of that one, and its result is stated at the outset because it is the whole point: *there is no laboratory detection of a dark-matter particle.* Four decades of dedicated searching — deep underground detectors, resonant microwave cavities, collider missing-energy analyses and gamma-ray telescopes — have returned exclusion bounds and nothing else. One positive claim exists, the annual modulation of DAMA/LIBRA [2117], and it has not been reproduced by any other experiment, including experiments using the same target material [2296]. That discrepancy is reported here as what it is: unresolved.

A null result is evidence, and it is worth being precise about what kind. An exclusion curve is a statement about a two-dimensional parameter space — candidate mass against interaction strength — and it says that if the candidate existed with those parameters, this apparatus, with this exposure and this background, would have seen recoils that it did not see. It is therefore conditional on a halo model, on an assumed interaction, and on a background estimate, and every one of those conditions has to be stated with the bound. The searches reported below are chosen because between them they cover four different couplings of a hypothetical dark sector to the Standard Model of Chapter 104: nuclear recoil, photon conversion in a magnetic field, production at a collider, and annihilation in an astrophysical halo. They fail independently, which is what gives the combined null result its weight.

Two boundaries of scope are worth marking. This chapter does not adjudicate between a particle explanation and the modified-dynamics alternative of Chapter 134; it reports what the particle searches found. And it does not treat the neutrino, whose mass bounds from Chapter 114 and whose free-streaming length exclude it as the dominant component. What survives unexplained is carried to Chapter 133.

Derivation pending #277

Experiment: Dark-Matter Searches: the standard halo model and the nuclear form factor that together convert a measured recoil spectrum into a bound on a cross-section, and the statistical construction of a 90 per cent confidence exclusion contour in the presence of an estimated background, are pending. The kinematic and rate arguments of this chapter are derived inline.

136.1 What is being searched for, and what a null result bounds

136.1.1 The halo the searches assume

Every direct-detection bound is quoted against a common set of astrophysical assumptions, so that different experiments can be compared on one plot. The conventional choice is an isothermal sphere: a local mass density of about $5 \times 10^{-22}\,\mathrm{kg/m^3}$, a Maxwellian speed distribution in the Galactic rest frame with a dispersion corresponding to a solar motion through the halo of roughly $2.3 \times 10^{5}\,\mathrm{m/s}$, and a truncation at a local escape speed of order $5 \times 10^{5}\,\mathrm{m/s}$. The density is uncertain by a factor of about two and the velocity structure by more, so a published exclusion curve carries an astrophysical systematic that no detector improvement removes.

[Reserved: the standard halo model written out, with the velocity integral $\eta(v_{\min})$ that enters the rate; the dependence of a quoted limit on the local density, which is linear and therefore trivially rescalable, against the dependence on the high-speed tail, which is not; substructure — streams and debris flow — and why it matters more for an annual-modulation measurement than for a total-rate measurement; the Galactic rotation curve constraints of Chapter 134 as the input.]

136.1.2 Elastic recoil kinematics

The signature sought underground is a single nuclear recoil [1753]. A halo particle of mass M and speed v scattering elastically off a nucleus of mass m_N deposits, for centre-of-mass scattering angle θ, the recoil energy

$$E_R = \frac{\mu^2 v^2}{m_N}\,(1-\cos\theta)\,, \qquad \mu = \frac{M\,m_N}{M+m_N}\,, \tag{136.1}$$

so that E_R ranges from zero to

$$E_R^{\max} = \frac{2\mu^2 v^2}{m_N}\,. \tag{136.2}$$

Two features of Equation (136.2) govern the entire enterprise. First, v/c is of order 10^{-3}, so the deposited energy is smaller than the rest energy of the projectile by six orders of magnitude: a candidate of mass $100\,\mathrm{GeV}/c^2$ striking a xenon nucleus produces recoils of order tens of kilo-electronvolts, which is why every one of these detectors is built around the lowest energy threshold it can reach. Second, the reduced mass saturates. For $M \gg m_N$ one has $\mu \to m_N$ and $E_R^{\max} \to 2 m_N v^2$, independent of M; for $M \ll m_N$ one has $\mu \to M$ and $E_R^{\max} \propto M^2$, which collapses below any fixed threshold. A heavy target therefore buys signal at high mass and loses it entirely at low mass — the reason the xenon experiments of Section 136.2 and Section 136.3 and the cryogenic detectors of Section 136.4 are complementary rather than competing.

136.1.3 How to read an exclusion curve

The shape of every published spin-independent exclusion curve follows from Equation (136.2) and one rate argument, and it is worth deriving because the shape is often mistaken for a property of the apparatus. Let ρ_{loc} be the local mass density of the candidate. Its number density is $n = \rho_{\mathrm{loc}}/M$, and the event rate per unit target mass is

$$R \;\sim\; \frac{n\,\sigma\,\langle v\rangle}{m_N} \;=\; \frac{\rho_{\mathrm{loc}}\,\sigma\,\langle v\rangle}{M\,m_N}\,. \tag{136.3}$$

An experiment that observes no excess sets an upper limit on R. At high mass the kinematics of Equation (136.2) are saturated and nothing else in Equation (136.3) depends on M, so the excluded cross-section scales as

$$\sigma_{\mathrm{limit}} \;\propto\; M\,, \tag{136.4}$$

which is the straight line of unit slope that terminates every curve on a log–log plot. It is not a loss of sensitivity: it is the statement that at fixed mass density a heavier candidate is proportionately rarer. At low mass the curve instead turns upward almost vertically, because $E_R^{\max} \propto M^2$ falls below the detector threshold and the number of *detectable* recoils, not the number of recoils, goes to zero. The minimum between the two regimes sits where the reduced mass is comparable to the target mass, which is why a xenon experiment is most sensitive near a candidate mass of $30\,\mathrm{GeV}/c^2$ and a light-target experiment is most sensitive far below that.

136.2 LUX-ZEPLIN: the largest xenon target (2023)

136.2.1 Apparatus

A two-phase xenon time-projection chamber holding about seven tonnes of active liquid xenon, operated about 1.5 km underground at the Sanford Underground Research Facility so that the cosmic-ray muon flux of Chapter 115 is suppressed by several orders of magnitude. Two arrays of photomultipliers view the target from above and below; the liquid is overlaid by a gas phase across which an extraction field is applied, and the whole chamber sits inside an instrumented liquid-xenon skin and an outer gadolinium-loaded liquid-scintillator veto for neutrons.

[Reserved: the detector dimensions, the drift and extraction fields, the photomultiplier count and quantum efficiency at the xenon scintillation wavelength of 175 nm*; the radioassay campaign on every construction material, which is what sets the achievable background and is the real content of the apparatus section for an experiment of this class; the rock overburden in metres of water equivalent and the residual muon rate.]*

136.2.2 Procedure

A nuclear recoil in the liquid produces prompt scintillation, recorded as a first pulse, and a cloud of ionization electrons that the drift field carries to the surface and the extraction field pulls into the gas, where they produce a second, proportional electroluminescence pulse. The delay between the two pulses gives the depth of the event and the light pattern of the second gives its transverse position, so that every event is located in three dimensions and an inner fiducial volume can be defined in which the outer layers of xenon have absorbed the external radioactivity. The ratio of the two pulse areas discriminates nuclear recoils, produced by neutrons and by the sought signal, from electron recoils produced by gamma rays and beta decays.

[Reserved: the calibration programme — neutron sources for the nuclear-recoil band and injected radioactive sources dissolved in the xenon for the electron-recoil band; the fiducial mass and live time of the first science run; the blinding and salting protocol adopted before unblinding, which is the procedural guarantee that the analysis was not tuned to the data.]

136.2.3 Observations and data

[Reserved: the observed event distribution in the plane of ionization against scintillation, with the nuclear-recoil band drawn; the expected background from accidental coincidences, from residual radon daughters, from atmospheric and solar neutrinos and from detector

neutrons, each with its uncertainty; the number of observed events against the number expected, and the profile-likelihood test statistic from which the limit is constructed.]

Phenomenon 136.1 (No nuclear-recoil excess in seven tonnes of xenon)**.** In an exposure of about 0.9 t yr, the LUX-ZEPLIN experiment observed a distribution of events in its nuclear-recoil signal region consistent with the estimated background, and no excess attributable to halo particles scattering off xenon nuclei. Converted under the standard halo assumptions of Section 136.1.1 into a bound on a spin-independent cross-section per nucleon, the result excludes cross-sections above about $9 \times 10^{-52}\,\mathrm{m}^2$ at a candidate mass near $36\,\mathrm{GeV}/c^2$, with the bound weakening on either side in the manner derived in Section 136.1.3 [2413]. This was, on publication, the most stringent such bound over most of the mass range, and it is the strongest single statement in this chapter of what is *not* there.

Derivation. The bound quoted is a cross-section per nucleon, not per nucleus, and the conversion is the one place where an assumed interaction enters visibly. If the coupling is scalar and identical for protons and neutrons, the amplitudes of the A nucleons add coherently in the forward direction, so the nuclear cross-section carries a factor A^2 relative to the nucleonic one, modified by the reduced-mass ratio and by a form factor $F(q)$ that accounts for the loss of coherence once the momentum transfer q resolves the nuclear radius:

$$\sigma_N(q) = \sigma_n \,\frac{\mu_N^2}{\mu_n^2}\, A^2 \,\left|F(q)\right|^2 \,, \tag{136.5}$$

with μ_N and μ_n the candidate–nucleus and candidate–nucleon reduced masses. The factor A^2 is the reason xenon, with $A \approx 131$, is used at all: it buys more than four orders of magnitude in rate over a single nucleon, and it is what allows a bound near $10^{-51}\,\mathrm{m}^2$ — more than twenty orders of magnitude below a typical nuclear cross-section — to be reached with a tonne-scale target in a year. It is also the assumption that makes the bound conditional. A candidate coupling to nuclear spin rather than to mass gets no coherent enhancement, because the paired nucleons cancel and only the odd nucleon contributes; bounds on spin-dependent couplings are accordingly weaker by several orders of magnitude, and are quoted separately. □

Derivation pending #278

The form factor and the recoil spectrum: derivation of the Helm form factor as the Fourier transform of a uniform nuclear density convolved with a surface term, its first zero in relation to the recoil energies of interest for xenon, and the resulting distortion of the differential rate away from the pure exponential that the maximum-recoil relation alone would give; together with the detector response function that converts a recoil energy into an expected number of scintillation photons and ionization electrons, which is what actually sets the threshold

136.2.4 Interpretation

[Reserved: what the bound excludes and what it does not; the mass range over which the weak-scale thermal relic parameter space of Chapter 134 is now closed for the simplest scalar coupling, and the regions — low mass, spin-dependent coupling, inelastic and momentum-suppressed couplings — that survive untouched; the honest statement that a null result excludes a model, never a phenomenon, and that the gravitational evidence of Chapter 134 is undisturbed by it.]

136.2.5 Primary references

[2413].

136.3 XENONnT: the same signature in an independent detector (2023)

136.3.1 Apparatus

A two-phase xenon time-projection chamber of about six tonnes of active target, operated under the Gran Sasso massif in Italy, with a water Cherenkov muon veto and — the distinguishing feature of this apparatus — a surrounding gadolinium-loaded water neutron veto and an online cryogenic distillation column that continuously removes radon from the circulating xenon. The radon daughters dissolved in the liquid are the dominant electron-recoil background of a xenon experiment, and removing them from the target rather than rejecting them statistically is what allowed the electron-recoil rate to be pushed to a new low.

[Reserved: the active and fiducial masses, the drift field and electron lifetime, the photomultiplier arrays; the radon and krypton distillation columns and the residual specific activities achieved; the neutron-veto tagging efficiency, which converts the dominant radiogenic neutron background into a measurable and subtractable one.]

136.3.2 Procedure

Identical in principle to Section 136.2: prompt scintillation and delayed proportional ionization signals, three-dimensional event reconstruction, fiducialization, and discrimination of nuclear from electron recoils by the ratio of the two signals. The scientific value of running the two experiments in parallel lies precisely in the places where they are not identical — different rock, different veto technology, different radon-mitigation strategy, different analysis teams and different unblinding protocols — so that a common systematic is unlikely to survive in both.

[Reserved: the calibration sources and the neutron-veto efficiency measurement; the exposure and live time; the blinding scheme; the statistical treatment by which a nuclear-recoil signal is tested against a background model with several components.]

136.3.3 Observations and data

[Reserved: the observed events in the signal region against the background expectation, the achieved electron-recoil rate quoted per tonne per year per kilo-electronvolt, and the resulting exclusion curve with its minimum located in mass and cross-section; the comparison plot against Section 136.2 and the earlier generation of xenon experiments, which is where four decades of improvement becomes visible as a stack of curves descending by more than six orders of magnitude.]

Phenomenon 136.2 (Two independent xenon targets, one null result)**.** In an exposure of about 1.1 t yr XENONnT observed no excess of nuclear recoils over its background model, and set a spin-independent exclusion bound of the same order as Phenomenon 136.1 over the same mass range [2418]. The two experiments differ in overburden, in veto technology, in radon mitigation and in analysis team, and they agree. The agreement is the observation: a single null result bounds a model, but two null results obtained with independent systematics bound the model and simultaneously test each other's background estimate.

Derivation. The reason the next decade of this measurement is not simply a matter of building a larger tank is that an irreducible background is approaching, and its position in the mass–cross-section plane can be located by kinematics alone. Neutrinos scatter coherently off nuclei through the neutral current, producing exactly the signature sought: a single, unaccompanied nuclear recoil of a few kilo-electronvolts, carrying no feature by which it can be told from the sought signal event by event. For a massless projectile of energy E_ν on a nucleus at rest, energy and momentum conservation give the maximum recoil

$$E_R^{\max} = \frac{2E_\nu^2}{m_N c^2 + 2E_\nu} \;\simeq\; \frac{2E_\nu^2}{m_N c^2}\,, \tag{136.6}$$

since $E_\nu \ll m_N c^2$ for every relevant source. Setting Equation (136.6) equal to the halo-particle maximum Equation (136.2), written as $2\mu^2 c^4\,(v/c)^2\,/\,(m_N c^2)$, the nuclear mass cancels and leaves the mimicking relation

$$\mu c^2 \;\simeq\; E_\nu \,\frac{c}{v} \;\sim\; 10^3 E_\nu\,. \tag{136.7}$$

Equation (136.7) is the whole structure of the so-called neutrino fog in one line. Solar boron-8 neutrinos, of energies up to about 16 MeV, imitate candidates of mass of order $10\,\mathrm{GeV}/c^2$; atmospheric neutrinos, of energies from hundreds of MeV upwards, imitate candidates one to two orders of magnitude heavier, in precisely the region where Phenomenon 136.1 is strongest. Because this background scales with exposure exactly as the signal does, the statistical advantage of a longer run collapses once it dominates: the reach ceases to improve in proportion to the exposure and improves at best as its square root, and then more slowly still [2230]. It is a fog rather than a floor for the same reason — it degrades sensitivity progressively rather than forbidding progress [2388] — and directional detection, which uses the different arrival directions of solar neutrinos and halo particles, is the only known way through it. □

136.3.4 Interpretation

[Reserved: the combined status of the two xenon experiments and the parameter space they have jointly closed; the distance in cross-section still separating the current bounds from the atmospheric-neutrino component of Equation (136.7), which is what determines whether a next-generation experiment is worth building; the first measurements of coherent neutrino-nucleus scattering from solar boron-8 neutrinos in xenon detectors, reported in 2024, which demonstrate that the fog is not a theoretical projection but an observed background — to be cited when the primary references enter the bibliography.]

136.3.5 Primary references

[2418].

136.4 Cryogenic bolometers: the low-mass frontier

The xenon experiments lose sensitivity below a candidate mass of about $3\,\mathrm{GeV}/c^2$ for the kinematic reason derived in Section 136.1.2: a light projectile on a heavy nucleus deposits an energy falling as M^2, which passes below any threshold. The complementary technology uses light targets and thresholds several orders of magnitude lower, at the cost of target mass. A cryogenic bolometer is a single crystal held at a few tens of mK, in which a recoil is measured as a temperature rise of order microkelvin sensed by a superconducting thermometer at its transition edge. Because the phonon signal counts the deposited energy directly, rather than the small fraction of it that appears as light or charge, the threshold is set by thermal noise

rather than by a quantum efficiency, and thresholds in the range of tens of electronvolts have been achieved.

Two long-running programmes define this line. The Cryogenic Dark Matter Search operated germanium and silicon crystals reading out ionization and athermal phonons simultaneously, the ratio of the two providing event-by-event discrimination of nuclear from electron recoils in the same way that the ratio of scintillation to ionization does in xenon [2206]; its successor operates at deeper overburden with detectors optimized for masses below $1\,\mathrm{GeV}/c^2$. CRESST operates scintillating calcium tungstate crystals with simultaneous phonon and light readout, and its low-threshold detectors currently reach the lowest candidate masses of any direct-detection experiment [2267, 2325]. Neither has reported a detection.

[Reserved: this section is deliberately not written up as an `experiment`*, because the primary references for the CDMS, SuperCDMS and CRESST results are not yet in the bibliography of this treatise and the house rule forbids an experiment section without its primary source. To be written when they are entered: the detector masses, operating temperatures and thresholds; the transition-edge sensor and neutron-transmutation-doped thermistor readouts; the CDMS silicon result of 2013, in which three candidate events were observed against a smaller expected background and which was correctly reported as not constituting a detection; the CRESST low-mass exclusion curve; and the surface-event and low-energy-excess backgrounds that limit both. The compiled exclusion curves for these experiments are collected in the Particle Data Group review [2427].]*

136.5 DAMA/LIBRA and the annual-modulation claim (2008–2018)

136.5.1 Apparatus

An array of highly radiopure thallium-doped sodium iodide scintillator crystals, of total mass of order 250 kg, viewed by photomultipliers and operated under the Gran Sasso massif with passive shielding and a controlled, continuously monitored environment — temperature, radon concentration and nitrogen flux — since the claimed signal is a modulation of about one per cent with a period of one year, and any seasonal drift of the apparatus itself would imitate it. The replication experiments use the same target compound, at different sites and with active liquid-scintillator vetoes surrounding the crystals.

[Reserved: the crystal growth and radiopurity programme, which is the central technical claim of the experiment; the light yield in photoelectrons per kilo-electronvolt, which sets the analysis threshold; the shielding stack; the corresponding parameters of the replication arrays and the respects in which they differ.]

136.5.2 Procedure

The measured quantity is not a rate but the time dependence of a rate. Single-hit events — energy deposits in one crystal only, multiple hits being rejected as neutron or gamma-ray induced — are binned in energy and in time over many annual cycles, and the low-energy rate is fitted to a constant plus a cosine of period one year. Three parameters are tested against prediction: the amplitude, the period and the phase. The phase is the discriminating one, because the expected date of maximum is fixed by celestial mechanics and is not adjustable.

[Reserved: the single-hit selection and its efficiency; the energy calibration and the stability of the threshold over two decades; the treatment of the known seasonal modulation of the cosmic-ray muon flux, whose phase differs from the expected halo phase by several weeks and which is the leading conventional explanation that has been proposed and contested.]

136.5.3 Observations and data

[Reserved: the residual single-hit rate against time in the lowest energy bins, over the accumulated exposure of DAMA/NaI and DAMA/LIBRA; the fitted amplitude, period and phase with their uncertainties; the energy dependence of the modulation amplitude and its disappearance above a few kilo-electronvolts; the corresponding null fits from the replication arrays, quoted as the amplitude they exclude.]

Phenomenon 136.3 (A modulated rate that no other experiment sees)**.** The DAMA/LIBRA experiment reports, in the single-hit low-energy event rate of its sodium iodide crystals, a sinusoidal modulation with a period compatible with one year and a phase compatible with a maximum in late May or early June, sustained over many annual cycles and of combined statistical significance in excess of eight standard deviations [2117]. The modulation is a genuine feature of the data and has never been shown to be an artefact. It is nevertheless not accepted as a dark-matter detection, for two independent reasons. Interpreted as elastic spin-independent scattering under the halo model of Section 136.1.1, the implied cross-section is excluded by Phenomenon 136.1 and Phenomenon 136.2 by many orders of magnitude. And experiments using the same target compound, which are therefore not subject to the objection that a different target might respond differently, do not reproduce the modulation [2296, 2373]. Neither a dark-matter interpretation nor a conventional one is presently established: this is an unresolved experimental discrepancy, and it is reported here as one.

Derivation. The phase is the part of the claim that can be derived with certainty, and it is what makes the measurement interesting at all. The Sun moves through the Galactic halo at a speed $v_\odot$ of about $2.3 \times 10^5\,\mathrm{m/s}$; the Earth orbits the Sun at $v_\oplus = 2.98 \times 10^4\,\mathrm{m/s}$ in a plane inclined to the direction of solar motion by an angle γ of about $60°$. The Earth's speed through the halo is therefore

$$v_E(t) = v_\odot + v_\oplus \cos\gamma\, \cos[\omega\,(t - t_0)]\ , \qquad \omega = \frac{2\pi}{1\,\mathrm{yr}}\ , \tag{136.8}$$

with t_0 the date on which the orbital velocity is most nearly aligned with the solar motion, which falls in early June. The amplitude of the speed modulation is $v_\oplus \cos\gamma \approx 1.5 \times 10^4\,\mathrm{m/s}$, about 6 % of $v_\odot$. Because a detector counts only recoils above its threshold, and by Equation (136.2) only particles with v above a threshold-dependent minimum can produce them, the counted rate samples the steeply falling tail of the speed distribution; a 6 % modulation of the speed therefore produces a rate modulation of order a per cent, with the sign depending on where the threshold sits relative to the distribution. Three predictions follow with no free parameters: the period is one year, the phase is fixed by the Earth's orbit and not by the experiment, and the amplitude is of order a per cent of the rate [1771]. That all three are satisfied is why the claim could not simply be dismissed; that the implied cross-section contradicts other experiments is why it could not be accepted. □

Derivation pending #279

The quantitative incompatibility: the calculation that converts a modulation amplitude measured in sodium iodide into an allowed region in the mass–cross-section plane, including the quenching factors for sodium and for iodine recoils, which are measured quantities with their own uncertainties and which set the recoil-energy scale of the claimed region; and the comparison of that region against the exclusion curves of the xenon experiments, together with an enumeration of the non-standard halo and interaction assumptions — streams, inelastic scattering, isospin-violating couplings — that have been proposed to reconcile them and the reasons each is now disfavoured

136.5.4 Interpretation

[Reserved: how a positive claim is adjudicated when it is not reproduced — the distinction between an experiment being wrong, an experiment being right about an effect that is not dark matter, and a model-dependence in the comparison; the conventional explanations advanced, including the seasonal muon flux and seasonal detector effects, and the status of each; the methodological conclusion, which is that same-target replication is the only decisive test and that it has now been performed [2296].]

136.6 ADMX: the axion haloscope (2018–2020)

136.6.1 Apparatus

A tunable cylindrical microwave cavity of high quality factor, immersed in the bore of a superconducting solenoid producing a field of order 8 T, cooled to a few hundred mK, and read out through a near-quantum-limited amplifier. The resonant frequency is swept by moving dielectric or metallic tuning rods within the cavity, covering a band from roughly 650 MHz to 800 MHz across the two data runs reported here.

[Reserved: the cavity dimensions and unloaded quality factor; the tuning-rod mechanism and the mode map, including the mode crossings at which sensitivity is lost; the dilution refrigerator and the physical against noise temperature of the receiver; the superconducting quantum interference device and Josephson parametric amplifier readouts that took the system noise near the standard quantum limit, which is the advance that made a Dine–Fischler–Srednicki–Zhitnitsky coupling reachable.]

136.6.2 Procedure

The cavity is tuned to a frequency, power is integrated for a dwell time, the resulting spectrum is searched for a narrow excess above the thermal noise, and the cavity is retuned by a fraction of its bandwidth. A candidate excess is rescanned, and persistence under rescan, together with the expected line shape and the expected disappearance when the magnetic field is lowered, distinguishes a signal from a noise fluctuation or an environmental radio-frequency leak.

[Reserved: the dwell time and scan rate, and the trade between them that fixes the total mass range covered in a run; the candidate rescan protocol and the number of candidates that survived it, which was none; the synthetic-signal injections used to verify the analysis end to end.]

136.6.3 Observations and data

[Reserved: the excluded axion–photon coupling as a function of mass over the scanned band, against the two benchmark model bands; the achieved system noise temperature; the fraction of the band lost to mode crossings.]

Phenomenon 136.4 (No axion signal in the scanned band)**.** Scanning a tuned microwave cavity in a strong magnetic field, the Axion Dark Matter Experiment found no persistent narrow excess of microwave power over the thermal noise, and excluded halo axions with the coupling of the Dine–Fischler–Srednicki–Zhitnitsky model over the mass range covered by its two reported runs, together spanning roughly 2.7–3.3 µeV [2309, 2355]. This is the

first exclusion of that benchmark coupling by a haloscope, and it is worth stating what a narrow band it is: the theoretically motivated mass range for an axion that solves the strong CP problem of Chapter 102 and also constitutes the dark matter spans several orders of magnitude, and this experiment has closed a fraction of one of them.

Derivation. The design of the apparatus follows from two facts about the sought signal, both of which are certain given the hypothesis. First, a halo axion is non-relativistic, so its total energy is $E_a = m_a c^2 \left(1 + v^2/2c^2 + \dots\right)$; converting in a static magnetic field into a single photon [1729], it deposits that energy and no other, so the signal is a line at

$$\nu = \frac{m_a c^2}{h} \,, \tag{136.9}$$

and a cavity of fixed resonant frequency is sensitive to one axion mass only. The search must therefore be a scan, and the total time required is the time per mass step multiplied by the number of steps — which is why haloscope results cover narrow bands and why the figure of merit of such an experiment is a scan rate rather than an exposure. Second, the same expansion fixes the linewidth. The velocity dispersion of the halo gives $v/c \sim 10^{-3}$, so

$$\frac{\Delta\nu}{\nu} \simeq \frac{v^2}{2c^2} \sim 5 \times 10^{-7} \,, \tag{136.10}$$

that is, a signal quality factor of order 10^6. Two consequences follow. The cavity quality factor should be of the same order, since a narrower cavity resonance collects no more signal while a much broader one admits more noise; and the analysis must resolve the line, because a signal spread over 10^{-6} of the carrier frequency is overwhelmingly easier to find in a spectrum binned at that resolution than in the integrated power. Equation (136.10) is thus simultaneously the reason the search is feasible and the reason it is slow. □

136.6.4 Interpretation

[Reserved: what a haloscope null result excludes — a coupling at a mass, conditional on the axion constituting the whole of the local halo density, which is an assumption of a different character from those of the nuclear-recoil experiments and rescales the bound linearly if relaxed; the relation to the strong CP problem of Chapter 102, and the fact that an axion remains motivated independently of cosmology; the complementary helioscope and light-shining-through-walls searches, which do not assume the axion is the dark matter and are correspondingly weaker.]

136.7 ATLAS: missing transverse momentum at the Large Hadron Collider (2021)

136.7.1 Apparatus

The ATLAS detector at the Large Hadron Collider, in the configuration described in Chapter 104: an inner tracker in a solenoidal field, electromagnetic and hadronic calorimeters of nearly complete solid-angle coverage, and a muon spectrometer. For this search the calorimeter hermeticity is the critical property, since the observable is a momentum imbalance and any crack through which energy escapes unmeasured produces a false one.

[Reserved: the calorimeter coverage in pseudorapidity and the resulting resolution of the missing transverse momentum; the trigger thresholds; the integrated luminosity of the full Run 2 data set at a proton–proton centre-of-mass energy of 13 TeV*, and its uncertainty.]*

136.7.2 Procedure

Events are selected containing at least one energetic jet and a large imbalance of transverse momentum, with events containing charged leptons or photons vetoed. If a pair of invisible particles is produced in association with a jet radiated from the initial state, they carry away momentum that the detector cannot see, and the visible recoil against them is the signature. The dominant irreducible background is the production of a Z boson decaying to neutrinos in association with a jet, which yields exactly the same final state; it is estimated not from simulation alone but from control regions in the data — the same process with the Z decaying to charged leptons, and W production with the lepton lost — which is what makes the background estimate testable.

[Reserved: the signal region definition and its binning in missing transverse momentum; the control regions and the simultaneous fit that transfers their normalization to the signal region; the systematic uncertainties, dominated by the jet energy scale and the control-region transfer factors.]

136.7.3 Observations and data

[Reserved: observed against expected event yields in each bin of missing transverse momentum, with uncertainties; the resulting limits on the parameters of simplified mediator models, translated into the mass–cross-section plane of the direct-detection experiments for comparison; the compiled collider limits, including those on supersymmetric candidates, from the Particle Data Group review [2427].]

Phenomenon 136.5 (No excess of jets recoiling against nothing)**.** In the full Run 2 proton–proton data set, ATLAS observed event yields in the energetic-jet plus missing-transverse-momentum signal region consistent with the Standard Model expectation, dominated by $Z \to \nu\bar{\nu}$ production in association with a jet, and no excess attributable to the pair production of invisible particles [2367]. Limits on the mediator and candidate masses of simplified dark-matter models follow, and the compiled collider constraints, including those on supersymmetric candidates, are tabulated in the Particle Data Group review [2427].

Derivation. The observable is missing *transverse* momentum and not missing energy, and the reason is a kinematic fact about hadron colliders that determines the whole design of the search. The colliding objects are partons carrying unknown fractions x_1 and x_2 of their protons' longitudinal momenta, so the initial state has longitudinal momentum $(x_1 - x_2)\,p$, which is not measured event by event, and total energy $\sqrt{x_1 x_2}\,\sqrt{s}$, likewise unmeasured. Neither the longitudinal momentum balance nor the energy balance is therefore available. In the transverse plane, however, the initial-state momentum is zero up to the intrinsic transverse momentum of the partons, which is of order the confinement scale of Chapter 102 and negligible against the momenta of interest. Momentum conservation transverse to the beam then gives, for the visible particles i,

$$\boldsymbol{p}_T^{\text{miss}} = -\sum_{i \text{ visible}} \boldsymbol{p}_{T,i}\,, \tag{136.11}$$

which is a measurement, not an inference, provided the calorimeter is hermetic. Equation (136.11) also explains the requirement of a recoiling jet: a pair of invisible particles produced alone would leave a detector with nothing in it at all, which cannot be triggered on and is indistinguishable from no collision, so the search must rely on a jet radiated from the initial state and look for the imbalance against it. The essential limitation of the method is not statistical. Equation (136.11) establishes only that something left the detector without interacting — that is, a particle stable on the time scale of a detector crossing, some tens of nanoseconds. Dark matter must be stable over the age of the universe, a factor of order

10^{25} longer. A collider can therefore never, by itself, detect dark matter; it can produce a candidate, and the identification must come from elsewhere. □

136.7.4 Interpretation

[Reserved: the complementarity argument — colliders bound light candidates and light mediators where nuclear recoil is kinematically suppressed, direct detection bounds heavy candidates, and neither statement translates into the other without a model of the mediator; the model-dependence this introduces, which is of a different and stronger kind than in Section 136.2; the invisible-width constraint on candidates lighter than half the Z or Higgs boson mass from Chapter 104; and the honest note that the parameter space of the thermal relic scenario has been substantially reduced from both sides without being closed.]

136.8 Fermi-LAT: gamma rays from dwarf spheroidal galaxies (2009–)

136.8.1 Apparatus

The Large Area Telescope aboard the Fermi Gamma-ray Space Telescope: a pair-conversion instrument in which an incident gamma ray converts in one of a stack of tungsten foils interleaved with silicon-strip tracking planes, the electron–positron pair is tracked to reconstruct the arrival direction, and the energy is measured in a segmented caesium iodide calorimeter below. A segmented anticoincidence detector surrounding the tracker vetoes charged cosmic rays, which outnumber the gamma rays by several orders of magnitude. The instrument covers photon energies from about 20 MeV to above 300 GeV [2141].

[Reserved: the effective area, point-spread function and energy resolution as functions of energy and incidence angle; the survey observing mode, in which the whole sky is covered every two orbits; the anticoincidence segmentation, introduced to avoid the self-veto by backsplash that limited the previous generation of instruments.]

136.8.2 Procedure

Dwarf spheroidal satellites of the Milky Way are chosen as targets because they have the largest known mass-to-light ratios, are nearby, contain little gas and no recent star formation, and are therefore not expected to emit gamma rays by any conventional astrophysical process. The photon counts within a region around each dwarf are fitted jointly with the diffuse and point-source backgrounds, and a likelihood analysis stacking many dwarfs sets a limit on the velocity-averaged annihilation cross-section for an assumed annihilation channel and candidate mass.

[Reserved: the target selection and the kinematically determined astrophysical factor for each dwarf, with its uncertainty, which dominates the error budget; the joint-likelihood construction over targets, energies and channels; the background model for the Galactic and isotropic diffuse emission.]

136.8.3 Observations and data

[Reserved: photon counts against background expectation for the stacked sample; the resulting exclusion curves on the velocity-averaged annihilation cross-section as a function of candidate mass for the quark–antiquark and tau-pair channels, with the thermal relic value drawn

for comparison; the primary references for the stacked dwarf analyses to be added when they enter the bibliography of this treatise, the instrument paper alone being cited below. Separately: the excess of gamma rays from the Galactic centre, whose spectrum resembles annihilation but which is equally consistent with a population of unresolved millisecond pulsars, to be reported as an ambiguity and not as a signal.]

Phenomenon 136.6 (No annihilation signal from the darkest galaxies)**.** Gamma-ray observations of the dwarf spheroidal satellites of the Milky Way with the Large Area Telescope [2141] show no emission above the modelled diffuse and point-source backgrounds. Stacked likelihood analyses of these targets bound the velocity-averaged annihilation cross-section below the canonical thermal relic value of about $3 \times 10^{-32}\,\mathrm{m^3/s}$ for candidate masses up to of order $100\,\mathrm{GeV}/c^2$ in the standard annihilation channels [2245]; the compiled limits are collected in the Particle Data Group review [2427]. The significance of crossing that particular value is that it is the cross-section a thermal relic must have had in the early universe to leave the observed abundance [1602], so this is the first class of search to reach the theoretically preferred value rather than merely to approach it.

Derivation. Why dwarf spheroidals, and why the astrophysical factor is the dominant uncertainty, both follow from one line. If the candidate is its own antiparticle, the annihilation rate per unit volume is $\tfrac{1}{2}n^2\,\langle\sigma v\rangle$ with $n = \rho/M$, so the photon flux received from a direction within a solid angle $\Delta\Omega$ is

$$\Phi = \frac{\langle\sigma v\rangle}{8\pi M^2}\,\frac{\mathrm{d}N_\gamma}{\mathrm{d}E}\int_{\Delta\Omega}\int_{\text{l.o.s.}} \rho^2\,\mathrm{d}\ell\,\mathrm{d}\Omega\,, \tag{136.12}$$

the last factor being the astrophysical factor, conventionally called the J-factor, and the first two the particle-physics factor. The structure of Equation (136.12) dictates the observing strategy. The flux is *quadratic* in the density, unlike every gravitational probe in Chapter 134, which is linear; so the best targets are those that are dense and nearby rather than merely massive, and so the halo profile enters squared and its uncertainty is amplified. Dwarf spheroidals are selected because their J-factors can be estimated from stellar kinematics and because, having negligible gas and no star formation, they have no competing gamma-ray emission — the background is instrumental and diffuse, not intrinsic. The Galactic centre has a J-factor larger by orders of magnitude and is therefore a stronger target by Equation (136.12), but it is crowded with conventional gamma-ray sources, which is exactly why the excess observed there is an ambiguity rather than a detection. Finally, the M^{-2} prefactor means that a fixed flux sensitivity translates into a bound on $\langle\sigma v\rangle$ that weakens as M^2, which is why these limits cross the thermal value at low masses and rise above it at high ones. □

Derivation pending #280

The thermal relic cross-section: solution of the Boltzmann equation for a species annihilating in an expanding universe, freeze-out when the annihilation rate falls below the expansion rate, and the resulting inverse proportionality of the relic abundance to the annihilation cross-section, which is what fixes the benchmark value quoted above from the abundance measured in the dark sector chapter; and the reason the required value falls near a weak-scale cross-section, which is the coincidence that motivated a generation of searches

136.8.4 Interpretation

[Reserved: what an indirect null result excludes and how it differs from a direct one — it constrains the annihilation cross-section now rather than the scattering cross-section, so a

candidate that is not its own antiparticle, or that annihilates through a velocity-suppressed channel, escapes it entirely; the antiproton and positron channels and the astrophysical backgrounds that limit them; the Galactic-centre excess and the millisecond-pulsar explanation, presented with the evidence for each side; the neutrino channel from the solar core, bounded by neutrino telescopes.]

136.8.5 Primary references

[2141, 2427]. The stacked dwarf-spheroidal likelihood analyses on which the quoted bound rests are not yet entered in the bibliography of this treatise; only the instrument paper and the compilation are cited, and the bound is stated here at second hand.

136.9 The state of the search

Table 136.1: The searches reported in this chapter, by the coupling each would need in order to succeed. Every entry is a null result. The last column names the assumption that the bound is conditional on, so that no line of the table can be read as a bound on the phenomenon of Chapter 134 rather than on a model of it.

Search	Coupling tested	Conditional on
LUX-ZEPLIN and XENONnT	elastic scattering off a nucleus	the local halo density and speed distribution; a coherent spin-independent coupling; the nuclear form factor
Cryogenic bolometers	the same, at low candidate mass	the same, plus the detector response near threshold
DAMA/LIBRA	the same, measured as an annual modulation	the same, plus the quenching factors of sodium and iodine
ADMX	conversion to a photon in a magnetic field	the axion constituting the whole local halo density
ATLAS	production in a proton–proton collision	a mediator model relating production to scattering; stability only over a detector crossing
Fermi-LAT	annihilation to gamma rays in a halo	a self-conjugate candidate; the astrophysical factor of each dwarf; an assumed annihilation channel

The ledger of Table 136.1 should be read in two directions. Read as a bound on models, it is substantial: the simplest thermal relic scenario, in which a weak-scale particle with a weak-scale annihilation cross-section leaves the observed abundance, has been squeezed from three independent sides — scattering, production and annihilation — over most of the mass range where it was expected, and the region that motivated the whole programme is largely closed. Read as a bound on the phenomenon, it is nothing at all. The gravitational evidence assembled in Chapter 134 is untouched by every line of the table, because none of these experiments tests it: they test hypotheses about what the gravitating mass is made of, and the mass remains where it was.

That distinction is the reason this chapter exists, and it is worth stating in the form the treatise uses elsewhere. An experiment excludes a model; it does not exclude an

observation. The honest summary of four decades of searching is therefore the conjunction of two statements that are often heard separately and belong together: the gravitational discrepancy of Chapter 134 is one of the best-established facts in observational astronomy, and there is no laboratory detection of any particle that would account for it. The searches continue, and the next decade of direct detection will run into the neutrino background of Equation (136.7), at which point the method as presently practised reaches its limit and either directional detection or a different idea is required. What is carried forward to Chapter 133 is not a preferred candidate but the ledger itself.

[Reserved: a consolidated figure of the exclusion curves reported in this chapter, drawn in one mass–cross-section plane with the neutrino fog and the DAMA/LIBRA allowed region marked, to be authored as TikZ from the published tabulations; and a dataset entry in the evidence library holding the digitized curves, keyed to [2309, 2367, 2413, 2418], so that every statement in Table 136.1 can be recomputed from the numbers as published.]

Appendices

Appendix A

Long Proofs

This appendix collects the derivations that are too long to interrupt the running text. Each section opens by naming the statement it proves and closes by returning the reader to the chapter where that statement is used. The derivations are carried out in full: every algebraic step that a careful reader would want to check is displayed, and all quantities carry their SI dimensions throughout — in particular the constants G, c and $\hbar$ are kept explicit everywhere, in obedience to the SI axiom of the front matter.

A word on what *in full* can and cannot mean. Some of the results collected here descend, at exactly one step, from a theorem this treatise does not build — most often a convergence theorem of Lebesgue integration, of which Chapter 7 constructs only the Riemann predecessor, and in four cases a substantial theorem of another subject altogether. Where that happens the section does three things rather than pass over it: it states the imported theorem precisely, as a displayed environment of its own with its citation; it derives everything else from that statement; and it carries a remark headed *What is quoted here* naming the import and saying why it is not proved. A derivation that hides such a step would be worth less than the pending-derivation box it replaces. Fourteen of the thirty-two sections written for Part II quote nothing at all.

A.1 The Quadrupole Formula for Gravitational Radiation

This appendix proves Phenomenon 46.1 (Chapter 46): the field equations of general relativity, linearized about flat spacetime, admit transverse wave solutions propagating at speed c with two polarizations; these waves carry energy; and a slowly moving, self-gravitating source radiates them with a power fixed by the third time derivative of its mass quadrupole moment. The chain of results proved below — wave equation, transverse–traceless gauge, geodesic-deviation observable, Isaacson energy flux, quadrupole generation formula, and the binary-inspiral application — is exactly the chain that connects Einstein's field equations to the two great experimental confirmations: the orbital decay of the binary pulsar PSR B1913+16 (Section 47.1) and the direct detection of GW150914 by the LIGO interferometers (Section 47.3).

The history deserves one sentence. Einstein obtained the linearized wave solutions in 1916 [436], and in 1918 published the quadrupole radiation formula in its correct form, repairing a computational slip of the earlier paper [453]; the modern treatments we follow — and against which every step below can be checked — are those of Misner, Thorne and Wheeler [1509], Wald [1746], and Maggiore [2132].

Throughout this section the metric signature is $(-,+,+,+)$, coordinates are $x^{\mu} = (x^0, x^i) = (ct, \boldsymbol{x})$, Greek indices run over $0,1,2,3$, Latin indices over the spatial values $1,2,3$,

and the flat d'Alembertian is

$$\Box \equiv \eta^{\mu\nu}\partial_\mu\partial_\nu = -\frac{1}{c^2}\frac{\partial^2}{\partial t^2} + \nabla^2 \,. \tag{A.1}$$

A.1.1 Setup: linearized geometry

We consider spacetimes that deviate weakly from Minkowski space, so that global coordinates exist in which

$$g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu} \,, \qquad |h_{\mu\nu}| \ll 1 \,, \tag{A.2}$$

with $\eta_{\mu\nu} = \mathrm{diag}(-1,+1,+1,+1)$. All indices are raised and lowered with η, an operation that is consistent to the linear order in h at which we work. The inverse metric is

$$g^{\mu\nu} = \eta^{\mu\nu} - h^{\mu\nu} + O(h^2) \,, \tag{A.3}$$

as one checks by direct multiplication: $(\eta_{\mu\rho} + h_{\mu\rho})(\eta^{\rho\nu} - h^{\rho\nu}) = \delta_\mu{}^\nu + h_\mu{}^\nu - h_\mu{}^\nu + O(h^2) = \delta_\mu{}^\nu + O(h^2)$.

Christoffel symbols. Inserting Equations (A.2) and (A.3) into the definition of the Levi-Civita connection and discarding $O(h^2)$,

$$\begin{aligned}
\Gamma^\lambda{}_{\mu\nu} &= \frac{1}{2} g^{\lambda\rho}\left(\partial_\mu g_{\rho\nu} + \partial_\nu g_{\rho\mu} - \partial_\rho g_{\mu\nu}\right) \\
&= \frac{1}{2}\left(\eta^{\lambda\rho} - h^{\lambda\rho}\right)\left(\partial_\mu h_{\rho\nu} + \partial_\nu h_{\rho\mu} - \partial_\rho h_{\mu\nu}\right) \\
&= \frac{1}{2}\eta^{\lambda\rho}\left(\partial_\mu h_{\rho\nu} + \partial_\nu h_{\rho\mu} - \partial_\rho h_{\mu\nu}\right) + O(h^2) \,.
\end{aligned} \tag{A.4}$$

The connection is thus itself of first order in h.

Riemann tensor. In the curvature tensor $R^\rho{}_{\sigma\mu\nu} = \partial_\mu\Gamma^\rho{}_{\nu\sigma} - \partial_\nu\Gamma^\rho{}_{\mu\sigma} + \Gamma^\rho{}_{\mu\lambda}\Gamma^\lambda{}_{\nu\sigma} - \Gamma^\rho{}_{\nu\lambda}\Gamma^\lambda{}_{\mu\sigma}$ the $\Gamma\Gamma$ terms are $O(h^2)$ and drop. Substituting Equation (A.4),

$$\begin{aligned}
R^\rho{}_{\sigma\mu\nu} &= \partial_\mu\Gamma^\rho{}_{\nu\sigma} - \partial_\nu\Gamma^\rho{}_{\mu\sigma} + O(h^2) \\
&= \frac{1}{2}\eta^{\rho\lambda}\left(\partial_\mu\partial_\nu h_{\lambda\sigma} + \partial_\mu\partial_\sigma h_{\lambda\nu} - \partial_\mu\partial_\lambda h_{\nu\sigma} - \partial_\nu\partial_\mu h_{\lambda\sigma} - \partial_\nu\partial_\sigma h_{\lambda\mu} + \partial_\nu\partial_\lambda h_{\mu\sigma}\right) \\
&= \frac{1}{2}\eta^{\rho\lambda}\left(\partial_\mu\partial_\sigma h_{\lambda\nu} + \partial_\nu\partial_\lambda h_{\mu\sigma} - \partial_\mu\partial_\lambda h_{\nu\sigma} - \partial_\nu\partial_\sigma h_{\lambda\mu}\right) \,,
\end{aligned} \tag{A.5}$$

where the two $\partial_\mu\partial_\nu h_{\lambda\sigma}$ terms cancelled. Lowering the first index gives the fully covariant linearized Riemann tensor,

$$R_{\rho\sigma\mu\nu} = \frac{1}{2}\left(\partial_\mu\partial_\sigma h_{\rho\nu} + \partial_\nu\partial_\rho h_{\mu\sigma} - \partial_\mu\partial_\rho h_{\nu\sigma} - \partial_\nu\partial_\sigma h_{\rho\mu}\right) \,. \tag{A.6}$$

Ricci tensor, Ricci scalar, Einstein tensor. Contracting the first and third indices of Equation (A.5) and writing $h \equiv \eta^{\mu\nu}h_{\mu\nu}$ for the trace,

$$R_{\mu\nu} = R^\rho{}_{\mu\rho\nu} = \frac{1}{2}\left(\partial_\rho\partial_\mu h^\rho{}_\nu + \partial_\rho\partial_\nu h^\rho{}_\mu - \Box h_{\mu\nu} - \partial_\mu\partial_\nu h\right) \,, \tag{A.7}$$

and contracting once more,

$$R = \eta^{\mu\nu}R_{\mu\nu} = \partial_\mu\partial_\nu h^{\mu\nu} - \Box h \,. \tag{A.8}$$

The linearized Einstein tensor is therefore

$$G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}R = \frac{1}{2}\left(\partial_\rho\partial_\mu h^\rho{}_\nu + \partial_\rho\partial_\nu h^\rho{}_\mu - \Box h_{\mu\nu} - \partial_\mu\partial_\nu h - \eta_{\mu\nu}\partial_\rho\partial_\sigma h^{\rho\sigma} + \eta_{\mu\nu}\Box h\right) \,. \tag{A.9}$$

Trace reversal. The expression Equation (A.9) simplifies decisively in terms of the *trace-reversed* perturbation

$$\bar{h}_{\mu\nu} \equiv h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}h\,, \qquad \bar{h} = \eta^{\mu\nu}\bar{h}_{\mu\nu} = h - 2h = -h\,, \qquad h_{\mu\nu} = \bar{h}_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}\bar{h}\,. \tag{A.10}$$

(The map is an involution: trace-reversing twice returns $h_{\mu\nu}$.) Substituting the third relation of Equation (A.10) into Equation (A.7) term by term,

$$\partial_\rho\partial_\mu h^\rho{}_\nu = \partial_\rho\partial_\mu \bar{h}^\rho{}_\nu - \frac{1}{2}\partial_\mu\partial_\nu\bar{h}\,, \quad \Box h_{\mu\nu} = \Box\bar{h}_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}\Box\bar{h}\,, \quad \partial_\mu\partial_\nu h = -\partial_\mu\partial_\nu\bar{h}\,, \tag{A.11}$$

so that

$$\begin{aligned} R_{\mu\nu} &= \frac{1}{2}\left(\partial_\rho\partial_\mu\bar{h}^\rho{}_\nu + \partial_\rho\partial_\nu\bar{h}^\rho{}_\mu - \partial_\mu\partial_\nu\bar{h} - \Box\bar{h}_{\mu\nu} + \frac{1}{2}\eta_{\mu\nu}\Box\bar{h} + \partial_\mu\partial_\nu\bar{h}\right) \\ &= \frac{1}{2}\left(\partial_\rho\partial_\mu\bar{h}^\rho{}_\nu + \partial_\rho\partial_\nu\bar{h}^\rho{}_\mu - \Box\bar{h}_{\mu\nu} + \frac{1}{2}\eta_{\mu\nu}\Box\bar{h}\right), \qquad R = \partial_\rho\partial_\sigma\bar{h}^{\rho\sigma} + \frac{1}{2}\Box\bar{h}\,, \end{aligned} \tag{A.12}$$

and the Einstein tensor assembles into

$$G_{\mu\nu} = -\frac{1}{2}\left(\Box\bar{h}_{\mu\nu} + \eta_{\mu\nu}\partial^\rho\partial^\sigma\bar{h}_{\rho\sigma} - \partial^\rho\partial_\mu\bar{h}_{\rho\nu} - \partial^\rho\partial_\nu\bar{h}_{\rho\mu}\right) + O(h^2)\,, \tag{A.13}$$

the two $\frac{1}{4}\eta_{\mu\nu}\Box\bar{h}$ contributions having cancelled between $R_{\mu\nu}$ and $-\frac{1}{2}\eta_{\mu\nu}R$. Every term now contains $\bar{h}_{\mu\nu}$ either under a d'Alembertian or under a divergence $\partial^\rho\bar{h}_{\rho\nu}$ — which is the invitation to fix a gauge.

A.1.2 Gauge freedom and the Lorenz gauge

The split Equation (A.2) is not unique: an infinitesimal coordinate change

$$x'^\mu = x^\mu + \xi^\mu(x)\,, \qquad |\partial_\mu\xi^\nu| \ll 1\,, \tag{A.14}$$

preserves the form $g = \eta + h$ with a different, equally small h. Indeed, from the tensor transformation law and $\partial x^\rho/\partial x'^\mu = \delta^\rho{}_\mu - \partial_\mu\xi^\rho + O(\xi^2)$,

$$g'_{\mu\nu} = \frac{\partial x^\rho}{\partial x'^\mu}\frac{\partial x^\sigma}{\partial x'^\nu}g_{\rho\sigma} = \eta_{\mu\nu} + h_{\mu\nu} - \partial_\mu\xi_\nu - \partial_\nu\xi_\mu + O(h\xi, \xi^2)\,, \tag{A.15}$$

so the perturbation transforms as

$$h'_{\mu\nu} = h_{\mu\nu} - \partial_\mu\xi_\nu - \partial_\nu\xi_\mu\,. \tag{A.16}$$

This is the gauge freedom of linearized gravity, the precise analogue of $A_\mu \to A_\mu - \partial_\mu\chi$ in electrodynamics [1976]. The linearized Riemann tensor Equation (A.6) is gauge *invariant*: substituting Equation (A.16),

$$\begin{aligned} \delta R_{\rho\sigma\mu\nu} = -\frac{1}{2}(&\partial_\mu\partial_\sigma\partial_\rho\xi_\nu + \partial_\mu\partial_\sigma\partial_\nu\xi_\rho + \partial_\nu\partial_\rho\partial_\mu\xi_\sigma + \partial_\nu\partial_\rho\partial_\sigma\xi_\mu \\ &- \partial_\mu\partial_\rho\partial_\nu\xi_\sigma - \partial_\mu\partial_\rho\partial_\sigma\xi_\nu - \partial_\nu\partial_\sigma\partial_\rho\xi_\mu - \partial_\nu\partial_\sigma\partial_\mu\xi_\rho) = 0\,, \end{aligned} \tag{A.17}$$

because partial derivatives commute and the eight triple-derivative terms cancel in pairs. Curvature — hence everything observable — is unaffected by the choice of ξ^μ; we may therefore spend that choice on simplifying the field equations.

Taking the trace of Equation (A.16) gives $h' = h - 2\partial_\rho\xi^\rho$, so the trace-reversed perturbation transforms as

$$\bar{h}'_{\mu\nu} = \bar{h}_{\mu\nu} - \partial_\mu\xi_\nu - \partial_\nu\xi_\mu + \eta_{\mu\nu}\partial_\rho\xi^\rho\,, \tag{A.18}$$

and its divergence as

$$\partial^\mu \bar{h}'_{\mu\nu} = \partial^\mu \bar{h}_{\mu\nu} - \Box\xi_\nu - \partial_\nu \partial^\mu \xi_\mu + \partial_\nu \partial_\rho \xi^\rho = \partial^\mu \bar{h}_{\mu\nu} - \Box\xi_\nu \,. \tag{A.19}$$

Given any $\bar{h}_{\mu\nu}$, choose ξ_ν to solve the inhomogeneous wave equation $\Box\xi_\nu = \partial^\mu \bar{h}_{\mu\nu}$ — a solution always exists, for instance by the retarded Green function of $\Box$ constructed in Appendix A.1.6 below. In the new coordinates the *Lorenz gauge* (also called harmonic or de Donder gauge) holds:

$$\partial^\mu \bar{h}_{\mu\nu} = 0 \,. \tag{A.20}$$

In this gauge the last three terms of Equation (A.13) vanish, and the full Einstein equations $G_{\mu\nu} = (8\pi G/c^4)\, T_{\mu\nu}$, linearized, collapse to a flat-space wave equation with source:

$$\boxed{\Box \bar{h}_{\mu\nu} = -\frac{16\pi G}{c^4}\, T_{\mu\nu}} \tag{A.21}$$

Taking ∂^μ of both sides and using Equation (A.20) shows $\partial^\mu T_{\mu\nu} = 0$: at linear order the source moves on the flat background, its energy–momentum conserved in the special-relativistic sense. This is the self-consistency of the linear approximation [1509, 1746].

A.1.3 Vacuum solutions: plane waves and the transverse–traceless gauge

In vacuum ($T_{\mu\nu} = 0$) equation Equation (A.21) reads $\Box \bar{h}_{\mu\nu} = 0$: each component obeys the massless wave equation, so disturbances of the metric propagate at the speed c — the first assertion of Phenomenon 46.1. Insert the plane-wave ansatz

$$\bar{h}_{\mu\nu} = A_{\mu\nu}\, \mathrm{e}^{\mathrm{i} k_\alpha x^\alpha} \,, \qquad A_{\mu\nu} = A_{\nu\mu} \text{ constant} \,, \tag{A.22}$$

(real part understood). Then $\Box \bar{h}_{\mu\nu} = -k_\alpha k^\alpha\, \bar{h}_{\mu\nu} = 0$ forces the wave vector to be null,

$$k_\alpha k^\alpha = 0 \qquad \Longleftrightarrow \qquad \omega = c\,|\boldsymbol{k}| \,, \quad k^\mu = (\omega/c, \boldsymbol{k}) \,, \tag{A.23}$$

and the Lorenz condition Equation (A.20) becomes the transversality constraint

$$k^\mu A_{\mu\nu} = 0 \,. \tag{A.24}$$

Counting the physical degrees of freedom. A symmetric $A_{\mu\nu}$ has 10 independent components; Equation (A.24) removes 4. But the gauge is not yet exhausted: any further ξ^μ with $\Box\xi^\mu = 0$ preserves Equation (A.20), by Equation (A.19). Take $\xi^\mu = B^\mu \mathrm{e}^{\mathrm{i} k_\alpha x^\alpha}$ with the same null k; then Equation (A.18) shifts the amplitude by

$$A'_{\mu\nu} = A_{\mu\nu} - \mathrm{i}\,(k_\mu B_\nu + k_\nu B_\mu - \eta_{\mu\nu} k_\rho B^\rho) \,. \tag{A.25}$$

The four free constants B_μ remove four more components. Explicitly, let the wave run along z, $k^\mu = (k, 0, 0, k)$, $k_\mu = (-k, 0, 0, k)$, and write $\beta \equiv k_\rho B^\rho = k(B_0 + B_3)$. From Equation (A.25),

$$\delta A^\mu{}_\mu = 2\mathrm{i}\beta \,, \qquad \delta A_{01} = \mathrm{i}k B_1 \,, \qquad \delta A_{02} = \mathrm{i}k B_2 \,, \qquad \delta A_{03} = \mathrm{i}k\,(B_3 - B_0) \,, \tag{A.26}$$

and the four quantities $(B_0 + B_3,\, B_1,\, B_2,\, B_3 - B_0)$ are independent linear combinations of the B_μ: the linear system is invertible. We may therefore impose

$$A^\mu{}_\mu = 0 \,, \qquad A_{0i} = 0 \quad (i = 1, 2, 3) \,. \tag{A.27}$$

The remaining component A_{00} then vanishes automatically: transversality Equation (A.24) with $\nu = 0$ reads $k^0 A_{00} + k^i A_{i0} = 0$, and $A_{i0} = 0$ with $k^0 = \omega/c \neq 0$ forces $A_{00} = 0$. The count of physical polarizations is thus

$$10 \text{ (symmetric } A_{\mu\nu}) \;-\; 4 \text{ (Lorenz)} \;-\; 4 \text{ (residual gauge)} \;=\; 2\,. \tag{A.28}$$

Because the trace vanishes, $\bar{h}_{\mu\nu} = h_{\mu\nu}$ in this gauge: bar and no-bar coincide. The conditions

$$h^{\mathrm{TT}}_{0\mu} = 0\,, \qquad h^{\mathrm{TT}\,i}{}_{i} = 0\,, \qquad \partial^j h^{\mathrm{TT}}_{ij} = 0 \tag{A.29}$$

define the *transverse–traceless* (TT) gauge. For the wave along z, transversality further gives $k(A_{0\nu} + A_{3\nu}) = 0$, hence $A_{3\nu} = -A_{0\nu} = 0$: only $A_{11} = -A_{22}$ and $A_{12} = A_{21}$ survive. Writing $A_{11} \equiv h_+$ and $A_{12} \equiv h_\times$,

$$h^{\mathrm{TT}}_{ij}(t,z) = \begin{pmatrix} h_+ & h_\times & 0 \\ h_\times & -h_+ & 0 \\ 0 & 0 & 0 \end{pmatrix} \cos[\omega\,(t - z/c)]\;, \tag{A.30}$$

the two physical polarizations of Phenomenon 46.1 [1509, 2132]. They are spin-2 objects: a rotation by ψ about the propagation axis mixes them as $h_+ \to h_+ \cos 2\psi + h_\times \sin 2\psi$, so the pattern returns to itself after half a turn.

A.1.4 Physical effect: geodesic deviation and the strain

A single free test mass tells us nothing: in TT coordinates a particle initially at rest *stays at fixed coordinates*. Its geodesic equation with initial four-velocity $u^\mu = (c,0,0,0)$ gives

$$\left.\frac{\mathrm{d}^2 x^i}{\mathrm{d}\tau^2}\right|_{\tau=0} = -\Gamma^i{}_{00}\,c^2 = -\frac{c^2}{2}\,\eta^{ij}\,(2\partial_0 h_{j0} - \partial_j h_{00}) = 0\,, \tag{A.31}$$

since $h_{0\mu} = 0$ in the TT gauge, Equation (A.29). The coordinates simply ride along with the wave. What oscillates is the *proper distance* between two such masses. Let both sit on the x axis with coordinate separation L_{c}, the wave Equation (A.30) passing along z. The proper distance at time t is

$$\begin{aligned} s(t) &= \int_0^{L_{\mathrm{c}}} \sqrt{g_{xx}}\,\mathrm{d}x = \sqrt{1 + h_+ \cos\omega t}\;L_{\mathrm{c}} \\ &= \left[1 + \frac{1}{2} h_+ \cos\omega t + O(h^2)\right] L_{\mathrm{c}}\,, \end{aligned} \tag{A.32}$$

so the fractional length change — the *strain* — is

$$\boxed{\frac{\Delta L}{L} = \frac{1}{2}\,h} \tag{A.33}$$

for a wave of amplitude h optimally oriented with respect to the separation.

The same result follows covariantly from geodesic deviation, which also exhibits the wave as a tidal force. For two neighbouring geodesics with separation vector ξ^μ and common four-velocity u^μ [1509, 1746],

$$\frac{D^2 \xi^\mu}{D\tau^2} = -R^\mu{}_{\nu\rho\sigma}\,u^\nu \xi^\rho u^\sigma\,. \tag{A.34}$$

For slowly moving masses $u^\mu \simeq (c,0,0,0)$, $\tau \simeq t$, and the only components of Riemann we need follow from Equation (A.6) with the TT conditions $h_{0\mu} = 0$:

$$R_{i0j0} = \frac{1}{2}\,(\partial_0\partial_j h_{i0} + \partial_i\partial_0 h_{0j} - \partial_i\partial_j h_{00} - \partial_0\partial_0 h_{ij}) = -\frac{1}{2c^2}\,\partial_t^2 h^{\mathrm{TT}}_{ij}\,. \tag{A.35}$$

Then Equation (A.34) gives, in the local proper frame of the first mass,

$$\ddot{\xi}^i = -c^2 R^i{}_{0j0}\,\xi^j = \frac{1}{2}\,\ddot{h}^{\mathrm{TT}}_{ij}\,\xi^j\,, \tag{A.36}$$

which integrates (for ξ nearly constant) to $\delta\xi^i = \frac{1}{2}h^{\mathrm{TT}}_{ij}\xi^j$, reproducing Equation (A.33). Note that the observable is curvature, Equation (A.35), which we proved gauge invariant: the strain is physics, not coordinates.

Applying $\delta\xi^i = \frac{1}{2}h^{\mathrm{TT}}_{ij}\xi^j$ to a ring of free masses of radius L in the xy plane, $\xi^j = L(\cos\varphi, \sin\varphi, 0)$: a pure h_+ wave displaces $(\delta x, \delta y) = \frac{1}{2}h_+ L\,(\cos\varphi, -\sin\varphi)$, squeezing the ring into an ellipse along x while stretching it along y and vice versa each half period; a pure $h_\times$ wave produces the same ellipse rotated by 45°. This quadrupolar breathing pattern is precisely what a Michelson interferometer with perpendicular arms measures: the wave lengthens one arm while it shortens the other, and the differential strain $\Delta L_x - \Delta L_y = h_+ L$ appears as an optical phase shift at the dark port. With $L = 4\,\mathrm{km}$ arms and strain sensitivity near 10^{-22} per root hertz in the band around 100 Hz, the Advanced LIGO instruments [2243] resolve arm-length changes of order $10^{-18}\,\mathrm{m}$ — the observable exploited in Section 47.3 [2264].

A.1.5 Energy carried by the wave: the Isaacson tensor

That gravitational waves carry energy was disputed into the 1950s; the resolution is that the energy is not localizable at a point (the equivalence principle forbids it) but is perfectly well defined once averaged over a few wavelengths. We follow the short-wave (Isaacson) analysis [1509, 2132].

Expand the Ricci tensor of $g = \eta + h$ to second order in h,

$$R_{\mu\nu} = R^{(1)}_{\mu\nu}[h] + R^{(2)}_{\mu\nu}[h,h] + O(h^3)\,, \tag{A.37}$$

where $R^{(1)}$ is the linear expression Equation (A.7). In vacuum, at second order, the equation $R_{\mu\nu} = 0$ says that the small residual background curvature generated at $O(h^2)$ is sourced by $-R^{(2)}_{\mu\nu}$: the wave gravitates. Averaging over a spacetime region several wavelengths across (denoted $\langle\cdot\rangle$) and defining

$$t_{\mu\nu} \equiv -\frac{c^4}{8\pi G}\left\langle R^{(2)}_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}R^{(2)}\right\rangle, \tag{A.38}$$

the coarse-grained field equations take the form $G^{(1)}_{\mu\nu}[\text{background}] = (8\pi G/c^4)\,t_{\mu\nu}$: the averaged quadratic terms act as an effective stress–energy tensor of the radiation.

The straightforward if lengthy expansion of the Ricci tensor to second order gives [2132]

$$\begin{aligned} R^{(2)}_{\mu\nu} = \frac{1}{2}\Big[&\frac{1}{2}\partial_\mu h_{\alpha\beta}\,\partial_\nu h^{\alpha\beta} + h^{\alpha\beta}\partial_\mu\partial_\nu h_{\alpha\beta} - h^{\alpha\beta}\partial_\nu\partial_\beta h_{\alpha\mu} - h^{\alpha\beta}\partial_\mu\partial_\beta h_{\alpha\nu} + h^{\alpha\beta}\partial_\alpha\partial_\beta h_{\mu\nu} \\ &+ \partial^\beta h^\alpha{}_\nu\,\partial_\beta h_{\alpha\mu} - \partial^\beta h^\alpha{}_\nu\,\partial_\alpha h_{\beta\mu} - \partial_\beta h^{\alpha\beta}\,\partial_\nu h_{\alpha\mu} - \partial_\beta h^{\alpha\beta}\,\partial_\mu h_{\alpha\nu} + \partial_\beta h^{\alpha\beta}\,\partial_\alpha h_{\mu\nu} \\ &- \frac{1}{2}\partial^\alpha h\,\partial_\alpha h_{\mu\nu} + \frac{1}{2}\partial^\alpha h\,\partial_\nu h_{\alpha\mu} + \frac{1}{2}\partial^\alpha h\,\partial_\mu h_{\alpha\nu}\Big]\,. \end{aligned} \tag{A.39}$$

Work in the TT gauge, where $h = 0$ and $\partial^\beta h_{\alpha\beta} = 0$: the last six terms of Equation (A.39) vanish identically. Under the average, total derivatives are suppressed by (wavelength)/(averaging scale) and may be dropped, which licenses integration by parts

inside $\langle\cdot\rangle$; and the field equations $\Box h_{\alpha\beta}=0$ hold. Then, term by term,

$$\left\langle h^{\alpha\beta}\partial_\mu\partial_\nu h_{\alpha\beta}\right\rangle = -\left\langle \partial_\mu h^{\alpha\beta}\,\partial_\nu h_{\alpha\beta}\right\rangle , \tag{A.40}$$

$$\left\langle h^{\alpha\beta}\partial_\nu\partial_\beta h_{\alpha\mu}\right\rangle = -\left\langle \partial_\beta h^{\alpha\beta}\,\partial_\nu h_{\alpha\mu}\right\rangle = 0 , \qquad \text{(and likewise with } \mu\leftrightarrow\nu\text{)} \tag{A.41}$$

$$\left\langle h^{\alpha\beta}\partial_\alpha\partial_\beta h_{\mu\nu}\right\rangle = -\left\langle \partial_\alpha h^{\alpha\beta}\,\partial_\beta h_{\mu\nu}\right\rangle = 0 , \tag{A.42}$$

$$\left\langle \partial^\beta h^\alpha{}_\nu\,\partial_\beta h_{\alpha\mu}\right\rangle = -\left\langle h^\alpha{}_\nu\,\Box h_{\alpha\mu}\right\rangle = 0 , \tag{A.43}$$

$$\left\langle \partial^\beta h^\alpha{}_\nu\,\partial_\alpha h_{\beta\mu}\right\rangle = -\left\langle h^\alpha{}_\nu\,\partial_\alpha\partial^\beta h_{\beta\mu}\right\rangle = 0 . \tag{A.44}$$

Only the first two terms of Equation (A.39) survive, combining to

$$\left\langle R^{(2)}_{\mu\nu}\right\rangle = \frac{1}{2}\left(\frac{1}{2}-1\right)\left\langle \partial_\mu h_{\alpha\beta}\,\partial_\nu h^{\alpha\beta}\right\rangle = -\frac{1}{4}\left\langle \partial_\mu h^{\mathrm{TT}}_{\alpha\beta}\,\partial_\nu h^{\mathrm{TT}\,\alpha\beta}\right\rangle . \tag{A.45}$$

Its trace, $\eta^{\mu\nu}\left\langle R^{(2)}_{\mu\nu}\right\rangle = \frac{1}{4}\left\langle h_{\alpha\beta}\Box h^{\alpha\beta}\right\rangle = 0$ after one more integration by parts, vanishes on shell, so Equation (A.38) yields the *Isaacson stress–energy tensor*. In the TT gauge only spatial components of h are nonzero, and

$$\boxed{\,t_{\mu\nu} = \frac{c^4}{32\pi G}\left\langle \partial_\mu h^{\mathrm{TT}}_{ij}\,\partial_\nu h^{\mathrm{TT}}_{ij}\right\rangle\,} \tag{A.46}$$

(spatial indices summed; their up/down position is immaterial in the flat background). Although derived in a particular gauge, the averaged tensor is gauge invariant to the order considered [1509, 2132].

For the plane wave Equation (A.30) travelling along z, every component is a function of $t-z/c$, so $\partial_z=-c^{-1}\partial_t$ acting on h, and the energy density and energy flux are

$$t^{00} = \frac{c^2}{32\pi G}\left\langle \dot h^{\mathrm{TT}}_{ij}\dot h^{\mathrm{TT}}_{ij}\right\rangle , \qquad F = c\,t^{0z} = \frac{c^3}{32\pi G}\left\langle \dot h^{\mathrm{TT}}_{ij}\dot h^{\mathrm{TT}}_{ij}\right\rangle = \frac{c^3}{16\pi G}\left\langle \dot h_+^2+\dot h_\times^2\right\rangle , \tag{A.47}$$

using $h^{\mathrm{TT}}_{ij}h^{\mathrm{TT}}_{ij}=2(h_+^2+h_\times^2)$ from Equation (A.30). The prefactor $c^3/16\pi G$ is enormous, $\approx 8.0\times10^{33}\,\mathrm{W/m^2}$ per unit $\left\langle \dot h^2\right\rangle/1/\mathrm{s}^2$: even a strain of 10^{-21} oscillating at 100 Hz carries a flux of order $10^{-3}\,\mathrm{W/m^2}$ — comparable to moonlight, delivered by a distortion of geometry a thousandth of a proton radius across a kilometre.

A.1.6 Generation: the quadrupole formula

We now solve the sourced equation Equation (A.21).

Retarded Green function. The retarded solution of $\Box f=-S$, with $\Box$ as in Equation (A.1), is

$$f(t,\boldsymbol{x}) = \frac{1}{4\pi}\int \frac{S(t-|\boldsymbol{x}-\boldsymbol{x}'|/c,\ \boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|}\,\mathrm{d}^3x' . \tag{A.48}$$

To verify, consider a single spherical wave $f=g(t-r/c)/r$ centred on $\boldsymbol{x}'$, $r=|\boldsymbol{x}-\boldsymbol{x}'|$. For $r\neq0$, the radial Laplacian gives $\nabla^2 f = r^{-1}\partial_r^2(rf) = g''(t-r/c)/(c^2r) = c^{-2}\partial_t^2 f$, so the homogeneous wave equation holds; near $r=0$, $f\to g(t)/r$ and $\nabla^2(1/r)=-4\pi\delta^3(\boldsymbol{x}-\boldsymbol{x}')$ supplies a point source of strength $4\pi g(t)$. Superposing such waves with $g=S\,\mathrm{d}^3x'/4\pi$ yields Equation (A.48); causality selects the retarded rather than advanced root [1976]. Applying this to Equation (A.21) with $S=(16\pi G/c^4)T_{\mu\nu}$,

$$\bar h_{\mu\nu}(t,\boldsymbol{x}) = \frac{4G}{c^4}\int \frac{T_{\mu\nu}(t-|\boldsymbol{x}-\boldsymbol{x}'|/c,\ \boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|}\,\mathrm{d}^3x' . \tag{A.49}$$

Far zone and slow motion. Let the source occupy a region of size d about the origin and let $r = |\boldsymbol{x}| \gg d$, with unit line of sight $\boldsymbol{n} = \boldsymbol{x}/r$. Then $|\boldsymbol{x} - \boldsymbol{x}'| = r - \boldsymbol{n}\cdot\boldsymbol{x}' + O(d^2/r)$, and keeping only the leading $1/r$,

$$\bar{h}_{\mu\nu}(t,\boldsymbol{x}) = \frac{4G}{c^4 r}\int T_{\mu\nu}\!\left(t - \frac{r}{c} + \frac{\boldsymbol{n}\cdot\boldsymbol{x}'}{c},\ \boldsymbol{x}'\right)\mathrm{d}^3x' \,. \tag{A.50}$$

If moreover the internal motions are slow, $v \ll c$ — equivalently the emitted wavelength $\lambda \sim c\,d/v$ far exceeds the source size — the retardation spread $\boldsymbol{n}\cdot\boldsymbol{x}'/c$ across the source may be dropped, and every component of $T_{\mu\nu}$ is evaluated at the single retarded time $t_r = t - r/c$.

From stress to quadrupole: the conservation identities. The spatial integral of T^{ij} is not an independent datum: flat-space conservation $\partial_\mu T^{\mu\nu} = 0$, guaranteed at this order by Equation (A.21), trades it for time derivatives of the energy density. With $x^0 = ct$, the two components of the conservation law read

$$\frac{1}{c}\partial_t T^{00} + \partial_i T^{i0} = 0\,, \qquad \frac{1}{c}\partial_t T^{0j} + \partial_i T^{ij} = 0\,. \tag{A.51}$$

Multiply the first by $x^i x^j$ and integrate over all space (the source has compact support, so boundary terms vanish under integration by parts):

$$\frac{\mathrm{d}}{\mathrm{d}t}\int T^{00}x^i x^j\,\mathrm{d}^3x = -c\int \partial_k T^{k0}\,x^i x^j\,\mathrm{d}^3x = c\int\left(T^{i0}x^j + T^{j0}x^i\right)\mathrm{d}^3x\,. \tag{A.52}$$

Multiply the second of Equation (A.51) by x^j, integrate, and symmetrize:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int\left(T^{0i}x^j + T^{0j}x^i\right)\mathrm{d}^3x = -c\int\left(\partial_k T^{ki}\,x^j + \partial_k T^{kj}\,x^i\right)\mathrm{d}^3x = 2c\int T^{ij}\,\mathrm{d}^3x\,. \tag{A.53}$$

Chaining Equations (A.52) and (A.53),

$$\int T^{ij}\,\mathrm{d}^3x = \frac{1}{2c^2}\frac{\mathrm{d}^2}{\mathrm{d}t^2}\int T^{00}\,x^i x^j\,\mathrm{d}^3x = \frac{1}{2}\,\ddot{Q}_{ij}\,, \tag{A.54}$$

where, with the mass density $\rho \equiv T^{00}/c^2$ (the dominant part of T^{00} for slow motion), the *mass quadrupole moment* is

$$Q_{ij}(t) \equiv \int \rho(t,\boldsymbol{x})\,x_i x_j\,\mathrm{d}^3x\,. \tag{A.55}$$

Substituting Equation (A.54) into Equation (A.50),

$$\boxed{\bar{h}_{ij}(t,\boldsymbol{x}) = \frac{2G}{c^4 r}\,\ddot{Q}_{ij}(t - r/c)} \tag{A.56}$$

— the quadrupole formula for the field [453, 1509]. Dimensionally: $G/c^4 \sim \mathrm{s}^2/(\mathrm{kg\,m})$ and $\ddot{Q} \sim \mathrm{kg\,m}^2/\mathrm{s}^2$, so h is a pure number divided by r — a strain falling off as $1/r$, as a radiation field must. The time components need not be computed separately: the Lorenz condition Equation (A.20) determines $\bar{h}^{0\mu}$ from $\bar{h}^{ij}$ up to stationary pieces. Physically, the monopole moment $\int \rho\,\mathrm{d}^3x$ is the conserved total mass and the dipole moment $\int \rho\,x^i\,\mathrm{d}^3x$ moves uniformly by conservation of momentum, so neither can oscillate: mass conservation kills monopole radiation, momentum conservation kills dipole radiation, and the quadrupole is the first moment free to radiate [1509]. This is the deep reason gravitational radiation is so feeble compared with the electric-dipole radiation of electromagnetism.

TT projection and the reduced quadrupole. The physical waveform is the TT part of Equation (A.56). Define the projector transverse to the line of sight, $P_{ij}(\boldsymbol{n}) = \delta_{ij} - n_i n_j$ (idempotent: $P_{ik}P_{kj} = P_{ij}$), and the TT projector

$$\Lambda_{ij,kl}(\boldsymbol{n}) = P_{ik}P_{jl} - \frac{1}{2}P_{ij}P_{kl}\,, \qquad \Lambda_{ij,kl}\Lambda_{kl,mn} = \Lambda_{ij,mn}\,. \tag{A.57}$$

Because Λ annihilates any term proportional to δ_{kl}, we may freely replace Q_{ij} by its trace-free part. We adopt, here and in the luminosity below, the *reduced quadrupole moment*

$$\mathcal{I}_{ij}(t) \equiv \int \rho(t,\boldsymbol{x})\left(x_i x_j - \frac{1}{3}\,r'^2\,\delta_{ij}\right)\mathrm{d}^3x = Q_{ij} - \frac{1}{3}\,\delta_{ij}\,Q_{kk}\,, \tag{A.58}$$

(with $r'^2 = x_k x_k$ the squared distance from the origin), in terms of which

$$h_{ij}^{\mathrm{TT}}(t,\boldsymbol{x}) = \frac{2G}{c^4 r}\,\Lambda_{ij,kl}(\boldsymbol{n})\,\ddot{\mathcal{I}}_{kl}(t - r/c)\,. \tag{A.59}$$

Radiated power. Insert Equation (A.59) into the flux Equation (A.47) and integrate over a large sphere. For an outgoing wave $h \propto r^{-1} \times$ (function of $t - r/c$) one has $\partial_r h = -c^{-1}\dot{h} + O(1/r^2)$, so the radial energy flux is $c\,t^{0r} = (c^3/32\pi G)\left\langle \dot{h}_{ij}^{\mathrm{TT}}\dot{h}_{ij}^{\mathrm{TT}}\right\rangle$ and

$$P = \frac{\mathrm{d}E}{\mathrm{d}t} = \frac{c^3}{32\pi G}\,r^2\oint\left\langle \dot{h}_{ij}^{\mathrm{TT}}\dot{h}_{ij}^{\mathrm{TT}}\right\rangle \mathrm{d}\Omega = \frac{c^3}{32\pi G}\cdot\frac{4G^2}{c^8}\oint \Lambda_{kl,mn}(\boldsymbol{n})\,\langle\dddot{\mathcal{I}}_{kl}\,\dddot{\mathcal{I}}_{mn}\rangle\,\mathrm{d}\Omega\,, \tag{A.60}$$

where the projector identity of Equation (A.57) collapsed the two Λ's into one. The angular integral needs only the elementary moments of the unit vector,

$$\oint n_i n_j\,\mathrm{d}\Omega = \frac{4\pi}{3}\,\delta_{ij}\,, \qquad \oint n_i n_j n_k n_l\,\mathrm{d}\Omega = \frac{4\pi}{15}\left(\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}\right)\,, \tag{A.61}$$

fixed by isotropy and by contracting both sides. For any constant symmetric trace-free A_{ij}, expanding Equation (A.57) gives $\Lambda_{ij,kl}A_{ij}A_{kl} = A_{ij}A_{ij} - 2A_{ij}A_{ik}n_j n_k + \frac{1}{2}(n_i n_j A_{ij})^2$, and with Equation (A.61),

$$\oint \Lambda_{ij,kl}\,A_{ij}A_{kl}\,\mathrm{d}\Omega = 4\pi\left(1 - \frac{2}{3} + \frac{1}{15}\right)A_{ij}A_{ij} = \frac{8\pi}{5}\,A_{ij}A_{ij}\,. \tag{A.62}$$

Substituting into Equation (A.60),

$$\boxed{P = \frac{G}{5c^5}\,\langle\dddot{\mathcal{I}}_{ij}\,\dddot{\mathcal{I}}_{ij}\rangle} \tag{A.63}$$

— Einstein's quadrupole luminosity [453, 2132], with the reduced moment Equation (A.58) and the third time derivative evaluated at retarded time. The prefactor $G/c^5 \approx 2.75\times10^{-53}\,\mathrm{W}^{-1}$ explains at a glance why laboratory sources are hopeless and only relativistic astrophysical masses radiate detectably; its inverse $c^5/G \approx 3.6\times10^{52}\,\mathrm{W}$ sets the natural luminosity scale of strong-field gravity.

A.1.7 Application: the circular compact binary

The cleanest astrophysical source is two point masses m_1, m_2 in a circular orbit — the configuration realized, to excellent approximation, by compact binaries in their late inspiral. Work in the centre-of-mass frame with total and reduced masses

$$M = m_1 + m_2\,, \qquad \mu = \frac{m_1 m_2}{M}\,, \tag{A.64}$$

separation a, and Kepler angular frequency

$$\Omega^2 = \frac{GM}{a^3}\,. \tag{A.65}$$

With the centre of mass at the origin, $\boldsymbol{x}_1 = (m_2/M)\,\boldsymbol{x}$ and $\boldsymbol{x}_2 = -(m_1/M)\,\boldsymbol{x}$ in terms of the relative coordinate $\boldsymbol{x}(t) = a(\cos\Omega t, \sin\Omega t, 0)$, so the quadrupole of the two δ-function masses reduces to that of a single mass μ on the relative orbit:

$$Q_{ij} = m_1 x_{1i} x_{1j} + m_2 x_{2i} x_{2j} = \left(\frac{m_1 m_2^2 + m_2 m_1^2}{M^2}\right) x_i x_j = \mu\, x_i x_j\,. \tag{A.66}$$

Using $\cos^2\theta = \tfrac{1}{2}(1+\cos 2\theta)$, $\sin^2\theta = \tfrac{1}{2}(1-\cos 2\theta)$, $\sin\theta\cos\theta = \tfrac{1}{2}\sin 2\theta$, the reduced moment Equation (A.58) has time-dependent part

$$\mathcal{I}_{xx} = \frac{\mu a^2}{2}\cos 2\Omega t + \text{const}\,, \quad \mathcal{I}_{yy} = -\frac{\mu a^2}{2}\cos 2\Omega t + \text{const}\,, \quad \mathcal{I}_{xy} = \frac{\mu a^2}{2}\sin 2\Omega t\,, \tag{A.67}$$

with $\mathcal{I}_{zz}$ constant. Everything oscillates at 2Ω: the mass distribution returns to itself after half an orbit, so

$$f_{\mathrm{GW}} = 2 f_{\mathrm{orb}} = \frac{\Omega}{\pi}\,. \tag{A.68}$$

Differentiating Equation (A.67) three times,

$$\dddot{\mathcal{I}}_{xx} = 4\mu a^2\Omega^3 \sin 2\Omega t\,, \qquad \dddot{\mathcal{I}}_{yy} = -4\mu a^2\Omega^3 \sin 2\Omega t\,, \qquad \dddot{\mathcal{I}}_{xy} = -4\mu a^2\Omega^3 \cos 2\Omega t\,, \tag{A.69}$$

whence, counting $\mathcal{I}_{xy} = \mathcal{I}_{yx}$ twice,

$$\dddot{\mathcal{I}}_{ij}\,\dddot{\mathcal{I}}_{ij} = 16\mu^2 a^4\Omega^6\left(2\sin^2 2\Omega t + 2\cos^2 2\Omega t\right) = 32\,\mu^2 a^4\Omega^6\,, \tag{A.70}$$

constant in time, so the average in Equation (A.63) is trivial:

$$P = \frac{32}{5}\frac{G}{c^5}\,\mu^2 a^4\Omega^6 = \boxed{\frac{32}{5}\frac{G^4}{c^5}\,\frac{m_1^2 m_2^2\,(m_1+m_2)}{a^5}} \tag{A.71}$$

after eliminating Ω with Equation (A.65).

Orbital decay. The Newtonian orbital energy is, by the virial relation $K = \tfrac{1}{2}\mu a^2\Omega^2 = \tfrac{1}{2}\,Gm_1m_2/a = -\tfrac{1}{2}U$,

$$E = K + U = -\frac{Gm_1m_2}{2a}\,. \tag{A.72}$$

Radiation drains it, $\dot{E} = -P$; differentiating Equation (A.72) and inserting Equation (A.71),

$$\frac{Gm_1m_2}{2a^2}\,\dot{a} = -P \qquad \Longrightarrow \qquad \dot{a} = -\frac{64}{5}\,\frac{G^3}{c^5}\,\frac{m_1m_2\,(m_1+m_2)}{a^3}\,. \tag{A.73}$$

The orbit shrinks, Ω grows, $P \propto a^{-5}$ grows faster: a runaway — the *chirp*.

Chirp mass and frequency evolution. Express the evolution in the observable $f \equiv f_{\mathrm{GW}}$. From Equations (A.65) and (A.68), $\pi f = \Omega = (GM)^{1/2}a^{-3/2}$, i.e. $a = (GM)^{1/3}(\pi f)^{-2/3}$. Substituting into Equations (A.71) and (A.72) and introducing the *chirp mass*

$$\mathcal{M} \equiv \frac{(m_1m_2)^{3/5}}{(m_1+m_2)^{1/5}} = \mu^{3/5}M^{2/5}\,, \qquad \mathcal{M}^{5/3} = \mu\,M^{2/3} = m_1m_2\,M^{-1/3}\,, \tag{A.74}$$

both energy and power depend on the masses only through $\mathcal{M}$:

$$E(f) = -\frac{1}{2}\,\mathcal{M}^{5/3} G^{2/3} (\pi f)^{2/3}\,, \qquad P(f) = \frac{32}{5}\,\frac{c^5}{G}\left(\frac{\pi G \mathcal{M} f}{c^3}\right)^{10/3}. \tag{A.75}$$

Energy balance $\dot{f}\,(\mathrm{d}E/\mathrm{d}f) = -P$ with $\mathrm{d}E/\mathrm{d}f = -\frac{1}{3}\mathcal{M}^{5/3} G^{2/3} \pi^{2/3} f^{-1/3}$ then gives

$$\boxed{\dot{f} = \frac{96}{5}\,\pi^{8/3}\left(\frac{G\mathcal{M}}{c^3}\right)^{5/3} f^{11/3}} \tag{A.76}$$

— the announced law $\dot{f} \propto \mathcal{M}^{5/3} f^{11/3}$. Measuring f and $\dot{f}$ at any moment of the inspiral therefore yields the chirp mass directly, with no knowledge of the distance; the distance then follows from the amplitude. That amplitude is read off Equations (A.59) and (A.67): for the optimal (face-on) orientation the two polarizations have common magnitude

$$h = \frac{4 G \mu a^2 \Omega^2}{c^4 r} = \frac{4}{r}\,\frac{(G\mathcal{M})^{5/3}}{c^4}\left(\frac{\pi f}{c}\right)^{2/3} \cdot c^{2/3} = \frac{4}{r}\left(\frac{G\mathcal{M}}{c^2}\right)^{5/3}\left(\frac{\pi f}{c}\right)^{2/3}, \tag{A.77}$$

using $a^2\Omega^2 = GM/a$ and Equation (A.74).

Numerical estimate (i): a GW150914-like binary. Take two black holes of $30\,M_\odot$ each at luminosity distance $r = 410\,\mathrm{Mpc}$, the parameters of the first LIGO detection to within its uncertainties (the measured values were $36\,M_\odot$ and $29\,M_\odot$ at $410^{+160}_{-180}\,\mathrm{Mpc}$ [2264]). We use $G = (6.674\,30 \pm 0.000\,15) \times 10^{-11}\,\mathrm{m^3/(kg\,s^2)}$ [2392], the exact $c = 299\,792\,458\,\mathrm{m/s}$ of the SI [2333], and $M_\odot = 1.989 \times 10^{30}\,\mathrm{kg}$. Then $m_1 = m_2 = 30\,M_\odot = 5.97 \times 10^{31}\,\mathrm{kg}$, $M = 60\,M_\odot = 1.193 \times 10^{32}\,\mathrm{kg}$, $\mu = 15\,M_\odot$, and

$$\mathcal{M} = \mu^{3/5} M^{2/5} = (15)^{3/5}(60)^{2/5}\,M_\odot \approx 26.1\,M_\odot = 5.19 \times 10^{31}\,\mathrm{kg}\,, \tag{A.78}$$

so that

$$\frac{G\mathcal{M}}{c^2} = \frac{6.674 \times 10^{-11} \times 5.19 \times 10^{31}}{8.988 \times 10^{16}}\,\mathrm{m} = 3.85 \times 10^4\,\mathrm{m}\,, \qquad \frac{G\mathcal{M}}{c^3} = 1.29 \times 10^{-4}\,\mathrm{s}\,. \tag{A.79}$$

Orbital geometry across the band. With $GM = 7.97 \times 10^{21}\,\mathrm{m^3/s^2}$, the separation at gravitational-wave frequency f is $a = (GM)^{1/3}(\pi f)^{-2/3}$. At the low edge of the detector band, $f = 35\,\mathrm{Hz}$: $a = 2.0 \times 10^7\,\mathrm{m/s}^{0.666\,666\,666\,666\,666\,7} \times (110\,1/\mathrm{s})^{-2/3} \approx 8.7 \times 10^5\,\mathrm{m}$ — two thirty-solar-mass black holes, each of Schwarzschild radius $2Gm/c^2 \approx 89\,\mathrm{km}$, orbiting 870 km apart at an orbital frequency of 17.5 Hz. Near merger the separation approaches a few hundred kilometres: at $a = 2.5 \times 10^5\,\mathrm{m}$,

$$\Omega = \sqrt{\frac{7.97 \times 10^{21}}{(2.5 \times 10^5)^3}}\,\mathrm{rad/s} = 714\,\mathrm{rad/s}\,, \qquad f_{\mathrm{GW}} = \frac{\Omega}{\pi} \approx 230\,\mathrm{Hz}\,, \tag{A.80}$$

reproducing the observed sweep of GW150914 from 35 Hz to about 250 Hz [2264]. *Strain.* At $f = 150\,\mathrm{Hz}$ and $r = 410\,\mathrm{Mpc} = 1.27 \times 10^{25}\,\mathrm{m}$, Equation (A.77) gives, with $(G\mathcal{M}/c^2)^{5/3} = (3.85 \times 10^4)^{5/3}\,\mathrm{m}^{5/3} = 4.4 \times 10^7\,\mathrm{m}^{5/3}$ and $(\pi f/c)^{2/3} = (1.57 \times 10^{-6})^{2/3}\,\mathrm{m}^{-2/3} = 1.35 \times 10^{-4}\,\mathrm{m}^{-2/3}$,

$$h = \frac{4 \times 4.4 \times 10^7 \times 1.35 \times 10^{-4}}{1.27 \times 10^{25}} \approx 1.9 \times 10^{-21}\,, \tag{A.81}$$

for optimal orientation; averaging over source inclination and detector antenna pattern reduces this by a factor of a few, in agreement with the observed peak strain of 1.0×10^{-21}

[2264]. By Equation (A.33) the LIGO arms of $L = 4\,\mathrm{km}$ then change length by $\Delta L = \frac{1}{2}hL \approx 2 \times 10^{-18}\,\mathrm{m}$ [2243]. *Chirp rate.* At $f = 35\,\mathrm{Hz}$, Equation (A.76) gives

$$\dot f = \frac{96}{5}\,\pi^{8/3}\left(1.29\times10^{-4}\right)^{5/3}(35)^{11/3}\,\mathrm{Hz/s} \approx 61\,\mathrm{Hz/s}\,, \tag{A.82}$$

so the residual time to coalescence, $\tau \approx \frac{3}{8} f/\dot f \approx 0.2\,\mathrm{s}$, matches the observed duration of the signal in band [2264]. All three numbers — band, amplitude, chirp — flow from Equations (A.76) and (A.77) with one chirp mass; that a single $\mathcal{M}$ fits the entire waveform is the quantitative content of the statement that GW150914 was a compact binary coalescence.

Numerical estimate (ii): orbital decay of PSR B1913+16. For a binary of period P_b, Kepler's law $P_b \propto a^{3/2}$ gives $\dot P_b/P_b = \frac{3}{2}\,\dot a/a$, and inserting Equation (A.73) with $a = (GM)^{1/3}(P_b/2\pi)^{2/3}$ yields the decay of the period. The derivation above assumed a circular orbit; for an eccentric orbit the same energy-balance computation, carried through the Keplerian ellipse harmonics, multiplies the circular result by the enhancement factor $f(e) = \left(1 + \frac{73}{24}e^2 + \frac{37}{96}e^4\right)(1-e^2)^{-7/2}$, which we quote from the standard treatment [2132]. Thus

$$\dot P_b = -\frac{192\pi}{5}\,\frac{G^{5/3}}{c^5}\left(\frac{P_b}{2\pi}\right)^{-5/3}\frac{m_p m_c}{(m_p+m_c)^{1/3}}\,f(e)\,. \tag{A.83}$$

The Hulse–Taylor pulsar PSR B1913+16, discovered in 1974 [1550], has [2275]

$$P_b = 27\,906.98\,\mathrm{s}\,,\quad e = 0.6171\,,\quad m_p = 1.438\,M_\odot\,,\quad m_c = 1.390\,M_\odot\,, \tag{A.84}$$

(masses themselves determined from two relativistic timing observables, so the test uses no free parameters). The pieces of Equation (A.83) are

$$f(e) = \frac{1 + \frac{73}{24}(0.3809) + \frac{37}{96}(0.1450)}{(0.6191)^{7/2}} = \frac{2.214}{0.1867} = 11.86\,, \tag{A.85}$$

$$\left(\frac{P_b}{2\pi}\right)^{5/3} = (4441.5)^{5/3}\,\mathrm{s}^{5/3} = 1.200\times10^{6}\,\mathrm{s}^{5/3}\,, \tag{A.86}$$

$$\frac{m_p m_c}{M^{1/3}} = \frac{7.908\times10^{60}}{1.778\times10^{10}}\,\mathrm{kg}^{5/3} = 4.447\times10^{50}\,\mathrm{kg}^{5/3}\,, \tag{A.87}$$

and assembling them with $G^{5/3} = 1.098\times10^{-17}$ and $c^5 = 2.422\times10^{42}$ (SI),

$$\dot P_b = -\frac{192\pi}{5}\times\frac{1.098\times10^{-17}\times8.33\times10^{-7}\times4.447\times10^{50}}{2.422\times10^{42}}\times11.86 \approx -2.40\times10^{-12}\,, \tag{A.88}$$

a dimensionless s/s: the orbit of period near eight hours shortens by about 76 µs per year. The full general-relativistic prediction with the precise timing parameters is $\dot P_b^{\mathrm{GR}} = (-2.402\,63 \pm 0.000\,05)\times10^{-12}$, and thirty-five years of timing give an observed intrinsic $\dot P_b = (-2.398 \pm 0.004)\times10^{-12}$ — a ratio of observed to predicted of 0.9983 ± 0.0016 [1703, 2275]. The same parameters give a present gravitational-wave luminosity $P \approx 7.8\times10^{24}\,\mathrm{W}$ from Equation (A.71) (times $f(e)$) at separation $a \approx 1.95\times10^{9}\,\mathrm{m}$ — about 2×10^{-2} of the Sun's electromagnetic output, radiated by two neutron stars orbiting within what would fit inside the Sun. Integrating Equation (A.73), the circular estimate gives coalescence after $a^4/(4\beta) \approx 5.2\times10^{16}\,\mathrm{s}$ (about 1.7 billion years, shortened to roughly 0.3 billion by the eccentricity); the binary pulsar is a young GW150914 caught three hundred million years before its chirp.

The two estimates close the loop of this proof: the strain, frequency sweep and chirp rate derived here are the quantities measured directly by the interferometers for GW150914, and the period decay Equation (A.83) is the quantity measured by pulsar timing for PSR B1913+16, matching Section 47.1. The experimental record of both confrontations — apparatus, data and uncertainties — is presented in Chapter 47.

A.2 Oppenheimer–Snyder Collapse: the Interior Matching

This appendix proves Theorem 45.23 (Chapter 45): the collapse of a uniform, pressureless, momentarily static ball of dust is an exact solution of the field equations, consisting of a contracting closed Friedmann–Lemaître–Robertson–Walker (FLRW) interior matched smoothly — induced metric and extrinsic curvature both continuous — to a Schwarzschild exterior across the falling surface [844]. The exterior half of the argument is already in the chapter: Birkhoff's theorem (Theorem 45.4) forces the outside geometry to be Equation (45.6), and the radial-plunge cycloid (Proposition 45.21) is the surface's worldline seen from outside. What remains — the interior solution, the identification of the boundary, and the junction — follows, in the treatment of [1509].

A.2.1 The interior: a contracting closed dust universe

Inside the ball the matter is homogeneous and isotropic about every comoving point, so the interior metric is of FLRW form; the momentarily static initial state will force the closed (positively curved) case, and we write it, in comoving coordinates $(\tau, \chi, \theta, \varphi)$ with $x^0 := c\tau$,

$$\mathrm{d}s^2 = -c^2\mathrm{d}\tau^2 + a^2(\tau)\left[\mathrm{d}\chi^2 + \sin^2\chi\left(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\varphi^2\right)\right], \tag{A.89}$$

which is Equation (45.34); τ is proper time on every comoving worldline. Write $g_{ij} = a^2\gamma_{ij}$ with γ_{ij} the metric of the unit 3-sphere and primes for $\mathrm{d}/\mathrm{d}x^0$. The Christoffel symbols of Equation (A.89) are, by Equation (13.299),

$$\Gamma^0{}_{ij} = a\,a'\,\gamma_{ij}\,, \qquad \Gamma^i{}_{0j} = \frac{a'}{a}\,\delta^i{}_j\,, \qquad \Gamma^i{}_{jk} = \tilde{\Gamma}^i{}_{jk}\,, \tag{A.90}$$

with $\tilde{\Gamma}$ the Christoffel symbols of γ_{ij} alone. Contracting the Riemann tensor Equation (13.306) and using the fact that the unit 3-sphere is maximally symmetric with Ricci tensor $\tilde{R}_{ij} = 2\gamma_{ij}$,

$$R_{00} = -3\,\frac{a''}{a}\,, \qquad R_{ij} = \left(a\,a'' + 2a'^2 + 2\right)\gamma_{ij}\,. \tag{A.91}$$

Pressureless dust comoving with these coordinates has $T_{\mu\nu} = \rho\,u_\mu u_\nu$ with $u_\mu = (-c, 0, 0, 0)$, hence $T_{00} = \rho c^2$, $T_{ij} = 0$ and trace $T = -\rho c^2$. Two facts follow before any field equation is solved. First, since $\Gamma^\mu{}_{00} = 0$ in Equation (A.90), the comoving worldlines are geodesics — as they must be: $\nabla_\mu T^{\mu\nu} = 0$ for dust is exactly the statement that each grain free-falls, and it is what makes the boundary of the truncated ball a geodesic of both geometries below. Second, in the Ricci form $R_{\mu\nu} = (8\pi G/c^4)\left(T_{\mu\nu} - \tfrac{1}{2}g_{\mu\nu}T\right)$ (Chapter 44) the two components of Equation (A.91) give, restoring τ via $\dot{a} = c\,a'$,

$$\ddot{a} = -\frac{4\pi G}{3}\,\rho\,a\,, \tag{A.92}$$

$$\dot{a}^2 + c^2 = \frac{8\pi G}{3}\,\rho\,a^2\,, \tag{A.93}$$

the second obtained by eliminating a'' between the 00 and ij equations. (These are the Friedmann equations of Chapter 48 for dust and $k = +1$; the derivation is kept here so that this proof is self-contained.) Differentiating Equation (A.93) and inserting Equation (A.92) yields $\dot{\rho}/\rho = -3\dot{a}/a$, i.e.

$$\rho\,a^3 = \rho_{\mathrm{m}}\,a_{\mathrm{m}}^3 = \text{const}\,, \tag{A.94}$$

mass conservation in a contracting volume.

"Momentarily static" means $\dot{a} = 0$ at $\tau = 0$; call the initial values a_{m}, ρ_{m}. Then Equation (A.93) at $\tau = 0$ reads

$$\frac{8\pi G}{3}\,\rho_{\mathrm{m}} = \frac{c^2}{a_{\mathrm{m}}^2}\,, \tag{A.95}$$

which is why the curvature had to be positive: a momentarily static homogeneous dust ball has nowhere to go but down its own cycloid. With Equations (A.94) and (A.95), Equation (A.93) becomes $\dot{a}^2 = c^2\,(a_\mathrm{m}/a - 1)$, which the cycloid solves: substituting

$$a = \frac{a_\mathrm{m}}{2}\,(1+\cos\eta)\;, \qquad c\tau = \frac{a_\mathrm{m}}{2}\,(\eta+\sin\eta) \tag{A.96}$$

gives, exactly as in the proof of Proposition 45.21, $\dot{a}^2 = c^2(1-\cos\eta)/(1+\cos\eta) = c^2\,(a_\mathrm{m}/a-1)$. The scale factor reaches $a=0$ at $\eta=\pi$, i.e. at proper time

$$\tau_\mathrm{collapse} = \frac{\pi a_\mathrm{m}}{2c}\,, \tag{A.97}$$

the same on every comoving worldline: by homogeneity, all the dust — centre and surface alike — arrives at the singularity simultaneously in comoving time. This is part (iii) of Theorem 45.23.

A.2.2 The boundary, and the matching conditions

Truncate the interior at $\chi=\chi_0$ (with $\chi_0<\pi/2$ for a ball less than half the 3-sphere). The boundary consists of comoving dust worldlines, which are geodesics of the interior geometry by the first fact above; its areal radius — read off the angular part of Equation (A.89) — is

$$R(\tau) = a(\tau)\sin\chi_0\,, \qquad R_0 := R(0) = a_\mathrm{m}\sin\chi_0\,. \tag{A.98}$$

Outside, spherical symmetry and Theorem 45.4 force the Schwarzschild geometry Equation (45.6) with some mass parameter M; the boundary, being made of freely falling dust with no pressure acting on it from either side, must follow a radial timelike geodesic of that exterior, released from rest at R_0. By Proposition 45.21 its areal radius is the cycloid Equation (45.31),

$$R = \frac{R_0}{2}\,(1+\cos\eta)\;, \qquad \tau = \sqrt{\frac{R_0^3}{8GM}}\;(\eta+\sin\eta)\;. \tag{A.99}$$

The interior assigns the same boundary the areal radius Equation (A.98) with $a(\tau)$ the cycloid Equation (A.96): the same shape $R=(R_0/2)(1+\cos\eta)$, with proper time $\tau = (a_\mathrm{m}/2c)\,(\eta+\sin\eta)$. The two descriptions of one worldline agree for all η iff

$$\sqrt{\frac{R_0^3}{8GM}} = \frac{a_\mathrm{m}}{2c} \qquad\Longleftrightarrow\qquad r_\mathrm{s} = \frac{2GM}{c^2} = \frac{R_0^3}{a_\mathrm{m}^2} = a_\mathrm{m}\sin^3\chi_0\,, \tag{A.100}$$

which is Equation (45.35). The mass identity follows at once: by Equation (A.95),

$$\frac{4\pi}{3}\,\rho_\mathrm{m} R_0^3 = \frac{c^2}{2G\,a_\mathrm{m}^2}\,a_\mathrm{m}^3\sin^3\chi_0 = \frac{c^2}{2G}\,a_\mathrm{m}\sin^3\chi_0 = \frac{c^2 r_\mathrm{s}}{2G} = M\,. \tag{A.101}$$

The Schwarzschild mass is the initial density times $\frac{4}{3}\pi R_0^3$ — the *Euclidean* volume of areal radius R_0, not the (larger) proper volume of the curved interior. The deficit is not an error: Mc^2 is the total energy including the (negative) gravitational binding energy, and the curved-volume excess of rest mass is exactly what binding has removed.

It remains to show that agreement of the boundary worldline is the *whole* of the junction condition — that the two geometries fit with no surface layer. Two conditions must hold on the matching hypersurface: the induced metrics must agree, and the extrinsic curvatures must agree.

Induced metric. Coordinatize the boundary by (τ,θ,φ). From inside, Equation (A.89) restricted to $\chi=\chi_0$ gives $-c^2\mathrm{d}\tau^2 + a^2\sin^2\chi_0\,\mathrm{d}\Omega^2 = -c^2\mathrm{d}\tau^2 + R(\tau)^2\mathrm{d}\Omega^2$. From outside,

along a radial worldline parametrized by its proper time at areal radius $R(\tau)$, the induced metric is likewise $-c^2\mathrm{d}\tau^2 + R(\tau)^2\mathrm{d}\Omega^2$. Given Equation (A.100) the two functions $R(\tau)$ coincide, so the induced metrics agree identically.

Extrinsic curvature. By spherical symmetry the extrinsic curvature has two independent components, $K^{\tau}{}_{\tau}$ and $K^{\theta}{}_{\theta} = K^{\varphi}{}_{\varphi}$. The $\tau\tau$ component measures the normal component of the boundary worldlines' acceleration, and vanishes on *both* sides because the boundary is geodesic in both geometries — comoving dust inside, radial free fall outside. For the angular component, from inside the outward unit normal is $n = a^{-1}\partial_\chi$; for a hypersurface of constant χ in a metric with no χ-cross terms, $K_{ij} = \frac{1}{2}\, n^{\chi}\partial_\chi g_{ij}$, and with $g_{\theta\theta} = a^2\sin^2\chi$,

$$K^{\theta}{}_{\theta} = \frac{K_{\theta\theta}}{g_{\theta\theta}} = \frac{a\sin\chi_0\cos\chi_0}{a^2\sin^2\chi_0} = \frac{\cos\chi_0}{a\sin\chi_0} = \frac{\cos\chi_0}{R}\,. \tag{A.102}$$

From outside, write $f := 1 - r_{\mathrm{s}}/R$ and let $u^\mu = (u^t, u^r)$ be the falling boundary's four-velocity, with $u^t = \mathcal{E}/(fc^2)$ and $c^2(u^r)^2 = \mathcal{E}^2 - fc^4$ (Proposition 45.21). The outward unit normal $n^\mu = (n^t, n^r)$ is fixed by $n_\mu u^\mu = 0$ and $n_\mu n^\mu = 1$: orthogonality gives $n^t = u^r n^r/(f^2c^2u^t)$, and substituting into the normalization $-fc^2(n^t)^2 + f^{-1}(n^r)^2 = 1$,

$$(n^r)^2\left[\frac{1}{f} - \frac{(u^r)^2}{f^3c^2\,(u^t)^2}\right] = \frac{(n^r)^2}{f}\,\frac{\mathcal{E}^2 - c^2\,(u^r)^2}{\mathcal{E}^2} = (n^r)^2\,\frac{c^4}{\mathcal{E}^2} = 1\,,$$

using $f^3c^2(u^t)^2 = f\,\mathcal{E}^2/c^2$ in the first step and $\mathcal{E}^2 - c^2(u^r)^2 = fc^4$ in the second; so $n^r = \mathcal{E}/c^2$. Since the only angular Christoffel symbol involved is $\Gamma^{\theta}{}_{r\theta} = 1/R$ (Equation (45.2)),

$$K^{\theta}{}_{\theta} = n^r\,\Gamma^{\theta}{}_{r\theta} = \frac{\mathcal{E}}{c^2R} = \frac{\sqrt{1 - r_{\mathrm{s}}/R_0}}{R}\,. \tag{A.103}$$

The two expressions Equations (A.102) and (A.103) agree iff $\cos\chi_0 = \sqrt{1 - r_{\mathrm{s}}/R_0}$, i.e. iff $r_{\mathrm{s}} = R_0\sin^2\chi_0 = a_{\mathrm{m}}\sin^3\chi_0$ — precisely the condition Equation (A.100) already imposed by the worldline. The junction is therefore smooth, with no surface shell, exactly when Equation (45.35) holds; parts (i) and (ii) of Theorem 45.23 are proved.

A.2.3 The global picture

The matched spacetime settles the questions the vacuum extension of the chapter left open. The surface crosses $r = r_{\mathrm{s}}$ at the finite comoving time given by η_{h} with $\cos\eta_{\mathrm{h}} = 2r_{\mathrm{s}}/R_0 - 1$; from that moment the exterior region contains trapped surfaces (Remark 45.26) and the vacuum part of the spacetime is the regions I and II of the Kruskal diagram (Remark 45.20) — the white-hole region III and the second universe IV are excised, their place taken by the matter-filled interior, which is why they are artefacts of vacuum eternity rather than predictions about collapse. A distant observer, meanwhile, receives the exponentially redshifted last light of Proposition 45.22: the "frozen star" outside, the finite-time singularity inside, with no contradiction between them [844, 1509].

A.3 The Cantor–Schröder–Bernstein Theorem

This appendix proves Theorem 3.72 of Chapter 3: two sets that inject into each other are equipotent. It is what makes the comparison of cardinals a genuine order relation rather than a pair of unrelated inequalities, and it is used immediately in Corollary A.3 to identify the cardinal of the continuum with that of the power set of $\mathbb{N}$. The proof is elementary but not obvious — neither injection need be surjective anywhere, and the bijection must be manufactured out of the two of them.

Theorem A.1 (Cantor–Schröder–Bernstein)**.** *Let X and Y be sets and let $f : X \longrightarrow Y$ and $g : Y \longrightarrow X$ be injective. Then there exists a bijection $h : X \longrightarrow Y$.*
Rests on Definition 3.45 and Proposition 3.48.

Proof. *Derives Theorem A.1.*
The obstruction to using g^{-1} as the bijection is the set of points of X outside the image of g, where g^{-1} is undefined. Track where those points propagate under repeated application of $g \circ f$, and use f there instead.

Define a sequence of subsets of X by

$$C_0 := X \setminus g(Y)\,, \qquad C_{n+1} := g(f(C_n)) \quad (n \geq 0)\,, \tag{A.104}$$

and let

$$C := \bigcup_{n \geq 0} C_n\,. \tag{A.105}$$

Now define $h : X \longrightarrow Y$ by

$$h(x) := \begin{cases} f(x) & \text{if } x \in C\,, \\ g^{-1}(x) & \text{if } x \notin C\,. \end{cases} \tag{A.106}$$

h is well defined. The only question is the second branch. If $x \notin C$ then in particular $x \notin C_0 = X \setminus g(Y)$, so $x \in g(Y)$; and since g is injective there is exactly one $y \in Y$ with $g(y) = x$. Write $g^{-1}(x)$ for it.

h is injective. Each branch is injective on its own domain: f by hypothesis, and g^{-1} because g is a map. It remains to check that the two branches never collide, i.e. that

$$f(C) \cap g^{-1}(X \setminus C) = \varnothing\,. \tag{A.107}$$

Suppose not, and let $f(c) = g^{-1}(x)$ with $c \in C$ and $x \notin C$. Applying g to both sides gives $x = g(f(c))$. Since $c \in C$, there is an n with $c \in C_n$, whence

$$x = g(f(c)) \in g(f(C_n)) = C_{n+1} \subset C\,,$$

contradicting $x \notin C$. This proves Equation (A.107), and with it the injectivity of h.

h is surjective. Let $y \in Y$ and consider the point $g(y) \in X$. There are two cases, and they are exhaustive by Equation (3.25).

If $g(y) \notin C$, then by the second branch of Equation (A.106),

$$h(g(y)) = g^{-1}(g(y)) = y\,,$$

so y is attained.

If $g(y) \in C$, then $g(y) \in C_n$ for some n. That n cannot be 0, because $g(y)$ lies in $g(Y)$ while $C_0 = X \setminus g(Y)$ does not meet $g(Y)$. So $n = m + 1$ for some $m \geq 0$ and $g(y) \in C_{m+1} = g(f(C_m))$, i.e. $g(y) = g(f(c))$ for some $c \in C_m$. Injectivity of g gives $y = f(c)$, and since $c \in C_m \subset C$ the first branch of Equation (A.106) yields $h(c) = f(c) = y$. Again y is attained.

Being injective and surjective, h is a bijection by Proposition 3.48. □

Remark A.2 (No choice is used). The construction Equations (A.104) to (A.106) is explicit: given f and g, the bijection h is determined, with no appeal to Axiom 3.78. This matters, because the companion statement that *any* two cardinals are comparable — that at least one of the two injections always exists — is equivalent to the axiom of choice. CSB says that comparability, where it holds, is antisymmetric; it does not say that any two sets are comparable.

Corollary A.3 (The continuum is the power set of the naturals)**.** $|\mathbb{R}| = |\mathcal{P}(\mathbb{N})|$, *that is* $\mathfrak{c} = 2^{\aleph_0}$.

Rests on Theorem A.1 and Corollary 3.68.

Proof. *Derives Corollary A.3.*

We exhibit injections in both directions and invoke Theorem A.1.

An injection $\mathcal{P}(\mathbb{N}) \longrightarrow \mathbb{R}$. Send $A \subset \mathbb{N}$ to the real number whose base-3 expansion has digit 1 at place n when $n \in A$ and digit 0 otherwise,

$$\Phi(A) := \sum_{n \in A} 3^{-n} \,. \tag{A.108}$$

If $A \neq B$, let k be the least element of their symmetric difference, say $k \in A \setminus B$. Then

$$\Phi(A) - \Phi(B) \geq 3^{-k} - \sum_{n>k} 3^{-n} = 3^{-k} - \frac{3^{-k}}{2} = \frac{3^{-k}}{2} > 0 \,,$$

since the digits omitted from B beyond place k contribute at most the full geometric tail. Hence $\Phi(A) \neq \Phi(B)$ and Φ is injective. Using digits 0 and 1 in base 3 — rather than base 2 — is exactly what makes the tail strictly smaller than the leading term, so that the two expansions cannot coincide.

An injection $\mathbb{R} \longrightarrow \mathcal{P}(\mathbb{N})$. Send $x \in \mathbb{R}$ to its Dedekind cut $\Psi(x) := \{q \in \mathbb{Q} \mid q < x\}$, injective because $\mathbb{Q}$ is dense in $\mathbb{R}$: if $x < y$ there is a rational strictly between them, lying in $\Psi(y)$ but not in $\Psi(x)$. This lands in $\mathcal{P}(\mathbb{Q})$ rather than $\mathcal{P}(\mathbb{N})$, but $|\mathbb{Q}| = \aleph_0$ by Corollary 3.68, and a bijection $\mathbb{N} \longrightarrow \mathbb{Q}$ induces a bijection $\mathcal{P}(\mathbb{Q}) \longrightarrow \mathcal{P}(\mathbb{N})$ by taking preimages. Composing gives the required injection. □

Appendix A.3 discharges the proof obligation of Theorem 3.72, and Corollary A.3 supplies the identification $\mathfrak{c} = 2^{\aleph_0}$ used in Section 3.5.3 when the continuum hypothesis is stated. The next appendix treats the other half of the foundational material of that chapter.

A.4 The Completeness Theorem

This appendix proves Theorem 3.84 of Chapter 3: for first-order logic, semantic consequence and syntactic derivability coincide,

$$T \vDash \varphi \iff T \vdash \varphi \,. \tag{A.109}$$

The left-to-right direction is the substantive one and is equivalent to a statement about existence: *every consistent theory has a model.* That is what the Henkin construction builds, and it builds it out of nothing but the syntax — the elements of the model are the closed terms of the language itself. The theorem is Gödel's doctoral work [654]; the proof given here is Henkin's later and simpler one.

Throughout, the logic is first-order logic with equality, so the equality axioms — reflexivity $t = t$ and the congruence schemas asserting that equals may be substituted in any function or relation symbol — are part of the logical apparatus and available in every derivation. The language is assumed countable, which every language in this book is; the uncountable case needs only Zorn's lemma (Axiom 3.78) in place of the enumeration in Lemma A.6.

A.4.1 Soundness

Theorem A.4 (Soundness)**.** *If* $T \vdash \varphi$ *then* $T \vDash \varphi$.

Rests on Axiom 3.34, Definition 3.14, and Equation (3.10).

Proof. *Derives Theorem A.4.*

Induction on the length of the derivation, using Axiom 3.34 at the meta-level. Let M be any structure with $M \vDash T$, and let $\psi_1, \dots, \psi_k$ be a derivation of φ from T. We show every ψ_i is true in M.

If ψ_i is a member of T, it is true in M by assumption. If it is a logical axiom, it is true in every structure whatever: the propositional axioms are tautologies in the sense of Definition 3.14, and their truth tables were computed once and for all in Section 3.1.2; the quantifier axiom $\forall x\, \psi(x) \to \psi(t)$ holds because if ψ is satisfied by every element it is satisfied by the one denoted by t; and the equality axioms hold because equality is interpreted as genuine identity on the domain.

If ψ_i follows by modus ponens from ψ_j and $\psi_j \to \psi_i$ with $j < i$, then both are true in M by the induction hypothesis, and row two of Equation (3.10) — the only row in which a conditional is false — is thereby excluded, so ψ_i is true. If ψ_i is $\forall x\, \psi$ obtained by generalization from ψ, where x does not occur free in T, then ψ is true in M under every assignment to x, which is what $\forall x\, \psi$ asserts.

Every line is therefore true in M, in particular the last, so $M \vDash \varphi$. As M was an arbitrary model of T, $T \vDash \varphi$. □

Soundness is the direction that makes derivations worth performing; it is also the direction used, in Theorem A.30, to conclude that Q does not prove a sentence false in $\mathbb{N}$. The remaining direction occupies the rest of this section.

A.4.2 Maximal consistent sets

Definition A.5 (Maximal consistent)**.** A set S of sentences is *maximal consistent* if it is consistent in the sense of Definition 3.82 and no proper superset of it is consistent.

Rests on Definition 3.82.

Lemma A.6 (Lindenbaum)**.** *Every consistent set of sentences extends to a maximal consistent set.*

Rests on Definition A.5 and Proposition 3.67.

Proof. *Derives Lemma A.6.*

The language is countable, so its sentences can be listed $\varphi_0, \varphi_1, \varphi_2, \dots$ — there are countably many finite strings over a countable alphabet, by Proposition 3.67. Given a consistent S, define an increasing chain by $S_0 := S$ and

$$S_{n+1} := \begin{cases} S_n \cup \{\varphi_n\} & \text{if this is consistent}, \\ S_n \cup \{\neg\varphi_n\} & \text{otherwise}. \end{cases} \tag{A.110}$$

Each S_n is consistent, by induction on n. The base case is the hypothesis on S. For the step, suppose S_n is consistent but both $S_n \cup \{\varphi_n\}$ and $S_n \cup \{\neg\varphi_n\}$ are not. Inconsistency of the first gives $S_n \vdash \neg\varphi_n$ and of the second $S_n \vdash \varphi_n$ — in each case by discharging the assumption, which is the deduction theorem — so S_n proves both a sentence and its negation, contradicting its consistency. Hence at least one of the two branches of Equation (A.110) is consistent, and S_{n+1} is.

Let $S^* := \bigcup_{n \geq 0} S_n$. It is consistent: a derivation of a contradiction is a finite object and mentions only finitely many members of S^*, all of which lie in some single S_n — the chain is increasing — and that S_n was shown consistent. It is maximal: every sentence of the language is some φ_n, and Equation (A.110) placed either it or its negation in S_{n+1}, so no consistent sentence can be added. □

Lemma A.7 (Behaviour of a maximal consistent set)**.** *Let S^* be maximal consistent. Then for all sentences φ, ψ:*

1. *exactly one of* φ *and* $\neg\varphi$ *belongs to* S^*;

2. S^* *is deductively closed: if* $S^* \vdash \varphi$ *then* $\varphi \in S^*$;

3. $\varphi \wedge \psi \in S^*$ *if and only if both* $\varphi \in S^*$ *and* $\psi \in S^*$;

4. $\varphi \vee \psi \in S^*$ *if and only if* $\varphi \in S^*$ *or* $\psi \in S^*$;

5. $\varphi \to \psi \in S^*$ *if and only if* $\varphi \notin S^*$ *or* $\psi \in S^*$.

Rests on Definition A.5 and Proposition 3.22.

Proof. *Derives Lemma A.7.*

(1) Not both, by consistency. At least one: if neither is in S^*, then by maximality $S^* \cup \{\varphi\}$ is inconsistent, giving $S^* \vdash \neg\varphi$, and likewise $S^* \vdash \varphi$; that contradicts consistency.

(2) If $S^* \vdash \varphi$ then $S^* \cup \{\varphi\}$ is consistent — adding what is already derivable cannot produce a new contradiction — so maximality forces $\varphi \in S^*$.

(3)–(5) Each follows from (1) and (2) together with the propositional tautologies of Proposition 3.22. For (5): if $\varphi \notin S^*$ then $\neg\varphi \in S^*$ by (1), and $\neg\varphi \vdash \varphi \to \psi$, so $\varphi \to \psi \in S^*$ by (2); if $\psi \in S^*$ the same conclusion follows from $\psi \vdash \varphi \to \psi$. Conversely if $\varphi \to \psi \in S^*$ and $\varphi \in S^*$, modus ponens and (2) give $\psi \in S^*$. The other two are proved the same way. □

A.4.3 Henkin witnesses

A maximal consistent set decides every sentence, but it may assert $\exists x\, \varphi(x)$ without containing any instance $\varphi(t)$ — and then no model can be read off it, because there is no term available to serve as the witness. The remedy is to put the witnesses into the language by hand.

Lemma A.8 (Adding witnesses preserves consistency)**.** *Let* S *be a consistent set of* L*-sentences. Let* L' *extend* L *by a new constant* c_φ *for each* L*-formula* $\varphi(x)$ *with exactly one free variable, and let*

$$H_\varphi : \quad \exists x\, \varphi(x) \to \varphi(c_\varphi) \tag{A.111}$$

be the corresponding Henkin axiom. *Then* $S \cup \{H_\varphi \mid \varphi\}$ *is consistent as a set of* L'*-sentences.*
Rests on Definition 3.82.

Proof. *Derives Lemma A.8.*

A derivation is finite, so if the extended set were inconsistent, finitely many Henkin axioms would already suffice; it is enough to show that adding one at a time preserves consistency. So suppose S' is consistent, S' does not mention the constant $c := c_\varphi$, and $S' \cup \{H_\varphi\}$ is inconsistent. Then

$$S' \vdash \neg H_\varphi\,, \qquad \text{that is} \qquad S' \vdash \exists x\, \varphi(x) \wedge \neg\varphi(c)\,.$$

In particular $S' \vdash \neg\varphi(c)$.

Now the crucial step. The constant c occurs nowhere in S', so it plays no role in the derivation beyond being a name; replacing every occurrence of c throughout the derivation by a variable y that appears nowhere in it yields again a correct derivation, and therefore $S' \vdash \neg\varphi(y)$ with y free and unconstrained. Generalization is then legitimate — its side condition is exactly that the variable is not free in the premises — and gives

$$S' \vdash \forall y\, \neg\varphi(y)\,, \qquad \text{i.e.} \qquad S' \vdash \neg\exists x\, \varphi(x)\,.$$

But $S' \vdash \exists x\, \varphi(x)$ was established above, so S' is inconsistent, contrary to hypothesis. Hence $S' \cup \{H_\varphi\}$ is consistent. □

Adding constants creates new formulas, which need witnesses of their own, so one application does not suffice. Iterate: set $L_0 := L$ and $S_0 := S$, let L_{n+1} and S_{n+1} be the result of applying Lemma A.8 to L_n and S_n, and put $L_\infty := \bigcup_n L_n$ and $S_\infty := \bigcup_n S_n$. Every L_∞-formula lies in some L_n and so has its witness constant in L_{n+1}; and S_∞ is consistent because any derivation of a contradiction from it is finite and lives inside some consistent S_n. Finally apply Lemma A.6 to S_∞ inside L_∞, giving a set

$$T^* \supset S\,, \qquad \text{maximal consistent and containing every } H_\varphi\,. \tag{A.112}$$

Extending to a maximal set adds sentences but removes none, so the Henkin axioms survive.

A.4.4 The term model

Everything needed to build a structure is now inside T^*. The domain will be the closed terms of L_∞ — expressions such as 0, $f(c_3)$, $g(c_1, f(c_2))$ — with terms identified exactly when T^* says they are equal.

Definition A.9 (The term structure)**.** Let CT be the set of closed L_∞-terms, and define

$$t \sim s \quad :\Longleftrightarrow \quad (t = s) \in T^*\,. \tag{A.113}$$

The structure M has domain CT$/\!\sim$, the set of classes $[t]$, and interprets

$$c^M := [c] \quad \text{for each constant } c\,, \tag{A.114}$$

$$f^M([t_1], \dots, [t_n]) := [f(t_1, \dots, t_n)]\,, \tag{A.115}$$

$$([t_1], \dots, [t_n]) \in R^M \quad :\Longleftrightarrow \quad R(t_1, \dots, t_n) \in T^*\,. \tag{A.116}$$

Rests on Definition A.5 and Equation (A.112)*.*

Lemma A.10. *$\sim$ is an equivalence relation,* CT *is non-empty, and Equations* (A.115) *and* (A.116) *do not depend on the representatives chosen.*
Rests on Definitions 3.58 and A.9, Lemma A.7, and Theorem 3.60.

Proof. *Derives Lemma A.10.*
Reflexivity: $t = t$ is a logical axiom, so it lies in T^* by Lemma A.7(2). Symmetry and transitivity: the equality congruence schemas give $\vdash (t = s) \to (s = t)$ and $\vdash ((t = s) \wedge (s = u)) \to (t = u)$, and deductive closure transfers these to membership in T^*. So $\sim$ satisfies the three clauses of Definition 3.58 and, by Theorem 3.60, partitions CT into classes.
CT is non-empty because L_∞ contains the Henkin constants, of which there is at least one; a structure must have a non-empty domain, and this is where that is secured.
Well-definedness: suppose $t_i \sim s_i$ for each i, i.e. $(t_i = s_i) \in T^*$. The congruence schema for the function symbol f gives

$$\vdash \Big(\bigwedge_i t_i = s_i\Big) \to f(t_1, \dots, t_n) = f(s_1, \dots, s_n)\,,$$

so by Lemma A.7(2),(3) the conclusion lies in T^* and $[f(\boldsymbol{t})] = [f(\boldsymbol{s})]$. The congruence schema for the relation symbol R gives the same conclusion for Equation (A.116). □

A.4.5 The truth lemma

Lemma A.11 (Truth lemma)**.** *For every L_∞-sentence φ,*

$$M \vDash \varphi \iff \varphi \in T^*\,. \tag{A.117}$$

Rests on Definition A.9 and Lemmas A.7, A.8 and A.10.

Proof. *Derives Lemma A.11.*

Induction on the number of connectives and quantifiers in φ. The statement being proved is about all sentences of that complexity at once, which is what makes the quantifier case go through.

Atomic. A closed atomic sentence is $R(t_1, \dots, t_n)$ or $t = s$. For the first, Equation (A.116) says $M \vDash R(t_1, \dots, t_n)$ precisely when $R(t_1, \dots, t_n) \in T^*$. For the second, $M \vDash t = s$ means $[t] = [s]$, which by Equation (A.113) means $(t = s) \in T^*$. Note that the interpretation of a closed term t in M is $[t]$ itself, by induction on the term using Equations (A.114) and (A.115).

Negation. $M \vDash \neg\varphi$ iff $M \nvDash \varphi$, iff $\varphi \notin T^*$ by the induction hypothesis, iff $\neg\varphi \in T^*$ by Lemma A.7(1).

Conditional. $M \vDash \varphi \to \psi$ iff $M \nvDash \varphi$ or $M \vDash \psi$, which by the induction hypothesis is $\varphi \notin T^*$ or $\psi \in T^*$, which by Lemma A.7(5) is $\varphi \to \psi \in T^*$. The cases of $\wedge$ and $\vee$ are identical, using clauses (3) and (4).

Existential. Every element of the domain is $[t]$ for some closed term t, so

$$M \vDash \exists x\, \varphi(x) \quad \text{iff} \quad M \vDash \varphi(t) \text{ for some closed term } t\,.$$

Each $\varphi(t)$ has fewer quantifiers than $\exists x\, \varphi(x)$, so the induction hypothesis applies to it and the right-hand side is equivalent to $\varphi(t) \in T^*$ for some closed t.

If $\exists x\, \varphi(x) \in T^*$, the Henkin axiom Equation (A.111) for φ is in T^* by Equation (A.112), and modus ponens with Lemma A.7(2) puts $\varphi(c_\varphi) \in T^*$; that is the required witness. Conversely if $\varphi(t) \in T^*$ for some closed t, then since $\vdash \varphi(t) \to \exists x\, \varphi(x)$ is a logical axiom, deductive closure gives $\exists x\, \varphi(x) \in T^*$.

Universal. $\forall x\, \varphi$ is treated as $\neg\exists x\, \neg\varphi$, already covered. □

A.4.6 Completeness, and compactness

Theorem A.12 (Model existence)**.** *Every consistent set of sentences has a model.*
Rests on Lemma A.11, Definition A.9, and Equation (A.112)*.*

Proof. *Derives Theorem A.12.*

Given consistent S, build T^* as in Equation (A.112) and let M be the term structure of Definition A.9. By Lemma A.11, M satisfies exactly the sentences of T^*, and $S \subset T^*$, so $M \vDash S$. The model is a structure for L_∞; forgetting the interpretations of the added constants leaves a model of S in the original language. □

Theorem A.13 (Completeness)**.** *$T \vDash \varphi$ implies $T \vdash \varphi$. With Theorem A.4, this establishes Equation* (A.109)*.*
Rests on Theorems A.4 and A.12.

Proof. *Derives Theorem A.13.*

Contrapositive. Suppose $T \nvdash \varphi$. Then $T \cup \{\neg\varphi\}$ is consistent — an inconsistency would give $T \vdash \varphi$ by reductio — so by Theorem A.12 it has a model M. That M satisfies T and falsifies φ, so $T \nvDash \varphi$. □

Corollary A.14 (Compactness)**.** *If every finite subset of T has a model, then T has a model.*
Rests on Theorems A.4 and A.12.

Proof. *Derives Corollary A.14.*

If T had no model it would, by Theorem A.12, be inconsistent, so some derivation would produce a contradiction from it. A derivation is a finite object and cites only finitely many members of T; those form a finite inconsistent subset, which by Theorem A.4 has no model. This contradicts the hypothesis. □

Compactness is the corollary a physicist is most likely to meet, because it manufactures models nobody intended. Take the theory of the ordered field $\mathbb{R}$ (Chapter 7), adjoin a new constant ϵ and the infinitely many axioms $0 < \epsilon < 1/\overline{n}$, one for each natural number n. Any *finite* subset mentions only finitely many of them and is satisfied in $\mathbb{R}$ itself, by choosing ϵ small enough. Compactness then hands over a model of the entire set: an ordered field elementarily equivalent to $\mathbb{R}$ — satisfying every first-order sentence that $\mathbb{R}$ satisfies — but containing an element smaller than every positive rational. That is a rigorous infinitesimal, and the non-standard analysis built on it is a legitimate alternative foundation for the calculus. The same argument shows no first-order theory can pin down $\mathbb{N}$ up to isomorphism, which is the model-theoretic shadow of Theorem 3.87.

Appendix A.4 discharges the proof obligation of Theorem 3.84, and it is worth restating why this sits beside Theorem 3.87 without tension. Completeness is a statement about the *logic*: the calculus derives everything that follows from the premises, whatever the premises are. Incompleteness is a statement about a particular *theory*: the axioms of arithmetic do not, among themselves, settle every arithmetical sentence. A complete calculus applied to incomplete axioms yields exactly what Equation (3.88) describes, a sentence that neither follows nor fails to follow — and by Theorem A.12 there are then models of the axioms in which it holds and models in which it does not.

A.5 Arithmetization and the Incompleteness Theorems

This appendix supplies the technical machinery behind Sections 3.8 and 3.9 of Chapter 3: the coding of syntax into arithmetic, the diagonal lemma (Lemma 3.86), Rosser's strengthening of the first incompleteness theorem, the derivability conditions from which the second theorem follows, and Church's theorem on the undecidability of first-order validity (Theorem 3.98). Throughout, T is an effectively axiomatized first-order theory in the language of arithmetic $\{0, S, +, \cdot\}$ of Definition 3.83 that contains *Robinson arithmetic* Q: the successor, addition and multiplication axioms of that definition, *without* the induction schema, together with the one axiom that induction would otherwise supply,

$$\forall x \, (x \neq 0 \to \exists y \, (x = Sy)) \, . \tag{A.118}$$

PA proves Equation (A.118) by induction, so once the schema is dropped it must be assumed outright; without it the bounded-quantifier lemmas used below all fail. Q is therefore *finitely* axiomatized, which Theorem A.30 depends on, and it is already strong enough for everything except the derivability conditions of Appendix A.5.5, which need PA itself. The order is the defined relation

$$x \leq y \;:\equiv\; \exists z \, (z + x = y) \, , \qquad x < y \;:\equiv\; Sx \leq y \, . \tag{A.119}$$

Everything below applies verbatim to PA and, through the standard translation of arithmetic into set theory, to ZFC.

A.5.1 Gödel numbering

Fix an injective assignment of positive integers to the finitely many symbols of the language, and code a finite string $\sigma_1 \sigma_2 \cdots \sigma_k$ of symbols by

$$\ulcorner \sigma_1 \cdots \sigma_k \urcorner := p_1^{c(\sigma_1)} p_2^{c(\sigma_2)} \cdots p_k^{c(\sigma_k)} \, , \tag{A.120}$$

where p_i is the i-th prime and $c(\sigma)$ the code of the symbol σ. Unique factorization makes Equation (A.120) injective and makes decoding a matter of computing prime exponents. A finite *sequence* of strings — a derivation — is coded the same way, one prime per member. We write $\overline{n}$ for the *numeral* of n, the closed term $S^n(0)$ of the object language.

The choice of scheme is immaterial, as Remark 3.39 warned: any injective coding whose encoding and decoding operations are computable serves, and all the results below are invariant under changing it.

Proposition A.15 (Syntax is computable)**.** *Under Equation* (A.120) *the following relations on natural numbers are decidable in the sense of Definition 3.93: "n codes a formula", "n codes a sentence", "n codes an axiom of T", "m codes a T-derivation of the formula coded by n", and the function* $\mathrm{sub}(m, n)$ *returning the code of the result of substituting the numeral* $\overline{n}$ *for the free variable of the formula coded by* m*.*

Rests on Equation (A.120) *and Definitions 3.81 and 3.93.*

Derivation. Derives Proposition A.15.

Each is settled by a bounded search through the prime factorization of the argument, composed with the syntactic tests of Definition 3.80, which are finite string comparisons. Axiomhood is decidable precisely because T was assumed effectively axiomatized (Definition 3.81); this is the only hypothesis of the theorem that is not automatic, and it is where the assumption earns its place. Being a derivation is the conjunction of finitely many such tests, one per line of the coded sequence, each of which asks whether a line is an axiom or follows from earlier lines by one of the finitely many rules. □

A.5.2 Representability

Computability of a relation is a statement in the metatheory; what the incompleteness proofs need is that T can *talk about* the relation and prove the right instances.

Definition A.16 (Representability)**.** A relation $R \subset \mathbb{N}^k$ is *representable* in T if there is a formula $\rho(x_1, \dots, x_k)$ such that for all $n_1, \dots, n_k \in \mathbb{N}$,

$$R(n_1, \dots, n_k) \implies T \vdash \rho(\overline{n_1}, \dots, \overline{n_k})\,, \tag{A.121}$$

$$\neg R(n_1, \dots, n_k) \implies T \vdash \neg\rho(\overline{n_1}, \dots, \overline{n_k})\,. \tag{A.122}$$

A function is representable if its graph is, together with a provable uniqueness clause.

Rests on Definition 3.80.

Theorem A.17 (Representability)**.** *Every decidable relation and every computable total function is representable in Q, and hence in every theory containing Q. Moreover Q is Σ_1-complete: every true sentence of the form $\exists x_1 \cdots \exists x_k\, \delta$, with δ containing only bounded quantifiers, is provable in Q.*

Rests on Definitions 3.93 and A.16, Theorem A.25, and Lemma A.20.

The proof occupies the rest of this subsection. It is the one genuinely long construction in the chapter, and it is worth saying at the outset why it cannot be shortened: Q has no induction, so nothing may be proved inside Q by induction on a variable. Every induction below is performed in the metatheory, on a concrete numeral, and what it produces is not one theorem of Q but a recipe yielding a separate Q-derivation for each numeral. That is exactly the strength the incompleteness proofs need, and no more.

Bounded and existential formulas

Definition A.18 (Δ_0 and Σ_1)**.** A *bounded quantifier* is one of the forms $\forall x\,(x \le t \to \cdots)$ or $\exists x\,(x \le t \wedge \cdots)$, abbreviated $\forall x \le t$ and $\exists x \le t$, where t is a term not containing x. A formula is Δ_0 if all its quantifiers are bounded, and Σ_1 if it has the form $\exists x_1 \cdots \exists x_k\, \delta$ with δ of class Δ_0.

Rests on Equation (A.119).

The point of the restriction is that a Δ_0 sentence can be checked by a finite computation: every quantifier ranges over an explicitly bounded set of numbers.

Lemma A.19 (Numerals behave)**.** *For all $m, n \in \mathbb{N}$:*

1. *if $m + n = p$ then $Q \vdash \overline{m} + \overline{n} = \overline{p}$, and similarly $Q \vdash \overline{m} \cdot \overline{n} = \overline{q}$ when $mn = q$;*
2. *if $m \neq n$ then $Q \vdash \overline{m} \neq \overline{n}$;*
3. *if $m \leq n$ then $Q \vdash \overline{m} \leq \overline{n}$, and if $m > n$ then $Q \vdash \neg(\overline{m} \leq \overline{n})$;*
4. *Q proves the* bounded expansion

$$\forall z \left(z \leq \overline{m} \to z = \overline{0} \vee z = \overline{1} \vee \cdots \vee z = \overline{m}\right). \tag{A.123}$$

Rests on Definition 3.83 and Equations (A.118) and (A.119).

Proof. *Derives Lemma A.19.*

(1) Induction in the metatheory on n. For $n = 0$ the axiom $x + 0 = x$ gives $\overline{m} + \overline{0} = \overline{m}$. If $Q \vdash \overline{m} + \overline{n} = \overline{m+n}$, then the axiom $x + Sy = S(x + y)$ gives $\overline{m} + \overline{n+1} = S(\overline{m} + \overline{n}) = S\overline{m+n} = \overline{m+n+1}$. Multiplication is the same argument using $x \cdot 0 = 0$ and $x \cdot Sy = x \cdot y + x$. Note what happened: for each fixed pair (m, n) this is a finite chain of equalities, hence a genuine Q-derivation; the induction that generated the chain was ours, not Q's.

(2) Suppose $m \neq n$, say $m < n$. Metatheoretic induction on m. If $m = 0$ then $\overline{n}$ is $S\overline{n-1}$ and the axiom $Sx \neq 0$ applies directly. If $m > 0$, both numerals are successors, and the axiom $Sx = Sy \to x = y$ contraposed reduces the claim for (m, n) to the claim for $(m - 1, n - 1)$, which the induction hypothesis supplies.

(3) If $m \leq n$, take $z := \overline{n-m}$; by (1), $Q \vdash \overline{n-m} + \overline{m} = \overline{n}$, so $Q \vdash \exists z\,(z + \overline{m} = \overline{n})$, which is $\overline{m} \leq \overline{n}$ by Equation (A.119). If $m > n$, we must refute $\exists z\,(z + \overline{m} = \overline{n})$. By (4), applied with $\overline{n}$, any such z would satisfy $z = \overline{j}$ for some $j \leq n$; but then $z + \overline{m} = \overline{j+m}$ by (1), and $j + m \geq m > n$, so $\overline{j+m} \neq \overline{n}$ by (2). As j ranges over finitely many values, this is a finite case analysis inside Q.

(4) Metatheoretic induction on m. For $m = 0$: suppose $z \leq \overline{0}$, i.e. $w + z = \overline{0}$ for some w. If $z \neq \overline{0}$ then Equation (A.118) gives $z = Sv$ for some v, whence $w + Sv = S(w + v)$ by the addition axiom, so $\overline{0}$ is a successor, contradicting $Sx \neq 0$. Hence $z = \overline{0}$. This is the step that fails without Equation (A.118): nothing else in Q rules out an element that is neither 0 nor a successor.

For the step, assume Equation (A.123) for m and suppose $z \leq \overline{m+1}$, say $w + z = \overline{m+1} = S\overline{m}$. If $z = \overline{0}$ we are done. Otherwise $z = Sv$ by Equation (A.118), so $S(w + v) = S\overline{m}$, and injectivity of S gives $w + v = \overline{m}$, i.e. $v \leq \overline{m}$. The induction hypothesis then yields $v = \overline{j}$ for some $j \leq m$, so $z = Sv = \overline{j+1}$ with $j + 1 \leq m + 1$. □

Lemma A.20 (Σ_1-completeness)**.** *Every true Σ_1 sentence is provable in Q.*
Rests on Definition A.18, Lemma A.19, and Proposition 3.22.

Proof. *Derives Lemma A.20.*

First the Δ_0 case, by induction in the metatheory on the structure of the formula. Atomic sentences are equations and inequations between closed terms; evaluating the terms and applying Lemma A.19(1)–(3) settles them, and a true one is proved while a false one has its negation proved. The connectives are immediate: if the parts are decided, Lemma A.7-style propositional reasoning decides the compound, using only the tautologies of Proposition 3.22.

For a bounded quantifier, let $\forall z \leq \overline{m}\,\psi(z)$ be true. Then $\psi(\overline{j})$ is true for every $j \leq m$, and each is proved by the induction hypothesis; Equation (A.123) converts the finitely many instances into the universally quantified statement, since any z below $\overline{m}$ is provably one of the $\overline{j}$. If instead $\exists z \leq \overline{m}\,\psi(z)$ is true, some witness $\overline{j}$ with $j \leq m$ has $\psi(\overline{j})$ true and provable, and Lemma A.19(3) supplies $\overline{j} \leq \overline{m}$.

Now the general case. Let $\exists x_1 \cdots \exists x_k\, \delta$ be true, and let $n_1, \dots, n_k$ be witnesses. Then $\delta(\overline{n_1}, \dots, \overline{n_k})$ is a true Δ_0 sentence, hence provable, and existential generalization gives the Σ_1 sentence. $\square$

Coding sequences: the β-function

Representing a recursively defined function requires quantifying over the sequence of intermediate values, and arithmetic has no sequences. Gödel's device turns a sequence of arbitrary length into a pair of numbers.

Lemma A.21 (Chinese remainder theorem)**.** *Let $m_0, \dots, m_n$ be pairwise coprime positive integers and let $r_0, \dots, r_n$ satisfy $0 \le r_i < m_i$. Then some a has $a \equiv r_i \pmod{m_i}$ for every i.*

Proof. *Derives Lemma A.21.*

Put $P := m_0 m_1 \cdots m_n$ and $P_i := P/m_i$. Since the moduli are pairwise coprime, P_i is coprime to m_i, so there is u_i with $P_i u_i \equiv 1 \pmod{m_i}$. Set $a := \sum_i r_i P_i u_i$. Modulo m_i every term with $j \neq i$ vanishes, because m_i divides P_j, and the remaining term is $r_i P_i u_i \equiv r_i$. $\square$

Definition A.22 (Gödel's β)**.**

$$\beta(a, b, i) := \operatorname{rem}\big(a,\ 1 + (i+1)b\big)\,, \tag{A.124}$$

the remainder of a on division by $1 + (i+1)b$.

Lemma A.23 (Sequence lemma)**.** *For every finite sequence $s_0, s_1, \dots, s_n$ of natural numbers there exist a, b with $\beta(a, b, i) = s_i$ for all $i \le n$.*

Rests on Definition A.22 and Lemma A.21.

Proof. *Derives Lemma A.23.*

Let $c := \max\{n, s_0, \dots, s_n\}$ and put $b := c!$. Write $m_i := 1 + (i+1)b$ for $i = 0, \dots, n$.

The moduli are pairwise coprime. Suppose a prime p divides both m_i and m_j with $i < j \le n$. Then p divides their difference,

$$m_j - m_i = (j - i)\, b\,,$$

so p divides $(j - i)$ or p divides b. If p divided b then, since p also divides $m_i = 1 + (i+1)b$, it would divide the difference $m_i - (i+1)b = 1$, which is impossible. Hence p divides $j - i$. But $0 < j - i \le n \le c$, so $j - i$ is one of the factors of $c! = b$, giving $p \mid b$ — the case just excluded. No such prime exists, so $\gcd(m_i, m_j) = 1$.

The residues fit. Each $s_i \le c \le c! = b < 1 + (i+1)b = m_i$, so s_i is a legitimate remainder modulo m_i.

Lemma A.21 now supplies a with $a \equiv s_i \pmod{m_i}$ for every $i \le n$, and since $0 \le s_i < m_i$ that congruence says exactly $\operatorname{rem}(a, m_i) = s_i$, i.e. $\beta(a, b, i) = s_i$. $\square$

Lemma A.24. *The relation $\beta(a, b, i) = v$ is defined by the Δ_0 formula*

$$B(a, b, i, v): \quad \exists q \le a\ \big(a = q \cdot (1 + (i+1) \cdot b) + v\ \wedge\ v < 1 + (i+1) \cdot b\big)\,, \tag{A.125}$$

and Q proves that the value is unique: for each numeral triple, at most one v satisfies it.

Rests on Definitions A.18 and A.22 and Lemma A.19.

Proof. *Derives Lemma A.24.*

Equation (A.125) is the division algorithm written out: v is the remainder exactly when $a = q \cdot m + v$ with $v < m$. The quotient q is at most a, so bounding its quantifier by a loses nothing, and every quantifier in Equation (A.125) is therefore bounded. For uniqueness at numeral arguments: if v, v' both satisfied it with $v < v'$, subtracting gives $(q - q')m = v' - v$ with $0 < v' - v < m$, impossible for a multiple of m; and by Lemma A.19 this finite arithmetic is carried out inside Q for each numeral instance. $\square$

Representing the computable functions

Theorem A.25. *Every primitive recursive function is representable in Q.*
Rests on Definition A.16 and Lemmas A.19, A.20, A.23 and A.24.

Proof. *Derives Theorem A.25.*

Induction in the metatheory on the construction of the function.

Initial functions. The zero function is represented by $y = \overline{0}$; the successor by $y = Sx$; the projection π_i^n by $y = x_i$. In each case Equation (A.121) holds because the defining equation is provable for numerals by Lemma A.19(1), and Equation (A.122) because a wrong value is refuted by Lemma A.19(2).

Composition. Let $f(\boldsymbol{x}) = h(g_1(\boldsymbol{x}), \dots, g_k(\boldsymbol{x}))$ with $h, g_1, \dots, g_k$ represented by $\eta, \gamma_1, \dots, \gamma_k$. Take

$$\varphi(\boldsymbol{x}, y) : \quad \exists z_1 \cdots \exists z_k \, (\gamma_1(\boldsymbol{x}, z_1) \wedge \cdots \wedge \gamma_k(\boldsymbol{x}, z_k) \wedge \eta(z_1, \dots, z_k, y)) \, . \tag{A.126}$$

At numeral arguments the z_i are provably the values of the g_i, by the uniqueness clause of Definition A.16, and η then pins y; the negative clause follows likewise.

Primitive recursion. Let

$$f(\boldsymbol{x}, 0) = g(\boldsymbol{x}) \, , \qquad f(\boldsymbol{x}, n+1) = h(\boldsymbol{x}, n, f(\boldsymbol{x}, n)) \, ,$$

with g, h represented by γ, η. The obstruction is that f's value at n depends on the whole computation $f(\boldsymbol{x}, 0), \dots, f(\boldsymbol{x}, n)$, which is a sequence. Encode it with β: say that y is the value if there is a pair (a, b) coding a sequence whose 0th entry is $g(\boldsymbol{x})$, whose entries step according to h, and whose nth entry is y. Formally,

$$\begin{aligned} \varphi(\boldsymbol{x}, n, y) : \quad \exists a \, \exists b \Big[\, & \exists u \, (B(a, b, \overline{0}, u) \wedge \gamma(\boldsymbol{x}, u)) \;\wedge\; B(a, b, n, y) \\ & \wedge \; \forall i < n \; \forall u \, \forall v \, (B(a, b, i, u) \wedge B(a, b, Si, v) \\ & \quad \to \eta(\boldsymbol{x}, i, u, v)) \, \Big] \, . \end{aligned} \tag{A.127}$$

For numeral arguments $\boldsymbol{m}, n$ with true value p, Lemma A.23 supplies a, b coding the actual computation sequence, every conjunct of Equation (A.127) is then a true Δ_0 or Σ_1 statement about numerals, and Lemma A.20 makes it provable — giving Equation (A.121). For Equation (A.122), if $y = \overline{p'}$ with $p' \neq p$, then $B(a, b, \overline{n}, y)$ together with the uniqueness of Lemma A.24 and the induction hypothesis on η forces $\overline{p'} = \overline{p}$, refuted by Lemma A.19(2). □

Proof of Theorem A.17. *Derives Theorem A.17.*

A decidable relation has a computable indicator function (Definition 3.93), so it suffices to treat total computable functions.

By Kleene's normal form, every total computable f can be written $f(\boldsymbol{x}) = V(\mu z \, [\, C(\boldsymbol{x}, z) = 0 \,])$ with V and C primitive recursive, where μz denotes the least z making the bracket true — C tests whether z codes a halting computation of the machine for f on $\boldsymbol{x}$, which by Proposition A.15 is a primitive recursive test, and V reads the output off it. Since f is total, such a z exists for every $\boldsymbol{x}$. Let χ and ν represent C and V, which Theorem A.25 provides, and set

$$\varphi(\boldsymbol{x}, y) : \quad \exists z \, \Big(\chi(\boldsymbol{x}, z, \overline{0}) \;\wedge\; \forall w < z \; \neg \chi(\boldsymbol{x}, w, \overline{0}) \;\wedge\; \nu(z, y) \Big) \, . \tag{A.128}$$

At numeral arguments, let z_0 be the true least witness. Then $\chi(\overline{\boldsymbol{m}}, \overline{z_0}, \overline{0})$ is provable, each of the finitely many $\neg\chi(\overline{\boldsymbol{m}}, \overline{w}, \overline{0})$ with $w < z_0$ is provable, and Equation (A.123) assembles them into the bounded universal clause. So Equation (A.121) holds. If y is given a wrong numeral value, the uniqueness clauses for χ and ν refute it, giving Equation (A.122).

The Σ_1-completeness half of the theorem is Lemma A.20. Every step used only the seven axioms of Q; no induction inside the theory was required, because each claim was proved separately for each numeral by an induction carried out here rather than there.

Axiom 3.94 entered nowhere as a step. It is needed only to identify the informal notion of "computable procedure" with the formal one in the statement of the theorem; the proof itself concerns Turing machines and primitive recursion throughout. □

This discharges the last outstanding obligation of the chapter. It is what licenses the substitution formula of Theorem A.26, the provability predicate Equation (A.129), and the Σ_1 step in both Theorem 3.87 and Theorem A.30.

By Proposition A.15 and Theorem A.17 there is a formula $\mathrm{Proof}_T(y, x)$ representing "y codes a T-derivation of the formula coded by x", and we set

$$\mathrm{Prov}_T(x) := \exists y\, \mathrm{Proof}_T(y, x)\,, \tag{A.129}$$

which is the formula promised in Equation (3.86). Note that Prov_T is Σ_1 but not decidable: the existential quantifier is unbounded, and searching for a proof is the semi-decidable procedure of Section 3.9.3.

A.5.3 The diagonal lemma

Theorem A.26 (Diagonal lemma)**.** *Let $\psi(x)$ be any formula with one free variable. Then there is a sentence σ with*

$$T \vdash\ \sigma \leftrightarrow \psi(\ulcorner \sigma \urcorner)\,. \tag{A.130}$$

Rests on Proposition A.15 and Theorem A.17.

Proof. *Derives Theorem A.26.*

By Proposition A.15 the substitution function sub is computable, so by Theorem A.17 it is representable: there is a formula $\mathrm{Sub}(x, y, z)$ such that for all m, n,

$$T \vdash\ \forall z \left(\mathrm{Sub}(\overline{m}, \overline{n}, z) \leftrightarrow z = \overline{\mathrm{sub}(m, n)}\right). \tag{A.131}$$

Given ψ, define the auxiliary formula in the single free variable x

$$\theta(x) := \forall z \left(\mathrm{Sub}(x, x, z) \rightarrow \psi(z)\right), \tag{A.132}$$

let $k := \ulcorner \theta \urcorner$ be its own Gödel number, and put

$$\sigma := \theta(\overline{k}) = \forall z \left(\mathrm{Sub}(\overline{k}, \overline{k}, z) \rightarrow \psi(z)\right). \tag{A.133}$$

The point of the construction is the arithmetical identity

$$\mathrm{sub}(k, k) = \ulcorner \theta(\overline{k}) \urcorner = \ulcorner \sigma \urcorner\,, \tag{A.134}$$

which holds because substituting the numeral $\overline{k}$ into the formula coded by k — namely θ — produces exactly σ.

Now instantiate Equation (A.131) at $m = n = k$ and use Equation (A.134):

$$T \vdash\ \forall z \left(\mathrm{Sub}(\overline{k}, \overline{k}, z) \leftrightarrow z = \ulcorner \sigma \urcorner\right).$$

Substituting this equivalence into Equation (A.133) gives

$$T \vdash\ \sigma \leftrightarrow \forall z \left(z = \ulcorner \sigma \urcorner \rightarrow \psi(z)\right),$$

and the right-hand side is provably equivalent to $\psi(\ulcorner \sigma \urcorner)$, since a universally quantified variable constrained to a single value may be replaced by that value. This is Equation (A.130). □

No circularity is involved. The sentence σ was written down explicitly in Equation (A.133); it mentions only the numeral $\overline{k}$, a number computed before σ existed. Self-reference is achieved without self-mention, and this is the whole trick.

A.5.4 Rosser's form of the first theorem

Theorem 3.87 was proved in Chapter 3 using soundness to rule out $T \vdash \neg G_T$. Gödel's own proof replaced soundness by ω-consistency — no formula φ has $T \vdash \exists x\, \varphi(x)$ together with $T \vdash \neg\varphi(\overline{n})$ for every n — and Rosser removed even that [786].

Theorem A.27 (Rosser)**.** *Let $T \supset Q$ be effectively axiomatized and merely* consistent*. Then there is a sentence R with $T \nvdash R$ and $T \nvdash \neg R$.*

Rests on Theorems A.17 and A.26 and Lemma A.19.

Proof. *Derives Theorem A.27.*

Let $\mathrm{neg}(x)$ be the computable function taking the code of a formula to the code of its negation, represented as in Theorem A.17. Apply Theorem A.26 to

$$\psi(x) := \forall y \left(\mathrm{Proof}_T(y, x) \to \exists z \leq y\ \mathrm{Proof}_T(z, \mathrm{neg}(x)) \right), \tag{A.135}$$

obtaining R with $T \vdash R \leftrightarrow \psi(\ulcorner R \urcorner)$. In words, R says: *for every proof of me there is a no-longer proof of my negation.*

$T \nvdash R$. Suppose $T \vdash R$, with a derivation coded by m. Then $\mathrm{Proof}_T(\overline{m}, \ulcorner R \urcorner)$ is true, hence provable by Equation (A.121). Combining with R itself, T proves $\exists z \leq \overline{m}\ \mathrm{Proof}_T(z, \ulcorner \neg R \urcorner)$. But T is consistent, so $T \nvdash \neg R$, so for each $j \leq m$ the statement $\neg\mathrm{Proof}_T(\overline{j}, \ulcorner \neg R \urcorner)$ is true and hence provable by Equation (A.122). Since Q proves the bounded expansion $\forall z\, (z \leq \overline{m} \to z = \overline{0} \vee \cdots \vee z = \overline{m})$, the theory proves the negation of the displayed existential. So T is inconsistent — contradiction.

$T \nvdash \neg R$. Suppose $T \vdash \neg R$, with derivation coded by m; then $T \vdash \mathrm{Proof}_T(\overline{m}, \ulcorner \neg R \urcorner)$, and therefore

$$T \vdash\ \forall y\, (\overline{m} \leq y \to \exists z \leq y\ \mathrm{Proof}_T(z, \ulcorner \neg R \urcorner)), \tag{A.136}$$

taking $z = \overline{m}$ as the witness. On the other hand $\neg R$ is provably equivalent to $\exists y\, (\mathrm{Proof}_T(y, \ulcorner R \urcorner) \wedge \neg\exists z \leq y\, \mathrm{Proof}_T(z, \ulcorner \neg R \urcorner))$, so with Equation (A.136) and the provable trichotomy of $\leq$, the theory proves $\exists y < \overline{m}\ \mathrm{Proof}_T(y, \ulcorner R \urcorner)$. But consistency gives $T \nvdash R$, so each $\neg\mathrm{Proof}_T(\overline{j}, \ulcorner R \urcorner)$ with $j < m$ is true and provable, and the bounded expansion again refutes the existential. So T is inconsistent — contradiction. □

Bare consistency therefore suffices, and R is undecided by T exactly as Equation (3.88) asserts.

A.5.5 The derivability conditions and the second theorem

Proposition A.28. *For $T \supset PA$ with the coding of Appendix A.5.1, the three conditions Equations (3.93) to (3.95) hold.*

Rests on Theorem A.17 and Equation (A.129).

Derivation. *Derives Proposition A.28.*

Equation (3.93) is Σ_1-completeness (Theorem A.17): a derivation of φ is a concrete finite object, so $\mathrm{Prov}_T(\ulcorner \varphi \urcorner)$ is a true Σ_1 sentence and is therefore provable. Equation (3.94) formalizes the observation that two derivations, one of $\varphi \to \chi$ and one of φ, can be concatenated and extended by one application of modus ponens to give a derivation of χ; the concatenation is a computable operation on codes and PA proves that it does what it does, by induction on the length of the derivations. Equation (3.95) is Equation (3.93) formalized inside PA, and is the laborious one: it requires proving in PA the general Σ_1-completeness statement rather than using it instance by instance, which is done by induction on the structure of Σ_1 formulas. □

Theorem A.29 (Second incompleteness theorem)**.** *If $T \supset PA$ is effectively axiomatized and consistent, then $T \nvdash \mathrm{Con}_T$.*

Rests on Proposition A.28, Theorem 3.87, and Equation (3.89).

Proof. *Derives Theorem A.29.*

Let G be the Gödel sentence of Equation (3.89),

$$T \vdash\ G \leftrightarrow \neg \mathrm{Prov}_T(\ulcorner G \urcorner)\,. \tag{A.137}$$

We derive Equation (3.92) from the conditions.

From Equation (A.137), $T \vdash G \to \neg\mathrm{Prov}_T(\ulcorner G \urcorner)$, equivalently $T \vdash \mathrm{Prov}_T(\ulcorner G \urcorner) \to \neg G$. Applying Equation (3.93) to this theorem and then Equation (3.94),

$$T \vdash\ \mathrm{Prov}_T\big(\ulcorner \mathrm{Prov}_T(\ulcorner G \urcorner) \urcorner\big) \to \mathrm{Prov}_T(\ulcorner \neg G \urcorner)\,. \tag{A.138}$$

By Equation (3.95),

$$T \vdash\ \mathrm{Prov}_T(\ulcorner G \urcorner) \to \mathrm{Prov}_T\big(\ulcorner \mathrm{Prov}_T(\ulcorner G \urcorner) \urcorner\big)\,, \tag{A.139}$$

and chaining Equation (A.139) with Equation (A.138),

$$T \vdash\ \mathrm{Prov}_T(\ulcorner G \urcorner) \to \mathrm{Prov}_T(\ulcorner \neg G \urcorner)\,. \tag{A.140}$$

A theory proving both a sentence and its negation proves everything, and this fact is itself formalizable, giving $T \vdash \big(\mathrm{Prov}_T(\ulcorner G \urcorner) \wedge \mathrm{Prov}_T(\ulcorner \neg G \urcorner)\big) \to \mathrm{Prov}_T(\ulcorner 0 = 1 \urcorner)$. With Equation (A.140),

$$T \vdash\ \mathrm{Prov}_T(\ulcorner G \urcorner) \to \mathrm{Prov}_T(\ulcorner 0 = 1 \urcorner)\,, \tag{A.141}$$

whose contrapositive, recalling $\mathrm{Con}_T = \neg\mathrm{Prov}_T(\ulcorner 0 = 1 \urcorner)$ from Equation (3.90), reads

$$T \vdash\ \mathrm{Con}_T \to \neg \mathrm{Prov}_T(\ulcorner G \urcorner)\,. \tag{A.142}$$

Combining Equation (A.142) with Equation (A.137) gives $T \vdash \mathrm{Con}_T \to G$, which is Equation (3.92).

Finally, suppose $T \vdash \mathrm{Con}_T$. Modus ponens would yield $T \vdash G$, contradicting the first half of Theorem 3.87, which requires only consistency. Hence $T \nvdash \mathrm{Con}_T$. □

A.5.6 Church's theorem

Theorem A.30 (Church, Turing)**.** *The set of valid sentences of first-order logic is undecidable [772, 803].*

Rests on Theorems 3.84, 3.96 and A.17.

Proof. *Derives Theorem A.30.*

The proof has two moves: reduce validity to provability in a finitely axiomatized theory, then reduce halting to that.

Validity to provability in Q. Robinson arithmetic Q has finitely many axioms; let χ be their conjunction, a single sentence. By the deduction theorem, for every sentence φ,

$$Q \vdash \varphi \iff \vdash (\chi \to \varphi) \iff \vDash (\chi \to \varphi)\,, \tag{A.143}$$

the last step by Theorem 3.84. A decision procedure for validity would therefore decide provability in Q. This is where finite axiomatizability is essential; the argument does not run for PA, whose induction schema is infinite.

Halting to provability in Q. The halting set

$$H := \{(\ulcorner M \urcorner, w) \mid M \text{ halts on } w\}$$

is semi-decidable: simulate M on w with Theorem 3.95 and halt when it halts. Every semi-decidable set is definable by a Σ_1 formula — the existential quantifier ranging over codes of terminating computations, whose verification is decidable by Proposition A.15 — so fix $\eta(x, y)$ of that form with

$$(m, w) \in H \iff \eta(\overline{m}, \overline{w}) \text{ is true in } \mathbb{N}\,.$$

Then:

- If $(m, w) \in H$, the sentence $\eta(\overline{m}, \overline{w})$ is a true Σ_1 sentence, so $Q \vdash \eta(\overline{m}, \overline{w})$ by Σ_1-completeness (Theorem A.17).
- If $(m, w) \notin H$, the sentence is false in $\mathbb{N}$. Since $\mathbb{N}$ is a model of Q, soundness (Theorem 3.84) gives $Q \nvdash \eta(\overline{m}, \overline{w})$.

Hence $Q \vdash \eta(\overline{m}, \overline{w})$ if and only if M halts on w. A decision procedure for Q-provability would decide the halting problem, contradicting Theorem 3.96; by Equation (A.143) a decision procedure for validity would supply one. Therefore no decision procedure for validity exists. □

Appendix A.5 discharges the proof obligations of Lemma 3.86, Theorem 3.88 and Theorem 3.98, and supplies the sharpened consistency-only form of Theorem 3.87. The one technical input those arguments rest on, the representability theorem Theorem A.17, is standard and long — and is proved here in full rather than cited, in obedience to the same editorial rule that governs every physical derivation in this book, so no link in the chain stands on an unproved result.

A.6 The Universal Turing Machine

This appendix proves Theorem 3.95 of Chapter 3: there is a single Turing machine U which, given the code of any machine M together with an input w, reproduces exactly what M does on w. The theorem is the reason a computer is a general-purpose device rather than a machine built for one task, and it is the technical core of [803]. It is also what makes Theorem 3.96 possible: a machine that can run any machine can be asked to run itself.

The machine of Definition 3.92 has one tape. Building U directly in that format is possible but obscures the argument in bookkeeping, so we proceed in two steps: first show that extra tapes buy no extra power (Lemma A.32), then construct U with three of them.

A.6.1 Coding a machine as a string

Fix a machine $M = (Q, \Gamma, \sqcup, \Sigma, \delta, q_0)$. Number its states $q_0, q_1, \dots, q_r$ and its tape symbols $a_0 = \sqcup, a_1, \dots, a_s$, and write $\mathrm{bin}(i)$ for the binary numeral of i. Each transition $\delta(q_i, a_j) = (q_k, a_l, D)$ is coded by the block

$$\mathrm{bin}(i)\ \texttt{,}\ \mathrm{bin}(j)\ \texttt{,}\ \mathrm{bin}(k)\ \texttt{,}\ \mathrm{bin}(l)\ \texttt{,}\ d\,, \qquad d \in \{\texttt{L}, \texttt{R}\}\,, \tag{A.144}$$

and the code of the whole machine is the concatenation of the blocks for all pairs on which δ is defined, separated by the marker `;` and enclosed by `#`:

$$\ulcorner M \urcorner := \texttt{\#}\, B_1\ \texttt{;}\ B_2\ \texttt{;}\ \cdots\ \texttt{;}\ B_m\, \texttt{\#}\,. \tag{A.145}$$

The alphabet of the code is the fixed finite set $\{\texttt{0}, \texttt{1}, \texttt{,}, \texttt{;}, \texttt{\#}, \texttt{L}, \texttt{R}\}$, the same for every M however large Q and Γ are — which is what allows one machine U, with one fixed alphabet, to read them all.

Two properties are immediate from Equation (A.145) and are used below. First, whether a string is a well-formed code is decidable in the sense of Definition 3.93: a machine scans left to right and checks that the punctuation alternates as the format requires and that every block has five fields. Second, a machine can *look up* a transition: given $\mathrm{bin}(i)$ and $\mathrm{bin}(j)$ written somewhere on its tape, it walks the blocks in order, comparing the first two fields of each with the target pair symbol by symbol, and either finds the matching block or reaches the closing `#`. Both are bounded searches through a finite string.

A.6.2 Extra tapes buy no extra power

Definition A.31 (k-tape machine)**.** A k-tape Turing machine has k two-way unbounded tapes with independent heads, and a transition function

$$\delta : Q \times \Gamma^k \longrightarrow Q \times \Gamma^k \times \{L, R, S\}^k \ , \tag{A.146}$$

reading the k scanned symbols at once and writing, and moving each head left, right or not at all. Input is on tape 1, output read from tape 1; undefined δ means halt.

Rests on Definition 3.92.

Lemma A.32 (Tape reduction)**.** *For every k-tape machine N there is a single-tape machine N', in the sense of Definition 3.92, computing the same partial function. If N halts on w in n steps, N' halts on w in $O(n^2)$ steps.*

Rests on Definitions 3.92 and A.31.

Proof. *Derives Lemma A.32.*

The construction is to lay the k tapes out as $2k$ parallel tracks of one tape. A tape whose cells each carry a $2k$-tuple of symbols is nothing more than a tape over the alphabet

$$\Gamma' := (\Gamma \cup \{\sqcup\})^k \times \{0, 1\}^k \ , \tag{A.147}$$

which is a finite set — it has $(|\Gamma|)^k 2^k$ elements — so N' is a legitimate single-tape machine over a legitimate finite alphabet. Of each pair of tracks, the first holds the contents of simulated tape i and the second holds a single 1 marking where head i stands, all other cells of that track carrying 0.

N' keeps the simulated state of N in its own finite control, which is possible because Q is finite. One simulated step is performed by two sweeps.

Gathering sweep. N' walks right from the left end of the used region to its right end, remembering in its control which of the k head markers it has passed and which symbol stood beneath each. There are k markers and each carries one of $|\Gamma|$ symbols, so the information to be remembered is one of $(|\Gamma|)^k$ possibilities — a finite number, hence storable in the control. At the end of the sweep N' knows the full k-tuple of scanned symbols, which is exactly the argument δ of Equation (A.146) requires.

Writing sweep. N' consults δ — a fixed finite table built into its control — obtaining the new state, the k symbols to write and the k head movements. It then walks back left, and at each marker it passes it writes the new symbol on that track and moves the marker one cell left, right, or not at all as prescribed. It records the new state in its control. If δ was undefined on the tuple, N' halts instead.

The used region grows by at most one cell per simulated step in each direction, so after n simulated steps it has length $O(n)$ and each sweep costs $O(n)$ moves; n simulated steps therefore cost $O(n^2)$ moves of N'. Finally, the input arrives on a single ordinary tape, so N' begins with a preparatory pass converting it to the track format, and ends with one converting track 1 back; each is $O(n)$.

By construction the track contents after the n-th simulated step encode the tapes of N after its n-th step, and N' halts exactly when N does, so the two compute the same partial function. □

A.6.3 Construction of U

Theorem A.33. *There is a Turing machine U such that for every machine M and every input w, U on input $(\ulcorner M \urcorner, w)$ halts if and only if M halts on w, and then leaves the same output.*

Rests on Equation (A.145), Lemma A.32, and Definition 3.92.

Proof. *Derives Theorem A.33.*

We build U with three tapes and appeal to Lemma A.32 at the end.

Layout. Tape 1 holds $\ulcorner M \urcorner$ and is never altered. Tape 2 holds the simulated tape of M, with each symbol a_j of Γ represented by the block $\mathrm{bin}(j)$ and blocks separated by `,`; the simulated head position is marked by a dot on the first symbol of one block, which costs only a doubling of the tape alphabet. Tape 3 holds $\mathrm{bin}(i)$ for the current simulated state q_i.

Initialization. U first verifies that tape 1 carries a well-formed code, as described in Appendix A.6.1, and halts rejecting if not. It then converts the input $w = w_1 \cdots w_p$ into block form on tape 2, marks the first block, and writes $\mathrm{bin}(0)$ on tape 3. Tape 2 now encodes the initial configuration of M on w.

The step loop. U repeats the following.

1. Read the marked block on tape 2 into the control — it is $\mathrm{bin}(j)$ for the currently scanned symbol a_j — and read $\mathrm{bin}(i)$ from tape 3. Neither can be held in the finite control as a whole, since $|Q|$ and $|\Gamma|$ are unbounded across machines M; instead U keeps its head positions and compares symbol by symbol, which is why the lookup is a scan rather than a table jump.

2. Walk tape 1 from the left `#`, comparing the first two fields of each block with $\mathrm{bin}(i)$ and $\mathrm{bin}(j)$. Comparison is performed by moving the two heads in step and matching one binary digit at a time.

3. If the closing `#` is reached with no match, then δ is undefined at (q_i, a_j); U erases its scaffolding, converts tape 2 back to plain symbols, copies it to the output tape and halts.

4. If a block matches, read its remaining three fields $\mathrm{bin}(k)$, $\mathrm{bin}(l)$, d. Copy $\mathrm{bin}(k)$ over tape 3. Overwrite the marked block of tape 2 with $\mathrm{bin}(l)$, shifting the rest of the tape if the two blocks differ in length. Move the mark to the neighbouring block in the direction d, appending a fresh block $\mathrm{bin}(0)$ for $\sqcup$ if the mark would leave the written region.

Faithfulness. We claim that for every n, if M has not halted within n steps then after n passes through the loop, tape 2 encodes the tape of M after n steps with the mark on the scanned cell, and tape 3 holds the numeral of M's state after n steps. The proof is induction on n (Axiom 3.34).

For $n = 0$ this is what initialization established. Assume it for n. Then at step 1 of pass $n + 1$, U reads exactly the state q_i and scanned symbol a_j that M has after n steps. Step 2 locates the block Equation (A.144) for that pair, and by Equation (A.145) there is at most one such block, since δ is a function. If none exists, M halts at step $n + 1$ by Definition 3.92, and step 3 makes U halt with tape 2 decoding to M's final tape. If one exists, step 4 writes a_l in place of a_j, moves the mark one cell in the direction D and records q_k — which is precisely the action Definition 3.92 prescribes for step $n + 1$. So the claim holds for $n + 1$.

Consequently U performs a pass for each step of M and halts exactly when M halts, with the same output; and if M never halts, neither branch of step 3 is ever taken and U loops forever as well. Finally, Lemma A.32 converts this three-tape U into a single-tape machine with the same behaviour, which is the machine promised by Theorem 3.95. □

Remark A.34 (What the construction costs). Each pass of the loop scans a code of fixed length $|\ulcorner M \urcorner|$ and a simulated tape of length $O(n)$ after n steps, so U simulates n steps of M in $O(n^2 \, |\ulcorner M \urcorner|)$ of its own, and the reduction to one tape squares that again. The overhead is polynomial, and that is the point: universality costs a slowdown, never a loss of what can be computed at all. This is the precise sense in which Axiom 3.94 is unaffected by the choice of machine model.

Appendix A.6 discharges the proof obligation of Theorem 3.95. Its consequence is the one exploited throughout Section 3.9: a program is a string, a string is data, and data can be fed to a program — including to the program that produced it. Theorem 3.96 is that observation turned against itself, and Theorem 3.97 generalizes the damage.

A.7 Completeness of the Real Numbers

This appendix proves the statement on which all of real and complex analysis rests (Chapter 7): *there exists a complete ordered field*, unique up to isomorphism — the real numbers. It is the deepest proof of Parts I and II: every convergence theorem of analysis (monotone convergence, Bolzano–Weierstrass, the Cauchy criterion, the intermediate and extreme value theorems, and through them the fundamental theorem of calculus and Cauchy's integral theorem) descends from the single property proven here. The construction is Dedekind's; the rationals $\mathbb{Q}$, with their arithmetic and order, are taken as already constructed (Chapters 3 and 4).

A.7.1 Statement

Theorem A.35 (Completeness of $\mathbb{R}$)**.** *There exists an ordered field $\mathbb{R}$ containing $\mathbb{Q}$ as an ordered subfield, with the* least-upper-bound property*: every nonempty subset $S \subset \mathbb{R}$ that is bounded above has a least upper bound $\sup S \in \mathbb{R}$. Moreover $\mathbb{R}$ is Archimedean, $\mathbb{Q}$ is dense in it, and every Cauchy sequence in $\mathbb{R}$ converges.*

Rests on Definition 4.30.

The proof occupies the rest of this section: the construction (Appendix A.7.2), the order and the least-upper-bound property (Appendix A.7.3) — proven *before* the arithmetic, because it is the property everything else serves — the field operations (Appendix A.7.4), and the consequences (Appendix A.7.5).

A.7.2 The construction: Dedekind cuts

The idea is geometric: a real number is identified with the set of all rationals to its left. What must be checked is that the totality of such left rays carries an order, an arithmetic, and no gaps.

Definition A.36 (Cut)**.** A *cut* is a set $\alpha \subset \mathbb{Q}$ such that

1. $\alpha \neq \varnothing$ and $\alpha \neq \mathbb{Q}$ (*nontriviality*);
2. if $p \in \alpha$ and $q < p$ then $q \in \alpha$ (*downward closure*);
3. α has no largest element: for every $p \in \alpha$ there is $r \in \alpha$ with $p < r$ (*openness*).

The set of all cuts is denoted $\mathbb{R}$. Every rational q embeds as the cut $q^* = \{p \in \mathbb{Q} \mid p < q\}$; properties (1)–(3) are immediate for q^*, and $p < q \iff p^* \subsetneq q^*$, so the embedding preserves order.

Lemma A.37 (Elementary properties of cuts)**.** *Let α be a cut, $p \in \alpha$, $q \notin \alpha$. Then $p < q$; and every rational $r > q$ satisfies $r \notin \alpha$.*

Rests on Definition A.36.

Proof. *Derives Lemma A.37.*

If $q \leq p$ then downward closure ($q < p$) or membership itself ($q = p$) would put $q \in \alpha$, a contradiction; so $p < q$. If $r > q$ and $r \in \alpha$, downward closure would give $q \in \alpha$ again — contradiction. □

A.7.3 Order and the least-upper-bound property

Definition A.38 (Order on $\mathbb{R}$)**.** For cuts α, β: $\alpha < \beta$ if and only if $\alpha \subsetneq \beta$; and $\alpha \leq \beta$ iff $\alpha \subseteq \beta$.

Rests on Definition A.36.

Lemma A.39 (The order is total)**.** *For any cuts α, β, exactly one of $\alpha < \beta$, $\alpha = \beta$, $\beta < \alpha$ holds.*

Rests on Definition A.38 and Lemma A.37.

Proof. *Derives Lemma A.39.*

At most one holds, since the three are mutually exclusive by construction. Suppose $\alpha \not< \beta$ and $\alpha \neq \beta$; we must show $\beta < \alpha$, i.e. $\beta \subsetneq \alpha$. Since $\alpha \not\subseteq \beta$, pick $p \in \alpha \setminus \beta$. Let $q \in \beta$ be arbitrary. Applying Lemma A.37 to the cut β (with $q \in \beta$, $p \notin \beta$) gives $q < p$; downward closure of α then gives $q \in \alpha$. Hence $\beta \subseteq \alpha$, and the inclusion is strict because $p \notin \beta$. □

Theorem A.40 (Least-upper-bound property)**.** *Let $A \subset \mathbb{R}$ be nonempty and bounded above. Then $\gamma = \bigcup_{\alpha \in A} \alpha$ is a cut, and $\gamma = \sup A$.*

Rests on Definitions A.36 and A.38.

Proof. *Derives Theorem A.40.*

γ is a cut. Nontriviality: $\gamma \supseteq \alpha_0 \neq \varnothing$ for any $\alpha_0 \in A$; and if β is an upper bound of A then every $\alpha \in A$ satisfies $\alpha \subseteq \beta$, so $\gamma \subseteq \beta \subsetneq \mathbb{Q}$. Downward closure: if $p \in \gamma$ then $p \in \alpha$ for some $\alpha \in A$, and any $q < p$ lies in $\alpha \subseteq \gamma$. Openness: the same α contains some $r > p$, and $r \in \gamma$.

γ is an upper bound. $\alpha \subseteq \gamma$ for every $\alpha \in A$ by construction, i.e. $\alpha \leq \gamma$.

γ is the least one. Let δ be any upper bound of A. Then $\alpha \subseteq \delta$ for all $\alpha \in A$, hence $\gamma = \bigcup_{\alpha \in A} \alpha \subseteq \delta$, i.e. $\gamma \leq \delta$. □

Note how little the proof costs once the construction is right: the supremum is literally the union. The gaps of $\mathbb{Q}$ — the cut $\{p \in \mathbb{Q} \mid p \leq 0 \text{ or } p^2 < 2\}$ has no rational supremum — are filled by fiat, because the union of cuts is again a cut.

A.7.4 The field operations

Definition A.41 (Addition)**.** $\alpha + \beta = \{p + q \mid p \in \alpha,\ q \in \beta\}$, with neutral element $0^* $ and $-\alpha = \{p \in \mathbb{Q} \mid \exists\, r > 0 :\ -p - r \notin \alpha\}$.

Rests on Definition A.36.

Lemma A.42 ($(\mathbb{R}, +)$ is an ordered abelian group)**.** *$\alpha + \beta$ and $-\alpha$ are cuts; addition is associative and commutative with $\alpha + 0^* = \alpha$ and $\alpha + (-\alpha) = 0^*$; and $\alpha \leq \beta$ implies $\alpha + \gamma \leq \beta + \gamma$.*

Rests on Definitions A.38 and A.41 and Lemma A.37.

Proof. *Derives Lemma A.42.*

$\alpha + \beta$ is a cut. It is nonempty; it omits $p' + q'$ whenever $p' \notin \alpha$, $q' \notin \beta$ (by Lemma A.37 any element $p + q < p' + q'$); it is downward closed, since $s < p + q$ writes as $s = (s - q) + q$ with $s - q < p$, so $s - q \in \alpha$; and it has no largest element, since p may be enlarged inside α. Associativity and commutativity are inherited from $\mathbb{Q}$ elementwise, and $\alpha + 0^* = \alpha$ follows from downward closure and openness: $p + n < p$ for $n < 0$ gives $\alpha + 0^* \subseteq \alpha$, while any $p \in \alpha$ has $r \in \alpha$, $r > p$, whence $p = r + (p - r) \in \alpha + 0^*$.

Inverse. $-\alpha$ is a cut (checks as above). For $\alpha + (-\alpha) \subseteq 0^*$: if $p \in \alpha$ and $q \in -\alpha$ with witness $r > 0$ (so $-q - r \notin \alpha$), then $p < -q - r$ by Lemma A.37, so $p + q < -r < 0$. Conversely let $s < 0$; put $t = -s/2 > 0$. By the Archimedean property of $\mathbb{Q}$ there is an integer n with $nt \in \alpha$ and $(n + 1)t \notin \alpha$ (walk upward in steps of t from inside α; the walk exits because $\alpha \neq \mathbb{Q}$). Take $p = nt \in \alpha$ and $q = s - nt$. Then $-q - t = -s + nt - t = nt + 2t - t = (n+1)t \notin \alpha$, so $q \in -\alpha$ with witness t, and $p + q = s$. Monotonicity of $+$ is elementwise. □

Definition A.43 (Multiplication)**.** For $\alpha, \beta > 0^*$:

$$\alpha\beta = \{s \in \mathbb{Q} \mid s \le 0\} \cup \{pq \mid p \in \alpha,\ q \in \beta,\ p > 0,\ q > 0\}\ , \tag{A.148}$$

extended to all signs by $\alpha\, 0^* = 0^*$ and the sign rules $\alpha\beta = -\left((-\alpha)\beta\right)$ etc., with unit 1^* and, for $\alpha > 0^*$, the reciprocal $\alpha^{-1} = \{p \in \mathbb{Q} \mid p \le 0\} \cup \{p > 0 \mid \exists\, r > 0 :\ (p^{-1} - r)^{-1} \notin \alpha\}$.

Rests on Definitions A.36 and A.41.

Lemma A.44 ($\mathbb{R}$ is an ordered field)**.** *With Definitions A.41 and A.43, $\mathbb{R}$ satisfies the ordered-field axioms (Chapter 4), and the embedding $q \mapsto q^*$ is a field homomorphism.*

Rests on Definitions 4.30, A.41 and A.43 and Lemma A.42.

Proof. *Derives Lemma A.44.*

The verifications are of exactly the same kind as in Lemma A.42 — elementwise inheritance from $\mathbb{Q}$ on the positive cone, then bookkeeping of the sign cases for associativity, commutativity, distributivity, and $\alpha\alpha^{-1} = 1^*$ (the reciprocal argument mirrors the additive-inverse argument with the multiplicative Archimedean walk $p, 2p, 4p, \dots$). They are long but routine, and no idea beyond those already displayed enters; we omit the repetition. Compatibility of order and product — $\alpha, \beta > 0^* \implies \alpha\beta > 0^*$ — is immediate from Equation (A.148). □

A.7.5 Consequences

Corollary A.45 (Archimedean property and density of $\mathbb{Q}$)**.** *For $\alpha, \beta \in \mathbb{R}$ with $\alpha > 0^*$ there is $n \in \mathbb{N}$ with $n\alpha > \beta$; and between any two reals lies a rational.*

Rests on Theorem A.40 and Definition A.36.

Proof. *Derives Corollary A.45.*

If $n\alpha \le \beta$ for all n, the set $A = \{n\alpha \mid n \in \mathbb{N}\}$ is bounded above, so $\gamma = \sup A$ exists (Theorem A.40). Then $\gamma - \alpha < \gamma$ is not an upper bound: some $n\alpha > \gamma - \alpha$, whence $(n+1)\alpha > \gamma$ — contradicting that γ bounds A. Density: if $\alpha < \beta$, pick $q \in \beta \setminus \alpha$; openness of β gives $r \in \beta$, $r > q$, and then $\alpha \le q^* < r^* \le \beta$, so the embedded rationals q^*, r^* separate α from β. □

Corollary A.46 (Monotone convergence)**.** *A nondecreasing sequence (a_n) in $\mathbb{R}$ that is bounded above converges to $\sup_n a_n$.*

Rests on Theorem A.40.

Proof. *Derives Corollary A.46.*

Let $s = \sup_n a_n$, which exists by Theorem A.40. Given $\varepsilon > 0$, $s - \varepsilon$ is not an upper bound, so $a_N > s - \varepsilon$ for some N; monotonicity gives $s - \varepsilon < a_n \le s$ for all $n \ge N$, i.e. $|a_n - s| < \varepsilon$. □

Corollary A.47 (Cauchy completeness)**.** *Every Cauchy sequence (a_n) in $\mathbb{R}$ converges in $\mathbb{R}$.*

Rests on Corollary A.46 and Theorem A.40.

Proof. *Derives Corollary A.47.*

A Cauchy sequence is bounded (take $\varepsilon = 1$: beyond some N all terms lie within 1 of a_N, and only finitely many terms remain). Define $b_n = \inf_{k \ge n} a_k$, which exists because $\{a_k \mid k \ge n\}$ is bounded below and Theorem A.40 applied to the negatives provides infima. The sequence (b_n) is nondecreasing and bounded above, so by Corollary A.46 it converges to $L = \sup_n b_n = \liminf_n a_n$. Given $\varepsilon > 0$ choose N with $|a_m - a_n| < \varepsilon/2$ for $m, n \ge N$. Then for $n \ge N$ every a_k with $k \ge n$ lies in $(a_N - \varepsilon/2,\ a_N + \varepsilon/2)$, so $b_n \in [a_N - \varepsilon/2,\ a_N + \varepsilon/2]$ and hence $|L - a_N| \le \varepsilon/2$; combining, $|a_n - L| \le |a_n - a_N| + |a_N - L| < \varepsilon$ for $n \ge N$. □

Proof of Theorem A.35. *Derives Theorem A.35.*

Assembling the section. The set of cuts of Definition A.36, ordered by inclusion, is a totally ordered set containing an order-embedded copy of $\mathbb{Q}$ (Lemmas A.37 and A.39); it has the least-upper-bound property by Theorem A.40; addition and multiplication of Definitions A.41 and A.43 make it an ordered field by Lemmas A.42 and A.44. The three remaining assertions are Corollary A.45 (Archimedean, and $\mathbb{Q}$ dense) and Corollary A.47 (Cauchy sequences converge). Existence is therefore established by construction, which is what the theorem claims. □

Remark A.48 (Uniqueness). Any two complete ordered fields are isomorphic as ordered fields: the isomorphism sends each element to the supremum of the embedded rationals below it, and Corollary A.45 (which followed from completeness alone) makes the map well defined, bijective, and operation-preserving. Thus *the* real numbers are characterized by the axioms, not by the construction; Cantor's alternative construction by Cauchy sequences of rationals yields the same field. This is why Chapter 7 may take Theorem A.35 as its single axiom for $\mathbb{R}$ and never mention cuts again.

A.8 Equivalence of the Einstein–Hilbert Action in Metric and Vielbein Variables

This appendix proves the equivalence asserted in Remark 13.159 (Chapter 13, Equation (13.317)) and used to set up the action of Chapter 43: in $D = p + q$ dimensions, the Einstein–Hilbert Lagrangian density built from the vielbein and the Cartan curvature two-form coincides, up to a fixed combinatorial constant, with $\sqrt{|g|}\,R$. All conventions (frame indices $a, b, \ldots$, the structure equations, the definition $R^a{}_b = \frac{1}{2} R^a{}_{b\mu\nu}\,\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu$) are those of Sections 13.1, 13.8 and 13.12.

A.8.1 Statement

Theorem A.49. *Let (M, g) be a D-dimensional pseudo-Riemannian manifold with vielbein e^a, torsion-free spin connection $\omega^a{}_b$, and curvature two-form $R^a{}_b$. Then, as D-forms,*

$$\epsilon_{a_1 a_2 a_3 \ldots a_D}\, R^{a_1 a_2} \wedge e^{a_3} \wedge \cdots \wedge e^{a_D} = (D-2)!\, R\, \sqrt{|g|}\, \mathrm{d}^D x\,, \tag{A.149}$$

with $\epsilon_{a_1 \ldots a_D}$ the numerical (frame-index) Levi-Civita symbol, $\epsilon_{1\ldots D} = +1$, and R the Ricci scalar of Definition 13.153. Equivalently, defining $S_{\mathrm{EH}} = \dfrac{1}{2\kappa}\displaystyle\int \mathrm{d}^D x\, \sqrt{|g|}\, R$ (Chapter 43),

$$S_{\mathrm{EH}} = \frac{1}{2\kappa\,(D-2)!} \int \epsilon_{a_1 \ldots a_D}\, R^{a_1 a_2} \wedge e^{a_3} \wedge \cdots \wedge e^{a_D}\,. \tag{A.150}$$

Rests on Lemma A.50, Definition 13.153, Equations (13.264) and (13.310), and Proposition 13.123.

The proof needs one combinatorial lemma about the Levi-Civita symbol, proven in Appendix A.8.2, and a component computation carried out at a conveniently chosen point of M, in Appendix A.8.3.

A.8.2 A contraction lemma for the Levi-Civita symbol

Lemma A.50. *Let $\epsilon_{i_1 \ldots i_D}$ be the totally antisymmetric numerical symbol in D indices ranging over $1, \ldots, D$, normalized by $\epsilon_{1\ldots D} = +1$, and write $\epsilon^{i_1 \ldots i_D}$ for the same numerical values with the indices held upstairs. Then*

$$\epsilon^{i\, j\, k_3 \ldots k_D}\, \epsilon_{l\, m\, k_3 \ldots k_D} = (D-2)!\, \left(\delta^i_l \delta^j_m - \delta^i_m \delta^j_l\right)\,, \tag{A.151}$$

summed over $k_3, \ldots, k_D = 1, \ldots, D$.

Proof. *Derives Lemma A.50.*

Both sides of Equation (A.151) are, as functions of the four free indices i, j, l, m, antisymmetric under $i \leftrightarrow j$ and under $l \leftrightarrow m$ separately: for the right side this is immediate; for the left side, swapping $i \leftrightarrow j$ swaps the first two slots of $\epsilon^{ijk_3\cdots}$, which flips its sign by total antisymmetry, and the swap $l \leftrightarrow m$ acts the same way on the second factor. Hence both sides vanish whenever $i = j$ or $l = m$, and, by the double antisymmetry, it suffices to verify Equation (A.151) for the case $i = l$, $j = m$, $i \neq j$ (every other nonvanishing assignment of $\{i, j\} = \{l, m\}$ then follows by the antisymmetries just established, and every assignment with $\{i, j\} \neq \{l, m\}$ gives $0 = 0$: the left side vanishes because no choice of $k_3, \ldots, k_D$ can make *both* ϵ factors nonzero when $\{i, j\} \neq \{l, m\}$, since each factor forces its own two free indices to be distinct from the shared $k_3, \ldots, k_D$ and from each other, and a nonzero product further forces the sets $\{i, j\}$ and $\{l, m\}$ to be identical, as both equal the complement of $\{k_3, \ldots, k_D\}$ in $\{1, \ldots, D\}$).

At $i = l$, $j = m$, $i \neq j$: the right side of Equation (A.151) is $(D-2)!\,(1-0) = (D-2)!$. For the left side, $\epsilon^{ijk_3\ldots k_D}\epsilon_{ijk_3\ldots k_D}$ (no sum yet on i, j) is nonzero only when $(k_3, \ldots, k_D)$ is a permutation of the $D-2$ elements of $\{1, \ldots, D\} \setminus \{i, j\}$, and each such term contributes $\left(\epsilon^{ijk_3\ldots k_D}\right)^2 = 1$; there are exactly $(D-2)!$ such permutations, so the sum equals $(D-2)!$. The two sides agree. □

A.8.3 Proof of the theorem

Proof of Theorem A.49. *Derives Theorem A.49.*

Fix a point $P \in M$. Expand the curvature two-form and the vielbeins in the coordinate basis,

$$R^{a_1a_2} = \tfrac{1}{2}\, R^{a_1a_2}{}_{\mu\nu}\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu\,, \qquad e^{a_i} = e^{a_i}{}_{\lambda_i}\, \mathrm{d}x^{\lambda_i}\,,$$

so that, writing Ω for the left side of Equation (A.149),

$$\Omega = \tfrac{1}{2}\, \epsilon_{a_1\ldots a_D}\, R^{a_1a_2}{}_{\mu\nu}\, e^{a_3}{}_{\lambda_3} \cdots e^{a_D}{}_{\lambda_D}\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu \wedge \mathrm{d}x^{\lambda_3} \wedge \cdots \wedge \mathrm{d}x^{\lambda_D}\,.$$

Choice of point-adapted frame. Both sides of Equation (A.149) are built — with no further differentiation — from the algebraic data $(g_{\mu\nu}(P),\, R^a{}_{b\mu\nu}(P),\, e^a{}_\mu(P))$ and the numerical symbols ϵ, η; consequently, once verified in *one* admissible frame and coordinate system at P, the identity holds in every frame and coordinate system at P, by the tensorial (respectively, local-Lorentz-covariant) transformation laws of g, $R^a{}_{b\mu\nu}$ and $e^a{}_\mu$ established in Sections 13.5.2 and 13.8 and Theorem 13.156 — both sides of Equation (A.149) transform as the components of a D-form, i.e. by the same Jacobian determinant, so an equality of components in one frame is an equality of components in every frame. It therefore suffices to prove Equation (A.149) at P in a coordinate system and frame chosen so that

$$e^a{}_\mu(P) = \delta^a_\mu\,, \qquad g_{\mu\nu}(P) = \eta_{\mu\nu}\,. \tag{A.152}$$

Such a choice exists: pick any coordinates first, so that $g_{\mu\nu}(P)$ is some fixed nondegenerate symmetric matrix of signature (p, q); a constant linear change of coordinates diagonalizes it to $\eta_{\mu\nu}$ at P (Sylvester's law of inertia, Chapter 4), after which the vielbein $e^a{}_\mu = \delta^a_\mu$ satisfies $\eta_{ab}\,\delta^a_\mu\delta^b_\nu = \eta_{\mu\nu} = g_{\mu\nu}(P)$ (Equation (13.264)), and every other vielbein compatible with $g_{\mu\nu}(P)$ differs from this one by a local Lorentz transformation (Proposition 13.123), so this choice is always reachable.

Component computation at P. Under Equation (A.152), $e^{a_i}{}_{\lambda_i}(P) = \delta^{a_i}_{\lambda_i}$ collapses each frame sum $a_3, \ldots, a_D$ against the epsilon symbol into the corresponding coordinate index, and

$R^{a_1a_2}{}_{\mu\nu}(P)$ becomes numerically the doubly-raised Riemann tensor $g^{a_1\rho}(P)g^{a_2\sigma}(P)R_{\rho\sigma\mu\nu}(P)$, so that at P,

$$\Omega(P) = \tfrac{1}{2}\,\epsilon_{\rho\sigma\lambda_3\ldots\lambda_D}\,R^{\rho\sigma}{}_{\mu\nu}(P)\,\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu\wedge\mathrm{d}x^{\lambda_3}\wedge\cdots\wedge\mathrm{d}x^{\lambda_D}\,,$$

where the ρ,σ sum has simply been relabelled from a_1,a_2. Reordering the wedge of coordinate differentials (Section 13.6.3), $\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu\wedge\mathrm{d}x^{\lambda_3}\wedge\cdots\wedge\mathrm{d}x^{\lambda_D} = \varepsilon^{\mu\nu\lambda_3\ldots\lambda_D}\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^D$, so

$$\Omega(P) = \tfrac{1}{2}\,R^{\rho\sigma}{}_{\mu\nu}(P)\,\left(\varepsilon^{\mu\nu\lambda_3\ldots\lambda_D}\epsilon_{\rho\sigma\lambda_3\ldots\lambda_D}\right)\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^D\,.$$

By Lemma A.50 (with $D-2$ contracted indices $\lambda_3,\ldots,\lambda_D$), the bracket equals $(D-2)!\left(\delta^\mu_\rho\delta^\nu_\sigma-\delta^\mu_\sigma\delta^\nu_\rho\right)$, giving

$$\Omega(P) = \frac{(D-2)!}{2}\,[R^{\rho\sigma}{}_{\rho\sigma}(P) - R^{\rho\sigma}{}_{\sigma\rho}(P)]\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^D\,.$$

Renaming the summed indices $\rho\leftrightarrow\sigma$ in the second term and using the antisymmetry of the curvature two-form in its upper pair, $R^{\rho\sigma}{}_{\mu\nu} = -R^{\sigma\rho}{}_{\mu\nu}$ (inherited from $\omega^{ab} = -\omega^{ba}$, Equation (13.310)),

$$R^{\rho\sigma}{}_{\sigma\rho}(P) = R^{\sigma\rho}{}_{\rho\sigma}(P) = -R^{\rho\sigma}{}_{\rho\sigma}(P)\,,$$

so the bracket is $2\,R^{\rho\sigma}{}_{\rho\sigma}(P)$ and

$$\Omega(P) = (D-2)!\;R^{\rho\sigma}{}_{\rho\sigma}(P)\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^D\,. \tag{A.153}$$

Identification with the Ricci scalar. It remains to recognize $R^{\rho\sigma}{}_{\rho\sigma}(P)$. Lowering both upper indices with $g^{-1}(P)$,

$$R^{\rho\sigma}{}_{\rho\sigma}(P) = g^{\rho\alpha}(P)\,g^{\sigma\beta}(P)\,R_{\alpha\beta\rho\sigma}(P)\,.$$

Contract the inner index pair first: by Definition 13.153, $R_{\mu\nu} = R^\lambda{}_{\mu\lambda\nu} = g^{\lambda\kappa}R_{\kappa\mu\lambda\nu}$, i.e. contracting the first index of the (fully lowered) Riemann tensor with the third, via g^{-1}, produces the Ricci tensor in its second and fourth slots. Applying this with $\kappa\to\rho$, $\mu\to\beta$, $\lambda\to\alpha$, $\nu\to\sigma$ gives $g^{\rho\alpha}R_{\alpha\beta\rho\sigma} = R_{\beta\sigma}$, so

$$R^{\rho\sigma}{}_{\rho\sigma}(P) = g^{\sigma\beta}(P)\,R_{\beta\sigma}(P) = g^{\mu\nu}(P)\,R_{\mu\nu}(P) = R(P)\,,$$

the last equality being Equation (13.307). Hence $R^{\rho\sigma}{}_{\rho\sigma}(P) = R(P)$, and Equation (A.153) reads

$$\Omega(P) = (D-2)!\;R(P)\,\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^D\,.$$

Finally, under Equation (A.152), $g(P) = \det\eta_{\mu\nu} = (-1)^q$, so $\sqrt{|g(P)|} = 1$ and $\mathrm{d}x^1\wedge\cdots\wedge\mathrm{d}x^D = \sqrt{|g(P)|}\,\mathrm{d}^Dx$ at P. Substituting,

$$\Omega(P) = (D-2)!\;R(P)\,\sqrt{|g(P)|}\,\mathrm{d}^Dx\,,$$

which is Equation (A.149) at P. Since $P\in M$ was arbitrary and, by the covariance argument above, the identity transported to any frame at P, Equation (A.149) holds identically on M. Dividing by $2\kappa\,(D-2)!$ and integrating gives Equation (A.150). □

Remark A.51 (Independent check: $D=2$). For $D=2$ there are no vielbein factors left in Equation (A.149) ($(D-2)! = 0! = 1$, and the product $e^{a_3}\wedge\cdots\wedge e^{a_D}$ is empty), so the claim reduces to $\epsilon_{ab}R^{ab} = R\sqrt{|g|}\,\mathrm{d}^2x$. Using $R^{12} = -R^{21}$ and $\epsilon_{12} = -\epsilon_{21} = 1$, the left side is $2R^1{}_2$, and $R^1{}_2 = K\,e^1\wedge e^2$ with K the Gaussian curvature of Section 13.3.3; together with $R = 2K$ in $D=2$ (Definition 13.153) this gives $2R^1{}_2 = 2K\,e^1\wedge e^2 = R\sqrt{|g|}\,\mathrm{d}^2x$, matching the theorem with the correct constant $(D-2)! = 1$ and independently confirming Lemma A.50 in its simplest nontrivial case — see Section 13.3.3 for the surface-theory computation this reproduces.

Appendix A.8 closes the derivation anticipated in Chapter 13; the action Equation (A.150) is put to use, and its variation carried out, in Chapters 43 and 44.

A.9 Wigner's Theorem on Quantum Symmetries

This appendix proves Theorem 94.3 (Chapter 94): every bijection of the unit rays of a Hilbert space that preserves transition probabilities is implemented by an operator that is either unitary or antiunitary, unique up to a phase. The theorem is stated in Wigner's 1931 monograph [687]; the proof below is Bargmann's [1269], streamlined but complete. Nothing in it assumes the Hilbert space separable: the basis index k may run over an arbitrary set.

Throughout, $\mathcal{H}$ is a complex Hilbert space with $\dim \mathcal{H} \geq 2$, the *unit ray* of a normalized vector is $[\psi] = \{e^{i\alpha}\psi \mid \alpha \in \mathbb{R}\}$, and T is a bijection of the set of unit rays with

$$|\langle \varphi' | \psi' \rangle| = |\langle \varphi | \psi \rangle| \qquad \text{for } [\psi'] = T[\psi],\ [\varphi'] = T[\varphi] \tag{A.154}$$

(representatives may be chosen arbitrarily: the modulus does not depend on the choice).

A.9.1 Orthonormal bases map to orthonormal bases

Lemma A.52. *Let $\{e_k\}$ be an orthonormal basis of $\mathcal{H}$ and choose any unit representatives $\psi_k \in T[e_k]$. Then $\{\psi_k\}$ is an orthonormal basis.*

Rests on Equation (A.154).

Proof. *Derives Lemma A.52.*

Orthonormality is Equation (A.154): $|\langle \psi_j | \psi_k \rangle| = |\langle e_j | e_k \rangle| = \delta_{jk}$. Completeness: let the unit vector χ be orthogonal to every ψ_k. Since T is surjective, $[\chi] = T[\varphi]$ for some unit φ, and then $|\langle \varphi | e_k \rangle| = |\langle \chi | \psi_k \rangle| = 0$ for every k, contradicting completeness of $\{e_k\}$ and $\|\varphi\| = 1$. □

A.9.2 Phase alignment along a basis

Fix the orthonormal basis $\{e_k\}$, single out one index, written $k = 1$, and abbreviate the normalized two- and three-component test vectors

$$u_k = \frac{e_1 + e_k}{\sqrt{2}} \quad (k \geq 2)\,, \qquad u_{jk} = \frac{e_1 + e_j + e_k}{\sqrt{3}} \quad (j \neq k\,,\ j,k \geq 2)\,. \tag{A.155}$$

Lemma A.53 (Aligned representatives)**.** *The representatives ψ_k of Lemma A.52 can be rephased, $f_1 = \psi_1$ and $f_k = e^{i\gamma_k}\psi_k$, so that the first relation below holds for every $k \geq 2$ and the remaining two for all $j \neq k$ with $j, k \geq 2$:*

$$T[u_k] = \left[\frac{f_1 + f_k}{\sqrt{2}}\right], \qquad T[u_{jk}] = \left[\frac{f_1 + f_j + f_k}{\sqrt{3}}\right], \qquad T\left[\frac{e_j + e_k}{\sqrt{2}}\right] = \left[\frac{f_j + f_k}{\sqrt{2}}\right]. \tag{A.156}$$

Rests on Lemma A.52 and Equations (A.154) and (A.155).

Proof. *Derives Lemma A.53.*

Expand a unit representative of $T[u_k]$ in the basis $\{\psi_j\}$: by Equation (A.154) tested against each $[e_j]$, its coefficients have moduli $1/\sqrt{2}$ at $j \in \{1, k\}$ and 0 elsewhere, so the representative is $(e^{i\alpha}\psi_1 + e^{i\beta}\psi_k)/\sqrt{2}$; multiplying by $e^{-i\alpha}$ (same ray) makes it $(\psi_1 + e^{i\gamma_k}\psi_k)/\sqrt{2}$ with a uniquely determined γ_k. Define $f_k = e^{i\gamma_k}\psi_k$; the first relation of Equation (A.156) holds by construction, and $f_k \in T[e_k]$ still. For the second: a representative of $T[u_{jk}]$ likewise reads $(f_1 + c_j f_j + c_k f_k)/\sqrt{3}$ with $|c_j| = |c_k| = 1$ after normalizing the f_1-coefficient; testing against $T[u_j]$ and $T[u_k]$ with Equation (A.154), $|1 + c_j| = |1 + 1| = 2$ forces $c_j = 1$, and similarly $c_k = 1$. For the third: a representative of $T[(e_j + e_k)/\sqrt{2}]$ is $(e^{i\mu} f_j + e^{i\nu} f_k)/\sqrt{2}$; testing against $T[u_{jk}]$, $|e^{-i\mu} + e^{-i\nu}| = 2$ forces $\mu = \nu$, and the common phase is dropped. □

A.9.3 The induced scalar map

Lemma A.54 (The map χ)**.** *For every $k \geq 2$ and $\alpha \in \mathbb{C}$ there is a unique $\chi_k(\alpha) \in \mathbb{C}$ with*

$$T\left[\frac{e_1 + \alpha e_k}{\sqrt{1+|\alpha|^2}}\right] = \left[\frac{f_1 + \chi_k(\alpha)\, f_k}{\sqrt{1+|\alpha|^2}}\right], \tag{A.157}$$

and $\chi_k(\alpha) \in \{\alpha, \bar{\alpha}\}$. Moreover a single alternative holds for all α and all k: either $\chi_k(\alpha) = \alpha$ for every k and α, or $\chi_k(\alpha) = \bar{\alpha}$ for every k and α. Write χ for the common map.

Rests on Lemma A.53 and Equation (A.154).

Proof. *Derives Lemma A.54.*

As in Lemma A.53, a representative of the left side has components only along f_1, f_k with moduli $1/\sqrt{1+|\alpha|^2}$ and $|\alpha|/\sqrt{1+|\alpha|^2}$; normalizing the f_1-component to be real positive determines the representative and hence $\chi_k(\alpha)$ uniquely, with $|\chi_k(\alpha)| = |\alpha|$. Testing against $T[u_k]$ via Equation (A.154) gives $|1 + \chi_k(\alpha)| = |1 + \alpha|$; together with equal moduli this forces $\Re\chi_k(\alpha) = \Re\alpha$, hence $\chi_k(\alpha) \in \{\alpha, \bar{\alpha}\}$.

No mixing within one k: suppose $\chi_k(\alpha) = \alpha$ and $\chi_k(\beta) = \bar{\beta}$ with $\Im\alpha \neq 0 \neq \Im\beta$. Test the rays Equation (A.157) for α and β against each other: Equation (A.154) demands $|1 + \bar{\alpha}\beta| = \left|1 + \bar{\alpha}\bar{\beta}\right|$, i.e. $\Re\left(\bar{\alpha}\beta\right) = \Re\left(\bar{\alpha}\bar{\beta}\right)$, i.e. $\Im\alpha\,\Im\beta = 0$ — a contradiction. Real α satisfy both alternatives, so χ_k is the identity on all of $\mathbb{C}$ or conjugation on all of $\mathbb{C}$.

No mixing across k: let $j \neq k$ and suppose $\chi_j = \mathrm{id}$ while χ_k is conjugation, and pick $\alpha = \beta = \mathrm{i}$. A representative of $T[(e_1 + \alpha e_j + \beta e_k)/\sqrt{3}]$, normalized so that its f_1-coefficient is real positive, reads $(f_1 + c_j f_j + c_k f_k)/\sqrt{3}$ with $|c_j| = |\alpha|$ and $|c_k| = |\beta|$ (tests against each $[e_m]$). Testing against the family Equation (A.157) with target j, at the two values $\gamma = 1$ and $\gamma = \mathrm{i}$, gives $\left|1 + \overline{\chi_j(\gamma)}\, c_j\right| = |1 + \bar{\gamma}\,\alpha|$, which pins the real and the imaginary part of c_j and forces $c_j = \chi_j(\alpha)$ — the within-target dichotomy just proved fixes χ_j globally, so $\chi_j(\gamma)$ is known at both test values — and likewise $c_k = \chi_k(\beta)$. Testing the resulting representative against $T[(e_j + e_k)/\sqrt{2}]$ — the third relation of Equation (A.156) — yields $|\chi_j(\alpha) + \chi_k(\beta)| = |\alpha + \beta| = 2$, whereas $\chi_j(\mathrm{i}) + \chi_k(\mathrm{i}) = \mathrm{i} + \bar{\mathrm{i}} = 0$: a contradiction. (When $\dim \mathcal{H} = 2$ there is a single k and this step is vacuous.) □

A.9.4 Proof of the theorem

Define, on finite linear combinations and extended by continuity,

$$U\left(\sum_k a_k e_k\right) = \sum_k \chi(a_k)\, f_k\,. \tag{A.158}$$

If $\chi = \mathrm{id}$, U is linear and maps the orthonormal basis $\{e_k\}$ to the orthonormal basis $\{f_k\}$ (Lemma A.52): it is unitary. If χ is conjugation, U is antilinear with $\langle U\varphi | U\psi\rangle = \overline{\langle\varphi|\psi\rangle}$: antiunitary.

Proof that U implements T. *Derives Theorem 94.3.*

Let $\psi = \sum_k a_k e_k$ be an arbitrary unit vector and $\varphi = \sum_k b_k f_k$ a unit representative of $T[\psi]$. Testing against each $[e_k]$ gives $|b_k| = |a_k|$. If only one $a_n \neq 0$, then $[\psi] = [e_n]$ and $T[\psi] = [f_n] = [U\psi]$ directly. Otherwise fix an index n with $a_n \neq 0$, taking $n = 1$ whenever $a_1 \neq 0$, and rephase φ so that $b_n = \chi(a_n)$ (possible since $|b_n| = |a_n|$). Components with $a_k = 0$ are settled at once: $|b_k| = |a_k| = 0$ gives $b_k = 0 = \chi(a_k)$; in particular, if $n \neq 1$ then $a_1 = 0$ by the choice of n, and only targets $k \geq 2$, $k \neq n$, remain to be pinned. For every such target and every $\gamma \in \mathbb{C}$ we claim

$$T\left[\frac{e_n + \gamma e_k}{\sqrt{1+|\gamma|^2}}\right] = \left[\frac{f_n + \chi(\gamma)\, f_k}{\sqrt{1+|\gamma|^2}}\right] \tag{A.159}$$

— with the *same* global χ. For $n = 1$ this is Lemma A.54 itself. For $n \geq 2$, the first two paragraphs of the proof of Lemma A.54, run with anchor n in place of 1 — the needed alignment inputs, the pair $(f_n + f_k)/\sqrt{2}$ and the triples based at n, are supplied by Equation (A.156) — yield Equation (A.159) with some uniform alternative $\chi_k^{(n)} \in \{\mathrm{id}, \text{conjugation}\}$ in place of χ. To identify the alternative, test the ray $[(e_n + \mathrm{i}e_k)/\sqrt{2}]$ against $T[(e_1 + e_n + \mathrm{i}e_k)/\sqrt{3}] = [(f_1 + f_n + \chi(\mathrm{i})\, f_k)/\sqrt{3}]$ — the latter expansion established exactly as in the no-mixing step of Lemma A.54 (anchor 1, targets n and k): Equation (A.154) demands

$$\left|1 + \overline{\chi_k^{(n)}(\mathrm{i})}\, \chi(\mathrm{i})\right| = |\langle e_n + \mathrm{i}e_k | e_1 + e_n + \mathrm{i}e_k\rangle| = 2\,,$$

and since $\chi_k^{(n)}(\mathrm{i}) = \pm\mathrm{i}$ and $\chi(\mathrm{i}) = \pm\mathrm{i}$, the left side equals 2 when $\chi_k^{(n)}(\mathrm{i}) = \chi(\mathrm{i})$ and 0 otherwise: hence $\chi_k^{(n)}(\mathrm{i}) = \chi(\mathrm{i})$, and the uniform dichotomy forces $\chi_k^{(n)} = \chi$, proving the claim. Applying Equation (A.154) to the ray Equation (A.159) against $[\psi]$:

$$|a_n + \bar{\gamma}\, a_k| = \left|b_n + \overline{\chi(\gamma)}\, b_k\right| \qquad \text{for all } \gamma \in \mathbb{C}\,.$$

Square both sides and cancel the equal terms $|a_n|^2 + |\gamma|^2\, |a_k|^2$:

$$\Re\,(\bar{a}_n\, \bar{\gamma}\, a_k) = \Re\left(\bar{b}_n\, \overline{\chi(\gamma)}\, b_k\right) = \Re\left(\overline{\chi(a_n)}\, \overline{\chi(\gamma)}\, b_k\right)\,.$$

For $\chi = \mathrm{id}$, running γ over 1 and i recovers both real and imaginary parts of $\bar{a}_n a_k$ and $\bar{a}_n b_k$ and forces $b_k = a_k = \chi(a_k)$; for χ conjugation, the same two tests force $b_k = \bar{a}_k = \chi(a_k)$. Hence $\varphi = \sum_k \chi(a_k) f_k = U\psi$, so $T[\psi] = [U\psi]$. □

Uniqueness up to phase, and exclusivity. *Derives Theorem 94.3.*

Let U and V both implement T and set $M = U^{-1}V$, an operator preserving every unit ray: $[M\psi] = [\psi]$. On the basis, $Me_k = \lambda_k e_k$ with $|\lambda_k| = 1$.

If U and V have the same linearity character, M is linear: $M(e_1 + e_k) = \lambda_1 e_1 + \lambda_k e_k$ must be proportional to $e_1 + e_k$, so $\lambda_k = \lambda_1$ for all k and $M = \lambda_1 \mathbb{1}$: $V = \lambda_1 U$.

If they had opposite character, M would be antilinear. Then $M(e_1 + e_k) = \lambda_1 e_1 + \lambda_k e_k \propto e_1 + e_k$ gives $\lambda_k = \lambda_1$, while $M(e_1 + \mathrm{i}e_k) = \lambda_1 e_1 - \mathrm{i}\lambda_k e_k \propto e_1 + \mathrm{i}e_k$ gives $\lambda_k = -\lambda_1$ — impossible. Hence for $\dim \mathcal{H} \geq 2$ a symmetry transformation is implemented *either* by unitaries *or* by antiunitaries, never both, and within its class the implementation is unique up to an overall phase. □

Remark A.55 (One dimension). If $\dim \mathcal{H} = 1$ there is a single unit ray, T is the identity, and it is implemented both by $\mathbb{1}$ (unitary) and by complex conjugation in any basis (antiunitary): the dichotomy of Theorem 94.3 genuinely requires $\dim \mathcal{H} \geq 2$.

Appendix A.9 discharges the proof obligation of Theorem 94.3; it is put to work in Corollary 94.4 — symmetries of a connected group act by honest unitaries — and through it in the whole classification of Chapter 94. The antiunitary branch is not an idle alternative: time reversal must take it, as Part XI will use.

A.10 The Classification of Kinematical Algebras

This appendix proves Theorem 14.90 (Chapter 14): under isotropy, the two discrete automorphisms, and noncompactness of the boosts, there are exactly eleven kinematical Lie algebras, organized as displayed in Table 14.1. The result is Bacry and Lévy-Leblond's [1364]; the derivation below is self-contained, and it is written out here because what it yields is not only a count but the parametrization that makes the whole family intelligible — three constants, two Jacobi constraints, and a lattice of limits that turns out to be exactly the contraction lattice.

A.10.1 The generators and the hypotheses

A *kinematical* algebra $\mathfrak{k}$ is a real ten-dimensional Lie algebra spanned by

$$J_i \text{ (rotations)}, \quad K_i \text{ (boosts)}, \quad P_i \text{ (space translations)}, \quad H \text{ (time translation)}, \tag{A.160}$$

with $i = 1, 2, 3$, subject to the three hypotheses of Theorem 14.90. Written out, they are the following.

(H1) Isotropy. The J_i close into $\mathfrak{so}(3)$, under which K_i and P_i are vectors and H is a scalar:

$$[J_i, J_j] = \epsilon_{ijk} J_k\,, \quad [J_i, K_j] = \epsilon_{ijk} K_k\,, \quad [J_i, P_j] = \epsilon_{ijk} P_k\,, \quad [J_i, H] = 0\,. \tag{A.161}$$

(H2) Parity and time reversal are automorphisms. The linear maps

$$\Pi: \quad (J_i, K_i, P_i, H) \longmapsto (J_i, -K_i, -P_i, H)\,, \tag{A.162}$$

$$\Theta: \quad (J_i, K_i, P_i, H) \longmapsto (J_i, -K_i, P_i, -H) \tag{A.163}$$

are automorphisms of $\mathfrak{k}$. These are the algebra-level statements of $\boldsymbol{x} \mapsto -\boldsymbol{x}$ and $t \mapsto -t$: a boost velocity reverses under either, a position reverses only under the first, and the generator of translation in time reverses only under the second.

(H3) Noncompact boosts. Each K_i generates a one-parameter subgroup isomorphic to $\mathbb{R}$ and not to a circle. Only the sign of one structure constant will turn out to be at stake, and (H3) is used exactly twice, in the last two cases of Appendix A.10.5.

A.10.2 Step one: the hypotheses reduce the algebra to five constants

Lemma A.56 (The general kinematical bracket)**.** *Hypotheses (H1) and (H2) force the brackets not already fixed by Equation* (A.161) *to take the form*

$$[K_i, K_j] = \alpha\, \epsilon_{ijk} J_k\,, \qquad [P_i, P_j] = \beta\, \epsilon_{ijk} J_k\,, \tag{A.164}$$

$$[K_i, P_j] = \gamma\, \delta_{ij} H\,, \qquad [K_i, H] = \mu\, P_i\,, \tag{A.165}$$

$$[P_i, H] = \nu\, K_i \tag{A.166}$$

for five real constants $\alpha, \beta, \gamma, \mu, \nu$.
Rests on Equations (A.160) *to* (A.163).

Proof. *Derives Lemma A.56.*

Each unknown bracket is an $\mathfrak{so}(3)$-covariant expression in the generators, so it may be expanded on the covariant objects available: the scalar H, the vectors J_k, K_k, P_k, and nothing else. Under (H2) each generator carries a definite pair of signs, and a bracket carries the product of the signs of its two entries:

	J_i	K_i	P_i	H
parity Π	$+$	$-$	$-$	$+$
time reversal Θ	$+$	$-$	$+$	$-$

The four cases are then immediate.

The bracket $[K_i, K_j]$. It is antisymmetric in ij, hence a vector, hence of the form $\epsilon_{ijk} V_k$ with $V \in \{J, K, P\}$. Its Π-sign is $(-)(-) = +$, which excludes K and P; only J survives. Its Θ-sign is $(-)(-) = +$, and J is Θ-even, so no further restriction arises. This gives the

first of Equation (A.164). The bracket $[P_i, P_j]$ is identical in structure, with Π-sign + and Θ-sign $(+)(+) = +$, giving the second.

The bracket $[K_i, P_j]$. As a rank-two tensor it decomposes into a trace, an antisymmetric part and a symmetric traceless part, of spins 0, 1 and 2. There is no spin-2 generator in Equation (A.160), so the symmetric traceless part vanishes identically. The trace part is $\gamma\,\delta_{ij}H$ and the antisymmetric part is $\delta\,\epsilon_{ijk}V_k$. The Π-sign is $(-)(-) = +$, which leaves H and J; the Θ-sign is $(-)(+) = -$, and H is Θ-odd while J is Θ-even, so the J term is forbidden and $\delta = 0$. This is the first of Equation (A.165), and it is worth pausing on: the reason a kinematical algebra cannot have $[K_i, P_j] \propto \epsilon_{ijk}J_k$ is time reversal alone.

The brackets with H. $[K_i, H]$ is a vector of Π-sign $(-)(+) = -$, excluding J, and of Θ-sign $(-)(-) = +$, excluding K (which is Θ-odd); only P survives. $[P_i, H]$ is a vector of Π-sign $-$, again excluding J, and of Θ-sign $(+)(-) = -$, excluding P; only K survives. These are the second of Equation (A.165) and Equation (A.166). □

A.10.3 Step two: the Jacobi identity eliminates two of the five

Lemma A.57 (The Jacobi constraints)**.** *The brackets of Lemma A.56 satisfy the Jacobi identity if and only if*

$$\boxed{\alpha = -\gamma\mu\,, \qquad \beta = \gamma\nu}\,. \tag{A.167}$$

A kinematical algebra is therefore determined by the three constants (γ, μ, ν) *alone.*

Rests on Lemma A.56 and Equation (A.161).

Proof. *Derives Lemma A.57.*

Every triple containing a J is satisfied automatically, because Equations (A.164) to (A.166) were constructed to be $\mathfrak{so}(3)$-covariant. Of the remaining triples, those built from three copies of one vector generator are also automatic: for (K_i, K_j, K_l) the cyclic sum is

$$\alpha\,(\epsilon_{ijk}\epsilon_{klm} + \epsilon_{jlk}\epsilon_{kim} + \epsilon_{lik}\epsilon_{kjm})\,K_m = 0$$

by three applications of $\epsilon_{kab}\epsilon_{kcd} = \delta_{ac}\delta_{bd} - \delta_{ad}\delta_{bc}$, the six resulting Kronecker terms cancelling in pairs; the triple (P_i, P_j, P_l) is the same computation with $\alpha \to \beta$ and $K \to P$. Four independent triples remain.

The triple (K_i, K_j, P_l). Using $[J_k, P_l] = \epsilon_{klm}P_m$ and then the same ϵ-identity,

$$\begin{aligned}
[[K_i, K_j]\,, P_l] &= \alpha\,\epsilon_{ijk}\epsilon_{klm}P_m = \alpha\,(\delta_{il}P_j - \delta_{jl}P_i)\ , \\
[[K_j, P_l]\,, K_i] &= \gamma\,\delta_{jl}\,[H, K_i] = -\gamma\mu\,\delta_{jl}P_i\,, \\
[[P_l, K_i]\,, K_j] &= -\gamma\,\delta_{il}\,[H, K_j] = +\gamma\mu\,\delta_{il}P_j\,.
\end{aligned}$$

The sum is $(\alpha + \gamma\mu)\,(\delta_{il}P_j - \delta_{jl}P_i)$, and the two tensors $\delta_{il}P_j$ and $\delta_{jl}P_i$ are linearly independent, so $\alpha = -\gamma\mu$.

The triple (P_i, P_j, K_l). Identically,

$$\begin{aligned}
[[P_i, P_j]\,, K_l] &= \beta\,(\delta_{il}K_j - \delta_{jl}K_i)\ , \\
[[P_j, K_l]\,, P_i] &= -\gamma\,\delta_{jl}\,[H, P_i] = +\gamma\nu\,\delta_{jl}K_i\,, \\
[[K_l, P_i]\,, P_j] &= \gamma\,\delta_{il}\,[H, P_j] = -\gamma\nu\,\delta_{il}K_j\,,
\end{aligned}$$

whose sum is $(\beta - \gamma\nu)\,(\delta_{il}K_j - \delta_{jl}K_i)$, so $\beta = \gamma\nu$.

The triples containing H. For (K_i, K_j, H) the three terms are $\alpha\epsilon_{ijk}\,[J_k, H] = 0$ by Equation (A.161), together with $\mu\,[P_j, K_i] - \mu\,[P_i, K_j] = \mu\gamma\delta_{ij}H - \mu\gamma\delta_{ij}H = 0$; the identity holds with no condition. The triple (P_i, P_j, H) is the same with $\mu \to \nu$. For (K_i, P_j, H),

$$\gamma\,\delta_{ij}\,[H, H] + \nu\,[K_j, K_i] - \mu\,[P_i, P_j] = -\,(\alpha\nu + \beta\mu)\,\epsilon_{ijk}J_k\,,$$

so $\alpha\nu + \beta\mu = 0$ — which is implied by Equation (A.167), since $-\gamma\mu\nu + \gamma\nu\mu = 0$. No further condition arises, and the two constraints of Equation (A.167) are the whole content of the Jacobi identity. □

A.10.4 Step three: rescaling reduces the constants to their signs

Two kinematical algebras describe the same kinematics if they differ only by a choice of units for boosts, lengths and times. The corresponding transformations

$$K_i \longmapsto \lambda K_i\,, \qquad P_i \longmapsto \rho P_i\,, \qquad H \longmapsto \sigma H\,, \qquad \lambda\rho\sigma \neq 0\,, \tag{A.168}$$

leave Equation (A.161) and both automorphisms of (H2) intact, and they exhaust that freedom: J is fixed by the normalization of Equation (A.161).

Lemma A.58 (Normal form)**.** *Under Equation* (A.168) *the three constants transform as*

$$\gamma \longmapsto \frac{\lambda\rho}{\sigma}\,\gamma\,, \qquad \mu \longmapsto \frac{\lambda\sigma}{\rho}\,\mu\,, \qquad \nu \longmapsto \frac{\rho\sigma}{\lambda}\,\nu\,. \tag{A.169}$$

Consequently:

1. *which of γ, μ, ν vanish is invariant;*
2. *every nonvanishing constant can be scaled to ± 1, and all of them simultaneously; and*
3. *the signs of the surviving constants are determined only up to a* simultaneous *flip of all three, so that the invariants are the pairwise products* $\operatorname{sgn}(\gamma\mu)$, $\operatorname{sgn}(\gamma\nu)$ *and* $\operatorname{sgn}(\mu\nu)$, *of which two are independent.*

Rests on Lemma A.57 and Equation (A.168)*.*

Proof. *Derives Lemma A.58.*

Equation (A.169) follows by substituting Equation (A.168) into Equations (A.165) and (A.166) and re-expressing the right-hand sides in the new generators; claim (1) is immediate from it, each constant being multiplied by a nonzero number. For (2), take logarithms of the absolute values: the exponents of (λ, ρ, σ) form the matrix

$$\begin{pmatrix} 1 & 1 & -1 \\ 1 & -1 & 1 \\ -1 & 1 & 1 \end{pmatrix}\,, \qquad \text{of determinant } -4 \neq 0\,,$$

so the system can be solved for $\log|\lambda|, \log|\rho|, \log|\sigma|$ whatever shifts are required; when only some constants are nonzero the corresponding subsystem is solvable a fortiori, the matrix having full rank on any subset of its rows. For (3), write $s_\lambda, s_\rho, s_\sigma$ for the signs of the scale factors. Each of the three coefficients in Equation (A.169) has the *same* sign, namely $s = s_\lambda s_\rho s_\sigma$, because each is a product of all three scale factors with one of them inverted and inversion does not change a sign. So all three constants are multiplied by one common $s \in \{\pm 1\}$, which may be chosen freely. The pairwise products are unchanged by that flip, and their own product is $(\gamma\mu\nu)^2 > 0$, so only two of them are independent. □

A.10.5 Step four: the enumeration

By Lemma A.58(1) the classification splits into the eight cases labelled by which of (γ, μ, ν) vanish; within each case, Lemma A.58(2) and (3) reduce the surviving constants to a sign pattern modulo one simultaneous flip. Writing $*$ for a nonzero constant, the count is as follows.

$(0,0,0)$ — **one algebra.** Every bracket among K, P, H vanishes, and with them α and β. This is the *static* algebra.

$(*,0,0)$ — **one algebra.** $\alpha = \beta = 0$, and the single surviving constant has a sign that the flip removes. Here $[K_i, P_j] = \delta_{ij} H$ with abelian boosts: the *Carroll* algebra.

$(0,*,0)$ — **one algebra.** Likewise one algebra, $[K_i, H] = P_i$ with every other new bracket zero: the *Galilei* algebra. Note that $\gamma = 0$ here, so $[K_i, P_j] = 0$ — the mass of Equation (25.15) is *not* in this algebra, which is exactly why it can only enter as a central extension.

$(0,0,*)$ — **one algebra.** The *para-Galilei* algebra, $[P_i, H] = K_i$.

$(0,*,*)$ — **two algebras.** $\alpha = \beta = 0$ and the invariant is $\operatorname{sgn}(\mu\nu)$: the *Newton–Hooke* algebras NH_+ and NH_-, whose difference is exponential against oscillatory behaviour of the free motion.

$(*,0,*)$ — **two algebras.** $\alpha = 0$ but $\beta = \gamma\nu \neq 0$, and the invariant is $\operatorname{sgn}\beta$. The set $\{J_i, P_i\}$ closes into $\mathfrak{so}(3,1)$ for $\beta < 0$ and into $\mathfrak{so}(4)$ for $\beta > 0$, while $\{K_i, H\}$ is an abelian ideal in both cases. These are *para-Poincaré* and the *inhomogeneous* $\mathrm{SO}(4)$. The boosts are abelian here, so (H3) is satisfied and neither is excluded.

$(*,*,0)$ — **one algebra.** $\beta = 0$ but $\alpha = -\gamma\mu \neq 0$, and the invariant is $\operatorname{sgn}\alpha$; now $\{J_i, K_i\}$ closes into $\mathfrak{so}(3,1)$ for $\alpha < 0$ and into $\mathfrak{so}(4)$ for $\alpha > 0$. In the second case the boosts generate a compact subgroup, so (H3) excludes it and only $\alpha < 0$ survives: the *Poincaré* algebra $\mathfrak{t}(4) \mathbin{\bar{\oplus}} \mathfrak{so}(3,1)$ of Equation (14.99).

$(*,*,*)$ — **two algebras.** Two independent sign invariants give four candidates; (H3) again forces $\alpha = -\gamma\mu < 0$, halving them to two, distinguished by $\operatorname{sgn}(\gamma\nu)$. These are the two simple algebras of Equations (14.109) and (14.110), $\mathfrak{so}(4,1)$ and $\mathfrak{so}(3,2)$: *de Sitter* and *anti-de Sitter*.

Adding the cases gives

$$1 + 1 + 1 + 1 + 2 + 2 + 1 + 2 = 11\,, \tag{A.170}$$

which proves Theorem 14.90. The assignment of the traditional names to the classes is Bacry and Lévy-Leblond's [1364]; what is established above is the count, the parametrization, and the structure of each class.

A.10.6 Two corollaries the enumeration makes visible

Corollary A.59 (The eight vanishing patterns are the contraction cube)**.** *Each of the three constants can be sent to zero by an Inönü–Wigner contraction, in the sense of Definition 14.83, that leaves the other two fixed:*

$$\nu \to 0: \quad P_i \mapsto \varepsilon P_i\,,\ H \mapsto \varepsilon H \qquad \textit{(the flat-space limit)}\,, \tag{A.171}$$

$$\gamma \to 0: \quad K_i \mapsto \varepsilon K_i\,,\ P_i \mapsto \varepsilon P_i \qquad \textit{(the nonrelativistic limit } c \to \infty)\,, \tag{A.172}$$

$$\mu \to 0: \quad K_i \mapsto \varepsilon K_i\,,\ H \mapsto \varepsilon H \qquad \textit{(the ultrarelativistic limit } c \to 0)\,, \tag{A.173}$$

in each case with $\varepsilon \to 0$. The three contractions commute, so from an algebra with all three constants nonzero they generate exactly the eight vanishing patterns of Appendix A.10.5. The kinematical cube *is therefore the lattice of subsets of $\{\gamma, \mu, \nu\}$: its eight vertices are the eight* cases*, not eight of the eleven algebras. Three of the eleven — one de Sitter, one Newton–Hooke, and the inhomogeneous* $\mathrm{SO}(4)$ *— are opposite-sign partners of a vertex rather than vertices of their own.*

Rests on Lemma A.58 and Definition 14.83.

Proof. *Derives Corollary A.59.*

Apply Equation (A.169) to each substitution. For Equation (A.171), $\lambda = 1$ and $\rho = \sigma = \varepsilon$ give $\gamma \mapsto \gamma$, $\mu \mapsto \mu$, $\nu \mapsto \varepsilon^2\nu$. For Equation (A.172), $\lambda = \rho = \varepsilon$ and $\sigma = 1$ give $\gamma \mapsto \varepsilon^2\gamma$

with μ and ν fixed. For Equation (A.173), $\lambda = \sigma = \varepsilon$ and $\rho = 1$ give $\mu \mapsto \varepsilon^2\mu$ with γ and ν fixed. In each case no structure constant diverges, so the limit exists and is a contraction. Commutativity is clear, the three substitutions acting as commuting diagonal matrices on (λ, ρ, σ). □

Corollary A.60 (The "para" algebras are exchanges, not new algebras)**.** *The linear map* Σ *exchanging boosts and space translations,*

$$\Sigma: \quad K_i \longmapsto P_i\,, \qquad P_i \longmapsto K_i\,, \qquad J_i \longmapsto J_i\,, \qquad H \longmapsto H\,, \tag{A.174}$$

carries the algebra with constants (γ, μ, ν) *to the algebra with constants* $(-\gamma, \nu, \mu)$*, and so exchanges the cases* $(*, *, 0)$ *and* $(*, 0, *)$*, and the cases* $(0, *, 0)$ *and* $(0, 0, *)$*. It therefore identifies,* as abstract Lie algebras*,*

$$\textit{Poincaré} \cong \textit{para-Poincaré}\,, \qquad \textit{Galilei} \cong \textit{para-Galilei}\,, \tag{A.175}$$

and identifies the inhomogeneous SO(4) *with the compact-boost algebra that (H3) excluded from the case* $(*, *, 0)$*.*

Rests on Lemmas A.56 and A.57.

Proof. *Derives Corollary A.60.*

Under Σ the bracket $[K_i, P_j] = \gamma\delta_{ij}H$ becomes $[P_i, K_j] = \gamma\delta_{ij}H$, that is $[K_j, P_i] = -\gamma\delta_{ij}H$, so $\gamma \mapsto -\gamma$; and $[K_i, H] = \mu P_i$ becomes $[P_i, H] = \mu K_i$, so $\nu \mapsto \mu$ and, symmetrically, $\mu \mapsto \nu$. The constrained constants follow from Equation (A.167): $\alpha' = -\gamma'\mu' = \gamma\nu = \beta$ and $\beta' = \gamma'\nu' = -\gamma\mu = \alpha$, so Σ exchanges the two quadratic constants as well. Applying this to Poincaré, which is $(\gamma, \mu, 0)$ with $\alpha < 0$, gives $(-\gamma, 0, \mu)$ with $\beta' = \alpha < 0$ — the case $(*, 0, *)$ with negative β, which is para-Poincaré. The same substitution applied to $(0, \mu, 0)$ gives $(0, 0, \mu)$, and applied to the excluded $\alpha > 0$ member of $(*, *, 0)$ gives the $\beta > 0$ member of $(*, 0, *)$, the inhomogeneous SO(4). □

Remark A.61 (Why the count is eleven, and what it is a count of). Corollary A.60 is the reason the eleven of Theorem 14.90 must be counted as eleven *kinematics* and not as eleven isomorphism classes of Lie algebras. The map Σ is an isomorphism of Lie algebras, but it is not an equivalence of kinematics: it fails to commute with the time reversal Equation (A.163), since it sends a Θ-odd generator to a Θ-even one, and it exchanges the physical roles of a boost and a translation. Two of the eleven are therefore abstractly the same algebra as another member of the list while describing a different physics, and Table 14.1 lists them separately for that reason. A statement of the theorem phrased as "eleven algebras up to isomorphism" is wrong, and the error is an easy one to make.

Appendix A.10 discharges the proof obligation of Theorem 14.90. Its yield for the rest of the book is Equation (A.167) and the three contractions of Corollary A.59. The second of them, Equation (A.172), is the $c \to \infty$ limit carrying the Poincaré algebra to the Galilei algebra, and the fact that it sets $\gamma = 0$ — so that $[K_i, P_j]$ vanishes identically in the contracted algebra — is precisely what leaves room for the mass to reappear there as the central charge of Proposition 25.14.

A.11 Invariant Bilinear Forms on an Expanded Algebra

This appendix proves Theorem 15.54 (Chapter 15): on $\mathfrak{g}_A = A \otimes \mathfrak{g}$ every invariant symmetric *bilinear* form has the factorised shape Equation (15.61), so for $k = 2$ the family constructed there is already the whole of it. This is the case the book uses — it is what makes Theorem 15.58 a statement about all invariant pairings and not merely about the ones written down. It is also the only case in which the statement is true: Proposition 15.55

exhibits an invariant symmetric 4-linear form that is not factorised, and Remark A.66 at the end says precisely which step of the argument below fails for $k \geq 3$ and why no repair is possible.

The hypothesis on $\mathfrak{g}$ needs care, and the care is not academic: the Lorentz algebra of the observed 3+1 dimensions is exactly the case where the naive hypothesis fails.

Definition A.62 (Absolutely simple)**.** A real Lie algebra $\mathfrak{g}$ is *absolutely simple* if its complexification $\mathfrak{g} \otimes_{\mathbb{R}} \mathbb{C}$ is a simple complex Lie algebra. Every absolutely simple algebra is simple; the converse fails, the standard counterexample being a complex simple algebra regarded as a real one.

Lemma A.63 (The invariant bilinear forms of an absolutely simple algebra form a line)**.** *Let $\mathfrak{g}$ be absolutely simple with Killing form $\kappa_{\mathfrak{g}}$. Then every invariant bilinear form on $\mathfrak{g}$ is a real multiple of $\kappa_{\mathfrak{g}}$; in particular the space of such forms is one-dimensional and every one of them is symmetric.*

Rests on Definition A.62.

Derivation. *Derives Lemma A.63.*

Let B be an invariant bilinear form, that is

$$B\left([Z,X],Y\right) + B\left(X,[Z,Y]\right) = 0 \qquad \text{for all } X,Y,Z \in \mathfrak{g}\,. \tag{A.176}$$

Define $\beta : \mathfrak{g} \to \mathfrak{g}^*$ by $\beta(X) = B(X,\cdot)$. Equation (A.176) says exactly that β intertwines the adjoint representation on $\mathfrak{g}$ with the coadjoint representation on $\mathfrak{g}^*$. Since $\mathfrak{g}$ is simple it is semisimple, so $\kappa_{\mathfrak{g}}$ is nondegenerate by Cartan's criterion and the induced map $\kappa_{\mathfrak{g}}^{\flat} : \mathfrak{g} \to \mathfrak{g}^*$ is an isomorphism of representations. Hence

$$T := \left(\kappa_{\mathfrak{g}}^{\flat}\right)^{-1} \circ \beta \in \mathrm{End}_{\mathfrak{g}}(\mathfrak{g})\,,$$

the algebra of endomorphisms commuting with the adjoint action, and $B = \kappa_{\mathfrak{g}}(T\,\cdot,\cdot)$.

It remains to show $\mathrm{End}_{\mathfrak{g}}(\mathfrak{g}) = \mathbb{R}$. Extending scalars,

$$\mathrm{End}_{\mathfrak{g}}(\mathfrak{g}) \otimes_{\mathbb{R}} \mathbb{C} \cong \mathrm{End}_{\mathfrak{g}_{\mathbb{C}}}\left(\mathfrak{g}_{\mathbb{C}}\right)\,, \qquad \mathfrak{g}_{\mathbb{C}} := \mathfrak{g} \otimes_{\mathbb{R}} \mathbb{C}\,,$$

since forming the commutant of a set of operators commutes with extension of scalars. By hypothesis $\mathfrak{g}_{\mathbb{C}}$ is simple, so its adjoint representation is irreducible over $\mathbb{C}$, and Schur's lemma over an algebraically closed field gives $\mathrm{End}_{\mathfrak{g}_{\mathbb{C}}}(\mathfrak{g}_{\mathbb{C}}) = \mathbb{C}$. Hence $\dim_{\mathbb{R}} \mathrm{End}_{\mathfrak{g}}(\mathfrak{g}) = 1$, so $T = \lambda\,\mathrm{id}$ and $B = \lambda\,\kappa_{\mathfrak{g}}$, which is symmetric. □

Theorem A.64 (Completeness of the factorised bilinear forms)**.** *Let $\mathfrak{g}$ be absolutely simple and let A be a finite-dimensional commutative associative unital $\mathbb{R}$-algebra. Then for every invariant symmetric bilinear form Ω on $\mathfrak{g}_A$ there is a* unique *linear functional $\phi : A \to \mathbb{R}$ with*

$$\boxed{\Omega\left(a \otimes X,\ b \otimes Y\right) = \phi(ab)\,\kappa_{\mathfrak{g}}(X,Y)} \qquad \textit{for all } a,b \in A,\ X,Y \in \mathfrak{g}\,. \tag{A.177}$$

Equivalently $\Omega = \langle\cdot,\cdot\rangle_{\kappa_{\mathfrak{g}},\phi}$ in the notation of Equation (15.61), and $\phi \mapsto \langle\cdot,\cdot\rangle_{\kappa_{\mathfrak{g}},\phi}$ is a linear isomorphism from A^* onto the space of invariant symmetric bilinear forms on $\mathfrak{g}_A$, which therefore has dimension $\dim A$.

Rests on Definition A.62, Lemmas 15.50 and A.63, Theorem 15.51, and Equation (15.2).

Derivation. *Derives Theorem A.64.*

Step 1: for fixed a,b the form is a multiple of the Killing form. Fix $a,b \in A$ and define the bilinear form

$$\omega_{a,b}(X,Y) := \Omega\left(a \otimes X,\ b \otimes Y\right) \tag{A.178}$$

on $\mathfrak{g}$. Invariance of Ω, applied with the element $1_A \otimes Z$ and using $[1_A \otimes Z, a \otimes X] = a \otimes [Z, X]$ from Equation (15.2), gives

$$\Omega\left(a \otimes [Z, X]\,,\ b \otimes Y\right) + \Omega\left(a \otimes X,\ b \otimes [Z, Y]\right) = 0\,,$$

that is, $\omega_{a,b}$ satisfies Equation (A.176). By Lemma A.63 there is a unique real number $\Psi(a, b)$ with

$$\omega_{a,b} = \Psi(a, b)\,\kappa_{\mathfrak{g}}\,. \tag{A.179}$$

Since Ω is bilinear in its two arguments and $\kappa_{\mathfrak{g}} \neq 0$, the function $\Psi : A \times A \to \mathbb{R}$ is bilinear; since Ω and $\kappa_{\mathfrak{g}}$ are symmetric, Ψ is symmetric.

Step 2: Ψ is a 2-trace. Now use invariance of Ω with a *general* element $c \otimes Z$. By Equation (15.2), $[c \otimes Z, a \otimes X] = (ca) \otimes [Z, X]$, so

$$\Omega\left((ca) \otimes [Z, X]\,,\ b \otimes Y\right) + \Omega\left(a \otimes X,\ (cb) \otimes [Z, Y]\right) = 0\,,$$

which by Equation (A.179) reads

$$\Psi(ca, b)\,\kappa_{\mathfrak{g}}\left([Z, X]\,, Y\right) + \Psi(a, cb)\,\kappa_{\mathfrak{g}}\left(X, [Z, Y]\right) = 0\,. \tag{A.180}$$

The Killing form is itself invariant, so $\kappa_{\mathfrak{g}}(X, [Z, Y]) = -\kappa_{\mathfrak{g}}([Z, X]\,, Y)$, and Equation (A.180) collapses to

$$\Big(\Psi(ca, b) - \Psi(a, cb)\Big)\,\kappa_{\mathfrak{g}}\left([Z, X]\,, Y\right) = 0 \qquad \text{for all } X, Y, Z \in \mathfrak{g}\,. \tag{A.181}$$

The Killing factor cannot vanish identically: a simple algebra is perfect, so the elements $[Z, X]$ span $\mathfrak{g}$, and $\kappa_{\mathfrak{g}}$ is nondegenerate, so some choice of X, Y, Z makes $\kappa_{\mathfrak{g}}([Z, X]\,, Y) \neq 0$. Hence

$$\Psi(ca, b) = \Psi(a, cb) \qquad \text{for all } a, b, c \in A\,, \tag{A.182}$$

which is Equation (15.58) at $k = 2$: Ψ is a 2-trace on A.

Step 3: a 2-trace is a linear functional of the product. By Lemma 15.50 with $k = 2$ there is a unique linear $\phi : A \to \mathbb{R}$, namely $\phi(x) = \Psi(x, 1_A)$, with $\Psi(a, b) = \phi(ab)$. Substituting into Equation (A.179) gives Equation (A.177).

Step 4: uniqueness and bijectivity. If ϕ and ϕ' both satisfy Equation (A.177) then $(\phi(ab) - \phi'(ab))\,\kappa_{\mathfrak{g}}(X, Y) = 0$; choosing X, Y with $\kappa_{\mathfrak{g}}(X, Y) \neq 0$ and $b = 1_A$ gives $\phi = \phi'$. Conversely every $\phi \in A^*$ produces an invariant symmetric bilinear form by the first part of Theorem 15.51, and the assignment is visibly linear in ϕ, while Equation (A.177) says it is onto. The two spaces are therefore isomorphic. □

Remark A.65 (The hypothesis is sharp, and 3+1 is where it bites). Lemma A.63 needs $\mathfrak{g}$ absolutely simple, not merely simple, and the difference is not a technicality in this book. The Lorentz algebra of four-dimensional spacetime, $\mathfrak{so}(3, 1)$, is simple as a real Lie algebra but *not* absolutely simple: its complexification is $\mathfrak{sl}_2(\mathbb{C}) \oplus \mathfrak{sl}_2(\mathbb{C})$, which is not simple — this is the self-dual/anti-self-dual splitting. Accordingly it carries a two-dimensional space of invariant symmetric bilinear forms, spanned by

$$\langle J_{\mu\nu}, J_{\rho\sigma}\rangle_1 = \eta_{\mu\rho}\eta_{\nu\sigma} - \eta_{\mu\sigma}\eta_{\nu\rho}\,, \qquad \langle J_{\mu\nu}, J_{\rho\sigma}\rangle_2 = \epsilon_{\mu\nu\rho\sigma}\,, \tag{A.183}$$

the first proportional to the Killing form and the second available only because $D = 4$ supplies a rank-four invariant alternating symbol. Both are invariant, and the two Chern–Weil 4-forms they generate are the two topological densities of four-dimensional gravity: the Killing form gives $R^{\mu\nu} \wedge R_{\mu\nu}$, the Pontryagin density, and $\epsilon_{\mu\nu\rho\sigma}$ gives $\epsilon_{\mu\nu\rho\sigma} R^{\mu\nu} \wedge R^{\rho\sigma}$, the Euler density of the Gauss–Bonnet term. That a four-dimensional gauge theory of the Lorentz group admits two such terms where a general dimension admits one is exactly this

failure of absolute simplicity. For such a $\mathfrak{g}$ the conclusion of Theorem A.64 must be replaced by a sum over a basis of the invariant forms of $\mathfrak{g}$, one functional ϕ for each. The algebras to which Theorem 15.29 attaches the three signs of the cosmological constant — $\mathfrak{so}(3,2)$ and $\mathfrak{so}(4,1)$ in 3+1 — *are* absolutely simple, their complexifications being $\mathfrak{sp}(4,\mathbb{C})$ and $\mathfrak{so}(5,\mathbb{C})$, so Theorem A.64 applies to them verbatim.

Remark A.66 (Why the argument stops at $k=2$, and why that is not a gap). It is worth being explicit about where the proof above uses $k=2$, because the manuscript this chapter follows [2434] states the converse for every k, and that statement is *false*.

Step 1 generalises without difficulty: evaluating invariance on $1_A \otimes Z$ shows, for any k, that $(X_1,\dots,X_k) \mapsto \Omega(a_1 \otimes X_1,\dots,a_k \otimes X_k)$ is an invariant k-linear form on $\mathfrak{g}$. Step 2 does not. It works here because the invariance relation for a bilinear form has exactly *two* terms, and the invariance of $\kappa_{\mathfrak{g}}$ itself collapses them into the single factor Equation (A.181); for $k \geq 3$ the same manipulation leaves a sum of $k-1$ terms with no reason to vanish separately. That is not a defect of the argument: by Proposition 15.55 there is an invariant symmetric 4-linear form on $\mathfrak{so}(2,1)\langle 1\rangle = \mathfrak{iso}(2,1)$ — the square of the standard pairing $\langle J_a, P_b\rangle = \eta_{ab}$ — which is not factorised at all, so no argument could have succeeded.

The structural reason is Theorem 15.53: the factorised forms are exactly the *balanced* ones, and a product of two invariant bilinear forms is not balanced, because $\phi(a_1a_2)\phi(a_3a_4)$ is not a function of $a_1a_2a_3a_4$. At $k=2$ no product is available, since $\mathrm{Inv}^1(\mathfrak{g}) = (\mathfrak{g}^*)^{\mathfrak{g}}$ vanishes for perfect $\mathfrak{g}$ — which is exactly what Theorem A.64 exploits without saying so, and is the whole of the difference between the two cases.

Appendix A.11 discharges the proof obligation of Theorem 15.54. Its yield for the rest of the book is that Theorem 15.58 classifies *all* invariant pairings on a resonant subalgebra and not merely the constructed ones, which is what makes the statement that the Galilei algebra admits none, while the Bargmann algebra does, a theorem rather than a failure to find one. Its other yield is negative and equally worth having: together with Proposition 15.55 it fixes the exact reach of the factorisation, which is $k=2$ and no further.

A.12 Darboux's Theorem: Local Canonical Coordinates

This appendix proves the geometric statement announced in Remark 5.116 of Chapter 5: a closed non-degenerate two-form on a manifold can be brought, in a neighbourhood of any point, to the constant normal form $\sum_i \mathrm{d}q^i \wedge \mathrm{d}p_i$. Symplectic geometry therefore has no local invariants whatever — no analogue of the curvature that distinguishes one Riemannian metric from another near a point — so that the absence of a signature established pointwise in Proposition 5.115 propagates to the manifold.

What is assumed as already available is exactly the differential-form machinery of Chapter 13: k-forms (Definition 13.98), the wedge product (Definition 13.102), the exterior derivative with its nilpotency and Leibniz rule (Definition 13.103 and Equations (13.245) and (13.246)), closed and exact forms (Definitions 13.105 and 13.106), the Lie derivative (Equation (13.267) and Proposition 13.127) and Cartan's magic formula (Proposition 13.128); from analysis, the mean value theorem (Theorem 7.35), the Cauchy criterion (Theorem 7.8), uniform continuity on a compact set (Theorem 7.25) and the Picard–Lindelöf theorem with its explicit contraction estimate (Theorem 9.8 and Corollary 9.9). Everything else — the pullback of a k-form, the smoothness of the flow of a time-dependent vector field, and the local converse of the Poincaré lemma — is built here, because the treatise does not carry it. The pointwise input is Proposition 5.115, and the argument that converts it into a statement about a varying form is the homotopy argument known as *Moser's trick*.

A.12.1 Statement

Definition A.67 (Symplectic manifold)**.** A *symplectic manifold* is a pair (M, ω) with M a smooth manifold (Definition 13.48) and ω a smooth two-form on M (Definition 13.98) which is

1. *closed*, $\mathrm{d}\omega = 0$ (Definition 13.105); and
2. *non-degenerate* at every point: for each $P \in M$ the matrix $\omega_{ij}(P)$ of components in any chart is invertible, equivalently $\omega_P(u, v) = 0$ for all $v \in T_M(P)$ forces $u = 0$.

Rests on Definitions 13.48, 13.98 and 13.105.

Theorem A.68 (Darboux)**.** *Let (M, ω) be a symplectic manifold and $P \in M$. Then $\dim M = 2m$ is even, and there is a chart $(u^1, \dots, u^{2m})$ of M defined on a neighbourhood of P, with $u(P) = 0$, in which*

$$\omega = \sum_{i=1}^{m} \mathrm{d}q^i \wedge \mathrm{d}p_i \,, \qquad q^i = u^i \,, \quad p_i = u^{m+i} \,. \tag{A.184}$$

Equivalently, the components of ω in this chart are the constant *block array Equation (5.144).*

Rests on Definition A.67, Proposition 5.115, and Equation (5.144).

Corollary A.69 (No local invariants)**.** *Any two symplectic manifolds of the same dimension are locally symplectomorphic: given $P \in M$ and $P' \in M'$ there are neighbourhoods $U \ni P$, $U' \ni P'$ and a diffeomorphism $f : U \longrightarrow U'$ with $f^*\omega' = \omega$. In particular no function of ω and its derivatives at a point can be a symplectic invariant.*

Rests on Theorem A.68.

Proof. *Derives Corollary A.69.*

Let u and u' be canonical charts around P and P' furnished by Theorem A.68, both with image containing a ball $B \subset \mathbb{R}^{2m}$ about the origin. Put $f = (u')^{-1} \circ u$ on $U = u^{-1}(B)$. Both ω and ω' read as the same constant form Equation (A.184) in their own charts, and the pullback of a form is computed chartwise (Definition A.70 below), so $f^*\omega' = \omega$. Any local invariant would have to take the same value at P and P', and ω, ω' were arbitrary. □

The proof of Theorem A.68 occupies the rest of this section. Appendix A.12.2 builds the pullback of a k-form and its two structural properties; Appendix A.12.3 proves that the flow of a time-dependent vector field exists and is smooth, and differentiates a pullback along it; Appendix A.12.4 proves the local converse of the Poincaré lemma on a star-shaped set; and Appendix A.12.5 assembles the three into Moser's homotopy argument.

Throughout, $|\cdot|$ is the Euclidean length on $\mathbb{R}^n$ (Equation (6.12)) and, for a real $n \times n$ matrix A,

$$\|A\| = \left(\sum_{i,j} (A_{ij})^2 \right)^{1/2} , \qquad \text{so that} \qquad |Av| \le \|A\|\,|v| \,, \quad \|AB\| \le \|A\|\,\|B\| \,, \tag{A.185}$$

the two inequalities following from the Cauchy–Schwarz inequality of Chapter 5 applied row by row.

A.12.2 The pullback of a k-form

Chapter 13 defines the pullback of a covector; the extension to a k-form is forced by the requirement that it act on k pushed-forward vectors.

Definition A.70 (Pullback)**.** Let $f : U \longrightarrow V$ be a smooth map between open subsets of $\mathbb{R}^m$ and $\mathbb{R}^n$, with components f^j, and let α be a k-form on V with components $\alpha_{j_1 \dots j_k}$. The *pullback* $f^*\alpha$ is the k-form on U with components

$$(f^*\alpha)_{i_1 \dots i_k}(x) = \alpha_{j_1 \dots j_k}(f(x))\, \partial_{i_1} f^{j_1}(x) \cdots \partial_{i_k} f^{j_k}(x) \,. \tag{A.186}$$

For $k = 1$ this is the covector pullback of Section 13.5.2, and for $k = 0$ it is $f^*g = g \circ f$. The right-hand side is totally antisymmetric in $i_1, \dots, i_k$ because α is antisymmetric in $j_1, \dots, j_k$ and the two index groups are contracted in order, so $f^*\alpha$ is again a k-form (Definition 13.98).

Rests on Definitions 7.65, 13.83 and 13.98.

Lemma A.71 (The pullback is an algebra map commuting with d)**.** *With f as above, and α, β forms on V of degrees k and l:*

$$f^*(\alpha \wedge \beta) = (f^*\alpha) \wedge (f^*\beta) \,, \tag{A.187}$$

$$f^*(\mathrm{d}\alpha) = \mathrm{d}(f^*\alpha) \,, \tag{A.188}$$

$$(g \circ f)^* \alpha = f^*(g^*\alpha) \,, \tag{A.189}$$

the last for a further smooth g defined on the target of the form.

Rests on Definition A.70 and Equations (13.245) and (13.246).

Proof. *Derives Lemma A.71.*

Composition. Equation (A.189) is the chain rule Equation (7.52) inserted k times into Equation (A.186): $\partial_i (g \circ f)^j = \partial_l g^j(f(x))\, \partial_i f^l(x)$.

Scalars and their differentials. For $k = 0$, $f^*g = g \circ f$ and $\partial_i(g \circ f) = \partial_j g(f(x))\, \partial_i f^j$, which is Equation (A.186) for the one-form $\mathrm{d}g$; hence

$$f^*(\mathrm{d}g) = \mathrm{d}(g \circ f) \,. \tag{A.190}$$

Wedge. It suffices to check Equation (A.187) on the components. Both sides are multilinear in α and β, so it is enough to take $\alpha = \mathrm{d}y^{a_1} \wedge \cdots \wedge \mathrm{d}y^{a_k}$ and $\beta = \mathrm{d}y^{b_1} \wedge \cdots \wedge \mathrm{d}y^{b_l}$ with the y the coordinates on V. By Definition 13.102 and Equation (A.186), the pullback of a wedge of coordinate differentials is the wedge of their pullbacks: for two of them,

$$\begin{aligned} \left(f^*\left(\mathrm{d}y^a \wedge \mathrm{d}y^b\right)\right)_{cd} &= \left(\delta^a{}_j \delta^b{}_k - \delta^a{}_k \delta^b{}_j\right) \partial_c f^j \, \partial_d f^k \\ &= \partial_c f^a \, \partial_d f^b - \partial_d f^a \, \partial_c f^b = \left(\mathrm{d}f^a \wedge \mathrm{d}f^b\right)_{cd} \,, \end{aligned}$$

and the same cancellation of index pairs, term by term over the permutations, gives $f^*(\mathrm{d}y^{a_1} \wedge \cdots \wedge \mathrm{d}y^{a_k}) = \mathrm{d}f^{a_1} \wedge \cdots \wedge \mathrm{d}f^{a_k}$, where $\mathrm{d}f^a = f^*\mathrm{d}y^a$ by Equation (A.190). Equation (A.187) follows because both sides then read $\mathrm{d}f^{a_1} \wedge \cdots \wedge \mathrm{d}f^{a_k} \wedge \mathrm{d}f^{b_1} \wedge \cdots \wedge \mathrm{d}f^{b_l}$.

Exterior derivative. Write $\alpha = \frac{1}{k!} \alpha_{a_1 \dots a_k}\, \mathrm{d}y^{a_1} \wedge \cdots \wedge \mathrm{d}y^{a_k}$. By the two paragraphs just proved,

$$f^*\alpha = \frac{1}{k!} (\alpha_{a_1 \dots a_k} \circ f)\, \mathrm{d}f^{a_1} \wedge \cdots \wedge \mathrm{d}f^{a_k} \,.$$

Applying d and using the Leibniz rule Equation (13.246) repeatedly, every term in which d falls on some $\mathrm{d}f^a$ vanishes by nilpotency Equation (13.245), so

$$\mathrm{d}(f^*\alpha) = \frac{1}{k!}\, \mathrm{d}(\alpha_{a_1 \dots a_k} \circ f) \wedge \mathrm{d}f^{a_1} \wedge \cdots \wedge \mathrm{d}f^{a_k} = f^*(\mathrm{d}\alpha) \,,$$

the last equality by Equation (A.190) applied to the component functions and one more use of the two paragraphs above. □

A.12.3 Flows of time-dependent vector fields

Moser's argument needs a family of diffeomorphisms generated by a vector field that changes with the parameter, and needs it to be smooth in the point as well as in the parameter. Chapter 9 supplies existence and uniqueness (Theorem 9.8); the dependence on the initial point is proved here.

Lemma A.72 (Iterated integral inequality)**.** *Let $u : [0,T] \longrightarrow [0,\infty)$ be continuous and suppose*

$$u(t) \le c + L\int_0^t u(s)\,\mathrm{d}s\,, \qquad 0 \le t \le T\,, \tag{A.191}$$

with constants $c \ge 0$, $L \ge 0$. Then $u(t) \le c\,\mathrm{e}^{Lt}$.

Rests on Theorem 7.43 and Definition 7.53.

Proof. *Derives Lemma A.72.*

Let $S = \max_{[0,T]} u$, finite by Theorem 7.24. We show by induction that for every $N \ge 0$

$$u(t) \le c\sum_{j=0}^{N} \frac{(Lt)^j}{j!} + S\,\frac{(Lt)^{N+1}}{(N+1)!}\,. \tag{A.192}$$

For $N = 0$, Equation (A.191) and $u \le S$ give $u(t) \le c + LSt$. Assuming Equation (A.192) at N and substituting it into Equation (A.191), term-by-term integration gives

$$u(t) \le c + L\int_0^t \left[c\sum_{j=0}^{N}\frac{(Ls)^j}{j!} + S\frac{(Ls)^{N+1}}{(N+1)!}\right]\mathrm{d}s = c\sum_{j=0}^{N+1}\frac{(Lt)^j}{j!} + S\frac{(Lt)^{N+2}}{(N+2)!}\,,$$

which is the statement at $N+1$. The last term of Equation (A.192) tends to 0 as $N \to \infty$, because the exponential series converges (Definition 7.53), and the sum tends to e^{Lt}. □

Lemma A.73 (Differentiation under the integral sign)**.** *Let $K \subset \mathbb{R}^n$ be open, $F : [0,1] \times K \longrightarrow \mathbb{R}$ continuous with $\partial F/\partial x^i$ existing and continuous on $[0,1] \times K$ for each i. Then $G(x) = \int_0^1 F(t,x)\,\mathrm{d}t$ has continuous partial derivatives on K and*

$$\partial_i G(x) = \int_0^1 \partial_i F(t,x)\,\mathrm{d}t\,. \tag{A.193}$$

Rests on Theorems 7.25 and 7.35 and Definition 7.65.

Proof. *Derives Lemma A.73.*

Fix $x \in K$ and $r > 0$ with $\overline{B}_r(x) \subset K$. For $0 < |s| \le r$ the mean value theorem Theorem 7.35 applied to $\lambda \mapsto F(t, x + \lambda \boldsymbol{e}_i)$ gives $\theta = \theta(t,s) \in (0,1)$ with

$$\frac{F(t, x + s\boldsymbol{e}_i) - F(t,x)}{s} = \partial_i F(t, x + \theta s\,\boldsymbol{e}_i)\,.$$

The set $[0,1] \times \overline{B}_r(x)$ is compact, so $\partial_i F$ is uniformly continuous there (Theorem 7.25): given $\varepsilon > 0$ there is $\delta > 0$ with $|\partial_i F(t,y) - \partial_i F(t,x)| < \varepsilon$ whenever $|y - x| < \delta$, uniformly in t. Hence for $|s| < \delta$ the difference quotient of G differs from $\int_0^1 \partial_i F(t,x)\mathrm{d}t$ by at most ε, which is Equation (A.193). Continuity of the right-hand side in x follows from the same uniform continuity. □

Theorem A.74 (Flow of a time-dependent vector field)**.** *Let $U \subseteq \mathbb{R}^n$ be open, let $X : [0,1] \times U \longrightarrow \mathbb{R}^n$ be smooth — all partial derivatives in (t,x) of every order exist and are continuous — and let $p \in U$ satisfy $X_t(p) = 0$ for every $t \in [0,1]$. Then there is an open ball $B \ni p$ with $\overline{B} \subset U$ and a smooth map $\psi : [0,1] \times B \longrightarrow U$ with*

$$\partial_t \psi(t,x) = X_t(\psi(t,x))\,, \qquad \psi(0,x) = x\,, \qquad \psi(t,p) = p\,, \tag{A.194}$$

and each $\psi_t = \psi(t,\cdot)$ is a diffeomorphism of B onto an open subset of U.

Rests on Theorem 9.8, Corollary 9.9, and Lemma A.72.

Proof. *Derives Theorem A.74.*

A Lipschitz box. Choose $r > 0$ with $\overline{B}_{2r}(p) \subset U$ and put $Q = [0,1] \times \overline{B}_{2r}(p)$, a compact set. On Q the continuous functions X and $\partial_j X^i$ are bounded (Theorem 7.24); set $M = \max_Q |X|$ and

$$L = \sqrt{n}\, \max_Q \|D_x X\| \,, \tag{A.195}$$

with $D_x X$ the matrix $\partial_j X^i$ and $\|\cdot\|$ as in Equation (A.185). Since $\overline{B}_{2r}(p)$ is convex, Theorem 7.35 applied componentwise along the segment from z to y bounds each component of the difference by $|\nabla_x X^i|\,|y-z| \le \|D_x X\|\,|y-z|$, and summing the n squares gives

$$|X_t(y) - X_t(z)| \le L\,|y-z| \,, \qquad y, z \in \overline{B}_{2r}(p)\,, \quad t \in [0,1]\,. \tag{A.196}$$

Existence on all of $[0,1]$. The constant curve $y \equiv p$ solves Equation (A.194) with $y(0) = p$, because $X_t(p) = 0$; by uniqueness in Theorem 9.8 it is *the* solution through p, which is the third assertion of Equation (A.194). Let now $x \in B := B_\delta(p)$ with $\delta = r\,\mathrm{e}^{-L}$, and let $\psi_t(x)$ be the maximal solution. So long as it remains in $\overline{B}_{2r}(p)$, the integral form of the equation and Equation (A.196) give

$$|\psi_t(x) - p| = \left| x - p + \int_0^t [X_s(\psi_s(x)) - X_s(p)]\,\mathrm{d}s \right| \le |x-p| + L\int_0^t |\psi_s(x) - p|\,\mathrm{d}s\,,$$

so Lemma A.72 yields

$$|\psi_t(x) - p| \le \mathrm{e}^L\,|x-p| < r\,. \tag{A.197}$$

The solution therefore never approaches the boundary of $\overline{B}_{2r}(p)$. Since the Picard step $h = \min\{1,\ r/M\}$ of Theorem 9.8 is the same at every starting time in $[0,1]$ and every starting point of $\overline{B}_r(p)$, the solution can be continued in steps of that fixed length and reaches $t = 1$ after finitely many of them.

Lipschitz dependence. For $x, y \in B$ the same computation with p replaced by y, using Equation (A.196) (both curves stay in $\overline{B}_r(p)$ by Equation (A.197)) and Lemma A.72, gives

$$|\psi_t(x) - \psi_t(y)| \le \mathrm{e}^L\,|x-y| \,, \qquad t \in [0,1]\,. \tag{A.198}$$

The variational equation. Put $A(t,x) = D_x X(t, \psi_t(x))$, continuous on $[0,1] \times B$ with $\|A\| \le L$, and let $\Phi(\cdot, x)$ be the unique solution of the linear system

$$\partial_t \Phi(t,x) = A(t,x)\,\Phi(t,x)\,, \qquad \Phi(0,x) = \mathbb{1}\,, \tag{A.199}$$

which exists on the whole of $[0,1]$ by Corollary 9.9. Its integral form and Lemma A.72 give $\|\Phi(t,x)\| \le \sqrt{n}\,\mathrm{e}^L$.

Φ *is continuous in* x. Subtracting the integral forms of Equation (A.199) at x and at y,

$$\Phi(t,x) - \Phi(t,y) = \int_0^t A(s,x)\,[\Phi(s,x) - \Phi(s,y)]\,\mathrm{d}s + \int_0^t [A(s,x) - A(s,y)]\,\Phi(s,y)\,\mathrm{d}s\,.$$

The second integral is bounded by $\sqrt{n}\,\mathrm{e}^L\,\eta(x,y)$ with $\eta(x,y) = \max_s \|A(s,x) - A(s,y)\|$, and $\eta(x,y) \to 0$ as $y \to x$: $D_x X$ is uniformly continuous on the compact Q (Theorem 7.25) and $|\psi_s(x) - \psi_s(y)| \le \mathrm{e}^L\,|x-y|$ by Equation (A.198). Lemma A.72 then gives $\|\Phi(t,x) - \Phi(t,y)\| \le \sqrt{n}\,\mathrm{e}^{2L}\eta(x,y)$.

Φ *is the derivative.* Fix $x \in B$ and let h be small enough that $x + h \in B$. Put $\Delta(t) = \psi_t(x+h) - \psi_t(x)$ and $R(t) = \Delta(t) - \Phi(t,x)h$, so $R(0) = 0$ and

$$\partial_t R(t) = X_t(\psi_t(x+h)) - X_t(\psi_t(x)) - A(t,x)\Phi(t,x)h = A(t,x)R(t) + \rho(t)\,,$$

where $\rho(t) = X_t(z+\Delta) - X_t(z) - D_x X(t,z)\Delta$ with $z = \psi_t(x)$. Applying Theorem 7.35 to $\lambda \mapsto X_t^i(z + \lambda\Delta)$ gives $\theta_i \in (0,1)$ with $\rho^i(t) = [\partial_j X^i(t, z + \theta_i\Delta) - \partial_j X^i(t,z)]\,\Delta^j$, whence

$|\rho(t)| \le w(|\Delta|)\,|\Delta|$, where w is $\sqrt{n}$ times a modulus of uniform continuity of D_xX on the compact set Q (Theorem 7.25), so that $w(\lambda) \to 0$ as $\lambda \to 0$. With $|\Delta| \le \mathrm{e}^{L}\,|h|$ from Equation (A.198), the integral form of the equation for R and Lemma A.72 give

$$|R(t)| \le \mathrm{e}^{L}\, w\Big(\mathrm{e}^{L}\,|h|\Big)\,\mathrm{e}^{L}\,|h|\ ,$$

so $|R(t)|\,/\,|h| \to 0$ as $h \to 0$. By Definition 7.67, ψ_t is differentiable at x with differential $\Phi(t,x)$; the previous paragraph makes the partial derivatives continuous, so ψ_t is C^1 (Definition 7.66).

Derivatives of every order. We show by induction on $k \ge 1$: if X is C^k then ψ is C^k in x. The case $k = 1$ is what was just proved. Let X be C^{k+1} and consider the enlarged system on $U \times \mathbb{R}^{n\times n}$,

$$\partial_t \begin{pmatrix} y \\ \Phi \end{pmatrix} = \begin{pmatrix} X_t(y) \\ D_xX(t,y)\,\Phi \end{pmatrix}\ , \qquad (y,\Phi)(0) = (x,\mathbb{1})\,, \tag{A.200}$$

whose right-hand side is C^k in (y,Φ) because X is C^{k+1}. Its solution is exactly $(\psi(t,x),\Phi(t,x))$, and the induction hypothesis applied to Equation (A.200) makes it C^k in the initial data, hence in x. So $\partial\psi/\partial x = \Phi$ is C^k in x, i.e. ψ is C^{k+1} in x. Since moreover $\partial_t\psi = X_t(\psi)$, every derivative in t is a polynomial expression in derivatives of X and of ψ in x; hence all mixed partial derivatives of ψ in (t,x) of every order exist and are continuous, and ψ is smooth.

Diffeomorphism. Fix $t \in [0,1]$ and let η_s be the flow built by the same construction for the field $Y_s(y) = -X_{t-s}(y)$, which also vanishes at p; let B_2 be its ball. That ball is the *same* for every t: the construction used only r, M and L, and those depend on X and the box Q alone, not on t, while $|Y|$ and $\|D_xY\|$ have the same maxima over Q as $|X|$ and $\|D_xX\|$. Shrinking B once and for all so that $\mathrm{e}^{L}\delta$ is smaller than the radius of B_2, Equation (A.197) puts $\psi_t(B)$ inside B_2 for every t. For $x \in B$ the curve $s \mapsto \psi_{t-s}(x)$ satisfies $\mathrm{d}/\mathrm{d}s = -X_{t-s}(\psi_{t-s}(x)) = Y_s(\cdot)$ and starts at $\psi_t(x)$, so uniqueness (Theorem 9.8) gives $\eta_t(\psi_t(x)) = \psi_0(x) = x$. Put $W = \{y \in B_2 \mid \eta_t(y) \in B\}$, open because η_t is continuous. Then $\psi_t(B) \subseteq W$; and for $y \in W$ the same uniqueness argument run backwards gives $\psi_t(\eta_t(y)) = y$, so $W \subseteq \psi_t(B)$. Hence $\psi_t : B \longrightarrow W$ is a bijection onto an open set, with inverse η_t, and both are smooth. □

Lemma A.75 (Differentiating a pullback along a flow)**.** *Let $\varphi : I \times U \longrightarrow V$ be smooth, $I \subseteq \mathbb{R}$ an interval, $U, V \subseteq \mathbb{R}^n$ open, and let X_t be a smooth time-dependent vector field on V with*

$$\partial_t\varphi_t(x) = X_t(\varphi_t(x))\,. \tag{A.201}$$

Let α_t be a smooth time-dependent k-form on V. Then

$$\frac{\mathrm{d}}{\mathrm{d}t}\,(\varphi_t^*\alpha_t) = \varphi_t^*\,(\mathcal{L}_{X_t}\alpha_t + \partial_t\alpha_t)\ , \tag{A.202}$$

where the Lie derivative of a k-form has the components

$$(\mathcal{L}_X\alpha)_{j_1\ldots j_k} = X^l\partial_l\alpha_{j_1\ldots j_k} + \sum_{a=1}^{k}\alpha_{j_1\ldots l\ldots j_k}\,\partial_{j_a}X^l\,, \tag{A.203}$$

the index l standing in the a-th slot.

Rests on Definition A.70 and Propositions 7.73 and 13.127.

Proof. *Derives Lemma A.75.*

By Equation (A.186),

$$(\varphi_t^*\alpha_t)_{i_1\ldots i_k}(x) = \alpha_{t,\,j_1\ldots j_k}(\varphi_t(x))\,\partial_{i_1}\varphi_t^{j_1}(x)\cdots\partial_{i_k}\varphi_t^{j_k}(x)\,.$$

Differentiate in t by the product rule. The first factor contributes, by the chain rule Equation (7.52) and Equation (A.201),

$$\left[\partial_t \alpha_{t,\, j_1 \dots j_k} + X_t^l \, \partial_l \alpha_{t,\, j_1 \dots j_k}\right] (\varphi_t(x)) \, \partial_{i_1} \varphi_t^{j_1} \cdots \partial_{i_k} \varphi_t^{j_k} \, .$$

For the remaining k factors, the mixed partial derivatives of φ may be exchanged (Proposition 7.73), so

$$\partial_t \, \partial_i \varphi_t^j(x) = \partial_i \left(X_t^j(\varphi_t(x)) \right) = \partial_l X_t^j(\varphi_t(x)) \, \partial_i \varphi_t^l(x) \, ,$$

again by Equation (7.52). The a-th such term is therefore

$$\alpha_{t,\, j_1 \dots j_a \dots j_k}(\varphi_t) \, \partial_l X_t^{j_a}(\varphi_t) \, \partial_{i_a} \varphi_t^l \prod_{b \neq a} \partial_{i_b} \varphi_t^{j_b} \, ,$$

which, after renaming the summation indices $j_a \leftrightarrow l$, is the pullback of the a-th drag term of Equation (A.203). Collecting the $k+1$ contributions gives Equation (A.202). Finally, taking $\alpha_t = \alpha$ independent of t, $\varphi_0 = \mathrm{id}$ and $X_t = X$, the identity at $t = 0$ reads $\mathrm{d}\left(\varphi_t^* \alpha\right) / \mathrm{d}t \big|_0 = \mathcal{L}_X \alpha$ with the right-hand side Equation (A.203): this is the definition Equation (13.267) of the Lie derivative, so Equation (A.203) is indeed the k-form case of Proposition 13.127 — one transport term and one drag term per index — and no separate verification is needed. □

A.12.4 The local converse of the Poincaré lemma

Lemma 13.107 states one half of the correspondence: an exact form is closed. The half needed here is the converse, which is false in general (it fails on a punctured plane) and true on a star-shaped set. Chapter 13 announces the dependence on topology but does not prove the positive statement; it is proved here.

Definition A.76 (Star-shaped set)**.** An open set $B \subseteq \mathbb{R}^n$ is *star-shaped about* $x_0 \in B$ if $x_0 + t\,(x - x_0) \in B$ for every $x \in B$ and every $t \in [0, 1]$. Every open ball is star-shaped about each of its points.

Rests on Definition 6.26.

Lemma A.77 (Poincaré lemma, converse form)**.** *Let $B \subseteq \mathbb{R}^n$ be open and star-shaped about x_0, and let α be a smooth closed k-form on B with $k \geq 1$. Then $\alpha = \mathrm{d}\sigma$, where σ is the $(k-1)$-form with components*

$$\sigma_{i_2 \dots i_k}(x) = \int_0^1 t^{k-1} \, (x - x_0)^j \, \alpha_{j\, i_2 \dots i_k}\big(x_0 + t(x - x_0)\big) \, \mathrm{d}t \, . \tag{A.204}$$

In particular $\sigma(x_0) = 0$, and for $k = 2$ the one-form σ vanishes at x_0.

Rests on Definition A.76, Lemmas A.73 and A.75, and Proposition 13.128.

Proof. *Derives Lemma A.77.*

Translating, take $x_0 = 0$. Put $\varphi_t(x) = tx$ for $t \in (0, 1]$, which maps B into B by Definition A.76, and

$$X_t(y) = \frac{y}{t} \, , \qquad \text{so that} \qquad \partial_t \varphi_t(x) = x = \frac{\varphi_t(x)}{t} = X_t(\varphi_t(x)) \, ,$$

which is Equation (A.201). Both φ and X are smooth on $(0, 1] \times B$. By Lemma A.75 with $\alpha_t = \alpha$ fixed, and by Cartan's magic formula Equation (13.276) together with $\mathrm{d}\alpha = 0$,

$$\frac{\mathrm{d}}{\mathrm{d}t} \left(\varphi_t^* \alpha\right) = \varphi_t^* \left(\mathcal{L}_{X_t} \alpha\right) = \varphi_t^* \left(\mathrm{d}\, i_{X_t} \alpha\right) = \mathrm{d}\left(\varphi_t^* \, i_{X_t} \alpha\right) \, , \tag{A.205}$$

the last step by Equation (A.188). The components of the form being differentiated are

$$(\varphi_t^*\, i_{X_t}\alpha)_{i_2\ldots i_k}(x) = t^{k-1}\, x^j\, \alpha_{j\, i_2\ldots i_k}(tx)\,, \tag{A.206}$$

since $(i_{X_t}\alpha)_{i_2\ldots i_k}(y) = t^{-1}y^j\alpha_{j\,i_2\ldots i_k}(y)$ by the interior-product convention of Proposition 13.128, each of the $k-1$ pullback factors $\partial_i\varphi_t^j = t\,\delta^j{}_i$ contributes a t, and $y = tx$ supplies $y^j/t = x^j$. The right-hand side of Equation (A.206) extends continuously to $t = 0$ because $k \geq 1$, and so do its partial derivatives in x, so σ of Equation (A.204) is a well-defined smooth $(k-1)$-form and, by Lemma A.73, d may be taken under the integral sign. Integrating Equation (A.205) from ε to 1,

$$\varphi_1^*\alpha - \varphi_\varepsilon^*\alpha = \mathrm{d}\int_\varepsilon^1 \varphi_t^*\, i_{X_t}\alpha\; \mathrm{d}t\,. \tag{A.207}$$

Now $\varphi_1 = \mathrm{id}$, so the first term is α; and $(\varphi_\varepsilon^*\alpha)_{i_1\ldots i_k}(x) = \varepsilon^k\alpha_{i_1\ldots i_k}(\varepsilon x)$ tends to 0 as $\varepsilon \to 0$, again because $k \geq 1$ and α is continuous at the origin. Letting $\varepsilon \to 0$ in Equation (A.207), with the interchange of d and the integral justified by Lemma A.73, gives $\alpha = \mathrm{d}\sigma$ with σ as in Equation (A.204). Setting $x = x_0$ there makes the factor $(x - x_0)^j$ vanish, so $\sigma(x_0) = 0$. □

A.12.5 Moser's homotopy argument

Proof of Theorem A.68. *Derives Theorem A.68.*

Step 1: the pointwise normal form. Let $n = \dim M$. The bilinear form ω_P on the n-dimensional real vector space $T_M(P)$ is antisymmetric and non-degenerate (Definition A.67), so Proposition 5.115 applies: $n = 2m$ is even and there is a basis $\{e_1, \ldots, e_m, f_1, \ldots, f_m\}$ of $T_M(P)$ in which Equation (5.143) holds, that is, in which the matrix of ω_P is Equation (5.144).

Step 2: a chart adapted at the point. Choose any chart $x = (x^1, \ldots, x^{2m})$ around P with $x(P) = 0$ and with the coordinate vectors ∂_i at P equal to that basis — possible because the coordinate frame of a chart may be composed with any constant invertible linear map (Definition 13.2), and the change of basis carrying the coordinate frame to $\{e_i, f_i\}$ is invertible. Let B_0 be an open ball in the image of the chart, centred at the origin. Define on B_0 the *constant-coefficient* two-form

$$\omega_0 = \sum_{i=1}^{m} \mathrm{d}x^i \wedge \mathrm{d}x^{m+i}\,, \qquad \text{components} \qquad (\omega_0)_{i,\,m+i} = +1 = -\,(\omega_0)_{m+i,\,i}\;, \tag{A.208}$$

all other components vanishing. Its matrix is exactly Equation (5.144), so by Step 1

$$\omega_0|_P = \omega|_P\;, \tag{A.209}$$

and $\mathrm{d}\omega_0 = 0$ because its components are constants (Definition 13.103).

Step 3: the interpolation. Put $\tau = \omega - \omega_0$ and

$$\omega_t = \omega_0 + t\,\tau = (1-t)\,\omega_0 + t\,\omega\,, \qquad t \in [0,1]\,. \tag{A.210}$$

Each ω_t is closed, since ω and ω_0 are; and by Equation (A.209), $\omega_t|_P = \omega|_P$ for *every* t, which is non-degenerate. The function

$$D(t,x) = \det\left[(\omega_t)_{ij}\,(x)\right]$$

is continuous on $[0,1] \times B_0$ — a polynomial in the components, which are continuous — and $D(t,0) \neq 0$ for every t. For each $t \in [0,1]$ continuity therefore supplies an open interval $I_t \ni t$ and a ball $B^{(t)} \ni 0$ on which D does not vanish; the intervals I_t cover the compact $[0,1]$

(Theorem 6.11), finitely many of them suffice, and the intersection B_1 of the corresponding finitely many balls is an open ball about the origin on which

$$\omega_t \text{ is non-degenerate for every } t \in [0,1]\,. \tag{A.211}$$

Step 4: the primitive. B_1 is star-shaped about the origin (Definition A.76) and τ is a closed two-form on it, so Lemma A.77 gives a smooth one-form σ on B_1 with

$$\mathrm{d}\sigma = \tau\,, \qquad \sigma(0) = 0\,. \tag{A.212}$$

The vanishing of σ at the origin — which is Equation (A.209) feeding through the explicit homotopy formula — is what will pin the point P and is the reason the argument is local rather than global.

Step 5: the vector field. Let $W^{ij}(t,x)$ be the inverse of the matrix $(\omega_t)_{ij}(x)$, which exists on $[0,1]\times B_1$ by Equation (A.211) and whose entries are smooth there, being rational functions of the components with non-vanishing denominator D. Define the time-dependent vector field

$$X_t^k(x) = -\,W^{ik}(t,x)\,\sigma_i(x)\,, \qquad \text{equivalently} \qquad i_{X_t}\omega_t = -\,\sigma\,, \tag{A.213}$$

the equivalence because $(i_X\omega_t)_i = X^j\,(\omega_t)_{ji}$, and contracting $X^j(\omega_t)_{ji} = -\sigma_i$ with W^{ik} returns Equation (A.213). It is smooth in (t,x), and by Equation (A.212)

$$X_t(0) = 0 \qquad \text{for every } t \in [0,1]\,. \tag{A.214}$$

Step 6: the flow. By Equation (A.214), Theorem A.74 applies: there is a ball $B_2 \ni 0$ and a smooth family $\psi_t : B_2 \longrightarrow B_1$, $t \in [0,1]$, of diffeomorphisms onto open sets, with $\psi_0 = \mathrm{id}$, $\partial_t\psi_t = X_t \circ \psi_t$ and $\psi_t(0) = 0$.

Step 7: the homotopy equation. By Lemma A.75, Cartan's magic formula Equation (13.276), $\mathrm{d}\omega_t = 0$, $\partial_t\omega_t = \tau$ and Equation (A.213),

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\,(\psi_t^*\omega_t) &= \psi_t^*\,(\mathcal{L}_{X_t}\omega_t + \partial_t\omega_t)\\ &= \psi_t^*\,(\mathrm{d}\,i_{X_t}\omega_t + i_{X_t}\mathrm{d}\omega_t + \tau)\\ &= \psi_t^*\,(\mathrm{d}(-\sigma) + 0 + \mathrm{d}\sigma) = 0\,,\end{aligned} \tag{A.215}$$

where the last line used Equation (A.212). Hence $\psi_t^*\omega_t$ is independent of t on B_2, and at $t=0$ it equals $\psi_0^*\omega_0 = \omega_0$. Taking $t = 1$,

$$\psi_1^*\omega = \omega_0 \qquad \text{on } B_2\,. \tag{A.216}$$

Step 8: reading off the chart. Let $W = \psi_1(B_2)$, an open neighbourhood of 0, and define on it

$$u^a = x^a \circ \psi_1^{-1}\,, \qquad a = 1,\dots,2m\,, \tag{A.217}$$

a chart of M around P with $u(P) = 0$, since ψ_1 is a diffeomorphism and $\psi_1(0) = 0$. Applying $\left(\psi_1^{-1}\right)^*$ to Equation (A.216) and using Equation (A.189), $\omega = \left(\psi_1^{-1}\right)^*\omega_0$ on W. By Equation (A.190), $\left(\psi_1^{-1}\right)^*\mathrm{d}x^a = \mathrm{d}\left(x^a\circ\psi_1^{-1}\right) = \mathrm{d}u^a$, and by Equation (A.187) the pullback distributes over the wedge, so Equation (A.208) becomes

$$\omega = \sum_{i=1}^{m} \mathrm{d}u^i \wedge \mathrm{d}u^{m+i}\,,$$

which is Equation (A.184) with $q^i = u^i$ and $p_i = u^{m+i}$. □

A.12.6 Reading the result

Remark A.78 (Where each hypothesis is used). Both hypotheses of Definition A.67 are load-bearing and they enter at different places. Non-degeneracy is used twice: at *one point* in Step 1, to get the linear normal form from Proposition 5.115, and on a *neighbourhood* in Step 5, to solve Equation (A.213) for X_t — without it the homotopy equation cannot be solved even though it is a linear algebraic equation. Closedness is used twice as well: in Step 4, where $\mathrm{d}\tau = 0$ is precisely the hypothesis of Lemma A.77, and in Step 7, where $i_{X_t}\mathrm{d}\omega_t$ is dropped from Cartan's formula. A non-degenerate two-form that is not closed has no canonical chart, and the obstruction is exactly the three-form $\mathrm{d}\omega$, which is a genuine local invariant.

Remark A.79 (The SI units of a symplectic form). Remark 5.116 records that on the phase space of a mechanical system the value $\omega(u, v)$ carries the SI unit J s, that of action and of $\hbar$. Nothing in the proof above disturbs this: the chart of Step 2 is obtained by a *constant* linear change of frame, which distributes the unit between the two halves of the canonical pair, and every later step is an identity between two-forms and so is unit-homogeneous. In the canonical chart of Equation (A.184) the product $q^i p_i$ carries J s while the individual factors do not have to: for a point particle of mass m moving in three-dimensional space, q^i is a Cartesian position in m and p_i the conjugate momentum in kg m/s, so each summand $\mathrm{d}q^i \wedge \mathrm{d}p_i$ carries $\mathrm{kg\,m^2/s} = \mathrm{J\,s}$, as it must.

Example A.80 (The phase space of one particle in space)**.** Take $M = T^*\mathbb{R}^3$, the phase space of a single particle moving in three-dimensional space: $m = 3$, $\dim M = 6$, global coordinates $(q^1, q^2, q^3, p_1, p_2, p_3)$ and $\omega = \sum_{i=1}^{3} \mathrm{d}q^i \wedge \mathrm{d}p_i$. Here the canonical chart is global and Theorem A.68 says nothing new. Its force appears when the same phase space is written in another coordinate system — spherical coordinates and their conjugate momenta, or the action–angle variables of an integrable system: the theorem guarantees that the transformed ω can always be brought back to Equation (A.184) near any point, so that no computation in one such system can disagree with a computation in another about a local question.

Rests on Theorem A.68 and Remark A.79.

Remark A.81 (Attribution). The theorem is Darboux's; the proof given here is not his, but the homotopy argument that interpolates between two forms and integrates a time-dependent vector field, introduced by Moser for volume forms [1317] and adapted to the symplectic case shortly afterwards. Darboux's own memoir is not in this treatise's bibliography, so that half of the attribution is made in words; nothing in Appendices A.12.2 to A.12.5 rests on either, every step above having been carried out from the material of Chapter 5, Chapter 7, Chapter 9 and Chapter 13.

Remark A.82. Appendix A.12 discharges the derivation owed at Remark 5.116 of Chapter 5, where Proposition 5.115 establishes the pointwise half of the statement — a non-degenerate antisymmetric form on a single vector space has no invariant but its dimension — and Darboux's theorem is named as the geometric counterpart that does *not* follow from it. The gap between the two is exactly Steps 3 to 7 above: the linear normal form can be achieved at every point separately by a basis that varies from point to point, and it is closedness of ω, through the Poincaré lemma and the homotopy equation, that lets those bases be chosen to fit together into a chart. The three tools built along the way — the pullback of a k-form (Definition A.70), the smoothness of a flow (Theorem A.74) and the converse Poincaré lemma (Lemma A.77) — belong with the differential-form machinery of Sections 13.6, 13.6.5 and 13.9 and are used again in Appendix A.29.

A.13 The Korn–Lichtenstein Theorem and the Elliptic Canonical Form

This appendix discharges the obligation recorded in Remark 10.14 of Chapter 10: the elliptic branch of Proposition 10.13, the reduction of a second-order operator in two independent variables to the canonical form $u_{\xi\xi}+u_{\eta\eta}$, under coefficients that are merely C^1 and therefore only locally Hölder. The chapter's argument constructs the required complex first integral by complexifying the characteristic equation, which needs the coefficients to be real analytic; nothing in real ordinary differential equation theory replaces that step, because what is really being asked for is not a first integral of an ordinary equation at all but a solution of a first-order elliptic *system* in two variables — a Beltrami equation.

Four things are done below. First the reduction is made exact: the canonical form exists at a point if and only if a Beltrami equation with a coefficient of modulus bounded away from 1 has a local solution with non-vanishing Jacobian, and each of the equivalent formulations is derived from the previous one with nothing left implicit (Appendix A.13.2). Then the problem is normalized so that the Beltrami coefficient is as small as one pleases, in the Hölder norm and not merely in the supremum norm (Appendix A.13.3); this is where the Hölder hypothesis is spent, and it is what turns an existence problem into a convergent series. Then the singular-integral machinery is set out and the one deep estimate is stated precisely as a quoted theorem, with a remark saying exactly what is assumed and why this treatise does not prove it (Appendix A.13.4). Finally the solution is constructed as an explicitly convergent Neumann series and the Jacobian is bounded below by hand (Appendix A.13.5), which completes the proof.

Throughout, x and y are the two *independent variables* of the partial differential equation — not two spatial dimensions — and $z=x+\mathrm{i}y$, $\bar z=x-\mathrm{i}y$, with

$$\partial_z=\tfrac12(\partial_x-\mathrm{i}\,\partial_y)\,,\qquad \partial_{\bar z}=\tfrac12(\partial_x+\mathrm{i}\,\partial_y)\,, \tag{A.218}$$

so that $\partial_x=\partial_z+\partial_{\bar z}$ and $\partial_y=\mathrm{i}(\partial_z-\partial_{\bar z})$, and $\nabla^2=4\partial_z\partial_{\bar z}$. We write $D_\rho=\{z\in\mathbb{C}\mid |z|<\rho\}$, and for $0<\alpha<1$

$$[f]_\alpha=\sup_{z\neq w}\frac{|f(z)-f(w)|}{|z-w|^{\alpha}}\,, \tag{A.219}$$

C^α denoting the functions with $[f]_\alpha<\infty$ and $C^{k,\alpha}$ those whose derivatives up to order k lie in C^α.

A.13.1 Statement

Theorem A.83 (Local canonical form for an elliptic operator with Hölder coefficients)**.** *Let $Lu=a\,u_{xx}+2b\,u_{xy}+c\,u_{yy}+\cdots$ be elliptic on a neighbourhood of P_0, that is $\Delta=b^2-ac<0$ there, with a,b,c of class C^α for some $\alpha\in(0,1)$ — in particular whenever they are C^1. Then there are a neighbourhood V of P_0 and a map $(\xi,\eta):V\longrightarrow\mathbb{R}^2$ of class $C^{1,\alpha}$ whose Jacobian $J_0=\xi_x\eta_y-\xi_y\eta_x$ is bounded away from 0 on V, such that the transformed principal coefficients of Equation (10.12) satisfy*

$$\tilde a=\tilde c=\delta\,J_0>0\,,\qquad \tilde b=0\,,\qquad \delta=\sqrt{ac-b^2}\,, \tag{A.220}$$

so that in the coordinates (ξ,η) the principal part of L is $\delta J_0(\partial_\xi^2+\partial_\eta^2)$, a positive multiple of the Laplacian. If in addition $a,b,c\in C^{1,\alpha}$, the map is of class $C^{2,\alpha}$ and the reduction is classical: the transformed operator is a genuine second-order operator with continuous coefficients, of the third form in Equation (10.10).

Rests on Proposition 10.13, Definition 10.6, and Equation (10.6).

Two remarks fix what Theorem A.83 does and does not claim, and the second is the reason the theorem is stated in two halves.

Remark A.84 (Why the principal part is the whole claim at C^1). The congruence Equation (10.6) that carries A to $\tilde{A}$ involves the Jacobian J and nothing else, so it is meaningful for any C^1 change of coordinates and is a pointwise statement of linear algebra. The *extra* term of Equation (10.7), by contrast, carries the second derivatives $\partial_i \partial_j y^a$ of the change; a $C^{1,\alpha}$ change does not have them, so for coefficients that are merely C^α the transformed equation is not literally an equation with continuous first-order coefficients — the first-order remainder exists only as a distribution. Nothing is wrong with the reduction; what is wrong is the naive reading of what "the equation becomes $u_{\xi\xi} + u_{\eta\eta} + \cdots$" asserts. This is why the theorem separates the two statements, and why the second half buys the classical form with one extra derivative on the coefficients. The chapter's sentence that the conclusion of Proposition 10.13 "does hold at C^1" is correct in the first sense and should be read in it.

Remark A.85. There is no loss in assuming $a > 0$. Ellipticity gives $ac > b^2 \geq 0$, so a and c are nonzero and of the same sign; replacing L by $-L$, which changes no solution of $Lu = f$ except by the sign of f, makes both positive. The matrix A of Equation (10.11) is then positive definite, and $\delta = \sqrt{ac - b^2} = \sqrt{\det A} > 0$ is continuous and bounded away from 0 near P_0.

A.13.2 From the canonical form to a Beltrami equation

Proposition A.86 (The complex characteristic equation)**.** *Let ξ, η be real C^1 functions near P_0 and set $\zeta = \xi + \mathrm{i}\eta$. Then, with $\tilde{a}, \tilde{b}, \tilde{c}$ the transformed principal coefficients of Equation (10.12),*

$$a\,\zeta_x^2 + 2b\,\zeta_x\zeta_y + c\,\zeta_y^2 = (\tilde{a} - \tilde{c}) + 2\mathrm{i}\,\tilde{b}\,. \tag{A.221}$$

Hence $\tilde{a} = \tilde{c}$ and $\tilde{b} = 0$ hold at a point if and only if ζ satisfies the characteristic equation Equation (10.8) there, with the complex $\nabla\zeta$ in place of $\nabla\phi$.

Rests on Equations (10.8) and (10.12).

Proof. *Derives Proposition A.86.*

Expand, using $\zeta_x = \xi_x + \mathrm{i}\eta_x$ and $\zeta_y = \xi_y + \mathrm{i}\eta_y$:

$$a\zeta_x^2 = a(\xi_x^2 - \eta_x^2) + 2\mathrm{i}a\,\xi_x\eta_x\,,$$

$$2b\,\zeta_x\zeta_y = 2b(\xi_x\xi_y - \eta_x\eta_y) + 2\mathrm{i}b(\xi_x\eta_y + \eta_x\xi_y)\,,$$

$$c\,\zeta_y^2 = c(\xi_y^2 - \eta_y^2) + 2\mathrm{i}c\,\xi_y\eta_y\,.$$

The real parts sum to $(a\xi_x^2 + 2b\xi_x\xi_y + c\xi_y^2) - (a\eta_x^2 + 2b\eta_x\eta_y + c\eta_y^2) = \tilde{a} - \tilde{c}$ by Equation (10.12), and the imaginary parts sum to twice the polarisation $a\xi_x\eta_x + b(\xi_x\eta_y + \eta_x\xi_y) + c\xi_y\eta_y = \tilde{b}$. □

Proposition A.87 (The isothermal system)**.** *Assume $a > 0$ and $\Delta < 0$, and write $\delta = \sqrt{ac - b^2} > 0$. A C^1 pair (ξ, η) satisfies the equation of Proposition A.86 with the branch $a\zeta_x + (b + \mathrm{i}\delta)\zeta_y = 0$ if and only if*

$$\eta_x = -\frac{b\,\xi_x + c\,\xi_y}{\delta}\,, \qquad \eta_y = \frac{a\,\xi_x + b\,\xi_y}{\delta}\,. \tag{A.222}$$

For such a pair,

$$J_0 = \xi_x\eta_y - \xi_y\eta_x = \frac{a\xi_x^2 + 2b\xi_x\xi_y + c\xi_y^2}{\delta} = \frac{\tilde{a}}{\delta}\,, \tag{A.223}$$

so $J_0 > 0$ exactly where $\nabla\xi \neq 0$, and Equation (A.220) holds there.

Rests on Proposition A.86 and Equation (10.11).

Proof. *Derives Proposition A.87.*

The quadratic $at^2 + 2bt + c$ has the two roots $t_\pm = (-b \pm \mathrm{i}\delta)/a$, so $a\zeta_x^2 + 2b\zeta_x\zeta_y + c\zeta_y^2 = a(\zeta_x - t_+\zeta_y)(\zeta_x - t_-\zeta_y)$ and the equation of Proposition A.86 holds if and only if one of the two factors vanishes. Take the factor $\zeta_x - t_-\zeta_y = 0$, i.e. $a\zeta_x + (b + \mathrm{i}\delta)\zeta_y = 0$ (the other branch is the complex conjugate statement and produces $\bar{\zeta}$). Separating real and imaginary parts of $a(\xi_x + \mathrm{i}\eta_x) + (b + \mathrm{i}\delta)(\xi_y + \mathrm{i}\eta_y) = 0$,

$$a\xi_x + b\xi_y - \delta\eta_y = 0\,, \qquad a\eta_x + b\eta_y + \delta\xi_y = 0\,. \tag{A.224}$$

The first is the second half of Equation (A.222). Substituting it into the second and using $\delta^2 = ac - b^2$, so that $b^2 + \delta^2 = ac$,

$$a\eta_x = -\delta\xi_y - \frac{b(a\xi_x + b\xi_y)}{\delta} = -\frac{ab\,\xi_x + (b^2 + \delta^2)\xi_y}{\delta} = -\frac{a(b\,\xi_x + c\,\xi_y)}{\delta}\,,$$

and dividing by $a \neq 0$ gives the first half. The steps are reversible, which is the "only if".

For Equation (A.223), substitute Equation (A.222):

$$\xi_x\eta_y - \xi_y\eta_x = \frac{\xi_x(a\xi_x + b\xi_y) + \xi_y(b\xi_x + c\xi_y)}{\delta}\,,$$

which is the displayed quadratic form. That form is $\boldsymbol{v}^{\mathsf{T}} A\,\boldsymbol{v}/\delta$ with $\boldsymbol{v} = (\xi_x, \xi_y)$ and A the positive definite matrix of Equation (10.11) (Remark A.85), so it is positive whenever $\boldsymbol{v} \neq 0$ and zero otherwise. Finally Proposition A.86 gives $\tilde{a} = \tilde{c}$ and $\tilde{b} = 0$, and Equation (A.223) identifies $\tilde{a} = \delta J_0$, which is Equation (A.220). □

Remark A.88 (Why this is not an ordinary differential equation). Eliminating η from Equation (A.222) by the equality of mixed partials $\partial_y\eta_x = \partial_x\eta_y$ gives, for ξ alone, the second-order equation in divergence form

$$\partial_x\!\left(\frac{a\,\xi_x + b\,\xi_y}{\delta}\right) + \partial_y\!\left(\frac{b\,\xi_x + c\,\xi_y}{\delta}\right) = 0\,, \tag{A.225}$$

whose principal part is again L's. That is the exact sense in which the elliptic branch of Proposition 10.13 is circular if attacked head-on: putting an elliptic operator in canonical form is equivalent to solving an elliptic equation with the same principal part. The hyperbolic and parabolic branches escape this because there the two characteristic directions are *real*, so the corresponding first integrals come from Theorem 9.8 applied to a real ordinary differential equation, which needs no more than continuity and a Lipschitz condition. The complex route below breaks the circle by solving Equation (A.225) not by elliptic theory but by inverting a constant-coefficient operator, $\partial_{\bar{z}}$, and treating everything else as a perturbation.

Proposition A.89 (Beltrami form). *With $a > 0$, $\Delta < 0$ and $\delta = \sqrt{ac - b^2}$, the branch $a\zeta_x + (b + \mathrm{i}\delta)\zeta_y = 0$ of Proposition A.87 is exactly the* Beltrami equation

$$\partial_{\bar{z}}\zeta = \mu\,\partial_z\zeta\,, \qquad \mu = -\frac{a - \delta + \mathrm{i}b}{a + \delta - \mathrm{i}b}\,, \tag{A.226}$$

and its coefficient satisfies

$$|\mu|^2 = \frac{(a - \delta)^2 + b^2}{(a + \delta)^2 + b^2} < 1\,, \tag{A.227}$$

with $\mu = 0$ exactly where A is a positive multiple of the identity. Moreover the Jacobian of $z \longmapsto \zeta$ is

$$J_0 = |\partial_z\zeta|^2 - |\partial_{\bar{z}}\zeta|^2 = \left(1 - |\mu|^2\right)\,|\partial_z\zeta|^2\,. \tag{A.228}$$

Rests on Proposition A.87 and Equation (A.218).

Proof. *Derives Proposition A.89.*

Substitute $\zeta_x = \partial_z\zeta + \partial_{\bar z}\zeta$ and $\zeta_y = \mathrm{i}(\partial_z\zeta - \partial_{\bar z}\zeta)$ from Equation (A.218) into $a\zeta_x + (b + \mathrm{i}\delta)\zeta_y = 0$ and use $(b+\mathrm{i}\delta)\mathrm{i} = -\delta + \mathrm{i}b$:

$$(a - \delta + \mathrm{i}b)\partial_z\zeta + (a + \delta - \mathrm{i}b)\partial_{\bar z}\zeta = 0\,.$$

The coefficient of $\partial_{\bar z}\zeta$ has modulus squared $(a+\delta)^2 + b^2 > 0$ and never vanishes, so the equation may be solved for $\partial_{\bar z}\zeta$, giving Equation (A.226). Its modulus is Equation (A.227), and $(a-\delta)^2 < (a+\delta)^2$ because a and δ are both positive; equality of the numerator with 0 requires $b = 0$ and $a = \delta = \sqrt{ac}$, i.e. $a = c$ and $b = 0$.

For Equation (A.228), write $A_1 = \zeta_x$ and $B_1 = \mathrm{i}\zeta_y$, so that $\partial_z\zeta = \frac{1}{2}(A_1 - B_1)$ and $\partial_{\bar z}\zeta = \frac{1}{2}(A_1 + B_1)$. Then

$$|\partial_z\zeta|^2 - |\partial_{\bar z}\zeta|^2 = \tfrac{1}{4}\left(|A_1 - B_1|^2 - |A_1 + B_1|^2\right) = -\Re(\bar A_1 B_1) = -\Re(\mathrm{i}\,\bar\zeta_x\zeta_y) = \Im(\bar\zeta_x\zeta_y)\,,$$

and $\bar\zeta_x\zeta_y = (\xi_x - \mathrm{i}\eta_x)(\xi_y + \mathrm{i}\eta_y)$ has imaginary part $\xi_x\eta_y - \eta_x\xi_y = J_0$. Inserting Equation (A.226) gives the second equality. □

Proposition A.89 reduces Theorem A.83 to a single question: does Equation (A.226) have a local $C^{1,\alpha}$ solution with $\partial_z\zeta \neq 0$? Note that Equation (A.228) has already disposed of the Jacobian: because $|\mu|$ is bounded away from 1, a solution whose $\partial_z\zeta$ does not vanish automatically has J_0 bounded away from 0, and no separate argument is needed.

A.13.3 Normalizing the Beltrami coefficient

Lemma A.90 (Affine normalization)**.** *There is an invertible real linear change of the independent variables after which $A(P_0) = \mathbb{1}$, $\delta(P_0) = 1$ and $\mu(P_0) = 0$, the transformed coefficients being again of class C^α and again elliptic.*

Rests on Proposition A.89 and Theorem 10.8.

Proof. *Derives Lemma A.90.*

$A(P_0)$ is symmetric and positive definite (Remark A.85), so it factors as $A(P_0) = S\,S^{\mathsf T}$ with S real and invertible — take $S = O\Lambda^{1/2}$ with $A(P_0) = O\Lambda O^{\mathsf T}$ its orthogonal diagonalization, the eigenvalues in Λ being positive. Change variables by $\hat{\boldsymbol{x}} = S^{-1}\boldsymbol{x}$, whose Jacobian is the constant matrix $J = S^{-1}$; by Equation (10.6) the new principal matrix is

$$\hat A = S^{-1}A\,(S^{-1})^{\mathsf T}\,, \qquad \hat A(P_0) = S^{-1}S\,S^{\mathsf T}(S^{\mathsf T})^{-1} = \mathbb{1}\,. \tag{A.229}$$

Congruence with a constant matrix preserves Hölder continuity and, by Theorem 10.8, ellipticity. At P_0 one then has $\hat a = \hat c = 1$, $\hat b = 0$, $\hat\delta = 1$, and Equation (A.226) gives $\mu(P_0) = -(1-1+0)/(1+1-0) = 0$. Since a composition of two changes of coordinates with non-vanishing Jacobians is again one, proving Theorem A.83 for the normalized problem proves it in general. □

Lemma A.91 (Smallness after rescaling)**.** *Assume the normalization of Lemma A.90 and identify P_0 with $0 \in \mathbb{C}$. Fix once and for all a cutoff $\chi \in C^\infty(\mathbb{C})$ with $0 \le \chi \le 1$, $\chi = 1$ on $\overline{D_1}$ and $\chi = 0$ off D_2. For $r > 0$ put*

$$\nu_r(z) = \chi(z)\,\mu(rz)\,. \tag{A.230}$$

Then $\nu_r \in C^\alpha(\mathbb{C})$ vanishes off $\overline{D_2}$, coincides with $z \longmapsto \mu(rz)$ on $\overline{D_1}$, satisfies $\|\nu_r\|_\infty \le \sup|\mu| < 1$, and

$$\|\nu_r\|_\infty + [\nu_r]_\alpha \le K\,r^\alpha\,[\mu]_\alpha \longrightarrow 0 \qquad (r \to 0^+)\,, \tag{A.231}$$

with K depending only on χ and α. If moreover $a, b, c \in C^{1,\alpha}$, the same holds with the $C^{1,\alpha}$ norm in place of the C^α norm and r in place of r^α.

Rests on Lemma A.90 and Equation (A.219).

Proof. *Derives Lemma A.91.*

μ is a rational function of a, b, δ with non-vanishing denominator, hence of class C^α on a neighbourhood of 0; shrink that neighbourhood to a disc D_ρ and take $r < \rho/2$ so that $rz \in D_\rho$ for $z \in D_2$. Write $\mu^{(r)}(z) = \mu(rz)$. Since $\mu(0) = 0$ by Lemma A.90,

$$\left|\mu^{(r)}(z)\right| = |\mu(rz) - \mu(0)| \le [\mu]_\alpha \, |rz|^\alpha \le [\mu]_\alpha \, (2r)^\alpha \qquad (z \in D_2)\,, \tag{A.232}$$

and directly from Equation (A.219), $[\mu^{(r)}]_{\alpha, D_2} = r^\alpha [\mu]_\alpha$. For the product with the cutoff, use $|\chi f(z) - \chi f(w)| \le |\chi(z)|\,|f(z) - f(w)| + |f(w)|\,|\chi(z) - \chi(w)|$, so that

$$[\chi f]_\alpha \le \|\chi\|_\infty \, [f]_\alpha + \|f\|_\infty \, [\chi]_\alpha\,, \tag{A.233}$$

which with Equation (A.232) gives $[\nu_r]_\alpha \le r^\alpha [\mu]_\alpha + (2r)^\alpha [\mu]_\alpha [\chi]_\alpha$. Adding $\|\nu_r\|_\infty \le (2r)^\alpha [\mu]_\alpha$ gives Equation (A.231) with $K = 1 + 2^\alpha (1 + [\chi]_\alpha)$. The bound $\|\nu_r\|_\infty \le \sup|\mu| < 1$ is Equation (A.227) and $0 \le \chi \le 1$. Under the stronger hypothesis $a, b, c \in C^{1,\alpha}$ one has $\mu \in C^{1,\alpha}$ and $\partial \mu^{(r)} = r\,(\partial\mu)(rz)$, so every seminorm entering the $C^{1,\alpha}$ norm of $\mu^{(r)}$ carries at least one factor r, and the same product estimate applies. □

Remark A.92 (Where the Hölder hypothesis is spent). Lemma A.91 is the whole use made of the Hölder continuity of the coefficients, and it is worth seeing why mere continuity would not do. Continuity of μ at P_0 makes $\|\nu_r\|_\infty$ small, which is enough for an L^p theory but not for a Hölder one; what the exponent α buys is the factor r^α in Equation (A.231), which makes the *seminorm* small as well and thereby turns the Neumann series of Appendix A.13.5 into a convergent series in the very space where the solution's regularity is measured. A zooming argument of this kind is available only because the Beltrami equation is invariant under $z \longmapsto rz$: if $\hat\zeta$ solves $\partial_{\bar z}\hat\zeta = \mu^{(r)}\,\partial_z\hat\zeta$ on D_1, then $\zeta(w) = \hat\zeta(w/r)$ solves Equation (A.226) on D_r, both derivatives picking up the same factor $1/r$, and the Jacobian is multiplied by the positive number r^{-2}.

A.13.4 The Cauchy and Beurling transforms

Definition A.93 (Cauchy and Beurling transforms)**.** For f continuous and vanishing outside a compact set put

$$Pf(z) = \frac{1}{\pi}\int_{\mathbb{C}} \frac{f(w)}{z - w}\,\mathrm{d}A(w)\,, \qquad Tf(z) = -\frac{1}{\pi}\,\mathrm{p.v.}\!\int_{\mathbb{C}} \frac{f(w)}{(z-w)^2}\,\mathrm{d}A(w)\,, \tag{A.234}$$

$\mathrm{d}A$ being the area element of the plane and the principal value meaning the limit of the integral over $|z - w| > \varepsilon$ as $\varepsilon \to 0^+$. P is the *Cauchy transform* and T the *Beurling transform*.

Rests on Equation (A.218).

The integral defining Pf converges absolutely, the kernel $|z-w|^{-1}$ being integrable in the plane; the one defining Tf does not, and the principal value is not a notational convenience but the entire difficulty. The next lemma explains why P is the right object, and is the one part of the analytic package this treatise can prove outright, because it is the two-dimensional twin of Proposition 10.67.

Lemma A.94 (Fundamental solution of $\partial_{\bar z}$)**.** *In the sense of distributions on* $\mathbb{C} \cong \mathbb{R}^2$,

$$\nabla^2\!\left(\frac{1}{2\pi}\ln|z|\right) = \delta\,, \qquad \textit{and hence} \qquad \partial_{\bar z}\!\left(\frac{1}{\pi z}\right) = \delta\,. \tag{A.235}$$

Consequently $Pf = (\pi z)^{-1} * f$ *satisfies* $\partial_{\bar z} Pf = f$ *distributionally.*

Rests on Proposition 10.67 and Equation (A.218).

Proof. *Derives Lemma A.94.*

Let $G(z) = (2\pi)^{-1} \ln|z|$, which is harmonic on $\mathbb{C}\backslash\{0\}$ because $\nabla^2 \ln r = r^{-1}\partial_r(r\,\partial_r \ln r) = r^{-1}\partial_r(1) = 0$ in plane polar coordinates. Let φ be a test function. Since $\ln|z|$ is integrable near the origin, $\int G\nabla^2\varphi \,\mathrm{d}A = \lim_{\varepsilon\to 0^+} \int_{r>\varepsilon} G\nabla^2\varphi \,\mathrm{d}A$. On $r > \varepsilon$ apply Green's second identity Equation (10.41) with $p = 1$, $u = \varphi$, $v = G$; the term $\varphi\nabla^2 G$ vanishes, and the only boundary is the circle $r = \varepsilon$, whose outward normal for the region $r > \varepsilon$ points at the origin, so $\partial_\nu = -\partial_r$ there. Hence

$$-\int_{r>\varepsilon} G\,\nabla^2\varphi \,\mathrm{d}A = \oint_{r=\varepsilon} (-\varphi\,\partial_r G + G\,\partial_r\varphi)\,\mathrm{d}s = -\frac{1}{2\pi\varepsilon}\oint_{r=\varepsilon} \varphi\,\mathrm{d}s + \frac{\ln\varepsilon}{2\pi}\oint_{r=\varepsilon} \partial_r\varphi\,\mathrm{d}s\,,$$

using $\partial_r G = (2\pi r)^{-1}$. The circle has length $2\pi\varepsilon$, so the first term tends to $-\varphi(0)$ by continuity of φ and the second is bounded by $\varepsilon\,|\ln\varepsilon|\sup|\nabla\varphi| \to 0$. Thus $\int G\nabla^2\varphi\,\mathrm{d}A = \varphi(0)$, which is the first half of Equation (A.235). For the second, note $\nabla^2 = 4\partial_z\partial_{\bar z}$ and $\partial_z \ln|z| = \partial_z \frac{1}{2}\ln(z\bar z) = 1/(2z)$, so $\delta = 4\partial_{\bar z}\partial_z G = 4\partial_{\bar z}(1/(4\pi z)) = \partial_{\bar z}(1/(\pi z))$. Finally Equation (A.234) is the convolution of f with $1/(\pi z)$, and differentiating a convolution moves the derivative onto either factor. □

Theorem A.95 (Quoted: the Korn–Lichtenstein estimate for the Beurling transform)**.** *Let $0 < \alpha < 1$ and let $f \in C^\alpha(\mathbb{C})$ vanish outside $\overline{D_2}$. Then:*

1. *the principal value defining Tf in Equation (A.234) exists at every point of $\mathbb{C}$;*
2. *Pf is continuously differentiable on $\mathbb{C}$, with*

$$\partial_{\bar z} Pf = f\,, \qquad \partial_z Pf = Tf \tag{A.236}$$

   holding classically;

3. *$Tf \in C^\alpha(\mathbb{C})$ and*

$$\|Tf\|_\infty + [Tf]_\alpha \le C_\alpha\,[f]_\alpha\,, \tag{A.237}$$

   with C_α depending only on α;

4. *if in addition $f \in C^{k,\alpha}$ for an integer $k \ge 1$, then $Tf \in C^{k,\alpha}$ and $\|Tf\|_{C^{k,\alpha}} \le C_{k,\alpha}\,\|f\|_{C^{k,\alpha}}$.*

Remark A.96 (What is quoted here). Theorem A.95 is the only input of this section that is not proved, and it is worth being exact about its three parts. Part (ii) is half proved above: $\partial_{\bar z} Pf = f$ is Lemma A.94, and the Hölder hypothesis upgrades it from a distributional to a classical identity. Parts (i) and the second half of (ii) — that the singular integral converges and that it is the z-derivative of Pf — are the statement that differentiating the Newtonian-type potential Pf a second time is legitimate in the principal-value sense; the same question arises for the Newtonian potential of Proposition 10.67, where the chapter needed only one derivative and could avoid it. Part (iii) is the substantial content: it says the Beurling transform, a singular integral operator whose kernel $(z-w)^{-2}$ is exactly at the critical homogeneity for the plane, is bounded on Hölder spaces. That is the *Korn–Lichtenstein inequality*, proved for such kernels by Korn in 1914 and Lichtenstein in 1916 and placed in its general setting by the Calderón–Zygmund theory of singular integrals [997]; the standard modern account of the Beltrami equation built on it is Vekua's. The two original memoirs and Vekua's monograph are not entries of this bibliography, so those attributions are made in words; what the treatise does contain and does cite for the classical, real-analytic route is Courant and Hilbert [1222].

Why the estimate is not proved here is not a matter of length. Its proof requires the Calderón–Zygmund decomposition of a function relative to a cube, or an equivalent covering argument, and both rest on Lebesgue measure and on the maximal function; Chapter 7

develops the Riemann integral only, and the Lebesgue theory these arguments belong to is not built anywhere in this book. Everything else in this section — the reduction of Appendix A.13.2, the normalization of Appendix A.13.3, the convergent series and the Jacobian bound of Appendix A.13.5 — is elementary once Equation (A.237) is granted, and is carried out in full.

Remark A.97 (The shape of the estimate). Two features of Equation (A.237) are used below and are worth isolating. First, the right-hand side involves only the seminorm $[f]_\alpha$, which is legitimate because f vanishes off $\overline{D_2}$: every point of $\overline{D_2}$ lies within distance 4 of a point where f vanishes, so $\|f\|_\infty \le 4^\alpha [f]_\alpha$, and $[\,\cdot\,]_\alpha$ is therefore a genuine norm on the space of such f, complete because a $[\,\cdot\,]_\alpha$-Cauchy sequence converges uniformly and its limit inherits the seminorm bound. Second, the left-hand side controls $\|Tf\|_\infty$ as well as $[Tf]_\alpha$, and the supremum bound is what will be needed to keep $\partial_z \zeta$ away from zero.

A.13.5 The construction and the Jacobian

Proposition A.98 (A convergent Neumann series). *Let $\nu \in C^\alpha(\mathbb{C})$ vanish off $\overline{D_2}$ and set*

$$\varepsilon_\nu = \left(\|\nu\|_\infty + [\nu]_\alpha\right) C_\alpha \,, \tag{A.238}$$

with C_α the constant of Equation (A.237). If $\varepsilon_\nu < 1$ then the series

$$h = \sum_{n=0}^{\infty} h_n \,, \qquad h_0 = \nu \,, \qquad h_{n+1} = \nu\, T h_n \,, \tag{A.239}$$

converges in the space X of C^α functions vanishing off $\overline{D_2}$, and its sum is the unique element of X with

$$h = \nu(1 + Th) \,, \qquad [h]_\alpha \le \frac{[\nu]_\alpha}{1 - \varepsilon_\nu} \,. \tag{A.240}$$

Rests on Theorem A.95 and Equation (A.219).

Proof. *Derives Proposition A.98.*

Each h_n lies in X: it is a product one of whose factors is ν, which vanishes off $\overline{D_2}$, and it is Hölder because Th_{n-1} is, by Equation (A.237). By the product estimate Equation (A.233) applied to $\nu\, Tg$ and then Equation (A.237),

$$[\nu\, Tg]_\alpha \le \|\nu\|_\infty \,[Tg]_\alpha + [\nu]_\alpha \,\|Tg\|_\infty \le \left(\|\nu\|_\infty + [\nu]_\alpha\right)\left(\|Tg\|_\infty + [Tg]_\alpha\right) \le \varepsilon_\nu \,[g]_\alpha \tag{A.241}$$

for every $g \in X$. Hence $[h_n]_\alpha \le \varepsilon_\nu^n [\nu]_\alpha$ by induction, and the series Equation (A.239) is dominated term by term by a geometric series of ratio $\varepsilon_\nu < 1$. Since $[\,\cdot\,]_\alpha$ is a complete norm on X (Remark A.97), the series converges there, with the bound stated in Equation (A.240); the same domination and Lemma 9.6 give uniform convergence, so the sum may be rearranged and T applied term by term, T being bounded. Then

$$\nu(1 + Th) = \nu + \nu\, T\left(\sum_{n\ge 0} h_n\right) = h_0 + \sum_{n\ge 0} h_{n+1} = h \,,$$

which is Equation (A.240). Uniqueness: if $h, h' \in X$ both satisfy it, then $[h - h']_\alpha = [\nu T(h - h')]_\alpha \le \varepsilon_\nu [h - h']_\alpha$ by Equation (A.241), and $\varepsilon_\nu < 1$ forces $[h - h']_\alpha = 0$, hence $h = h'$ since both vanish off a compact set. □

Proposition A.99 (The solution and its Jacobian). *In the situation of Proposition A.98, suppose in addition*

$$\frac{C_\alpha [\nu]_\alpha}{1 - \varepsilon_\nu} \le \frac{1}{2} \,. \tag{A.242}$$

Then $\zeta(z) = z + Ph(z)$ is of class $C^{1,\alpha}$ on $\mathbb{C}$, solves $\partial_{\bar z}\zeta = \nu\,\partial_z\zeta$ there, and satisfies

$$|\partial_z\zeta| \geq \tfrac{1}{2}\,, \qquad J_0 = \left(1 - |\nu|^2\right)|\partial_z\zeta|^2 \geq \tfrac{1}{4}\left(1 - \|\nu\|_\infty^2\right) > 0\,. \tag{A.243}$$

Rests on Proposition A.98, Theorem A.95, and Equation (A.228).

Proof. *Derives Proposition A.99.*

By part (ii) of Theorem A.95 applied to $h \in X$,

$$\partial_{\bar z}\zeta = \partial_{\bar z} z + \partial_{\bar z} Ph = h\,, \qquad \partial_z\zeta = 1 + Th\,, \tag{A.244}$$

both continuous and Hölder by part (iii), so $\zeta \in C^{1,\alpha}$. The Beltrami equation $\partial_{\bar z}\zeta = \nu\,\partial_z\zeta$ reads, after Equation (A.244), precisely $h = \nu(1 + Th)$, which is Equation (A.240). For the Jacobian, Equation (A.237) and Equation (A.240) give

$$\|Th\|_\infty \leq C_\alpha [h]_\alpha \leq \frac{C_\alpha [\nu]_\alpha}{1 - \varepsilon_\nu} \leq \frac{1}{2}$$

by Equation (A.242), so $|\partial_z\zeta| = |1 + Th| \geq 1 - \frac{1}{2} = \frac{1}{2}$ everywhere. Equation (A.228) then yields the second half of Equation (A.243), and $\|\nu\|_\infty < 1$ makes it strictly positive. □

Proof of Theorem A.83. *Derives Theorem A.83.*

By Remark A.85 assume $a > 0$, and by Lemma A.90 assume further that $A(P_0) = \mathbb{1}$ and $\mu(P_0) = 0$, P_0 being the origin of $\mathbb{C}$; both reductions are linear changes of the independent variables with constant non-vanishing Jacobian, and composing them with the map constructed below gives the map of the theorem.

Let ν_r be the cutoff coefficient of Lemma A.91. By Equation (A.231) both ε_{ν_r} of Equation (A.238) and the left-hand side of Equation (A.242) are bounded by $C_\alpha K r^\alpha [\mu]_\alpha$ times a constant, so choosing r small enough makes $\varepsilon_{\nu_r} \leq \frac{1}{2}$ and Equation (A.242) hold. Fix such an r. Propositions A.98 and A.99 then produce $\hat\zeta \in C^{1,\alpha}(\mathbb{C})$ with $\partial_{\bar z}\hat\zeta = \nu_r \partial_z \hat\zeta$ and Jacobian bounded below by a positive constant.

On $\overline{D_1}$ one has $\nu_r(z) = \mu(rz)$, so $\zeta(w) = \hat\zeta(w/r)$ satisfies Equation (A.226) on D_r by the scaling identity of Remark A.92, with Jacobian multiplied by $r^{-2} > 0$ and hence still bounded away from 0. Set $V = D_r$ and $(\xi, \eta) = (\Re\zeta, \Im\zeta)$, which is $C^{1,\alpha}$. By Proposition A.89 the pair satisfies the branch $a\zeta_x + (b + \mathrm{i}\delta)\zeta_y = 0$ of the complex characteristic equation, so by Propositions A.86 and A.87 the transformed coefficients obey $\tilde b = 0$ and $\tilde a = \tilde c = \delta J_0 > 0$, which is Equation (A.220). The transformed principal part is therefore $\tilde a\, u_{\xi\xi} + \tilde c\, u_{\eta\eta} = \delta J_0 (u_{\xi\xi} + u_{\eta\eta})$, as claimed.

For the last sentence of the theorem, suppose $a, b, c \in C^{1,\alpha}$. Then $\mu \in C^{1,\alpha}$, and by the last clause of Lemma A.91 the quantity $\|\nu_r\|_{C^{1,\alpha}}$ is $O(r)$. Running Proposition A.98 in the space of $C^{1,\alpha}$ functions vanishing off $\overline{D_2}$ — legitimate because part (iv) of Theorem A.95 bounds T there, and because the product estimate Equation (A.233) has an evident $C^{1,\alpha}$ counterpart obtained by applying it to f and to each ∂f — gives $h \in C^{1,\alpha}$, hence $\zeta \in C^{2,\alpha}$ by Equation (A.244). The change of coordinates then has continuous second derivatives, the extra term of Equation (10.7) is an honest continuous first-order coefficient, and the transformed equation is the third canonical form of Equation (10.10) in the classical sense. □

Remark A.100 (What has been gained, and what the classical argument gives). For real-analytic coefficients the chapter's own construction is available and is much cheaper: complexify y, integrate the characteristic ordinary differential equation Equation (10.13) along the complex branch, and take real and imaginary parts. That argument produces an analytic ζ and needs nothing beyond existence for an analytic ordinary differential equation — which is the Cauchy–Kovalevskaya theorem Theorem 10.22 in its simplest instance. What it cannot do is survive the loss of analyticity, because a complexified non-analytic coefficient has no

meaning at all. The route taken here never complexifies the coefficients: it complexifies only the *unknown*, which turns one real second-order equation into one complex first-order equation, and then solves that by inverting the constant-coefficient operator $\partial_{\bar z}$ and treating the variable-coefficient part as a small perturbation. The price is Theorem A.95, and the gain is that C^1 coefficients suffice — which matters because the coefficients of a physical equation are material properties, measured and interpolated, and are never analytic for any reason a physicist could give.

Remark A.101. Appendix A.13 discharges the obligation stated in Remark 10.14 and completes the elliptic branch of Proposition 10.13 in Chapter 10. Its consequence for the chapter is that the trichotomy of Equation (10.10) is a statement about all elliptic operators with C^1 coefficients and not only about the real-analytic ones, so that the invariance of type proved in Theorem 10.8 is matched by an equally general normal form. One honest limitation survives and is stated in Remark A.84: at C^α coefficients the normal form is a statement about the principal part alone, and the classical form with continuous lower-order coefficients costs one more derivative. The single quoted input is Theorem A.95, delimited in Remark A.96.

A.14 The Cauchy–Kovalevskaya Theorem

This appendix proves Theorem 10.22 of Chapter 10: a Cauchy problem in normal form, with real-analytic coefficients and real-analytic data prescribed on a non-characteristic surface, has a real-analytic solution near the point in question, and it is the only analytic one. The method is Kovalevskaya's [190] and is the model for every convergence proof of this type: write the solution as a formal power series, observe that the equation and the data determine its coefficients by a recursion whose coefficients are *non-negative*, replace the data by larger data for which the same recursion can be summed in closed form, and conclude that the original series converges because it is dominated term by term by one that does.

The argument is arranged in four steps. The formal series and its recursion come first (Appendix A.14.1), together with the reduction of a normal problem of order k to a first-order quasilinear system with vanishing data — carried out at the level of formal series, which is all that is needed and avoids the compatibility questions a reduction of the differential problem would raise. The notion of a majorant and the standard majorizing function then follow (Appendix A.14.2), the explicit solution of the majorant problem (Appendix A.14.3), and the assembly (Appendix A.14.4). A closing remark exhibits Lewy's equation, which shows that the analyticity of the data cannot be weakened even to smoothness [1122].

Notation. $t \in \mathbb{R}$ and $x = (x_1, \dots, x_n) \in \mathbb{R}^n$; $\beta \in \mathbb{N}^n$ and $\gamma \in \mathbb{N}^m$ are multi-indices in the sense of Equation (10.2), with $\mathbb{N}$ containing 0; $x^\beta = x_1^{\beta_1} \cdots x_n^{\beta_n}$; e_k is the k-th coordinate multi-index; and a multi-index in the $1 + n$ variables (t, x) is written $\alpha = (\alpha_0, \alpha')$ with $\partial^\alpha = \partial_t^{\alpha_0} \partial_x^{\alpha'}$. A function is *real analytic* near a point if on some polydisc about it the function is the sum of an *absolutely* convergent power series; that is the only property of analyticity used below.

A.14.1 Formal series, the recursion, and the reduction

Definition A.102 (Normal Cauchy problem of order k)**.** A *normal Cauchy problem of order k* for the scalar unknown w is

$$\partial_t^k w = G\big(t, x, \{\partial^\gamma w\}_{|\gamma| \le k,\ \gamma_0 < k}\big)\,, \qquad \partial_t^p w(0, x) = \varphi_p(x) \quad (p = 0, \dots, k-1)\,, \tag{A.245}$$

with G and the φ_p real analytic near the relevant origins.

Rests on Definition 10.1 and Proposition 10.11.

Definition A.103 (First-order quasilinear system with zero data)**.** For the unknown $u = (u_1, \dots, u_m)$,

$$\partial_t u_i = \sum_{j=1}^{m} \sum_{k=1}^{n} a_{ij}^{k}(x,u)\, \partial_k u_j + b_i(x,u)\,, \qquad u_i(0,x) = 0\,, \tag{A.246}$$

with a_{ij}^{k} and b_i real analytic on a neighbourhood of $(x,u) = (0,0)$ in $\mathbb{R}^{n+m}$.

Rests on Definitions 10.2 and A.102.

Lemma A.104 (The recursion)**.** *Write the coefficients of Equation (A.246) as convergent series $a_{ij}^{k} = \sum_{\beta,\gamma} a_{ij,\beta\gamma}^{k}\, x^{\beta} u^{\gamma}$ and $b_i = \sum_{\beta,\gamma} b_{i,\beta\gamma}\, x^{\beta} u^{\gamma}$, and seek a formal solution $u_i = \sum_{\beta,l} u_{i,\beta,l}\, x^{\beta} t^{l}$. Then the coefficients $u_{i,\beta,l}$ are uniquely determined; they vanish for $l = 0$; and for every $l \geq 1$*

$$u_{i,\beta,l} = R_{i,\beta,l}\big(\big\{a_{ij,\beta'\gamma}^{k}\big\}, \{b_{i,\beta'\gamma}\}\big)\,, \tag{A.247}$$

where $R_{i,\beta,l}$ is a polynomial with non-negative rational coefficients, the same polynomial for every problem of the shape Equation (A.246) with the same m and n.

Rests on Definition A.103 and Equation (10.2).

Proof. *Derives Lemma A.104.*

The data give $u_{i,\beta,0} = 0$ for every i, β. Substitute the series into Equation (A.246). On the left,

$$\partial_t u_i = \sum_{\beta,l} (l+1)\, u_{i,\beta,l+1}\, x^{\beta} t^{l}\,. \tag{A.248}$$

On the right, $\partial_k u_j = \sum_{\beta,l} (\beta_k + 1) u_{j,\beta+e_k,l}\, x^{\beta} t^{l}$, whose coefficients are non-negative integers times coefficients of u; and $a_{ij}^{k}(x,u)$, being a power series in x and in u composed with the series for u, has coefficients that are polynomials with non-negative integer coefficients in the $a_{ij,\beta'\gamma}^{k}$ and the $u_{j',\beta',l'}$, since composition and multiplication of formal series involve only sums of products. The same holds for b_i. Multiplying the two series and collecting the coefficient of $x^{\beta} t^{l}$, the right-hand side is such a polynomial in which every u-coefficient carries a time index $l' \leq l$: a factor $t^{l'}$ from one series can only be accompanied by factors $t^{l''}$ with $l' + l'' \leq l$, and no negative powers occur.

Comparing with Equation (A.248),

$$u_{i,\beta,l+1} = \frac{1}{l+1}\, Q_{i,\beta,l}\big(\{a\}, \{b\}, \{u_{j,\beta',l'}\}_{l' \leq l}\big)\,, \tag{A.249}$$

with Q a polynomial with non-negative integer coefficients. Induction on l therefore determines every coefficient uniquely from the vanishing ones at $l = 0$, and substituting the previously obtained expressions into Equation (A.249) expresses $u_{i,\beta,l}$ as a polynomial in the coefficients of a and b alone. Non-negativity survives every substitution — the only new factors introduced are the positive rationals $1/(l+1)$ — which is Equation (A.247). That R does not depend on the particular a, b is clear from the construction: only m, n and the indices entered. □

Lemma A.105 (Formal reduction of a normal problem)**.** *Every normal Cauchy problem Equation (A.245) has a unique formal power series solution $\hat{w}$ about the origin. Moreover there is a system Equation (A.246), with m and with coefficients a_{ij}^{k}, b_i built analytically from G and the φ_p, whose unique formal solution $\hat{u}$ has one distinguished component equal to*

$$\hat{u}_{(0,0)} = \hat{w} - \sum_{p=0}^{k-1} \varphi_p(x)\, \frac{t^{p}}{p!}\,. \tag{A.250}$$

Rests on Lemma A.104 and Definition A.102.

Proof. *Derives Lemma A.105.*

Homogenization. Put $v = w - \sum_{p<k} \varphi_p(x) t^p/p!$. Since $\partial_t^p(\varphi_q t^q/q!)(0,x) = \delta_{pq}\varphi_q(x)$ for $p, q < k$, the new unknown satisfies $\partial_t^p v(0,x) = 0$ for $p < k$, and Equation (A.245) becomes an equation of the same shape with a new right-hand side that is G evaluated on the shifted arguments — again analytic near the origin, because it is the composition of G with polynomials in t whose coefficients are derivatives of the analytic φ_p.

The system. Take as unknowns the quantities u_α indexed by the multi-indices α in (t,x) with $|\alpha| \le k-1$, intended to be $\partial^\alpha v$, together with one extra unknown u_* intended to be t. Their equations are

1. $\partial_t u_* = 1$;
2. $\partial_t u_\alpha = u_{\alpha+e_t}$ whenever $|\alpha| \le k-2$, so that $|\alpha + e_t| \le k-1$;
3. for $|\alpha| = k-1$ with $\alpha_0 < k-1$ — so that α carries at least one x-derivative, say $\alpha \ge e_{x_j}$ — $\partial_t u_\alpha = \partial_{x_j} u_{\alpha+e_t-e_{x_j}}$, the index on the right having length $k-1$;
4. for $\alpha = (k-1)e_t$, $\partial_t u_\alpha = G\big(u_*, x, \{\cdot\}\big)$, where each argument $\partial^\gamma v$ with $|\gamma| \le k-1$ is the unknown u_γ and each argument with $|\gamma| = k$, $\gamma_0 < k$, carries an x-derivative and is written $\partial_{x_j} u_{\gamma-e_{x_j}}$.

Every right-hand side is analytic in (x,u) near the origin — the t-slot of G has been replaced by the unknown u_* — and depends linearly on the first x-derivatives of the unknowns, which is the shape of Equation (A.246). All data vanish: $u_*(0,x) = 0$, and $\partial^\alpha v(0,x) = \partial_x^{\alpha'}\big[\partial_t^{\alpha_0} v(0,x)\big] = 0$ because $\alpha_0 \le k-1$.

The two formal solutions agree. The recursion of Equation (A.245) determines a unique formal $\hat v$: rewriting the equation as $\partial_t^k v = \widetilde G$ and matching coefficients of $x^\beta t^l$ expresses l-th and higher t-coefficients in terms of lower ones exactly as in Lemma A.104, the data supplying the k lowest. Now form the formal derivatives $\partial^\alpha \hat v$ and $\hat u_* = t$. Formal differentiation is a ring homomorphism compatible with formal composition, so applying ∂^α to the formal identity $\partial_t^k \hat v = \widetilde G(\cdots)$ and to the trivial identities $\partial_t \partial^\alpha \hat v = \partial^{\alpha+e_t}\hat v$ shows that the family $(\partial^\alpha \hat v,\ t)$ satisfies every equation (i)–(iv) formally, with the correct vanishing data. By the uniqueness half of Lemma A.104 it *is* $\hat u$, and in particular $\hat u_{(0,0)} = \hat v$, which is Equation (A.250). □

Remark A.106. The reduction has been made at the level of formal series on purpose. A reduction of the *differential* problems would require showing that a solution of the system has components that really are the derivatives of its first one, which is an extra argument; here nothing of the kind is needed, because all the reduction is asked to do is to transport *convergence* from the system to the original problem, and convergence is a property of a formal series.

A.14.2 Majorants

Definition A.107 (Majorant)**.** For formal power series $f = \sum_\sigma f_\sigma w^\sigma$ and $F = \sum_\sigma F_\sigma w^\sigma$ in the same variables, write $f \ll F$ — "F majorizes f" — if $|f_\sigma| \le F_\sigma$ for every multi-index σ. In particular every coefficient of F is then non-negative.

Rests on Equation (10.2).

Lemma A.108 (The standard majorant)**.** *Let $g = \sum_\sigma g_\sigma w^\sigma$ be real analytic near the origin of $\mathbb{R}^N$, and let $r > 0$ be such that $C = \sum_\sigma |g_\sigma|\, r^{|\sigma|} < \infty$. Then $|g_\sigma| \le C\, r^{-|\sigma|}$ and*

$$g \ll \frac{C\, r}{r - (w_1 + \cdots + w_N)}\,. \tag{A.251}$$

Rests on Definition A.107.

Proof. *Derives Lemma A.108.*

The bound $|g_\sigma|\, r^{|\sigma|} \le C$ is immediate, every term of the defining sum being non-negative. For the majorant, expand the geometric series and then the powers by the multinomial theorem:

$$\frac{Cr}{r-(w_1+\cdots+w_N)} = C\sum_{q\ge 0}\frac{(w_1+\cdots+w_N)^q}{r^q} = C\sum_{\sigma}\frac{|\sigma|!}{\sigma!\, r^{|\sigma|}}\, w^\sigma\,, \tag{A.252}$$

where $\sigma! = \sigma_1!\cdots\sigma_N!$. The multinomial coefficient $|\sigma|!/\sigma!$ is a positive integer, hence at least 1, so the coefficient of w^σ in Equation (A.252) is at least $Cr^{-|\sigma|} \ge |g_\sigma|$. □

Lemma A.109 (Domination)**.** *Let Equation (A.246) have coefficients a, b and let A^k_{ij}, B_i be power series with $a^k_{ij} \ll A^k_{ij}$ and $b_i \ll B_i$. Let $U_{i,\beta,l}$ be the coefficients of the formal solution of the* majorant problem *— the system Equation (A.246) with A, B in place of a, b and the same vanishing data. Then*

$$|u_{i,\beta,l}| \le U_{i,\beta,l} \qquad \text{for every } i,\beta,l\,. \tag{A.253}$$

Rests on Lemma A.104 and Definition A.107.

Proof. *Derives Lemma A.109.*

By Lemma A.104 both sets of coefficients are given by the *same* polynomials $R_{i,\beta,l}$, evaluated at the coefficients of a, b and of A, B respectively. A polynomial with non-negative coefficients satisfies $|R(\boldsymbol{s})| \le R(|\boldsymbol{s}|)$ by the triangle inequality applied monomial by monomial, and is non-decreasing in each argument on the non-negative orthant; hence

$$|u_{i,\beta,l}| = |R_{i,\beta,l}(a,b)| \le R_{i,\beta,l}(|a|\,,|b|) \le R_{i,\beta,l}(A,B) = U_{i,\beta,l}\,,$$

the middle inequality using $|a| \le A$ and $|b| \le B$ coefficientwise. □

A.14.3 The majorant problem has a closed-form solution

Proposition A.110 (Explicit solution of the majorant problem)**.** *Fix $C, r > 0$ and take, in the notation of Lemma A.108 with the $N = n + m$ variables (x, u),*

$$A^k_{ij}(x,u) = B_i(x,u) = \frac{Cr}{r - s - (u_1+\cdots+u_m)}\,, \qquad s = x_1+\cdots+x_n\,. \tag{A.254}$$

Put $K = m(n+1)$. Then the functions $U_i = V$, $i = 1,\dots,m$, with

$$V(t,x) = \frac{1}{K}\left[(r-s) - \sqrt{(r-s)^2 - 2KCr\,t}\,\right], \tag{A.255}$$

solve the majorant problem, are real analytic on the polydisc

$$|x_k| < \frac{r}{4n} \quad (k=1,\dots,n)\,, \qquad |t| < \frac{9\,r}{32\,K\,C}\,, \tag{A.256}$$

and all their Taylor coefficients at the origin are non-negative.

Rests on Lemma A.108 and Definition A.103.

Proof. *Derives Proposition A.110.*

Write $\sigma = r - s$ and $R = \sqrt{\sigma^2 - 2KCrt}$, so $V = (\sigma - R)/K$. Since $\partial_t R = -KCr/R$ and $\partial_\sigma R = \sigma/R$,

$$\partial_t V = \frac{Cr}{R}\,, \qquad \partial_s V = -\partial_\sigma V = -\frac{1}{K}\left(1 - \frac{\sigma}{R}\right). \tag{A.257}$$

With $U_i = V$ for every i one has $U_1 + \cdots + U_m = mV$ and $\sum_{j,k} \partial_k U_j = mn\,\partial_s V$, so the majorant problem reads

$$\partial_t V = \frac{Cr}{\sigma - mV}\left(mn\,\partial_s V + 1\right). \tag{A.258}$$

Substituting Equation (A.257), the requirement Equation (A.258) is

$$\frac{Cr}{R} = \frac{Cr\left[1 - \dfrac{mn}{K} + \dfrac{mn\,\sigma}{K\,R}\right]}{\sigma\left(1 - \dfrac{m}{K}\right) + \dfrac{m}{K}R},$$

that is, after cross-multiplying by R and by the denominator,

$$\sigma\left(1 - \frac{m}{K}\right) + \frac{m}{K}R = R\left(1 - \frac{mn}{K}\right) + \frac{mn}{K}\,\sigma\,. \tag{A.259}$$

Because σ and R are functionally independent, Equation (A.259) holds identically if and only if the coefficients match separately: $1 - m/K = mn/K$ and $m/K = 1 - mn/K$. Both give $K = m + mn = m(n+1)$, which is the choice made. At $t = 0$, $R = |\sigma| = \sigma$ for $s < r$, so $V(0,x) = 0$: the data hold.

Analyticity and positivity. Factor

$$V = \frac{\sigma}{K}\left[1 - \sqrt{1 - \frac{2KCr\,t}{\sigma^2}}\right] = \frac{1}{K}\sum_{p\geq 1} c_p\,(2KCr)^p\,t^p\,\sigma^{1-2p}\,, \tag{A.260}$$

where $1 - \sqrt{1-y} = \sum_{p\geq 1} c_p y^p$ is the binomial series, whose coefficients $c_p = \dfrac{(2p-2)!}{2^{2p-1}\,p!\,(p-1)!}$ are strictly positive, and which converges absolutely for $|y| < 1$. Each factor $\sigma^{1-2p} = r^{1-2p}(1 - s/r)^{-(2p-1)}$ expands, for $|s| < r$, as $r^{1-2p}\sum_{d\geq 0}\binom{2p-2+d}{d}(s/r)^d$, again with positive coefficients, and $s^d = (x_1 + \cdots + x_n)^d$ expands with non-negative integer coefficients in the x^β. Hence every Taylor coefficient of V is non-negative, and the multiple series converges absolutely wherever $|s| < r$ and $2KCr\,|t| < (r - |s|)^2$. On the polydisc Equation (A.256) one has $|s| \leq \sum_k |x_k| < r/4$, so $(r - |s|)^2 > 9r^2/16$ and the second condition follows from $|t| < 9r/(32KC)$. □

Remark A.111. The choice Equation (A.254) is the whole trick, and its two features are independent. Making *all* the coefficient functions the same single function of s and of $u_1 + \cdots + u_m$ collapses the m-component system to one scalar equation in two variables; and making that function the geometric kernel $Cr/(r - s - \sum u_i)$ makes the resulting scalar equation quasilinear of first order with the closed-form solution Equation (A.255). Notice that Equation (A.258) is exactly an equation of the type treated by Proposition 10.15: written as $(\sigma - mV)\partial_t V - Crmn\,\partial_s V = Cr$ it is quasilinear of first order in the two variables (t,s), with characteristic system $\dot t = \sigma - mV$, $\dot s = -Crmn$, $\dot V = Cr$. It is because that system can be integrated — or, as done above, because the resulting closed form can be guessed and then verified — that the majorant problem is solvable at all; the square root in Equation (A.255) is the mark of the quadratic relation between V and t that the last two characteristic equations impose. That the exponent works out to $K = m(n+1)$ and not to something depending on the data is what makes the radius of convergence in Equation (A.256) explicit.

A.14.4 Proof of the theorem

Theorem A.112 (Cauchy–Kovalevskaya, first-order form)**.** *The problem Equation (A.246) has a real-analytic solution on a polydisc about the origin of $\mathbb{R}^{1+n}$, and it is the only analytic solution there.*

Rests on Lemmas A.108 and A.109 and Proposition A.110.

Proof. *Derives Theorem A.112.*

By hypothesis the a^k_{ij} and b_i are analytic near $(x,u)=(0,0)$; choose $r>0$ so small that all of them are represented by absolutely convergent series on the polydisc of radius r in the $n+m$ variables, and let C be the largest of the finitely many sums $\sum_{\beta\gamma}\left|a^k_{ij,\beta\gamma}\right| r^{|\beta|+|\gamma|}$ and $\sum_{\beta\gamma}|b_{i,\beta\gamma}|\,r^{|\beta|+|\gamma|}$. By Lemma A.108 every coefficient is then majorized by the function Equation (A.254).

Let $U_{i,\beta,l}$ be the formal solution of the majorant problem. By Proposition A.110 the function V of Equation (A.255) solves that problem and is analytic on the polydisc Equation (A.256); its Taylor coefficients therefore satisfy the recursion of Lemma A.104 for the majorant data, and by the uniqueness half of that lemma they *are* the $U_{i,\beta,l}$. Combining with Lemma A.109,

$$\sum_{\beta,l}|u_{i,\beta,l}|\;|x|^{\beta}\,|t|^{l}\le\sum_{\beta,l}U_{i,\beta,l}\;|x|^{\beta}\,|t|^{l}=V\big(|t|\,,|x|\big)<\infty \tag{A.261}$$

on Equation (A.256), where $|x|^{\beta}$ means $|x_1|^{\beta_1}\cdots$; the middle equality holds because all the U are non-negative, so the series is its own absolute value. Hence the formal series for each u_i converges absolutely on that polydisc and defines a function there.

The sum solves the problem. On any closed subpolydisc of ratio $\theta<1$ the differentiated series are dominated term by term by $\theta^{-1}\sup_{q\ge0}\big[(q+1)\theta^{q}\big]$ times the original one, hence converge uniformly by Lemma 9.6, so term-by-term differentiation in t and in each x_k is legitimate, one variable at a time, by Theorem 7.51. The coefficients satisfy Equation (A.249) by construction, so the analytic function $\partial_t u_i-\sum_{j,k}a^k_{ij}(x,u)\partial_k u_j-b_i(x,u)$ has every Taylor coefficient equal to zero and therefore vanishes identically; and $u_i(0,x)=0$ because $u_{i,\beta,0}=0$.

Uniqueness. An analytic solution on any polydisc about the origin has a Taylor series which, by the computation of Lemma A.104, must satisfy the same recursion with the same initial values; the coefficients are therefore those just constructed, and two analytic functions with the same Taylor series at a point agree near it. □

Proof of Theorem 10.22. *Derives Theorem 10.22.*

Let the problem be in the normal form Equation (A.245), which is what *normal Cauchy problem* means, with the initial surface already the slice $\{t=0\}$. By Lemma A.105 its unique formal solution $\hat w$ is recovered by Equation (A.250) from the distinguished component of the formal solution $\hat u$ of an associated system Equation (A.246). By Theorem A.112 that formal solution converges absolutely on a polydisc about the origin; hence so does $\hat u_{(0,0)}$, and hence so does $\hat w$, the finitely many extra terms $\varphi_p(x)t^p/p!$ being analytic. Its sum w is analytic, and its Taylor coefficients satisfy the recursion of the normal problem, so — by the argument already used in Theorem A.112 — the analytic function $\partial_t^k w-G(\cdots)$ has all Taylor coefficients zero and vanishes, while $\partial_t^p w(0,x)=\varphi_p(x)$ for $p<k$ by construction. Any other analytic solution has the same Taylor coefficients, by the same recursion, and therefore coincides with w near the origin. □

Remark A.113 (What is quoted here). The proof above is complete for a problem presented in the normal form Equation (A.245), which is the form Theorem 10.22 names. Bringing a general non-characteristic Cauchy problem to that form uses two facts that this treatise does not prove:

1. *Flattening the initial surface.* If the analytic hypersurface S is $\{\phi=0\}$ with $\nabla\phi\neq0$, the map $x\longmapsto(\phi(x),\psi_2(x),\dots)$ is an analytic change of coordinates near the point, by the analytic inverse function theorem.

2. *Solving for the highest normal derivative.* For a fully nonlinear equation $F(x,\{\partial^{\alpha}u\})=0$, non-characteristic means $\partial F/\partial(\partial_t^k u)\neq0$ at the point (Proposition 10.11 is the

linear instance of the same computation), and the analytic implicit function theorem then supplies an analytic G with $\partial_t^k u = G(\cdots)$.

Both are the analytic versions of theorems whose smooth versions belong to Chapter 7; both are themselves usually proved by the majorant method of this section, so nothing circular is being borrowed, but neither is derived here and neither is stated in the treatise. For a *linear* or quasilinear equation — which is every equation this book actually solves — step (ii) is not needed at all: being non-characteristic then means that the coefficient of $\partial_t^k u$ is nonzero, by Equation (10.8) and the computation in the proof of Proposition 10.11, and one divides by it. Nothing else in this section is quoted: the recursion, the reduction, the majorant, the closed-form solution and the convergence estimate are all carried out above.

Remark A.114 (Lewy's equation: analyticity cannot be dropped). Every hypothesis of Theorem 10.22 was used, and the analyticity of the *data* — not merely of the coefficients — is the one whose necessity is least obvious and most complete. Consider on $\mathbb{R}^3$, with coordinates (x_1, x_2, x_3), the first-order operator

$$Lu = \partial_1 u + \mathrm{i}\,\partial_2 u - 2\mathrm{i}(x_1 + \mathrm{i}x_2)\,\partial_3 u\,. \tag{A.262}$$

Its coefficients are polynomials, hence analytic, and it is elementary to check that it is non-characteristic in the x_3-direction at points where $x_1 + \mathrm{i}x_2 \neq 0$. Lewy proved that there exist $f \in C^\infty(\mathbb{R}^3)$ — real-valued, and depending on x_3 alone — for which $Lu = f$ has *no* solution of class C^1 on any neighbourhood of any point whatever [1122]. The failure is therefore not of uniqueness or of regularity but of existence, it is local and universal, and it is produced by an operator whose coefficients satisfy every hypothesis of Cauchy–Kovalevskaya. What is lost when f ceases to be analytic is exactly what the proof above consumed: the formal series still exists in the analytic case because the recursion Equation (A.249) always runs, and it is the majorant that turns it into a function. With a merely smooth right-hand side there is no series to majorize, and Equation (A.262) shows that nothing takes its place.

The reader should also keep in view the second limitation, which the chapter states in Remark 10.23 and which is independent of this one: even where the theorem applies it establishes existence and not well-posedness. Analytic data cannot be varied independently in disjoint regions, so continuous dependence in the sense of Definition 10.24 is not even being asked for, and the Cauchy problem Cauchy–Kovalevskaya solves for the Laplace equation is the ill-posed one of Remark 10.26.

Remark A.115. Appendix A.14 discharges the proof obligation of Theorem 10.22 in Chapter 10. The result is used in the treatise wherever an analytic construction is needed and nothing weaker will do: it is the existence statement behind the classical, real-analytic branch of Proposition 10.13 — the complex first integral constructed there by complexifying Equation (10.13) is supplied by this theorem, and Appendix A.13 is what replaces it when the coefficients are only C^1 — and it is the reason a formal power-series ansatz may be trusted at all when the data of a problem are analytic. Its limitations are the substance of Remark A.114 and Remark 10.23, and they are the reason the rest of Chapter 10 proceeds by energy estimates, transforms and Green's functions rather than by series.

A.15 The Stäckel Conditions and the Eleven Separable Systems

This appendix proves Theorem 10.34 of Chapter 10: the Helmholtz equation Equation (10.25) separates in an orthogonal coordinate system of three-dimensional Euclidean space if and only if the reciprocal squared scale factors are the first column of the inverse of a *Stäckel matrix* — a matrix each of whose rows depends on one coordinate alone — and the volume

element satisfies the accompanying *Robertson condition*. Both conditions are derived here, not postulated: they are read off by substituting the product ansatz into the Laplacian and demanding that the three separation constants enter the separated ordinary differential equations linearly. The three systems the treatise uses (Example 10.31, Example 10.32, Example 10.33) are then verified against the criterion, and so is the generic member of the family, the ellipsoidal system, from which all the others descend by confluence. The section closes with the enumeration of the eleven systems and with an exact statement of the one input that is quoted rather than proved.

Everything is set in the observed three-dimensional space, signature $3+0$, with the flat Euclidean metric; the classification is a statement about $\mathbb{R}^3$ and has no higher-dimensional counterpart in this treatise. Latin indices i, j, l run over $1, 2, 3$ and are *not* summed unless a summation sign is written, because the sums that appear below are not all over the same range.

A.15.1 Orthogonal coordinates and the Laplacian

Definition A.116 (Orthogonal curvilinear coordinates; scale factors)**.** Let $\boldsymbol{x} = \boldsymbol{x}(q^1, q^2, q^3)$ be a C^2 diffeomorphism of an open set of $\mathbb{R}^3$ onto another, with

$$\frac{\partial \boldsymbol{x}}{\partial q^i} \cdot \frac{\partial \boldsymbol{x}}{\partial q^j} = 0 \qquad (i \neq j)\,, \qquad h_i = \left| \frac{\partial \boldsymbol{x}}{\partial q^i} \right| > 0\,. \tag{A.263}$$

The h_i are the *scale factors*, the line element is $\mathrm{d}\ell^2 = \sum_i h_i^2\,(\mathrm{d}q^i)^2$, and the volume element is $\mathrm{d}^3x = g\,\mathrm{d}q^1\mathrm{d}q^2\mathrm{d}q^3$ with $g = h_1 h_2 h_3$.

Rests on Definition 7.66 and Equation (10.25).

Lemma A.117 (Laplacian in orthogonal coordinates)**.** *For $\psi \in C^2$,*

$$\nabla^2 \psi = \frac{1}{g} \sum_{i=1}^{3} \partial_i \left(\frac{g}{h_i^2}\, \partial_i \psi \right)\,, \qquad \partial_i = \frac{\partial}{\partial q^i}\,. \tag{A.264}$$

Rests on Definition A.116 and Theorem 7.101.

Proof. *Derives Lemma A.117.*

Let $\hat{\boldsymbol{e}}_i = h_i^{-1} \partial \boldsymbol{x}/\partial q^i$; by Equation (A.263) these form an orthonormal triad at each point. The gradient is characterized by $\mathrm{d}\psi = \nabla\psi \cdot \mathrm{d}\boldsymbol{x}$; writing $\mathrm{d}\boldsymbol{x} = \sum_i h_i\,\mathrm{d}q^i\,\hat{\boldsymbol{e}}_i$ and $\mathrm{d}\psi = \sum_i \partial_i\psi\,\mathrm{d}q^i$ and matching coefficients of the independent increments $\mathrm{d}q^i$,

$$\nabla\psi = \sum_i \frac{1}{h_i}\, \partial_i\psi\; \hat{\boldsymbol{e}}_i\,. \tag{A.265}$$

For the divergence of $\boldsymbol{V} = \sum_i V_i \hat{\boldsymbol{e}}_i$ apply the divergence theorem Equation (7.123) to the coordinate box $[q^1, q^1 + \mathrm{d}q^1] \times \cdots$. Its face at fixed q^1 has outward normal $-\hat{\boldsymbol{e}}_1$ and area $h_2 h_3\,\mathrm{d}q^2\mathrm{d}q^3 = (g/h_1)\,\mathrm{d}q^2\mathrm{d}q^3$, and the opposite face has the same area evaluated at $q^1 + \mathrm{d}q^1$; the net flux through the pair is therefore $\partial_1\big((g/h_1)V_1\big)\,\mathrm{d}q^1\mathrm{d}q^2\mathrm{d}q^3$ to first order. Summing over the three pairs and dividing by the volume $g\,\mathrm{d}q^1\mathrm{d}q^2\mathrm{d}q^3$,

$$\operatorname{div}\boldsymbol{V} = \frac{1}{g} \sum_i \partial_i \left(\frac{g}{h_i}\, V_i \right)\,. \tag{A.266}$$

Composing Equation (A.266) with Equation (A.265), so that $V_i = h_i^{-1}\partial_i\psi$, gives Equation (A.264). □

A.15.2 What separation means, and what it forces

Definition A.118 (Simple separation of the Helmholtz equation)**.** The Helmholtz equation Equation (10.25) *separates simply* in the orthogonal system (q^i) if there exist nowhere-vanishing functions $f_i(q^i)$ and functions $\phi_{ij}(q^i)$ $(i,j=1,2,3)$, each row index i carrying dependence on q^i alone, with

$$S=\det(\phi_{ij})\neq 0\,, \tag{A.267}$$

such that for every triple of constants $(\lambda_1,\lambda_2,\lambda_3)$ with $\lambda_1=k^2$, any solutions X_i of the three ordinary differential equations

$$\frac{1}{f_i}\frac{\mathrm{d}}{\mathrm{d}q^i}\left(f_i\frac{\mathrm{d}X_i}{\mathrm{d}q^i}\right)+\left(\sum_{j=1}^{3}\lambda_j\,\phi_{ij}(q^i)\right)X_i=0\qquad(i=1,2,3) \tag{A.268}$$

compose into a solution $\psi=X_1X_2X_3$ of Equation (10.25). The matrix $\Phi=(\phi_{ij})$ is the *Stäckel matrix* and S its *Stäckel determinant*.

Rests on Definition A.116 and Lemma 10.28.

Three remarks fix the content of Definition A.118 before it is used. First, the form Equation (A.268) is not a restriction but the general second-order linear equation in q^i with no first-derivative term beyond the one a weight can absorb: any equation $X''+pX'+\sigma X=0$ is brought to it by $f=\exp\int p$. Second, the requirement that the constants λ_j enter *linearly* is the definition of separation in Stäckel's sense, and it is the requirement that carries the physics: each λ_j is an eigenvalue of a commuting operator, and the separated problem is a Sturm–Liouville problem in each variable (Chapter 9) exactly because Equation (A.268) is linear in them. Third, $\lambda_1=k^2$ singles out the first column of Φ; the remaining two constants are free, and $S\neq 0$ is what makes them genuinely independent.

Lemma A.119 (Cofactor identities)**.** *Let $\Phi=(\phi_{ij})$ be a 3×3 matrix with $S=\det\Phi\neq 0$, and let M_{ij} be the cofactor of ϕ_{ij}, that is $(-1)^{i+j}$ times the determinant of the 2×2 matrix obtained by deleting row i and column j. Then*

$$\sum_{i=1}^{3}\phi_{ij}\,M_{i1}=S\,\delta_{j1}\,,\qquad(\Phi^{-1})_{1i}=\frac{M_{i1}}{S}\,, \tag{A.269}$$

and, if the i-th row of Φ depends on q^i alone, then M_{i1} does not depend on q^i at all.

Rests on Equation (A.267).

Proof. *Derives Lemma A.119.*

For $j=1$ the sum in Equation (A.269) is the Laplace expansion of $\det\Phi$ along the first column. For $j\neq 1$ it is the Laplace expansion along the first column of the matrix obtained from Φ by overwriting its first column with its j-th, since the cofactors M_{i1} do not involve the first column at all; that matrix has two equal columns and hence vanishing determinant. Dividing Equation (A.269) by S identifies M_{i1}/S as the $(1,i)$ entry of the inverse. The last assertion is immediate: the minor belonging to M_{i1} is built from the two rows other than the i-th, which by hypothesis carry no dependence on q^i. □

Theorem A.120 (Stäckel and Robertson conditions)**.** *The Helmholtz equation separates simply in the orthogonal system (q^i), in the sense of Definition A.118, if and only if there is a Stäckel matrix $\Phi=(\phi_{ij}(q^i))$ with $S=\det\Phi\neq 0$ such that*

$$\frac{1}{h_i^2}=\frac{M_{i1}}{S}\qquad(i=1,2,3)\,, \tag{A.270}$$

and the volume element satisfies the Robertson condition

$$\frac{h_1h_2h_3}{S}=f_1(q^1)\,f_2(q^2)\,f_3(q^3) \tag{A.271}$$

for some functions f_i of one variable each — the same f_i that weight the separated equations Equation (A.268).

Rests on Definition A.118 and Lemmas A.117 and A.119.

Sufficiency. Derives Theorem A.120.

Assume Equation (A.270) and Equation (A.271), and let the X_i solve Equation (A.268). Put $\psi = X_1X_2X_3$. By Equation (A.270) and $g = Sf_1f_2f_3$,

$$\frac{g}{h_i^2} = \frac{g}{S}\,M_{i1} = f_1f_2f_3\,M_{i1}\,, \tag{A.272}$$

and by the last clause of Lemma A.119 both M_{i1} and the factors f_l with $l \neq i$ are independent of q^i. Hence

$$\partial_i\left(\frac{g}{h_i^2}\,\partial_i\psi\right) = M_{i1}\left(\prod_{l\neq i} f_lX_l\right)\frac{\mathrm{d}}{\mathrm{d}q^i}\left(f_i\frac{\mathrm{d}X_i}{\mathrm{d}q^i}\right)\,, \tag{A.273}$$

because everything except f_iX_i' passes through ∂_i untouched. Insert Equation (A.273) into Equation (A.264) and divide by $\psi = X_1X_2X_3$, using $g = Sf_1f_2f_3$ once more:

$$\frac{\nabla^2\psi}{\psi} = \frac{1}{Sf_1f_2f_3}\sum_i M_{i1}\frac{\prod_{l\neq i} f_lX_l}{X_1X_2X_3}\left(f_iX_i'\right)' = \frac{1}{S}\sum_i M_{i1}\,\frac{1}{f_iX_i}\left(f_iX_i'\right)'\,. \tag{A.274}$$

The separated equations Equation (A.268) say that the last factor equals $-\sum_j \lambda_j\phi_{ij}$, so by the cofactor identity Equation (A.269)

$$\frac{\nabla^2\psi}{\psi} = -\frac{1}{S}\sum_j \lambda_j\sum_i \phi_{ij}M_{i1} = -\frac{1}{S}\sum_j \lambda_j\,S\,\delta_{j1} = -\lambda_1 = -k^2\,, \tag{A.275}$$

that is $\nabla^2\psi + k^2\psi = 0$. Note where each hypothesis acted: Equation (A.271) made Equation (A.273) a *one-variable* derivative, and Equation (A.270) collapsed the sum in Equation (A.275) onto the single constant λ_1, killing the two free constants exactly as separation requires. □

Necessity. Derives Theorem A.120.

Assume the equation separates simply and substitute $\psi = X_1X_2X_3$ into Equation (10.25) through Equation (A.264), dividing by ψ:

$$\sum_i \frac{1}{h_i^2}\left[\frac{X_i''}{X_i} + \frac{X_i'}{X_i}\,\partial_i\ln\frac{g}{h_i^2}\right] + k^2 = 0\,, \tag{A.276}$$

obtained by expanding $g^{-1}\partial_i\big((g/h_i^2)\partial_i\psi\big)$ and cancelling the $l \neq i$ factors of ψ.

Step 1: the weights. The i-th bracket in Equation (A.276) must be expressible through q^i and X_i alone — that is what makes the i-th separated equation an ordinary differential equation in q^i — and X_i is an arbitrary solution of one, so X_i''/X_i and X_i'/X_i are functionally independent quantities that cannot cancel each other's coefficients. Hence $\partial_i\ln(g/h_i^2)$ is a function of q^i alone. Call it $(\ln f_i)'(q^i)$, which defines $f_i > 0$ up to a constant; the bracket is then $\left(f_iX_i'\right)'/(f_iX_i)$, and Equation (A.276) reads

$$\sum_i \frac{E_i}{h_i^2} + k^2 = 0\,, \qquad E_i = \frac{1}{f_iX_i}\left(f_iX_i'\right)'\,, \tag{A.277}$$

each E_i a function of q^i alone.

Step 2: linearity in the constants. By hypothesis the separated equations carry the three constants linearly, so $E_i = -\sum_j \lambda_j\phi_{ij}(q^i)$ with $\lambda_1 = k^2$ and λ_2, λ_3 free. Substituting into Equation (A.277),

$$\sum_j \lambda_j\left[\sum_i \frac{\phi_{ij}}{h_i^2} - \delta_{j1}\right] = 0\,, \tag{A.278}$$

and since this must hold identically in the three independent constants λ_j, every bracket vanishes: $\sum_i \phi_{ij}/h_i^2 = \delta_{j1}$. In matrix language the row vector v with $v_i = 1/h_i^2$ satisfies $v\,\Phi = e_1^{\mathsf{T}}$, whence Φ is invertible — so $S \neq 0$, which is the independence of the constants — and $v_i = (\Phi^{-1})_{1i} = M_{i1}/S$ by Lemma A.119. That is Equation (A.270).

Step 3: the Robertson condition. Step 1 gave $\partial_i \ln(g/h_i^2) = (\ln f_i)'(q^i)$. Insert Equation (A.270): $g/h_i^2 = (g/S)\,M_{i1}$, and M_{i1} is independent of q^i by Lemma A.119, so its logarithmic q^i-derivative vanishes and

$$\partial_i \ln \frac{g}{S} = (\ln f_i)'(q^i) \qquad (i = 1, 2, 3)\,. \tag{A.279}$$

Write $\Lambda = \ln|g/S|$. Then $\partial_1\Lambda$ depends on q^1 alone, so $\Lambda = \ln|f_1(q^1)| + \Lambda_1(q^2, q^3)$; applying Equation (A.279) for $i = 2$ to this expression gives $\partial_2\Lambda_1 = (\ln f_2)'(q^2)$, hence $\Lambda_1 = \ln|f_2(q^2)| + \Lambda_2(q^3)$, and one more step gives $\Lambda_2 = \ln|f_3(q^3)|$ up to an additive constant, which is absorbed into any one f_i. Exponentiating, $|g/S| = |f_1 f_2 f_3|$; the sign is constant on a connected domain and is absorbed likewise, giving Equation (A.271). □

Remark A.121 (What the two conditions say). Equation (A.270) is a condition on the *metric alone* and is the substantive one: it says the three functions $1/h_i^2$, which in general are functions of all three coordinates, are the first column of the inverse of a matrix assembled out of nine functions of *one* coordinate each. That is an enormous restriction, and it is what makes the list of admissible systems finite. Equation (A.271) is a condition on the volume element relative to S, and is the one that distinguishes the Helmholtz operator from the Hamilton–Jacobi equation of Chapter 23: the latter involves no second derivatives of ψ and so imposes Equation (A.270) alone. Every system in the list below satisfies both, but the logical order matters — Stäckel's condition governs separation of the classical problem, Robertson's is the extra price of the wave operator, which is why the two subjects are *almost* but not exactly the same, as Remark 10.35 records.

A.15.3 The three systems the treatise uses

In each case we exhibit Φ, S, the cofactors M_{i1} and the weights f_i, and check Equation (A.270) and Equation (A.271) outright. The separation constants are named to match Section 10.2.1.

Example A.122 (Cartesian)**.** $h_1 = h_2 = h_3 = 1$, $g = 1$. With $\lambda_1 = k^2$, $\lambda_2 = \beta^2$, $\lambda_3 = \gamma^2$ the separated equations of Example 10.31 are $X'' + (k^2 - \beta^2 - \gamma^2)X = 0$, $Y'' + \beta^2 Y = 0$, $Z'' + \gamma^2 Z = 0$, so $f_i = 1$ and

$$\Phi = \begin{pmatrix} 1 & -1 & -1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad S = 1\,. \tag{A.280}$$

The cofactors of the first column are $M_{11} = +\det\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = 1$, $M_{21} = -\det\begin{pmatrix} -1 & -1 \\ 0 & 1 \end{pmatrix} = 1$ and $M_{31} = +\det\begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix} = 1$, all equal to $1/h_i^2$; and $g/S = 1 = f_1 f_2 f_3$.

Rests on Theorem A.120 and Example 10.31.

Example A.123 (Circular cylindrical)**.** $(q^1, q^2, q^3) = (\rho, \varphi, z)$ with $h_1 = 1$, $h_2 = \rho$, $h_3 = 1$ and $g = \rho$. Set $\lambda_1 = k^2$, $\lambda_2 = m^2$, $\lambda_3 = \gamma^2$; the separated equations of Example 10.32 are Equation (10.32), $\Psi'' + m^2\Psi = 0$ and $Z'' + \gamma^2 Z = 0$, so $f_1 = \rho$, $f_2 = f_3 = 1$ and

$$\Phi = \begin{pmatrix} 1 & -\rho^{-2} & -1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad S = 1\,. \tag{A.281}$$

Then $M_{11} = 1 = 1/h_1^2$, $M_{21} = -\det\begin{pmatrix} -\rho^{-2} & -1 \\ 0 & 1 \end{pmatrix} = \rho^{-2} = 1/h_2^2$ and $M_{31} = +\det\begin{pmatrix} -\rho^{-2} & -1 \\ 1 & 0 \end{pmatrix} = 1 = 1/h_3^2$; and $g/S = \rho = f_1 f_2 f_3$.

Rests on Theorem A.120 and Example 10.32.

Example A.124 (Spherical)**.** $(q^1, q^2, q^3) = (r, \theta, \varphi)$ with $h_1 = 1$, $h_2 = r$, $h_3 = r\sin\theta$ and $g = r^2 \sin\theta$. Set $\lambda_1 = k^2$, $\lambda_2 = l(l+1)$, $\lambda_3 = m^2$; the separated equations of Example 10.33 are Equation (10.34), the associated Legendre equation and $\Psi'' + m^2\Psi = 0$, so $f_1 = r^2$, $f_2 = \sin\theta$, $f_3 = 1$ and

$$\Phi = \begin{pmatrix} 1 & -r^{-2} & 0 \\ 0 & 1 & -(\sin\theta)^{-2} \\ 0 & 0 & 1 \end{pmatrix}, \qquad S = 1\,. \tag{A.282}$$

The first-column cofactors are $M_{11} = 1 = 1/h_1^2$, $M_{21} = -\det\begin{pmatrix} -r^{-2} & 0 \\ 0 & 1 \end{pmatrix} = r^{-2} = 1/h_2^2$ and $M_{31} = +\det\begin{pmatrix} -r^{-2} & 0 \\ 1 & -(\sin\theta)^{-2} \end{pmatrix} = r^{-2}(\sin\theta)^{-2} = 1/h_3^2$; and $g/S = r^2\sin\theta = f_1 f_2 f_3$. The three checks reproduce, in one line each, the structure the chapter obtained by hand: the centrifugal term $-l(l+1)/r^2$ of Equation (10.34) is the entry ϕ_{12}, and the term $-m^2/\sin^2\theta$ of the Legendre equation is ϕ_{23}.

Rests on Theorem A.120 and Example 10.33.

A.15.4 The generic system: confocal quadrics

The three systems just checked are degenerate members of one family. The generic member is the ellipsoidal system, and it is worth carrying out in full because everything else follows from it by letting parameters coincide or run to infinity.

Definition A.125 (Ellipsoidal coordinates)**.** Fix $a_1^2 > a_2^2 > a_3^2 > 0$ and write x_1, x_2, x_3 for Cartesian coordinates and

$$P(\theta) = (\theta + a_1^2)(\theta + a_2^2)(\theta + a_3^2)\,. \tag{A.283}$$

The *confocal family* is

$$\sum_{p=1}^{3} \frac{x_p^2}{\theta + a_p^2} = 1\,. \tag{A.284}$$

Through a generic point pass exactly three members of the family, with parameters $\xi_1 > \xi_2 > \xi_3$ interlacing the poles,

$$\xi_1 > -a_3^2 > \xi_2 > -a_2^2 > \xi_3 > -a_1^2\,, \tag{A.285}$$

an ellipsoid, a hyperboloid of one sheet and a hyperboloid of two sheets respectively. These are the *ellipsoidal coordinates*.

Rests on Definition A.116.

Lemma A.126 (Cartesian coordinates and scale factors)**.** *With the notation of Definition A.125,*

$$x_p^2 = \frac{\prod_{i=1}^{3}(\xi_i + a_p^2)}{\prod_{q\neq p}(a_p^2 - a_q^2)}\,, \tag{A.286}$$

the system is orthogonal, and

$$h_i^2 = \frac{\prod_{l\neq i}(\xi_i - \xi_l)}{4\,P(\xi_i)} > 0\,. \tag{A.287}$$

Rests on Definition A.125 and Equation (A.263).

Proof. *Derives Lemma A.126.*

Multiply Equation (A.284), in the form $1-\sum_p x_p^2/(\theta+a_p^2)=0$, by $P(\theta)$. The result,

$$P(\theta)-\sum_p x_p^2\prod_{q\neq p}(\theta+a_q^2)=\prod_i(\theta-\xi_i)\,, \tag{A.288}$$

is a monic cubic in θ whose roots are by definition ξ_1,ξ_2,ξ_3, which identifies it with the right-hand side. Evaluating Equation (A.288) at $\theta=-a_p^2$ kills P and every term of the sum except the p-th, giving $-x_p^2\prod_{q\neq p}(a_q^2-a_p^2)=-\prod_i(\xi_i+a_p^2)$, which is Equation (A.286) after the two sign changes in the denominator.

Differentiating Equation (A.286) with respect to ξ_i removes one factor from the numerator: $2x_p\,\partial_i x_p=x_p^2/(\xi_i+a_p^2)$, hence

$$\partial_i x_p=\frac{x_p}{2(\xi_i+a_p^2)}\,. \tag{A.289}$$

Divide Equation (A.288) by $P(\theta)$ and rearrange:

$$G(\theta)=\sum_p\frac{x_p^2}{\theta+a_p^2}=1-\frac{N(\theta)}{P(\theta)}\,,\qquad N(\theta)=\prod_i(\theta-\xi_i)\,. \tag{A.290}$$

For $i\neq j$ the inner product of the two coordinate tangent vectors is, by Equation (A.289) and the partial fraction $\big[(\xi_i+a)(\xi_j+a)\big]^{-1}=(\xi_j-\xi_i)^{-1}\big[(\xi_i+a)^{-1}-(\xi_j+a)^{-1}\big]$,

$$\sum_p\partial_i x_p\,\partial_j x_p=\frac14\sum_p\frac{x_p^2}{(\xi_i+a_p^2)(\xi_j+a_p^2)}=\frac{G(\xi_i)-G(\xi_j)}{4(\xi_j-\xi_i)}=0\,, \tag{A.291}$$

because $N(\xi_i)=N(\xi_j)=0$ makes $G(\xi_i)=G(\xi_j)=1$ by Equation (A.290): the system is orthogonal. For the scale factors, Equation (A.289) gives $h_i^2=\frac14\sum_p x_p^2(\xi_i+a_p^2)^{-2}=-\frac14 G'(\xi_i)$, and differentiating Equation (A.290),

$$G'(\theta)=-\frac{N'(\theta)P(\theta)-N(\theta)P'(\theta)}{P(\theta)^2}\,,\qquad G'(\xi_i)=-\frac{N'(\xi_i)}{P(\xi_i)}=-\frac{\prod_{l\neq i}(\xi_i-\xi_l)}{P(\xi_i)}\,, \tag{A.292}$$

using $N(\xi_i)=0$. That is Equation (A.287). Positivity follows from Equation (A.285): $P(\xi_1)>0$ and $\prod_{l\neq1}(\xi_1-\xi_l)>0$; $P(\xi_2)<0$ and $\prod_{l\neq2}(\xi_2-\xi_l)<0$; $P(\xi_3)>0$ and $\prod_{l\neq3}(\xi_3-\xi_l)>0$. □

Lemma A.127 (Lagrange's interpolation identity)**.** *For distinct ξ_1,ξ_2,ξ_3 and an integer $0\le p\le 2$,*

$$\sum_{i=1}^{3}\frac{\xi_i^{\,p}}{\prod_{l\neq i}(\xi_i-\xi_l)}=\delta_{p2}\,. \tag{A.293}$$

Rests on Equation (A.287).

Proof. *Derives Lemma A.127.*

The polynomial $L(\theta)=\sum_i\xi_i^{\,p}\prod_{l\neq i}\frac{\theta-\xi_l}{\xi_i-\xi_l}$ has degree at most 2 and agrees with θ^p at the three distinct points ξ_1,ξ_2,ξ_3. Since θ^p also has degree at most 2, their difference is a polynomial of degree at most 2 with three roots, hence identically zero: $L(\theta)=\theta^p$. Comparing the coefficients of θ^2 on the two sides gives Equation (A.293), the left-hand coefficient being the sum displayed and the right-hand one δ_{p2}. □

Proposition A.128 (The ellipsoidal system separates)**.** *The ellipsoidal system of Definition A.125 satisfies Equation (A.270) and Equation (A.271) with*

$$\phi_{ij}=\frac{\xi_i^{\,3-j}}{4\,P(\xi_i)}\,,\qquad S=\frac{W}{64\,P(\xi_1)P(\xi_2)P(\xi_3)}\,,\qquad W=\prod_{i<l}(\xi_i-\xi_l)\,, \tag{A.294}$$

and, with $\epsilon_1 = \epsilon_3 = +1$ *and* $\epsilon_2 = -1$ *the signs of* P *on the three intervals of Equation* (A.285),

$$f_1 = -2\sqrt{P(\xi_1)}\,, \qquad f_2 = 2\sqrt{-P(\xi_2)}\,, \qquad f_3 = 2\sqrt{P(\xi_3)}\,. \tag{A.295}$$

Only the product of the three signs is fixed, by Equation (A.271)*; the sign of an individual* f_i *is immaterial because* f_i *occurs twice in Equation* (A.268)*. The separated equations Equation* (A.268) *become the* Lamé wave equations

$$\frac{1}{\sqrt{\epsilon_i P}}\,\frac{\mathrm{d}}{\mathrm{d}\xi_i}\left(\sqrt{\epsilon_i P}\,\frac{\mathrm{d}X_i}{\mathrm{d}\xi_i}\right) + \frac{k^2\xi_i^2 + \lambda_2\xi_i + \lambda_3}{4\,P(\xi_i)}\,X_i = 0\,, \tag{A.296}$$

with P *evaluated at* ξ_i*.*

Rests on Lemmas A.126 and A.127 and Theorem A.120.

Proof. *Derives Proposition A.128.*

Each row of Φ in Equation (A.294) depends on ξ_i alone, as a Stäckel matrix must. By Equation (A.287), $1/h_i^2 = 4P(\xi_i)/\prod_{l\neq i}(\xi_i - \xi_l)$, so

$$\sum_i \frac{\phi_{ij}}{h_i^2} = \sum_i \frac{\xi_i^{3-j}}{\prod_{l\neq i}(\xi_i - \xi_l)} = \delta_{3-j,\,2} = \delta_{j1} \tag{A.297}$$

by Lemma A.127. By Step 2 of the proof of Theorem A.120 this identity is equivalent to Equation (A.270), and it also shows $S \neq 0$.

For the determinant, factor $1/(4P(\xi_i))$ out of the i-th row: $S = \left[64\prod_i P(\xi_i)\right]^{-1}\det(\xi_i^{3-j})$. Reversing the column order — one transposition, of columns 1 and 3 — turns $\det(\xi_i^{3-j})$ into $-\det(\xi_i^{j-1})$, and the latter is the Vandermonde determinant $\prod_{i<l}(\xi_l - \xi_i) = -W$; hence $\det(\xi_i^{3-j}) = W$ and S is as stated.

For Robertson, take the product of Equation (A.287) over i. The numerator is $\prod_i\prod_{l\neq i}(\xi_i - \xi_l) = \prod_{i<l}\left[-(\xi_i - \xi_l)^2\right] = -W^2$, so $g^2 = -W^2\left[64\prod_i P(\xi_i)\right]^{-1}$; the sign is consistent because $\prod_i P(\xi_i) < 0$ by Equation (A.285), and therefore

$$g = \frac{W}{8\prod_i \sqrt{\epsilon_i P(\xi_i)}}\,, \qquad S = \frac{-W}{64\prod_i \epsilon_i P(\xi_i)}\,, \tag{A.298}$$

the second because $\prod_i \epsilon_i = -1$. Dividing,

$$\frac{g}{S} = -8\,\frac{\prod_i \epsilon_i P(\xi_i)}{\prod_i \sqrt{\epsilon_i P(\xi_i)}} = -8\prod_i \sqrt{\epsilon_i P(\xi_i)} = \prod_i f_i(\xi_i)\,, \tag{A.299}$$

the last step by Equation (A.295), whose three signs multiply to -1: a product of three functions of one variable each, which is exactly Equation (A.271). Substituting f_i and $\sum_j \lambda_j\phi_{ij} = (k^2\xi_i^2 + \lambda_2\xi_i + \lambda_3)/(4P(\xi_i))$ into Equation (A.268) gives Equation (A.296), the constant factor 2 in f_i cancelling between the two occurrences. □

Remark A.129. For $k = 0$, Equation (A.296) is Lamé's equation and its polynomial solutions are the ellipsoidal harmonics, the analogue for a triaxial body of the spherical harmonics Equation (9.163). The chapter's three examples are visible in Equation (A.296) as limits: when two of the a_p^2 coincide one of the three coordinates becomes an angle and the corresponding Lamé equation degenerates to the associated Legendre equation Equation (9.157); when all three coincide the remaining two degenerate to the Legendre equation and to $\Psi'' + m^2\Psi = 0$, and Example A.124 is recovered.

A.15.5 The enumeration

What remains is to count the systems. The count has two halves, and only one of them is proved here.

Theorem A.130 (Quoted: separable systems are confocal-quadric systems)**.** *Let (q^i) be an orthogonal coordinate system of $\mathbb{R}^3$ in which the Helmholtz equation separates simply. Then, up to a Euclidean motion and a relabelling and reparametrization of the coordinates, the coordinate surfaces are the members of a confocal family of quadrics Equation* (A.284) *or of one of its degenerate limits.*

Remark A.131 (What is quoted here)*.* Theorem A.130 is the only statement in this section that is not proved. It is the substantial half of the classification: the assertion that a metric of flat space admitting a Stäckel matrix must have confocal quadrics for its coordinate surfaces. Its proof is a long analysis of the second-order system that Equation (A.270) imposes on the nine functions ϕ_{ij} together with the vanishing of the Riemann tensor of the Euclidean metric written in the coordinates q^i — a computation belonging to classical differential geometry rather than to the theory of partial differential equations, and one this treatise does not carry out anywhere. The result and the resulting tables of separated equations, system by system, are those of Morse and Feshbach [1023]; the differential-geometric analysis behind it is Eisenhart's, whose paper is not among the sources catalogued in this treatise's bibliography, so the attribution here is uncited and the reader who wishes to check it must go to the secondary account just named. Everything else in this section — the two conditions, their necessity and sufficiency, the ellipsoidal verification and the degeneration analysis below — is derived in full.

Granting Theorem A.130, the enumeration becomes a finite case analysis over the ways the confocal family Equation (A.284) can degenerate, and *that* we carry out. The family is fixed by the cubic P of Equation (A.283), i.e. by the three parameters $a_1^2 > a_2^2 > a_3^2$; a common shift of all three is a reparametrization $\theta \to \theta + c$ and changes nothing, so only the two differences $a_1^2 - a_2^2$ and $a_2^2 - a_3^2$ matter, and a common rescaling fixes the unit of length. The degenerations are then exhausted by three independent binary choices:

1. *Coincidence.* Either both differences are nonzero (three distinct foci), or exactly one vanishes (an axis of rotational symmetry appears, and there are two inequivalent ways for this to happen — the focal set degenerates to a segment when $a_2^2 = a_3^2$ and to a disc when $a_1^2 = a_2^2$), or both vanish (full rotational symmetry: concentric spheres).

2. *A focus at infinity.* One may let one root of P recede, $a_1^2 \to \infty$, while rescaling; the ellipsoids and one family of hyperboloids open up into paraboloids. This can be done to the generic family and to the rotationally symmetric one, but not to the spherical one, where there is nothing left to send away.

3. *Translation.* One may instead let the whole configuration become independent of one Cartesian direction, so that the quadrics become cylinders over a two-dimensional confocal family of conics. The two-dimensional families are themselves classified by the same first two choices, one dimension down: confocal conics with two distinct foci, confocal parabolas, concentric circles, or the degenerate family of parallel lines.

Reading the choices off gives the list, in which the first seven are the genuinely three-dimensional families and the last four the cylindrical ones.

Proposition A.132 (The count)**.** *The degeneration scheme just described yields exactly the eleven systems of Table A.1, and no others.*

Rests on Proposition A.128 and Theorem A.130.

Table A.1: The eleven orthogonal systems in which the three-dimensional Helmholtz equation separates simply, organized by the degeneration of the confocal quadric family that produces them. That each entry does separate is checked by exhibiting its Stäckel matrix, as done in the text for the Cartesian, cylindrical, spherical and ellipsoidal systems; that the list is complete rests on the one quoted classification theorem of this section.

System	Coordinate surfaces	Degeneration
Ellipsoidal	three confocal quadrics	none: $a_1^2 > a_2^2 > a_3^2$
Paraboloidal	elliptic and hyperbolic paraboloids	one focus to infinity
Prolate spheroidal	prolate spheroids, two-sheeted hyperboloids, half-planes	$a_2^2 = a_3^2$ (focal segment)
Oblate spheroidal	oblate spheroids, one-sheeted hyperboloids, half-planes	$a_1^2 = a_2^2$ (focal disc)
Parabolic	two families of paraboloids of revolution, half-planes	rotational, one focus to infinity
Spherical	spheres, cones of revolution, half-planes	$a_1^2 = a_2^2 = a_3^2$
Conical	spheres and two families of elliptic cones	spheres with the focal cone retained
Elliptic cylindrical	confocal elliptic and hyperbolic cylinders, planes	translational, two foci
Parabolic cylindrical	confocal parabolic cylinders, planes	translational, one focus at infinity
Circular cylindrical	circular cylinders, half-planes, planes	translational, coincident foci
Cartesian	three families of parallel planes	translational, all foci at infinity

Proof. *Derives Proposition A.132.*

Consider first the non-translational families. The coincidence pattern of the three parameters has four cases: all distinct; $a_2^2 = a_3^2$; $a_1^2 = a_2^2$; all equal. In the first three cases one may additionally send a focus to infinity or not, which doubles them — but the two rotationally symmetric cases have the *same* paraboloidal limit, because sending the distinct root to infinity destroys the distinction between a focal segment and a focal disc, leaving the single parabolic system. That gives $1 + 1$ (ellipsoidal, paraboloidal) plus $2 + 1$ (prolate, oblate, parabolic), i.e. five. The fully symmetric case admits no focus at infinity, but it does admit two inequivalent coordinate systems on the sphere: the one whose second and third coordinates are the polar angle and the azimuth — spherical — and the one in which the sphere is cut by two families of elliptic cones sharing a vertex, which is the conical system and is the residue of the ellipsoidal system when the quadrics have collapsed but their asymptotic cones have not. That gives seven.

The translational families are cylinders over a two-dimensional confocal family of conics, and the same analysis one dimension down applies to the plane cross-section: two distinct foci give confocal ellipses and hyperbolae (elliptic cylindrical); sending one focus to infinity gives confocal parabolae (parabolic cylindrical); coincident foci give concentric circles and their radii (circular cylindrical); and sending both to infinity gives two families of parallel lines (Cartesian). No further case arises, because a family of conics in the plane is fixed by the two foci alone, and their configuration — distinct, coincident, one at infinity, both at infinity — has exactly these four types. That gives four, and $7 + 4 = 11$. □

Proof of Theorem 10.34. *Derives Theorem 10.34.*

The criterion asserted by the theorem is Theorem A.120: separation holds if and only if the reciprocal squared scale factors are expressible through a matrix each of whose rows depends on one coordinate alone — explicitly, if and only if $1/h_i^2 = M_{i1}/S$ in Equation (A.270), together with the Robertson condition Equation (A.271) on the volume element, which the chapter's statement subsumes under "the Stäckel conditions". The list of eleven systems is Table A.1: that each of them separates is verified by exhibiting its Stäckel matrix, done in Examples A.122 to A.124 for the three the treatise uses and in Proposition A.128 for the generic one, from which the remaining entries follow by the confluences of Proposition A.132; and that there are no others is Proposition A.132 together with the quoted Theorem A.130. □

Remark A.133. Appendix A.15 discharges the proof obligation of Theorem 10.34 in Chapter 10. Two consequences are used elsewhere in the treatise. The first is negative and is the practical one recorded in Remark 10.35: a boundary that is not a coordinate surface of one of the eleven systems admits no separation, which is why the boundary chooses the coordinates and not the operator. The second is that Equation (A.270) alone — without Robertson's Equation (A.271) — is the condition for the Hamilton–Jacobi equation of Chapter 23 to separate, so the separation constants λ_2, λ_3 of Equation (A.268) are the quantum counterparts of the classical integrals of motion of an integrable system; the spherical case (Example A.124), where they are $l(l+1)$ and m^2, is the one worked out physically in Chapter 81.

A.16 The Mean-Value Property Characterizes Harmonic Functions

This appendix proves the continuous form of the converse half of Theorem 10.69 (Chapter 10): a function that is merely *continuous* on an open set and equals its own spherical average over every ball whose closure the set contains is automatically infinitely differentiable there, and harmonic. The chapter proves the converse only for $u \in C^2$, because the argument it uses

decides the sign of a Laplacian whose existence is exactly what is in question (Remark 10.70). The gap is closed here by constructing the smoothing device the chapter does not have — a radial mollifier — and showing that convolution against it returns the function unchanged. Once that is done the chapter's own sign argument applies verbatim.

Nothing is quoted. Everything below is built from the Riemann integral of a continuous function over a compact region, the mean value theorem of one-variable calculus, and the polar decomposition of a volume integral in $\mathbb{R}^3$ already used in Lemma 10.58 and in the proof of Theorem 10.69; in particular the Lebesgue theory that Chapter 7 deliberately does not develop is nowhere needed, because every integrand that appears is continuous with compact support.

Throughout, $\Omega \subset \mathbb{R}^3$ is open and nonempty, $B(\boldsymbol{x}, r) = \{\boldsymbol{y} \in \mathbb{R}^3 \mid |\boldsymbol{y} - \boldsymbol{x}| < r\}$, and $M_u(\boldsymbol{x}, r)$ is the spherical mean Equation (10.54). The space is the observed three-dimensional one; nothing in the argument depends on that choice beyond the numerical factor 4π.

A.16.1 Statement

Definition A.134 (Mean-value property)**.** A function $u \in C^0(\Omega)$ has the *mean-value property* on Ω if and only if

$$u(\boldsymbol{x}) = M_u(\boldsymbol{x}, r) = \frac{1}{4\pi} \int_{S^2} u(\boldsymbol{x} + r\boldsymbol{n}) \, \mathrm{d}\Omega \tag{A.300}$$

for every $\boldsymbol{x} \in \Omega$ and every $r > 0$ with $\overline{B(\boldsymbol{x}, r)} \subset \Omega$.

Rests on Equation (10.54) *and Definition 6.2.*

Theorem A.135 (Converse of the mean-value property)**.** *Let $u \in C^0(\Omega)$ have the mean-value property of Definition A.134. Then $u \in C^\infty(\Omega)$ and $\nabla^2 u = 0$ on Ω; that is, u is harmonic in the sense of Definition 10.66. Consequently the two conditions* harmonic *and* continuous with the mean-value property *define the same class of functions.*

Rests on Definitions 10.66 and A.134 and Theorem 10.69.

The proof occupies the rest of the section: an elementary lemma on differentiating an integral with respect to a parameter (Appendix A.16.2), the construction of the mollifier and the smoothness of the convolution (Appendix A.16.3), the reproduction identity $u * \rho_\varepsilon = u$ (Appendix A.16.4), and the assembly (Appendix A.16.5).

A.16.2 Differentiation under the integral sign

The one analytic tool the argument needs is stated and proved here, in the only form it will be used: the integrand is continuous, the domain of integration is a fixed compact set, and the parameter runs over an open set.

Lemma A.136 (Differentiation under the integral sign)**.** *Let $U \subset \mathbb{R}^3$ be open, let $Q \subset \mathbb{R}^3$ be a compact box, and let $F : U \times Q \longrightarrow \mathbb{R}$ be such that F and the partial derivative $\partial F / \partial x^i$ (taken in the first argument) are continuous on $U \times Q$ for one fixed i. Then*

$$g(\boldsymbol{x}) = \int_Q F(\boldsymbol{x}, \boldsymbol{y}) \, \mathrm{d}^3 y \tag{A.301}$$

has a continuous partial derivative $\partial_i g$ on U, and

$$\partial_i g(\boldsymbol{x}) = \int_Q \frac{\partial F}{\partial x^i}(\boldsymbol{x}, \boldsymbol{y}) \, \mathrm{d}^3 y \, . \tag{A.302}$$

Rests on Definition 7.66 and Theorem 6.11.

Proof. *Derives Lemma A.136.*

Fix $\boldsymbol{x} \in U$ and choose $r > 0$ with $\overline{B(\boldsymbol{x}, r)} \subset U$. The set $\overline{B(\boldsymbol{x}, r)} \times Q$ is compact, so $\partial F / \partial x^i$ is uniformly continuous on it: given $\varepsilon > 0$ there is $\delta \in (0, r)$ such that

$$|\boldsymbol{x}' - \boldsymbol{x}''| < \delta \quad \Longrightarrow \quad \left| \frac{\partial F}{\partial x^i}(\boldsymbol{x}', \boldsymbol{y}) - \frac{\partial F}{\partial x^i}(\boldsymbol{x}'', \boldsymbol{y}) \right| < \varepsilon \tag{A.303}$$

for every $\boldsymbol{y} \in Q$, the bound being uniform in $\boldsymbol{y}$ — which is the whole content of *uniform* continuity on the product and the reason the compactness of Q is needed.

Let $\boldsymbol{e}_i$ be the i-th coordinate vector and let $0 < |h| < \delta$. For each fixed $\boldsymbol{y}$ the mean value theorem applied to the function $s \longmapsto F(\boldsymbol{x} + s\boldsymbol{e}_i, \boldsymbol{y})$ on the interval between 0 and h supplies $\theta = \theta(h, \boldsymbol{y}) \in (0, 1)$ with

$$\frac{F(\boldsymbol{x} + h\boldsymbol{e}_i, \boldsymbol{y}) - F(\boldsymbol{x}, \boldsymbol{y})}{h} = \frac{\partial F}{\partial x^i}(\boldsymbol{x} + \theta h \boldsymbol{e}_i, \boldsymbol{y}) \,. \tag{A.304}$$

Both sides of Equation (A.304) are continuous in $\boldsymbol{y}$ — the left side manifestly, and hence the right side as well, whatever the measurability of θ — so both are Riemann integrable over Q. Subtracting Equation (A.302) and using Equation (A.303) with $|\theta h| < \delta$,

$$\left| \frac{g(\boldsymbol{x} + h\boldsymbol{e}_i) - g(\boldsymbol{x})}{h} - \int_Q \frac{\partial F}{\partial x^i}(\boldsymbol{x}, \boldsymbol{y}) \, \mathrm{d}^3 y \right| \leq \int_Q \varepsilon \, \mathrm{d}^3 y = \varepsilon \, |Q| \,, \tag{A.305}$$

with $|Q|$ the volume of the box. Since ε was arbitrary the difference quotient converges, which is Equation (A.302). Continuity of $\partial_i g$ follows from the same estimate with $\boldsymbol{x}'' = \boldsymbol{x}$ and $\boldsymbol{x}'$ a nearby point, the integral of a quantity bounded by ε being bounded by $\varepsilon \, |Q|$. □

Remark A.137. Lemma A.136 iterates: if F and all its partial derivatives in $\boldsymbol{x}$ of every order are continuous on $U \times Q$, then $g \in C^\infty(U)$ and every derivative may be taken under the integral sign, because the conclusion of the lemma is again a function of the same form with $\partial F / \partial x^i$ in place of F.

A.16.3 A radial mollifier

The device the chapter lacks is a smooth, radial, non-negative function supported in a ball and of unit integral. Its existence is not obvious: a function that is analytic cannot vanish on an open set without vanishing identically, so the construction must use a function that is smooth and *not* analytic. There is exactly one standard source of such a function.

Lemma A.138 (The flat exponential)**.** *Define* $f : \mathbb{R} \longrightarrow \mathbb{R}$ *by*

$$f(t) = \begin{cases} \mathrm{e}^{-1/t} \,, & t > 0 \,, \\ 0 \,, & t \leq 0 \,. \end{cases} \tag{A.306}$$

Then $f \in C^\infty(\mathbb{R})$, $f^{(n)}(0) = 0$ *for every* n, *and* $f(t) > 0$ *exactly for* $t > 0$.
Rests on Definition 7.66 and Theorem 7.38.

Proof. *Derives Lemma A.138.*

Derivatives for $t > 0$. We claim that for every $n \geq 0$ there is a polynomial p_n with

$$f^{(n)}(t) = p_n\!\left(\frac{1}{t}\right) \mathrm{e}^{-1/t} \,, \qquad t > 0 \,. \tag{A.307}$$

For $n = 0$ take $p_0 = 1$. Differentiating Equation (A.307) and using $\mathrm{d}(1/t)/\mathrm{d}t = -1/t^2$,

$$f^{(n+1)}(t) = \left[-\frac{1}{t^2} \, p_n'\!\left(\frac{1}{t}\right) + \frac{1}{t^2} \, p_n\!\left(\frac{1}{t}\right) \right] \mathrm{e}^{-1/t} \,, \tag{A.308}$$

so Equation (A.307) holds at $n+1$ with $p_{n+1}(s) = s^2\big(p_n(s) - p_n'(s)\big)$.

Decay at the origin. For $s > 0$ and any integer $m \geq 0$ the exponential series gives $\mathrm{e}^s \geq s^{m+1}/(m+1)!$, hence $s^m \mathrm{e}^{-s} \leq (m+1)!/s \longrightarrow 0$ as $s \to +\infty$. Consequently, for any polynomial p,

$$\lim_{t \to 0^+} p\left(\frac{1}{t}\right) \mathrm{e}^{-1/t} = \lim_{s \to +\infty} p(s)\, \mathrm{e}^{-s} = 0\,. \tag{A.309}$$

Derivatives at the origin. We show by induction that $f^{(n)}$ exists everywhere, is continuous, and $f^{(n)}(0) = 0$. For $n = 0$ this is Equation (A.309) with $p = 1$. Assume it at n. For $t < 0$ the difference quotient of $f^{(n)}$ at 0 vanishes identically; for $t > 0$ it is

$$\frac{f^{(n)}(t) - f^{(n)}(0)}{t} = \frac{1}{t}\, p_n\left(\frac{1}{t}\right) \mathrm{e}^{-1/t} = \big[s\, p_n(s)\big]\, \mathrm{e}^{-s}\,, \qquad s = \frac{1}{t}\,, \tag{A.310}$$

which tends to 0 by Equation (A.309) applied to the polynomial $s\, p_n(s)$. Hence $f^{(n+1)}(0)$ exists and is 0. It is continuous at 0 because $f^{(n+1)}(t) = p_{n+1}(1/t)\mathrm{e}^{-1/t} \to 0$ as $t \to 0^+$ by Equation (A.309) again, and vanishes for $t < 0$. Positivity for $t > 0$ is immediate. □

Definition A.139 (The standard radial mollifier)**.** With f of Equation (A.306) set

$$\rho(\boldsymbol{x}) = c_0\, f\Big(1 - |\boldsymbol{x}|^2\Big)\,, \qquad c_0^{-1} = \int_{\mathbb{R}^3} f\Big(1 - |\boldsymbol{x}|^2\Big)\, \mathrm{d}^3x\,, \tag{A.311}$$

and, for $\varepsilon > 0$, $\rho_\varepsilon(\boldsymbol{x}) = \varepsilon^{-3}\rho(\boldsymbol{x}/\varepsilon)$.

Rests on Lemma A.138.

Lemma A.140 (Properties of the mollifier)**.** *$\rho_\varepsilon \in C^\infty(\mathbb{R}^3)$; it is non-negative, vanishes outside $\overline{B(\mathbf{0}, \varepsilon)}$, depends on $\boldsymbol{x}$ only through $|\boldsymbol{x}|$, and $\int_{\mathbb{R}^3} \rho_\varepsilon\, \mathrm{d}^3x = 1$.*

Rests on Definition A.139 and Lemma A.138.

Proof. *Derives Lemma A.140.*

$|\boldsymbol{x}|^2 = x^2 + y^2 + z^2$ is a polynomial, hence C^∞, and the composition of a C^∞ function of one variable with a C^∞ function of three is C^∞ by the chain rule (Proposition 7.72); this is where Lemma A.138 is used, and it is the only place where smoothness that is not analyticity is needed. The argument $1 - |\boldsymbol{x}|^2$ is positive exactly on the open unit ball and non-positive outside it, so $\rho > 0$ there and $\rho = 0$ elsewhere; in particular ρ vanishes on a whole neighbourhood of every point of $|\boldsymbol{x}| = 1$ together with all its derivatives. The normalizing integral in Equation (A.311) is the integral of a continuous non-negative function that is positive on an open set, hence finite and strictly positive, so c_0 is well defined. Radial dependence is manifest. Finally the substitution $\boldsymbol{x} = \varepsilon \boldsymbol{z}$, whose Jacobian is ε^3, gives $\int \rho_\varepsilon(\boldsymbol{x}) \mathrm{d}^3x = \int \rho(\boldsymbol{z}) \mathrm{d}^3z = 1$, and rescales the support to $|\boldsymbol{x}| \leq \varepsilon$. □

Definition A.141 (Mollification)**.** For $u \in C^0(\Omega)$ and $\varepsilon > 0$ put

$$\Omega_\varepsilon = \Big\{ \boldsymbol{x} \in \Omega \mid \overline{B(\boldsymbol{x}, \varepsilon)} \subset \Omega \Big\}\,, \tag{A.312}$$

an open subset of Ω whose union over $\varepsilon > 0$ is Ω, and define on it

$$u_\varepsilon(\boldsymbol{x}) = \int_{B(\mathbf{0},\varepsilon)} \rho_\varepsilon(\boldsymbol{z})\, u(\boldsymbol{x} - \boldsymbol{z})\, \mathrm{d}^3z = \int_{B(\boldsymbol{x},\varepsilon)} \rho_\varepsilon(\boldsymbol{x} - \boldsymbol{y})\, u(\boldsymbol{y})\, \mathrm{d}^3y\,. \tag{A.313}$$

Rests on Definitions 6.2 and A.139.

The two integrals in Equation (A.313) agree by the substitution $\boldsymbol{y} = \boldsymbol{x} - \boldsymbol{z}$, of unit Jacobian; both integrands are continuous on a compact set, so both are ordinary Riemann integrals. That Ω_ε is open, and that every point of Ω lies in some Ω_ε, is immediate from Ω being open.

Proposition A.142 (The mollification is smooth)**.** *$u_\varepsilon \in C^\infty(\Omega_\varepsilon)$, and every partial derivative may be taken under the integral sign in the second form of Equation* (A.313)*.*

Rests on Lemmas A.136 and A.140.

Proof. *Derives Proposition A.142.*

Fix $\boldsymbol{x}_0 \in \Omega_\varepsilon$ and $\sigma > 0$ so small that $\overline{B(\boldsymbol{x}_0, \sigma+\varepsilon)} \subset \Omega$; let $U = B(\boldsymbol{x}_0, \sigma)$ and let Q be a closed box containing $\overline{B(\boldsymbol{x}_0, \sigma+\varepsilon)}$. Extend u from $\overline{B(\boldsymbol{x}_0, \sigma+\varepsilon)}$ to Q by any continuous function — the extension is irrelevant, because for $\boldsymbol{x} \in U$ the factor $\rho_\varepsilon(\boldsymbol{x}-\boldsymbol{y})$ already vanishes for $\boldsymbol{y}$ outside $\overline{B(\boldsymbol{x}_0, \sigma+\varepsilon)}$, so

$$u_\varepsilon(\boldsymbol{x}) = \int_Q F(\boldsymbol{x}, \boldsymbol{y})\, \mathrm{d}^3 y\,, \qquad F(\boldsymbol{x}, \boldsymbol{y}) = \rho_\varepsilon(\boldsymbol{x}-\boldsymbol{y})\, u(\boldsymbol{y})\,, \tag{A.314}$$

for every $\boldsymbol{x} \in U$. In Equation (A.314) the whole dependence on the parameter $\boldsymbol{x}$ sits in the factor ρ_ε, which by Lemma A.140 is C^∞; hence F and all its $\boldsymbol{x}$-derivatives of every order,

$$\partial_{\boldsymbol{x}}^\alpha F(\boldsymbol{x}, \boldsymbol{y}) = (\partial^\alpha \rho_\varepsilon)(\boldsymbol{x}-\boldsymbol{y})\, u(\boldsymbol{y})\,, \tag{A.315}$$

are continuous on $U \times Q$, being products of continuous functions. Lemma A.136 and Remark A.137 therefore apply and give $u_\varepsilon \in C^\infty(U)$ with $\partial^\alpha u_\varepsilon(\boldsymbol{x}) = \int_Q (\partial^\alpha \rho_\varepsilon)(\boldsymbol{x}-\boldsymbol{y})\, u(\boldsymbol{y})\, \mathrm{d}^3 y$. Since $\boldsymbol{x}_0 \in \Omega_\varepsilon$ was arbitrary, the conclusion holds on all of Ω_ε. □

A.16.4 The mollification reproduces the function

This is the step at which the mean-value hypothesis enters, and it is the reason the mollifier was required to be *radial*.

Proposition A.143 (Reproduction identity)**.** *Let $u \in C^0(\Omega)$ have the mean-value property. Then*

$$u_\varepsilon(\boldsymbol{x}) = u(\boldsymbol{x}) \qquad \text{for every } \boldsymbol{x} \in \Omega_\varepsilon \text{ and every } \varepsilon > 0\,. \tag{A.316}$$

Rests on Definitions A.134 and A.141 and Lemma A.140.

Proof. *Derives Proposition A.143.*

Write $\rho_\varepsilon(\boldsymbol{z}) = \varepsilon^{-3}\tilde{\rho}(|\boldsymbol{z}|/\varepsilon)$, where $\tilde{\rho}(s) = c_0 f(1-s^2)$ is the radial profile supplied by Lemma A.140. Decompose the first integral of Equation (A.313) into spheres, $\mathrm{d}^3 z = s^2\, \mathrm{d}s\, \mathrm{d}\Omega$ — the same decomposition already used in Lemma 10.58 to pass between a solid and a spherical integral, and legitimate here because the integrand is continuous on the compact ball:

$$u_\varepsilon(\boldsymbol{x}) = \int_0^\varepsilon \varepsilon^{-3}\tilde{\rho}\!\left(\frac{s}{\varepsilon}\right) s^2 \left[\int_{S^2} u(\boldsymbol{x} - s\boldsymbol{n})\, \mathrm{d}\Omega\right] \mathrm{d}s\,. \tag{A.317}$$

The inner integral is unchanged under $\boldsymbol{n} \longmapsto -\boldsymbol{n}$, which is a symmetry of the unit sphere and of its solid-angle element, so it equals $\int_{S^2} u(\boldsymbol{x}+s\boldsymbol{n})\, \mathrm{d}\Omega = 4\pi\, M_u(\boldsymbol{x}, s)$. For $\boldsymbol{x} \in \Omega_\varepsilon$ and $0 < s \le \varepsilon$ the closed ball $\overline{B(\boldsymbol{x}, s)}$ lies in Ω, so the mean-value property Equation (A.300) gives $M_u(\boldsymbol{x}, s) = u(\boldsymbol{x})$ — a constant, which comes out of the s-integral:

$$u_\varepsilon(\boldsymbol{x}) = u(\boldsymbol{x}) \int_0^\varepsilon 4\pi s^2\, \varepsilon^{-3}\tilde{\rho}\!\left(\frac{s}{\varepsilon}\right) \mathrm{d}s = u(\boldsymbol{x}) \int_{\mathbb{R}^3} \rho_\varepsilon(\boldsymbol{z})\, \mathrm{d}^3 z = u(\boldsymbol{x})\,, \tag{A.318}$$

the middle step being Equation (A.317) read backwards with $u \equiv 1$, and the last being the normalization of Lemma A.140. □

Remark A.144 (Why radial, and why the normalization matters). Both hypotheses on ρ are used and neither can be dropped. Radial dependence is what lets the weight ρ_ε be pulled outside the *angular* integral in Equation (A.317), leaving exactly a spherical mean for the hypothesis to act on; a non-radial bump would leave an angular weight and the mean-value property would say nothing about the result. Unit mass is what makes the surviving factor

equal to 1 rather than to some other constant. The identity Equation (A.316) is thus not an approximation statement — it is not $u_\varepsilon \to u$, which holds for every continuous u — but an exact equality, valid for each ε separately, and that exactness is the whole content of the argument.

A.16.5 Proof of the theorem

Proof of Theorem A.135. *Derives Theorem A.135.*

Smoothness. Let $\boldsymbol{x}_0 \in \Omega$. Since Ω is open there is $\varepsilon > 0$ with $\overline{B(\boldsymbol{x}_0, 2\varepsilon)} \subset \Omega$, and then $B(\boldsymbol{x}_0, \varepsilon) \subset \Omega_\varepsilon$. On Ω_ε we have $u = u_\varepsilon$ by Proposition A.143, and $u_\varepsilon \in C^\infty(\Omega_\varepsilon)$ by Proposition A.142. Hence u is C^∞ on a neighbourhood of $\boldsymbol{x}_0$. Smoothness being a local property and $\boldsymbol{x}_0$ arbitrary, $u \in C^\infty(\Omega)$. Note that the smoothing parameter ε is allowed to depend on the point, as it must: no single ε works near $\partial\Omega$.

Harmonicity. Now that $u \in C^2(\Omega)$ is established, the argument of Theorem 10.69 applies without change, and we repeat it for completeness. Suppose $\nabla^2 u(\boldsymbol{x}_0) > 0$ for some $\boldsymbol{x}_0 \in \Omega$. By continuity of $\nabla^2 u$ there is $r > 0$ with $\overline{B(\boldsymbol{x}_0, r)} \subset \Omega$ and $\nabla^2 u > 0$ throughout that ball. Darboux's identity Equation (10.55) then gives, for $0 < s \le r$,

$$\partial_s M_u(\boldsymbol{x}_0, s) = \frac{1}{4\pi s^2} \int_{B(\boldsymbol{x}_0, s)} \nabla^2 u \, \mathrm{d}^3 y > 0 \,, \tag{A.319}$$

so $s \longmapsto M_u(\boldsymbol{x}_0, s)$ is strictly increasing on $(0, r]$. But the mean-value property makes it constant, equal to $u(\boldsymbol{x}_0)$, on that whole interval — a contradiction. The case $\nabla^2 u(\boldsymbol{x}_0) < 0$ is the same argument with the inequalities reversed. Hence $\nabla^2 u \equiv 0$ on Ω, which is Definition 10.66.

The two classes coincide. A harmonic function is C^2 by definition and has the mean-value property by the direct half of Theorem 10.69; conversely a continuous function with the mean-value property is harmonic by what has just been proved. □

Corollary A.145 (Harmonic functions are smooth)**.** *Every harmonic function on Ω is of class $C^\infty(\Omega)$, although its definition (Definition 10.66) demands only C^2.*

Rests on Theorems 10.69 and A.135.

Proof. *Derives Corollary A.145.*

A harmonic u is continuous and has the mean-value property (Theorem 10.69); Theorem A.135 then returns $u \in C^\infty(\Omega)$. □

Corollary A.146 (Locally uniform limits of harmonic functions)**.** *If u_n are harmonic on Ω and $u_n \to u$ uniformly on every compact subset of Ω, then u is harmonic.*

Rests on Theorem A.135 and Definition A.134.

Proof. *Derives Corollary A.146.*

u is continuous, being a locally uniform limit of continuous functions. Fix $\boldsymbol{x}$ and r with $\overline{B(\boldsymbol{x}, r)} \subset \Omega$; the sphere $|\boldsymbol{y} - \boldsymbol{x}| = r$ is compact, so $u_n \to u$ uniformly on it and the averages converge: $M_u(\boldsymbol{x}, r) = \lim_n M_{u_n}(\boldsymbol{x}, r) = \lim_n u_n(\boldsymbol{x}) = u(\boldsymbol{x})$. Thus u is continuous with the mean-value property, and Theorem A.135 applies. The corresponding statement with C^2 convergence would be trivial; the point is that mere uniform convergence suffices, and it does so only because the characterization proved here does not mention derivatives at all. □

Remark A.147 (What is quoted here)*.* Nothing. The three inputs are the mean value theorem of one-variable calculus, uniform continuity of a continuous function on a compact set (Theorem 6.11), and the polar decomposition $\mathrm{d}^3 z = s^2 \, \mathrm{d}s \, \mathrm{d}\Omega$ of a volume integral, all of them already in force in Chapter 7 and used by the chapter itself in Lemma 10.58. Every integrand appearing above is continuous on a compact region, so the Riemann integral of Chapter 7 suffices throughout and no appeal to Lebesgue's theory — which this treatise does

not build — is made or needed. In particular Lemma A.136 is proved, not cited: the usual statement of differentiation under the integral sign is a dominated-convergence argument, and the compactness of the domain of integration replaces the domination here.

Remark A.148 (The scope of the improvement). The gain over Theorem 10.69 is not cosmetic. The C^2 converse cannot be applied to a function one has only constructed as a limit, an average or a supremum, because such a function is typically known to be continuous and nothing more; the continuous converse can, and Corollary A.146 is the first instance. It is also the cleanest statement of the rigidity of the Laplace equation: the second-order differential condition $\nabla^2 u = 0$ is equivalent to a condition — Equation (A.300) — that mentions no derivative whatever, and *that* is why solutions of it are automatically smooth while solutions of, say, the wave equation are not.

Remark A.149. Appendix A.16 discharges the proof obligation left open in Remark 10.70 and completes Theorem 10.69 of Chapter 10. The chapter uses only the C^2 form in what follows — the strong maximum principle Theorem 10.77 is proved from it — so nothing there depended on the present section; what the section adds is the equivalence that makes the mean-value property a *definition* of harmonicity rather than a consequence of one, and with it the stability under uniform limits recorded in Corollary A.146. The mollifier constructed in Appendix A.16.3 is the same device that underlies the smooth test functions of Chapter 17 and the approximation arguments of Section 10.6.2.

A.17 Kruzhkov's Doubling of Variables and the Entropy Solution

This appendix proves Theorem 10.103 of Chapter 10: a scalar conservation law Equation (10.81) with bounded measurable datum has at most one entropy solution in the sense of Definition 10.101, two entropy solutions contract in the mean, and at least one exists. The uniqueness half is Kruzhkov's argument by *doubling of variables*, and it is the whole content of the section; the existence half is the vanishing-viscosity limit already announced in Remark 10.100, whose architecture is set out in Appendix A.17.6 with its two compactness inputs named.

Three features of the argument are worth flagging before it begins, because each is what makes it work. The first is the choice of entropy: the family $\eta(u) = |u - k|$, indexed by a real constant k, is not C^2 and so is not admitted by Definition 10.101 directly; it is reached by approximation in Appendix A.17.3, and it is the family for which the entropy flux of two solutions can be compared. The second is that the comparison is carried out in *four* variables — u is evaluated at (t, x) and v at (s, y) — with each solution's own entropy inequality tested against the same function and the constant k taken to be the *other* solution. The third is the cancellation that makes the whole thing finite: with a test function of the form $\chi(\frac{t+s}{2}, \frac{x+y}{2})$ times a mollifier in the differences, the two entropy inequalities add so that the mollifier is differentiated in neither of them.

Throughout, $F \in C^1(\mathbb{R})$, u and v are entropy solutions of Equation (10.81) with bounded measurable data u_0, v_0,

$$|u|, |v| \le M_0 \quad \text{almost everywhere}, \qquad M = \max_{|w| \le M_0} |F'(w)| , \tag{A.320}$$

and φ denotes a non-negative test function of the kind appearing in Equation (10.92). Convexity of F, assumed in Theorem 10.103, is nowhere used below: Kruzhkov's theorem needs only that F be C^1, which is a strictly stronger result and is recorded in Remark A.165.

A.17.1 Statement

Definition A.150 (Kruzhkov entropy pair)**.** For $k \in \mathbb{R}$ put

$$\eta_k(w) = |w - k| \,, \qquad q_k(w) = \operatorname{sgn}(w-k)\big(F(w) - F(k)\big) \,. \tag{A.321}$$

Rests on Definitions 10.93 and 10.101.

Theorem A.151 (L^1 contraction on a cone)**.** *Let u, v be entropy solutions in the sense of Definition 10.101 obeying Equation (A.320). Then for almost every $0 < \tau_1 < \tau_2$ and every $R > 0$*

$$\int_{|x| \le R} |u(\tau_2, x) - v(\tau_2, x)| \, \mathrm{d}x \le \int_{|x| \le R + M(\tau_2 - \tau_1)} |u(\tau_1, x) - v(\tau_1, x)| \, \mathrm{d}x \,, \tag{A.322}$$

and, using Lemma A.154, the same inequality holds with $\tau_1 = 0$ and u, v replaced there by u_0, v_0. If in addition $u_0 - v_0$ is integrable on $\mathbb{R}$, then for almost every $t > 0$

$$\int_{\mathbb{R}} |u(t, x) - v(t, x)| \, \mathrm{d}x \le \int_{\mathbb{R}} |u_0(x) - v_0(x)| \, \mathrm{d}x \,. \tag{A.323}$$

Rests on Definitions 10.95, 10.101 and A.150.

Corollary A.152 (Uniqueness)**.** *An entropy solution with a given bounded measurable datum is unique up to a null set, and the solution map $u_0 \longmapsto u(t, \cdot)$ is a contraction for the L^1 distance — which is condition (iii) of Definition 10.24 with the mean as the norm.*
Rests on Theorem A.151 and Definition 10.24.

Proof. *Derives Corollary A.152.*

Let $u_0 = v_0$ almost everywhere. Then the right-hand side of Equation (A.322) with $\tau_1 = 0$ vanishes for every R, so $u(t, \cdot) = v(t, \cdot)$ almost everywhere on every bounded interval and hence on $\mathbb{R}$, for almost every t. Continuous dependence is Equation (A.323) itself, the map being 1-Lipschitz from L^1 to L^1. □

A.17.2 The inputs this treatise does not build

Remark A.153 (What is quoted here). Unlike the rest of Chapter 10, the subject of this section is not formulated in terms of the Riemann integral and cannot be. A weak solution in the sense of Definition 10.95 is a *bounded measurable* function, its defining identity is an integral over a region of the plane against an arbitrary test function, and the conclusions are statements valid *almost everywhere*; every one of these words belongs to Lebesgue's theory, which Chapter 7 does not develop — it builds the Riemann integral only, as Chapter 11 also records where it needs dominated convergence and declines to use it. The following facts are therefore assumed, and they are assumed for the definitions as much as for the proofs:

1. *The Lebesgue integral* of a bounded measurable function over a measurable subset of $\mathbb{R}^d$, its linearity and monotonicity, and the fact that a function vanishing almost everywhere has zero integral.

2. *Fubini's theorem* for a bounded measurable function on a product, used in Proposition A.159 to integrate one solution's entropy inequality over the other solution's variables, and again to change variables from (t, x, s, y) to sum and difference coordinates.

3. *Dominated convergence*, used at each passage to a limit.

4. *Continuity of translation in L^1*: for w bounded and measurable and K compact, $\int_K |w(\cdot + h) - w| \longrightarrow 0$ as $h \to 0$. Equivalently, almost every point is a Lebesgue point. This is the one substantial analytic fact of Proposition A.162, and it is exactly what replaces the continuity that a classical solution would have had.

5. *Lebesgue's differentiation theorem* in one variable, used in Appendix A.17.5 to pass from an average over a short time interval to a value at almost every instant.

6. *Kruzhkov's initial-layer lemma* (Lemma A.154): an entropy solution attains its datum in the local mean. This is the only *theorem* of the subject that is quoted rather than proved, and it is isolated as such below.

7. For the existence half only (Appendix A.17.6): classical solvability of the viscous problem, and a compactness theorem for families of uniformly bounded functions of uniformly bounded variation.

Everything else — the passage from the C^2 entropies of Definition 10.101 to the Kruzhkov family, the doubling, the cancellation, the limit, the cone estimate, and the derivation of the entropy inequality from the viscous equation — is carried out in full. The primary source is [1427], where the entropy class, the doubling of variables and the L^1 contraction first appear together.

Lemma A.154 (Quoted: the initial layer)**.** *Let u be an entropy solution in the sense of Definition 10.101 with datum u_0. Then for every compact $K \subset \mathbb{R}$*

$$\lim_{t \to 0^+} \int_K |u(t,x) - u_0(x)| \, \mathrm{d}x = 0 \,, \tag{A.324}$$

the limit being taken through the instants at which $u(t,\cdot)$ is defined.

Remark A.155. Equation (A.324) is stronger than what the definition plainly gives, and the gap is worth naming. Testing Equation (10.85) with $\varphi(x,t) = \rho(x)\alpha(t)$ shows that $t \longmapsto \int u(t,x)\rho(x)\,\mathrm{d}x$ agrees almost everywhere with an absolutely continuous function taking the value $\int u_0\rho$ at $t = 0$, so the datum is attained *weakly*; that much is a two-line computation from the definition. Weak attainment is not enough for Theorem A.151, because the functional $w \longmapsto \int |w|$ is only lower semicontinuous under weak convergence and the inequality needed runs the other way. Kruzhkov obtains Equation (A.324) from the entropy inequality itself applied with constant k and a test function concentrating at $t = 0$, which yields an upper bound on $\limsup_{t\to 0} \int |u(t,x) - k|\,\rho$ by $\int |u_0 - k|\,\rho$; a covering argument over a countable dense set of values k, together with approximation of u_0 by step functions, upgrades that to the strong statement. The argument is measure-theoretic throughout and is not reproduced here.

A.17.3 From the admissible entropies to Kruzhkov's family

Proposition A.156 (The Kruzhkov inequality)**.** *Let u be an entropy solution in the sense of Definition 10.101. Then for every $k \in \mathbb{R}$ and every non-negative test function φ,*

$$\int_0^\infty \!\! \int_{\mathbb{R}} \left[|u-k| \, \partial_t\varphi + q_k(u) \, \partial_x\varphi \right] \mathrm{d}x \, \mathrm{d}t + \int_{\mathbb{R}} |u_0(x) - k| \, \varphi(x,0) \, \mathrm{d}x \geq 0 \,, \tag{A.325}$$

with q_k of Equation (A.321).

Rests on Definitions 10.101 and A.150 and Equation (10.92).

Proof. *Derives Proposition A.156.*

For $\delta > 0$ set

$$\eta_\delta(w) = \sqrt{(w-k)^2 + \delta^2} - \delta \,, \qquad q_\delta(w) = \int_k^w \eta_\delta'(\lambda)\, F'(\lambda)\, \mathrm{d}\lambda \,. \tag{A.326}$$

Then η_δ is C^∞, with

$$\eta_\delta'(w) = \frac{w-k}{\sqrt{(w-k)^2 + \delta^2}} \,, \qquad \eta_\delta''(w) = \frac{\delta^2}{\left[(w-k)^2 + \delta^2\right]^{3/2}} > 0 \,, \tag{A.327}$$

so it is convex; q_δ is C^1 with $q'_\delta = \eta'_\delta F'$ by the fundamental theorem of calculus. Thus (η_δ, q_δ) is an admissible entropy pair in the sense of Definition 10.101, and Equation (10.92) holds for it.

Uniform convergence of the entropy. From $|w-k| \le \sqrt{(w-k)^2+\delta^2} \le |w-k| + \delta$,

$$|\eta_\delta(w) - |w-k|| \le \delta \qquad \text{for every } w\,. \tag{A.328}$$

Uniform convergence of the flux on the range. Let $|w| \le M_0$ and abbreviate $r_\delta(\lambda) = \operatorname{sgn}(\lambda-k) - \eta'_\delta(\lambda)$, so that $|r_\delta| \le 2$ and, for $|\lambda - k| \ge \varepsilon$,

$$|r_\delta(\lambda)| = 1 - \frac{|\lambda-k|}{\sqrt{(\lambda-k)^2+\delta^2}} \le 1 - \frac{\varepsilon}{\sqrt{\varepsilon^2+\delta^2}}\,. \tag{A.329}$$

Since $\operatorname{sgn}(\lambda-k)$ is constant and equal to $\operatorname{sgn}(w-k)$ for λ strictly between k and w, $\int_k^w \operatorname{sgn}(\lambda-k)F'(\lambda)\,\mathrm{d}\lambda = \operatorname{sgn}(w-k)\big(F(w)-F(k)\big) = q_k(w)$, whence

$$|q_k(w) - q_\delta(w)| \le \left| \int_k^w |r_\delta(\lambda)|\;|F'(\lambda)|\;\mathrm{d}\lambda \right| \le M\left[2\varepsilon + 2M_0\left(1 - \frac{\varepsilon}{\sqrt{\varepsilon^2+\delta^2}}\right)\right], \tag{A.330}$$

the interval of integration having been split at $|\lambda-k| = \varepsilon$ and its length bounded by $2M_0$ — here $|k| \le M_0$ may be assumed, since for $|k| > M_0$ the sign of $u-k$ is constant and Equation (A.325) reduces to Equation (10.85) with a sign. Choosing first ε and then δ, the right-hand side of Equation (A.330) is made arbitrarily small uniformly in w: $q_\delta \longrightarrow q_k$ uniformly on $[-M_0, M_0]$.

Passage to the limit. Apply Equation (10.92) to (η_δ, q_δ) and subtract the corresponding expression built from (η_k, q_k). Each of the three differences is bounded in modulus by the uniform bounds Equation (A.328) and Equation (A.330) times the integral of $|\partial_t\varphi|$, $|\partial_x\varphi|$ or $|\varphi(\cdot,0)|$ over the compact support of φ, a fixed finite number. Letting $\delta \to 0$ therefore gives Equation (A.325). No convergence theorem is needed at this step: the convergence is uniform on a set of finite measure. □

Lemma A.157 (Two elementary identities)**.** *For all $a, b \in [-M_0, M_0]$, with $\Phi(a,b) = \operatorname{sgn}(a-b)\big(F(a)-F(b)\big)$,*

$$\Phi(a,b) = F\big(\max(a,b)\big) - F\big(\min(a,b)\big)\,, \tag{A.331}$$

so that Φ is symmetric, continuous, and Lipschitz:

$$|\Phi(a,b)| \le M\;|a-b|\,, \qquad |\Phi(a,b) - \Phi(a',b')| \le M\big(|a-a'| + |b-b'|\big)\,. \tag{A.332}$$

Rests on Definition A.150 and Equation (A.320).

Proof. *Derives Lemma A.157.*

If $a > b$ then $\operatorname{sgn}(a-b) = 1$, $\max = a$, $\min = b$ and both sides of Equation (A.331) equal $F(a) - F(b)$; if $a < b$ then $\operatorname{sgn}(a-b) = -1$, $\max = b$, $\min = a$ and both sides equal $F(b) - F(a)$; if $a = b$ both vanish. Symmetry and continuity are then manifest, max and min being continuous. For the bounds, the mean value theorem gives $|F(\max) - F(\min)| \le M\,|\max - \min| = M\,|a-b|$, which is the first; and since $a \longmapsto \max(a,b)$ and $a \longmapsto \min(a,b)$ are 1-Lipschitz in each argument, so is $F \circ \max$ and $F \circ \min$ up to the factor M, giving the second. □

Remark A.158 (Why $|u-k|$ and not a general convex entropy)*.* Equation (A.331) is the reason Kruzhkov's family is the right one. What the doubling will produce is the pair $\big(|u-v|\,,\,\Phi(u,v)\big)$ built from two *solutions*, and for this to be usable it must be a genuine entropy pair in each variable separately with the other frozen — which is exactly what Definition A.150 provides, the frozen solution playing the role of the constant k. No single convex η of Definition 10.101 has that property, because a general η knows nothing about the second solution. The price is that $|u-k|$ is not C^2, and Proposition A.156 is what pays it.

A.17.4 Doubling the variables

Proposition A.159 (The doubled inequality)**.** *Let $\psi = \psi(t,x,s,y) \geq 0$ be smooth with compact support in $\{t>0\}\times\mathbb{R}\times\{s>0\}\times\mathbb{R}$. Then*

$$\iiiint \Big[|u(t,x)-v(s,y)|\,(\partial_t+\partial_s)\psi + \Phi\big(u(t,x),v(s,y)\big)\,(\partial_x+\partial_y)\psi \Big] \geq 0\,, \tag{A.333}$$

the integral being over (t,x,s,y) with $t,s>0$.

Rests on Proposition A.156 and Lemma A.157.

Proof. *Derives Proposition A.159.*

Fix (s,y) with $s>0$ and apply Equation (A.325) to the solution u, with the constant $k=v(s,y)$ — legitimate for almost every (s,y), since $|v(s,y)|\leq M_0$ is then a genuine real number — and with the non-negative test function $(t,x)\longmapsto\psi(t,x,s,y)$, which is smooth with compact support in $\{t>0\}\times\mathbb{R}$. The initial term is absent because ψ vanishes for t near 0. Recalling $q_{v(s,y)}\big(u(t,x)\big)=\Phi\big(u(t,x),v(s,y)\big)$ from Equation (A.321),

$$\int_0^\infty\!\!\int_{\mathbb{R}} \Big[|u-v(s,y)|\,\partial_t\psi + \Phi\big(u,v(s,y)\big)\,\partial_x\psi \Big]\mathrm{d}x\,\mathrm{d}t \geq 0\,. \tag{A.334}$$

The left-hand side of Equation (A.334) is a bounded measurable function of (s,y) — bounded because the integrand is bounded by $2M_0\,|\partial_t\psi| + 2MM_0\,|\partial_x\psi|$ using Equation (A.332) — so it may be integrated over $\{s>0\}\times\mathbb{R}$, and Fubini's theorem rearranges the result into a single integral over the four variables. This gives Equation (A.333) with only the ∂_t and ∂_x terms.

Now exchange the roles. Fix (t,x) with $t>0$ and apply Equation (A.325) to v, with $k=u(t,x)$ and the test function $(s,y)\longmapsto\psi(t,x,s,y)$; by the symmetry of Φ recorded in Lemma A.157, $q_{u(t,x)}\big(v(s,y)\big)=\Phi\big(v(s,y),u(t,x)\big)=\Phi\big(u(t,x),v(s,y)\big)$, and $|v-u|=|u-v|$. Integrating over (t,x) gives Equation (A.333) with the ∂_s and ∂_y terms. Adding the two inequalities gives Equation (A.333). □

Proposition A.160 (The cancellation)**.** *Let $\chi\geq 0$ be smooth with compact support in $(0,\infty)\times\mathbb{R}$, let $\theta\in C^\infty(\mathbb{R})$ be even and non-negative with support in $(-1,1)$ and $\int\theta=1$, and put $\theta_\delta(\sigma)=\delta^{-1}\theta(\sigma/\delta)$ and*

$$\psi_\delta(t,x,s,y)=\chi\Big(\frac{t+s}{2},\frac{x+y}{2}\Big)\,\theta_\delta\Big(\frac{t-s}{2}\Big)\,\theta_\delta\Big(\frac{x-y}{2}\Big)\,. \tag{A.335}$$

For δ small enough ψ_δ is admissible in Proposition A.159, and in the sum-and-difference coordinates

$$\tau=\frac{t+s}{2}\,,\quad \zeta=\frac{x+y}{2}\,,\quad \sigma=\frac{t-s}{2}\,,\quad \omega=\frac{x-y}{2}\,, \tag{A.336}$$

one has

$$(\partial_t+\partial_s)\psi_\delta=(\partial_\tau\chi)\,\theta_\delta(\sigma)\theta_\delta(\omega)\,,\qquad (\partial_x+\partial_y)\psi_\delta=(\partial_\zeta\chi)\,\theta_\delta(\sigma)\theta_\delta(\omega)\,. \tag{A.337}$$

Rests on Proposition A.159 and Equation (A.335).

Proof. *Derives Proposition A.160.*

By the chain rule applied to Equation (A.336), $\partial_t=\frac12\partial_\tau+\frac12\partial_\sigma$ and $\partial_s=\frac12\partial_\tau-\frac12\partial_\sigma$, so $\partial_t+\partial_s=\partial_\tau$; likewise $\partial_x+\partial_y=\partial_\zeta$. In Equation (A.335) the factors θ_δ depend only on σ and ω and are therefore annihilated by ∂_τ and ∂_ζ, while χ depends only on (τ,ζ); that is Equation (A.337). Admissibility: the support of ψ_δ lies within distance 2δ of the diagonal $t=s$, $x=y$ over the support of χ, so if 2δ is smaller than the distance from the support of χ to $\{\tau=0\}$ then $t,s>0$ throughout. □

Remark A.161. This is the step the method is named for and the only one that could fail. Had the mollifier been differentiated, each derivative would have produced a factor δ^{-1}, and the limit $\delta \to 0$ would have been meaningless. It survives because the two entropy inequalities are added, not subtracted, and because the sum of the two time derivatives — one for each copy of the equation — is a derivative along the diagonal, in whose direction the mollifier is constant. In effect the argument tests the difference of two solutions against a function that is smooth along the diagonal and singular across it, and only the diagonal direction is ever differentiated.

A.17.5 The limit and the cone estimate

Proposition A.162 (The limit $\delta \to 0$)**.** *For every non-negative χ smooth with compact support in $(0,\infty)\times\mathbb{R}$,*

$$\int_0^\infty\!\!\int_{\mathbb{R}} \Big[|u-v|\;\partial_t\chi + \Phi(u,v)\,\partial_x\chi \Big]\,\mathrm{d}x\,\mathrm{d}t \geq 0\,, \tag{A.338}$$

that is, $\partial_t|u-v| + \partial_x\Phi(u,v) \leq 0$ in the sense of distributions on $(0,\infty)\times\mathbb{R}$.
Rests on Proposition A.160 and Lemma A.157.

Proof. *Derives Proposition A.162.*

Insert Equation (A.337) into Equation (A.333) and change variables to Equation (A.336). The map $(t,x,s,y) \longmapsto (\tau,\zeta,\sigma,\omega)$ is linear with $\mathrm{d}t\,\mathrm{d}s = 2\,\mathrm{d}\tau\,\mathrm{d}\sigma$ and $\mathrm{d}x\,\mathrm{d}y = 2\,\mathrm{d}\zeta\,\mathrm{d}\omega$, so

$$\iint \left[\iint \Big(G_{\sigma\omega}\,\partial_\tau\chi + H_{\sigma\omega}\,\partial_\zeta\chi \Big)\theta_\delta(\sigma)\theta_\delta(\omega)\,\mathrm{d}\sigma\,\mathrm{d}\omega \right] \mathrm{d}\zeta\,\mathrm{d}\tau \geq 0\,, \tag{A.339}$$

after dividing by the positive constant 4, where

$$G_{\sigma\omega}(\tau,\zeta) = |u(\tau+\sigma,\zeta+\omega) - v(\tau-\sigma,\zeta-\omega)|\,, \quad H_{\sigma\omega}(\tau,\zeta) = \Phi\big(u(\tau{+}\sigma,\zeta{+}\omega), v(\tau{-}\sigma,\zeta{-}\omega)\big)\,. \tag{A.340}$$

Let K be a compact neighbourhood of the support of χ in $(0,\infty)\times\mathbb{R}$. By continuity of translation in L^1 (item 4 of Remark A.153) both $(\tau,\zeta) \longmapsto u(\tau{+}\sigma,\zeta{+}\omega)$ and $(\tau,\zeta) \longmapsto v(\tau{-}\sigma,\zeta{-}\omega)$ converge to u and v in $L^1(K)$ as $(\sigma,\omega)\to(0,0)$; hence, the maps $(a,b)\longmapsto|a-b|$ and $(a,b)\longmapsto\Phi(a,b)$ being Lipschitz by Equation (A.332),

$$\int_K \big| G_{\sigma\omega} - |u-v| \big| \longrightarrow 0\,, \qquad \int_K |H_{\sigma\omega} - \Phi(u,v)| \longrightarrow 0\,. \tag{A.341}$$

Denote by $\Xi(\sigma,\omega)$ the inner bracket of Equation (A.339) integrated against χ's derivatives, i.e. the quantity $\iint (G_{\sigma\omega}\partial_\tau\chi + H_{\sigma\omega}\partial_\zeta\chi)\mathrm{d}\zeta\,\mathrm{d}\tau$, and by Ξ_0 the left-hand side of Equation (A.338). Then $|\Xi(\sigma,\omega) - \Xi_0| \leq \|\nabla\chi\|_\infty \int_K (|G_{\sigma\omega} - |u-v|| + |H_{\sigma\omega} - \Phi(u,v)|)$, which by Equation (A.341) tends to 0 as $(\sigma,\omega)\to 0$. But Equation (A.339) says exactly $\iint \Xi(\sigma,\omega)\theta_\delta(\sigma)\theta_\delta(\omega) \geq 0$, an average of Ξ over the square $|\sigma|,|\omega| < \delta$ with a non-negative weight of total mass 1; as $\delta\to 0$ that average converges to Ξ_0. Hence $\Xi_0 \geq 0$, which is Equation (A.338). □

Proof of Theorem A.151. *Derives Theorem A.151.*

Write $w = |u-v|$ and $\Psi = \Phi(u,v)$, so that Equation (A.338) holds and $|\Psi| \leq M\,w$ by Equation (A.332).

The cone cutoff. Fix $R > 0$ and $T > 0$. For $\epsilon > 0$ let $\Lambda_\epsilon \in C^\infty(\mathbb{R})$ be non-decreasing with $\Lambda_\epsilon = 0$ on $(-\infty, 0]$, $\Lambda_\epsilon = 1$ on $[\epsilon,\infty)$ and $0 \leq \Lambda_\epsilon' \leq 2/\epsilon$; and let $n_\epsilon \in C^\infty(\mathbb{R})$ be even with $|n_\epsilon'| \leq 1$ and $|n_\epsilon(x) - |x|| \leq \epsilon$ — for instance $n_\epsilon = \sqrt{x^2+\epsilon^2}$. Put

$$\beta(t,x) = \Lambda_\epsilon\big(R + M(T-t) - n_\epsilon(x)\big)\,, \tag{A.342}$$

a smooth function with values in $[0,1]$, equal to 1 well inside the backward cone $\{n_\epsilon(x) \le R + M(T-t)\}$ and to 0 outside it. Let $\alpha \ge 0$ be smooth with compact support in $(0,T]$ and take $\chi = \alpha\beta$, which is admissible in Equation (A.338) after multiplication by a fixed spatial cutoff equal to 1 on the (bounded) support of β — the cone is bounded for $t \ge 0$ — so that χ has compact support.

The lateral term has a sign. Since $\partial_t\chi = \alpha'\beta + \alpha\,\partial_t\beta$ and $\partial_x\chi = \alpha\,\partial_x\beta$, with

$$\partial_t\beta = -M\,\Lambda_\epsilon'\,, \qquad \partial_x\beta = -\Lambda_\epsilon'\,n_\epsilon'(x)\,, \tag{A.343}$$

the contribution of the second group to Equation (A.338) is

$$\iint \alpha\,[w\,\partial_t\beta + \Psi\,\partial_x\beta] = -\iint \alpha\,\Lambda_\epsilon'\,[M\,w + \Psi\,n_\epsilon'] \le 0\,, \tag{A.344}$$

because $\alpha \ge 0$, $\Lambda_\epsilon' \ge 0$, and $Mw + \Psi n_\epsilon' \ge Mw - |\Psi| \ge 0$ by $|n_\epsilon'| \le 1$ and $|\Psi| \le Mw$. This is the point of choosing the slope of the cone to be M: the flux can never carry mass out through the lateral boundary faster than the boundary retreats. Subtracting Equation (A.344) from Equation (A.338) leaves

$$\int_0^\infty \alpha'(t)\,\left[\int_{\mathbb{R}} \beta(t,x)\,w(t,x)\,\mathrm{d}x\right]\mathrm{d}t \ge 0\,. \tag{A.345}$$

From an average to a value. Let $0 < \tau_1 < \tau_2 \le T$ and let $\alpha = \alpha_h$ rise smoothly from 0 to 1 on $[\tau_1, \tau_1 + h]$ and fall back to 0 on $[\tau_2, \tau_2 + h]$, with α_h' bounded by $2/h$ and of one sign on each interval. Then Equation (A.345) reads, in the limit of the standard smooth ramps,

$$\frac{1}{h}\int_{\tau_1}^{\tau_1+h} \Theta(t)\,\mathrm{d}t \;\ge\; \frac{1}{h}\int_{\tau_2}^{\tau_2+h} \Theta(t)\,\mathrm{d}t\,, \qquad \Theta(t) = \int_{\mathbb{R}} \beta(t,x)\,w(t,x)\,\mathrm{d}x\,, \tag{A.346}$$

up to an error tending to 0 with the width of the ramps. Θ is bounded and measurable, so by Lebesgue's differentiation theorem (item 5 of Remark A.153) the two averages converge, as $h \to 0$, to $\Theta(\tau_1)$ and $\Theta(\tau_2)$ for almost every τ_1, τ_2. Hence $\Theta(\tau_2) \le \Theta(\tau_1)$ for almost all $\tau_1 < \tau_2$.

Removing the smoothing. As $\epsilon \to 0$, $\beta(t,x)$ tends to 1 at every x with $|x| < R + M(T-t)$ and to 0 at every x with $|x| > R + M(T-t)$, and $0 \le \beta \le 1$ throughout; by dominated convergence, applied with the integrable majorant $2M_0\,\mathbf{1}_{\{|x| \le R+MT\}}$,

$$\int_{|x| \le R+M(T-\tau_2)} w(\tau_2,x)\,\mathrm{d}x \;\le\; \int_{|x| \le R+M(T-\tau_1)} w(\tau_1,x)\,\mathrm{d}x\,. \tag{A.347}$$

Choosing $T = \tau_2$ turns Equation (A.347) into Equation (A.322).

Down to $t = 0$. By Lemma A.154 applied to u and to v on the compact set $|x| \le R + M\tau_2$, $w(\tau_1,\cdot) \longrightarrow |u_0 - v_0|$ in the mean over that set as $\tau_1 \to 0^+$ — the triangle inequality gives $\big|\,|u(\tau_1) - v(\tau_1)| - |u_0 - v_0|\,\big| \le |u(\tau_1) - u_0| + |v(\tau_1) - v_0|$ — so the right-hand side of Equation (A.322) converges to $\int_{|x| \le R+M\tau_2} |u_0 - v_0|$ along a sequence of admissible τ_1, which proves the version with $\tau_1 = 0$.

The global statement. If $u_0 - v_0$ is integrable, let $R \to \infty$ in that version: the left-hand side increases to $\int_{\mathbb{R}} w(t,x)\,\mathrm{d}x$ by monotone passage on an increasing family of sets, and the right-hand side increases to $\int_{\mathbb{R}} |u_0 - v_0|$, giving Equation (A.323). □

A.17.6 Existence by vanishing viscosity

The uniqueness half is now complete. Existence is the limit $\varepsilon \to 0^+$ of the viscous problem, and the one step that is genuinely about entropy — and the only one that would be invisible in a purely functional-analytic account — is carried out here in full.

Proposition A.163 (The viscous problem produces the entropy inequality)**.** *Let u^ε be a bounded classical solution of*

$$\partial_t u^\varepsilon + \partial_x F(u^\varepsilon) = \varepsilon\, \partial_x^2 u^\varepsilon\,, \qquad u^\varepsilon(0,\cdot) = u_0^\varepsilon\,, \tag{A.348}$$

with $|u^\varepsilon| \le M_0$, and let (η, q) be an entropy pair in the sense of Definition 10.101. Then for every non-negative test function φ

$$\int_0^\infty \int_{\mathbb{R}} [\eta(u^\varepsilon)\partial_t\varphi + q(u^\varepsilon)\partial_x\varphi]\,\mathrm{d}x\,\mathrm{d}t + \int_{\mathbb{R}} \eta(u_0^\varepsilon)\varphi(x,0)\,\mathrm{d}x \;\ge\; -\varepsilon\, C_\varphi\,, \tag{A.349}$$

with $C_\varphi = \max_{|w|\le M_0} |\eta(w)| \cdot \iint |\partial_x^2\varphi|$, a constant independent of ε.
Rests on Definition 10.101, Equation (10.81), and Theorem 10.80.

Proof. *Derives Proposition A.163.*

Multiply Equation (A.348) by $\eta'(u^\varepsilon)$. On the left, the chain rule and $q' = \eta' F'$ give $\eta'(u^\varepsilon)\partial_t u^\varepsilon = \partial_t \eta(u^\varepsilon)$ and $\eta'(u^\varepsilon)\partial_x F(u^\varepsilon) = \eta'(u^\varepsilon)F'(u^\varepsilon)\partial_x u^\varepsilon = \partial_x q(u^\varepsilon)$. On the right,

$$\varepsilon\,\eta'(u^\varepsilon)\,\partial_x^2 u^\varepsilon = \varepsilon\,\partial_x^2\eta(u^\varepsilon) - \varepsilon\,\eta''(u^\varepsilon)\big(\partial_x u^\varepsilon\big)^2 \;\le\; \varepsilon\,\partial_x^2\eta(u^\varepsilon)\,, \tag{A.350}$$

the identity being the chain rule applied twice and the inequality being $\eta'' \ge 0$, which is the convexity demanded by Definition 10.101 and the *only* place it is used. Hence

$$\partial_t \eta(u^\varepsilon) + \partial_x q(u^\varepsilon) \le \varepsilon\,\partial_x^2\eta(u^\varepsilon) \tag{A.351}$$

pointwise. Multiply Equation (A.351) by $\varphi \ge 0$, integrate over $\{t>0\}\times\mathbb{R}$ and integrate by parts, all boundary terms at spatial infinity vanishing with φ and the one at $t=0$ producing $-\int \eta(u_0^\varepsilon)\varphi(x,0)\,\mathrm{d}x$:

$$-\iint [\eta\,\partial_t\varphi + q\,\partial_x\varphi] - \int \eta(u_0^\varepsilon)\varphi(x,0)\,\mathrm{d}x \;\le\; \varepsilon \iint \eta(u^\varepsilon)\,\partial_x^2\varphi\,,$$

and the right-hand side is bounded in modulus by εC_φ, which is Equation (A.349). The two integrations by parts on the viscous term are the reason the estimate is $O(\varepsilon)$ and not $O(1)$: all the differentiation has been moved onto the test function, and no derivative of u^ε survives. □

Remark A.164 (The remaining inputs for existence)*.* Proposition A.163 is the whole of the entropy argument; what it does not supply is a limit to take it to. Three further steps are needed, of which the first is elementary in this treatise and the other two are the quoted items (7) of Remark A.153.

1. *The supremum bound.* $|u^\varepsilon| \le \|u_0^\varepsilon\|_\infty \le \|u_0\|_\infty$, by the parabolic maximum principle Theorem 10.80 applied to Equation (A.348) on large space-time rectangles: the equation is of the form treated there with the extra first-order term $F'(u^\varepsilon)\partial_x u^\varepsilon$, which vanishes at an interior extremum and so does not disturb the argument. This is why M_0 and hence M in Equation (A.320) can be fixed independently of ε.

2. *Classical solvability of Equation* (A.348) for smooth bounded data $u_0^\varepsilon = u_0$ mollified, on $\{t>0\}\times\mathbb{R}$. This is parabolic theory and is quoted.

3. *Compactness.* The spatial derivative $p = \partial_x u^\varepsilon$ satisfies the linear parabolic equation $\partial_t p + \partial_x\big(F'(u^\varepsilon)p\big) = \varepsilon\partial_x^2 p$, from which the total variation $\int |p(t,x)|\,\mathrm{d}x$ is non-increasing in t; together with (i) this gives a family uniformly bounded and of uniformly bounded variation, and a compactness theorem for such families produces a sequence $\varepsilon_j \to 0$ with $u^{\varepsilon_j} \to u$ in L^1 on compact sets and almost everywhere. The compactness theorem is quoted.

Granting these, pass to the limit in Equation (A.349): η and q are continuous and $u^{\varepsilon_j} \to u$ almost everywhere with values in a fixed bounded interval, so dominated convergence carries both integrals, the data converge because $u_0^{\varepsilon} \to u_0$ in L^1 on compact sets, and the right-hand side tends to 0. The limit is exactly Equation (10.92). Taking $\eta(w) = w$ and $q = F$ — a legitimate, if degenerate, member of Definition 10.101, for which Equation (A.350) is an equality — gives the same statement with equality, which is Equation (10.85): the limit is a weak solution.

Proof of Theorem 10.103. *Derives Theorem 10.103.*

Existence is Remark A.164: the vanishing-viscosity limit is a weak solution in the sense of Definition 10.95 satisfying Equation (10.92) for every entropy pair, hence an entropy solution in the sense of Definition 10.101. *Uniqueness* and *continuous dependence in the mean* are Corollary A.152, which rests on Theorem A.151. The last clause of the chapter's statement — that where the solution is piecewise C^1 across a C^1 curve its jumps obey Equation (10.91) — is Proposition 10.102, proved in the chapter, and is not re-derived here. □

Remark A.165 (Convexity of the flux is not needed). Theorem 10.103 assumes F convex, and the chapter has good reason to: convexity is what makes Proposition 10.102 equate the entropy inequality with the geometric condition Equation (10.91), and it is what makes the shock picture of Section 10.6.3 the whole story. But the proof given above never used it. Only $F \in C^1$ entered, through the bound M of Equation (A.320) and the Lipschitz estimate Equation (A.332). What is lost without convexity is not uniqueness but the *description* of the admissible discontinuities: for a non-convex flux the entropy inequality still selects one solution, but the admissible jumps are described by a chord condition — the chord joining the two states must lie on one side of the graph of F between them — rather than by the simple inequality $u_- \geq u_+$. The function G of Equation (10.94) is exactly that chord difference, and the chapter's proof of Proposition 10.102 is where convexity is spent: it is used to pass from $G(u_-) = G(u_+) = 0$ to $G \leq 0$ between the two states, and that implication is what fails when F is not convex.

Remark A.166 (Why the entropy inequality and not the jump condition). The chapter already observes, in the paragraph following Definition 10.101, that Equation (10.91) presupposes one-sided limits that a bounded measurable weak solution need not have. The proof above shows what is gained by not presupposing them: at no point did the argument speak of a discontinuity, a curve, or a one-sided limit. It compared two solutions through their entropy inequalities alone, and the only regularity used — continuity of translation in the mean — is a property every bounded measurable function has. Example 10.98 is settled by the same stroke without any examination of the two candidate solutions: whichever of them satisfies Equation (10.92) is the only one that does.

Remark A.167. Appendix A.17 discharges the proof obligation of Theorem 10.103 in Chapter 10, and with it closes the pattern that Remark 10.104 describes: a nonlinear equation destroys its own classical solution in finite time (Proposition 10.94), weak solutions restore existence at the cost of uniqueness (Example 10.98), and the entropy inequality Equation (10.92) restores uniqueness, giving back all three of Hadamard's conditions (Definition 10.24) with the mean as the norm. The physical reading is Remark 10.100, and the gas-dynamical form of the admissible jump is Chapter 31. Six inputs are assumed and are listed in Remark A.153; five of them are the Lebesgue theory that this treatise deliberately does not build, and the sixth is Lemma A.154.

A.18 Lévy's Continuity Theorem

This appendix proves Theorem 11.45 of Chapter 11: if the characteristic functions of a sequence of random variables converge pointwise to a limit that is continuous at the origin, then that limit is itself a characteristic function and the variables converge in distribution. It is the bridge the central limit theorem crosses — Theorem 11.46 produces $\varphi_{Z_n}(t) \to \mathrm{e}^{-t^2/2}$ and needs to conclude $Z_n \to \mathcal{N}(0,1)$ — and it is used again in Appendix A.19 and Appendix A.20.

The route has four stages, each of which is a theorem in its own right: Helly's selection theorem, which extracts a limiting monotone function from any sequence of distribution functions (Appendix A.18.4); the Fourier inversion formula, which recovers the distribution from the transform and thereby shows the transform determines it (Appendix A.18.5); the tightness estimate, which is the single place continuity of the limit at the origin is used (Appendix A.18.6); and the assembly (Appendix A.18.7). Everything rests on one classical integral, Dirichlet's, which is evaluated first because the inversion formula is built out of it.

Throughout, $F_X(x) = \Pr(X \le x)$ is the distribution function of Definition 11.21 — non-decreasing, right-continuous, with limits 0 and 1 at $\mp\infty$, and *not* assumed continuous — and $\varphi_X(t) = \left\langle \mathrm{e}^{\mathrm{i}tX} \right\rangle$ the characteristic function of Definition 11.42. Convergence in distribution means $F_{X_n}(x) \to F_X(x)$ at every continuity point x of F_X. All the quantities here are pure numbers: t carries the reciprocal of the SI unit of X, so that tX, and with it every exponent below, is dimensionless.

A.18.1 Statement

Theorem A.168 (Lévy's continuity theorem)**.** *Let $X_1, X_2, \dots$ be real random variables with characteristic functions φ_n. Suppose $\varphi_n(t) \to \varphi(t)$ for every $t \in \mathbb{R}$, and suppose the limit function φ is continuous at $t = 0$. Then φ is the characteristic function of a random variable X, and $X_n \to X$ in distribution.*

Rests on Definitions 11.21 and 11.42.

The converse is elementary and is recorded at the end (Corollary A.181); it is the direction the theorem is *not* usually needed in.

A.18.2 The two facts imported from Lebesgue theory

Chapter 7 builds the Riemann–Darboux integral (Definition 7.39) and no more. Two theorems of the Lebesgue theory are used below and are not proved anywhere in this treatise; they are stated here in exactly the form in which they are applied, so that the reader can see precisely how much is being assumed.

Theorem A.169 (Dominated convergence)**.** *Let $Z, Z_1, Z_2, \dots$ be random variables with $Z_m \to Z$ pointwise (or in probability), and suppose there is a random variable D with $\langle D \rangle < \infty$ and $|Z_m| \le D$ for every m. Then $\langle Z_m \rangle \to \langle Z \rangle$. The same statement holds for a family indexed by a continuous parameter. In particular, if $|Z_m| \le c$ for a constant c, then $\langle Z_m \rangle \to \langle Z \rangle$ [1894].*

Rests on Definition 11.4.

Theorem A.170 (Fubini's theorem, bounded case)**.** *Let $h(t, \omega)$ be jointly measurable, let $|h| \le c$ for a constant c, and let $T < \infty$. Then*

$$\int_{-T}^{T} \langle h(t, \cdot) \rangle \, \mathrm{d}t = \left\langle \int_{-T}^{T} h(t, \cdot) \, \mathrm{d}t \right\rangle , \tag{A.352}$$

both sides being finite [1894].

Rests on Definition 11.4.

Remark A.171 (What is quoted here). Theorems A.169 and A.170 are the *only* statements in this appendix that are assumed rather than derived. Both belong to measure theory: dominated convergence is the theorem that makes the Lebesgue integral complete under limits — the property the Riemann integral lacks, which is why it cannot be proved from Chapter 7 — and Fubini's theorem is the corresponding statement for a product measure. This treatise develops neither, by the editorial choice recorded at Lemma 11.44, where the same gap was closed by an explicit truncation instead. No such elementary substitute is available here: the interchange Equation (A.352) is applied to the expectation of an oscillatory integral whose integrand depends on the random variable through $\mathrm{e}^{\mathrm{i}tX}$, and there is nothing to truncate. Each use below is flagged by name at the point where it occurs; there are four in all (two of each). Everything else — Helly's theorem, the Helly–Bray lemma, the Dirichlet integral, the inversion formula, the tightness estimate — is derived here from the real analysis of Chapter 7.

A.18.3 The Dirichlet integral

Lemma A.172 (Dirichlet)**.** *Write $S(Y)=\int_0^Y (\sin s)/s\,\mathrm{d}s$ for $Y>0$, the integrand being extended by the value 1 at $s=0$, where it is continuous. Then*

$$\lim_{Y\to\infty} S(Y)=\frac{\pi}{2}\,,\qquad \text{and}\qquad C_0\equiv\sup_{Y>0}|S(Y)|\;\le\;4\,. \tag{A.353}$$

Consequently, for every $u\in\mathbb{R}$ and $T>0$, $\int_0^T(\sin(tu))/t\,\mathrm{d}t=S(Tu)$ for $u>0$, $=-S(T|u|)$ for $u<0$ and $=0$ for $u=0$; so the integral is bounded by C_0 uniformly in T and u and tends to $\frac{\pi}{2}\operatorname{sgn}(u)$ as $T\to\infty$.

Rests on Theorem 7.43 and Equation (7.28).

Proof. *Derives Lemma A.172.*

The uniform bound. On $[0,1]$ the integrand is bounded by 1, so $\left|\int_0^1\right|\le 1$. For $Y\ge 1$ integrate by parts (Equation (7.28)) with $\sin s\,\mathrm{d}s=-\mathrm{d}\cos s$:

$$\int_1^Y\frac{\sin s}{s}\,\mathrm{d}s=\left[-\frac{\cos s}{s}\right]_1^Y-\int_1^Y\frac{\cos s}{s^2}\,\mathrm{d}s\,, \tag{A.354}$$

whose first term is at most $1/Y+\cos 1\le 2$ in modulus and whose second is at most $\int_1^\infty s^{-2}\mathrm{d}s=1$. Hence $|S(Y)|\le 1+2+1=4$ for $Y\ge 1$, and $|S(Y)|\le 1$ for $Y\le 1$. The same estimate applied on $[Y,Y']$ with $1\le Y<Y'$ gives

$$\left|\int_Y^{Y'}\frac{\sin s}{s}\,\mathrm{d}s\right|\;\le\;\frac{2}{Y}\,, \tag{A.355}$$

so $S(Y)$ satisfies the Cauchy criterion (Theorem 7.8) and the limit $D=\lim_{Y\to\infty}S(Y)$ exists.

The value. For $\lambda>0$ put $I(\lambda)=\int_0^\infty \mathrm{e}^{-\lambda s}(\sin s)/s\,\mathrm{d}s$, which converges absolutely since the integrand is bounded by $\mathrm{e}^{-\lambda s}$. Its λ-derivative is $-\mathrm{e}^{-\lambda s}\sin s$ in modulus at most $\mathrm{e}^{-\lambda_0 s}$ for $\lambda\ge\lambda_0>0$, an integrable bound independent of λ, so the difference quotients converge uniformly on $[\lambda_0,\infty)$ and differentiation under the integral sign is legitimate there:

$$I'(\lambda)=-\int_0^\infty \mathrm{e}^{-\lambda s}\sin s\,\mathrm{d}s=-\Im\int_0^\infty \mathrm{e}^{-(\lambda-\mathrm{i})s}\,\mathrm{d}s=-\Im\frac{1}{\lambda-\mathrm{i}}=-\frac{1}{1+\lambda^2}\,. \tag{A.356}$$

Also $|I(\lambda)|\le\int_0^\infty \mathrm{e}^{-\lambda s}\mathrm{d}s=1/\lambda\to 0$. Integrating Equation (A.356) from λ to ∞ therefore gives $I(\lambda)=\frac{\pi}{2}-\arctan\lambda$.

The two agree in the limit. Fix $Y\ge 1$ and estimate $I(\lambda)-D$ in three pieces. On $[0,Y]$, using $\left|\mathrm{e}^{-\lambda s}-1\right|\le\lambda s$ and $|\sin s|\le 1$,

$$\left|\int_0^Y\left(\mathrm{e}^{-\lambda s}-1\right)\frac{\sin s}{s}\,\mathrm{d}s\right|\;\le\;\int_0^Y\lambda\,\mathrm{d}s=\lambda Y\,.$$

The tail of D is at most $2/Y$ by Equation (A.355). For the tail of I, integrate by parts with $u = \mathrm{e}^{-\lambda s}/s$:

$$\left| \int_Y^\infty \mathrm{e}^{-\lambda s} \frac{\sin s}{s} \, \mathrm{d}s \right| \;\le\; \frac{\mathrm{e}^{-\lambda Y}}{Y} + \int_Y^\infty \mathrm{e}^{-\lambda s} \left(\frac{\lambda}{s} + \frac{1}{s^2} \right) \mathrm{d}s \;\le\; \frac{1}{Y} + \frac{1}{Y} + \frac{1}{Y} = \frac{3}{Y} \,,$$

the middle step bounding $1/s \le 1/Y$ in the λ-term and $\mathrm{e}^{-\lambda s} \le 1$ in the other. Hence $|I(\lambda) - D| \le \lambda Y + 5/Y$ for every $Y \ge 1$ and $\lambda > 0$. Given $\varepsilon > 0$ choose $Y = 10/\varepsilon$ and then $\lambda < \varepsilon/(2Y)$: the right side is below ε. So $D = \lim_{\lambda \downarrow 0} I(\lambda) = \frac{\pi}{2} - \arctan 0 = \frac{\pi}{2}$.

The final statement is the substitution $s = tu$ (Equation (7.27)), under which $(\sin(tu))/t \, \mathrm{d}t = (\sin s)/s \, \mathrm{d}s$ for $u > 0$; oddness of sin in u supplies the case $u < 0$. □

A.18.4 Helly's selection theorem

Theorem A.173 (Helly's selection theorem)**.** *Let $F_1, F_2, \dots$ be distribution functions. Then there are a subsequence $F_{n_1}, F_{n_2}, \dots$ and a non-decreasing, right-continuous $F : \mathbb{R} \to [0,1]$ such that $F_{n_k}(x) \to F(x)$ at every continuity point x of F.*

Rests on Definition 11.21 and Theorem 7.7.

The limit F need not be a distribution function: mass can escape to infinity, as it does for $F_n = F_{X+n}$, where $F \equiv 0$. Excluding that is precisely what tightness will do.

Proof. *Derives Theorem A.173.*

The diagonal argument. Enumerate the rationals, $\mathbb{Q} = \{q_1, q_2, \dots\}$. The numbers $F_n(q_1)$ lie in the bounded set $[0,1]$, so by Bolzano–Weierstrass (Theorem 7.7) some subsequence, indexed by an infinite set $N_1 \subseteq \mathbb{N}$, has $F_n(q_1)$ convergent along N_1; call the limit $G(q_1)$. Having chosen $N_1 \supseteq N_2 \supseteq \cdots \supseteq N_m$ with $F_n(q_i) \to G(q_i)$ along N_m for every $i \le m$, apply Theorem 7.7 again to the bounded sequence $(F_n(q_{m+1}))_{n \in N_m}$ to get $N_{m+1} \subseteq N_m$ and a limit $G(q_{m+1})$. Let n_k be the kth element of N_k, in increasing order and chosen larger than n_{k-1}, which is possible because each N_k is infinite. For each fixed i, all but the first $i-1$ terms of (n_k) lie in N_i, so

$$F_{n_k}(q) \;\longrightarrow\; G(q) \qquad \text{for every } q \in \mathbb{Q} \,. \tag{A.357}$$

Each F_n is non-decreasing with values in $[0,1]$, so G inherits both properties on $\mathbb{Q}$.

The limit function. Define $F(x) = \inf \{G(q) \mid q \in \mathbb{Q},\ q > x\}$. It is non-decreasing and $[0,1]$-valued because G is. It is right-continuous: given x and $\varepsilon > 0$, pick a rational $q > x$ with $G(q) < F(x) + \varepsilon$; every $y \in (x, q)$ then has $F(y) \le G(q) < F(x) + \varepsilon$, and monotonicity gives $F(y) \downarrow F(x)$ as $y \downarrow x$.

Two inequalities are used repeatedly and follow at once from the definition and the monotonicity of G: for rationals $r < s$,

$$F(r) \;\le\; G(s) \qquad \text{and} \qquad G(r) \;\le\; F(s) \,. \tag{A.358}$$

The first holds because $s > r$ makes $G(s)$ one of the numbers whose infimum is $F(r)$; the second because every rational $q > s$ has $G(q) \ge G(r)$, so the infimum defining $F(s)$ is at least $G(r)$.

Convergence at continuity points. Let x be a continuity point of F and let $\varepsilon > 0$. By left-continuity of F at x there is $y < x$ with $F(y) > F(x) - \varepsilon$; choose rationals r, s with $y < r < s < x$. Then $F_{n_k}(x) \ge F_{n_k}(s) \to G(s)$, and by Equation (A.358) twice, $G(s) \ge G(r) \ge F(y)$, whence

$$\liminf_k F_{n_k}(x) \;\ge\; F(y) \;>\; F(x) - \varepsilon \,.$$

For the other side, continuity gives $z > x$ with $F(z) < F(x) + \varepsilon$; choose a rational $q \in (x, z)$. Then $F_{n_k}(x) \le F_{n_k}(q) \to G(q)$, and $G(q) \le F(z)$ by the second inequality

of Equation (A.358), so $\limsup_k F_{n_k}(x) \le F(z) < F(x) + \varepsilon$. As $\varepsilon > 0$ was arbitrary, $F_{n_k}(x) \to F(x)$. □

Definition A.174 (Tightness)**.** A family $\{X_n\}$ of random variables is *tight* when for every $\varepsilon > 0$ there is $K < \infty$ with $\Pr(|X_n| > K) \le \varepsilon$ for every n.
Rests on Definition 11.21.

Lemma A.175 (Tightness makes the Helly limit proper)**.** *If in Theorem A.173 the underlying variables are tight, then the limit F satisfies $F(x) \to 0$ as $x \to -\infty$ and $F(x) \to 1$ as $x \to +\infty$: it is a distribution function.*
Rests on Theorem A.173 and Definition A.174.

Proof. *Derives Lemma A.175.*

Given $\varepsilon > 0$ take K as in Definition A.174. A monotone function has at most countably many discontinuities — the open intervals $(F(x^-), F(x^+))$ belonging to distinct jumps are disjoint and each contains a rational — so continuity points are dense and we may pick continuity points $x > K$ and $x' < -K$. Then $F(x) = \lim_k F_{n_k}(x) \ge \liminf_k \Pr(|X_{n_k}| \le K) \ge 1 - \varepsilon$ and $F(x') = \lim_k F_{n_k}(x') \le \varepsilon$. Monotonicity extends both to all larger, respectively smaller, arguments. □

Lemma A.176 (Helly–Bray)**.** *Let F_n, F be distribution functions with $F_n(x) \to F(x)$ at every continuity point of F, and let $g : \mathbb{R} \to \mathbb{R}$ be bounded and continuous. Then*

$$\langle g(X_n) \rangle \longrightarrow \langle g(X) \rangle \,, \tag{A.359}$$

where X_n, X have distribution functions F_n, F.
Rests on Theorems 7.25 and A.173.

Proof. *Derives Lemma A.176.*

Write $\|g\|_\infty = \sup |g|$ and let $\varepsilon > 0$. Since F is a distribution function and its continuity points are dense, choose continuity points $a < b$ with $F(a) < \varepsilon$ and $1 - F(b) < \varepsilon$; then for n large $F_n(a) < 2\varepsilon$ and $1 - F_n(b) < 2\varepsilon$. The contributions to $\langle g(X_n) \rangle$ and $\langle g(X) \rangle$ from outside $(a, b]$ are therefore at most $2\varepsilon \, \|g\|_\infty$ and $\varepsilon \, \|g\|_\infty$ in modulus.

On the compact interval $[a, b]$ the function g is uniformly continuous (Theorem 7.25), so there is $\delta > 0$ with $|g(x) - g(y)| < \varepsilon$ whenever $|x - y| < \delta$ inside $[a, b]$. Choose continuity points $a = x_0 < x_1 < \cdots < x_m = b$ of F with $x_j - x_{j-1} < \delta$ — possible because continuity points are dense. Then for any distribution function H,

$$\left| \int_{(a,b]} g \, \mathrm{d}H - \sum_{j=1}^{m} g(x_j) \, [H(x_j) - H(x_{j-1})] \right| \le \varepsilon \,,$$

because on each $(x_{j-1}, x_j]$ the integrand differs from $g(x_j)$ by less than ε and the increments of H sum to at most 1. Applying this to $H = F_n$ and to $H = F$, and using $F_n(x_j) \to F(x_j)$ at each of the finitely many partition points, gives

$$\limsup_n \, |\langle g(X_n) \rangle - \langle g(X) \rangle| \le 2\varepsilon + 3\varepsilon \, \|g\|_\infty \,.$$

Since $\varepsilon > 0$ was arbitrary, the limit is 0. □

A.18.5 The inversion formula

Theorem A.177 (Fourier inversion for a distribution function)**.** *Let X have distribution function F and characteristic function φ, and let $a < b$. Then*

$$\lim_{T \to \infty} \frac{1}{2\pi} \int_{-T}^{T} \frac{\mathrm{e}^{-\mathrm{i}ta} - \mathrm{e}^{-\mathrm{i}tb}}{\mathrm{i}t} \, \varphi(t) \, \mathrm{d}t = \frac{F(b) + F(b^-)}{2} - \frac{F(a) + F(a^-)}{2} \,, \tag{A.360}$$

the integrand being extended by its limit $b-a$ at $t=0$. In particular, if a and b are continuity points of F the right-hand side is $F(b)-F(a)$.

Rests on Definition 11.42 and Lemma A.172.

Proof. *Derives Theorem A.177.*

Write J_T for the integral on the left. For real u, v,

$$\left|\frac{\mathrm{e}^{\mathrm{i}tu}-\mathrm{e}^{\mathrm{i}tv}}{\mathrm{i}t}\right| = \left|\int_v^u \mathrm{e}^{\mathrm{i}ts}\,\mathrm{d}s\right| \;\le\; |u-v|\,, \tag{A.361}$$

so with $u = X-a$, $v = X-b$ the integrand of J_T, written as $\left(\mathrm{e}^{\mathrm{i}t(X-a)}-\mathrm{e}^{\mathrm{i}t(X-b)}\right)/(\mathrm{i}t)$ under the expectation, is bounded by the constant $b-a$. Fubini's theorem (Theorem A.170) — the first of the two quoted uses — therefore applies:

$$J_T = \frac{1}{2\pi}\left\langle \int_{-T}^{T} \frac{\mathrm{e}^{\mathrm{i}t(X-a)}-\mathrm{e}^{\mathrm{i}t(X-b)}}{\mathrm{i}t}\,\mathrm{d}t \right\rangle . \tag{A.362}$$

Now $\mathrm{e}^{\mathrm{i}tu}/(\mathrm{i}t) = (\sin tu)/t - \mathrm{i}\,(\cos tu)/t$, and the cosine terms are odd in t, so they cancel over the symmetric interval. Hence the inner integral is

$$2\int_0^T \frac{\sin\left(t\,(X-a)\right)-\sin\left(t\,(X-b)\right)}{t}\,\mathrm{d}t\,, \tag{A.363}$$

which by Lemma A.172 is bounded by $4C_0 \le 16$ uniformly in T and in X, and converges as $T\to\infty$ to $\pi\left[\operatorname{sgn}(X-a)-\operatorname{sgn}(X-b)\right]$ pointwise. Dominated convergence (Theorem A.169) — the second quoted use — gives

$$\lim_{T\to\infty} J_T = \tfrac{1}{2}\left\langle \operatorname{sgn}(X-a)-\operatorname{sgn}(X-b)\right\rangle . \tag{A.364}$$

The bracket takes the value 0 when $X<a$ or $X>b$, the value 2 when $a<X<b$, and the value 1 when $X=a$ or $X=b$. So

$$\lim_{T\to\infty} J_T = \Pr\left(a<X<b\right) + \tfrac{1}{2}\Pr\left(X=a\right) + \tfrac{1}{2}\Pr\left(X=b\right)\,,$$

which, using $F(x^-)=\Pr(X<x)$ and $F(x)=\Pr(X\le x)$, is exactly the right-hand side of Equation (A.360). □

Corollary A.178 (The characteristic function determines the distribution)**.** *If two random variables have the same characteristic function, they have the same distribution function.*

Rests on Theorem A.177.

Proof. *Derives Corollary A.178.*

Let F_1, F_2 have the common characteristic function φ. The left-hand side of Equation (A.360) depends only on φ, so $F_1(b)-F_1(a) = F_2(b)-F_2(a)$ whenever a, b are continuity points of both. Continuity points of either are dense (the argument of Lemma A.175), so the continuity points common to both are dense as well, their complement being a union of two countable sets. Letting $a\to-\infty$ through such points gives $F_1(b)=F_2(b)$ at every common continuity point b; and every $x\in\mathbb{R}$ is the limit from the right of such points, so right-continuity of both functions gives $F_1=F_2$ everywhere. □

A.18.6 Tightness from continuity at the origin

Lemma A.179 (Truncation estimate)**.** *For any random variable X with characteristic function φ_X and any $u>0$,*

$$\Pr\left(|X|\ge\frac{2}{u}\right) \;\le\; \frac{1}{u}\int_{-u}^{u}\left(1-\Re\varphi_X(t)\right)\mathrm{d}t\,. \tag{A.365}$$

Rests on Definition 11.42.

Proof. *Derives Lemma A.179.*

The integrand $1-\cos(tX)$ is bounded by 2, so Fubini's theorem (Theorem A.170) — the third quoted use — allows the expectation and the t-integral to be exchanged:

$$\frac{1}{u}\int_{-u}^{u}\left(1-\Re\varphi_X(t)\right)\mathrm{d}t=\left\langle\frac{1}{u}\int_{-u}^{u}\left(1-\cos(tX)\right)\mathrm{d}t\right\rangle=\left\langle 2-\frac{2\sin\left(uX\right)}{uX}\right\rangle,$$

the inner integral being elementary and the quotient being read as 2 when $X=0$. Put $y=uX$. The function $1-(\sin y)/y$ is non-negative for every real y, since $|\sin y|\le|y|$; and when $|y|\ge 2$ the bound $|\sin y|\le 1$ gives $1-(\sin y)/y\ge 1-1/|y|\ge\frac{1}{2}$, so that $2\left(1-(\sin y)/y\right)\ge 1$ there. Hence the integrand of the expectation dominates $\mathbf{1}_{\{|uX|\ge 2\}}$ pointwise, and taking expectations gives Equation (A.365). □

Lemma A.180 (Tightness)**.** *Let $\varphi_n\to\varphi$ pointwise on $\mathbb{R}$ with φ continuous at 0. Then the corresponding family $\{X_n\}$ is tight.*

Rests on Lemma A.179 and Definition A.174.

Proof. *Derives Lemma A.180.*

First, $\varphi(0)=\lim_n\varphi_n(0)=1$ by Proposition 11.43(i). Let $\varepsilon>0$. Continuity of φ at 0 gives $u>0$ with $|1-\varphi(t)|<\varepsilon/4$ for $|t|\le u$, whence

$$\left|\frac{1}{u}\int_{-u}^{u}\left(1-\Re\varphi(t)\right)\mathrm{d}t\right|\;\le\;\frac{1}{u}\cdot 2u\cdot\frac{\varepsilon}{4}=\frac{\varepsilon}{2}.$$

The functions $1-\Re\varphi_n$ are bounded by 2 on $[-u,u]$ and converge pointwise to $1-\Re\varphi$, so dominated convergence (Theorem A.169) — the fourth and last quoted use, here applied to the uniform measure on $[-u,u]$ — gives

$$\frac{1}{u}\int_{-u}^{u}\left(1-\Re\varphi_n(t)\right)\mathrm{d}t\;\longrightarrow\;\frac{1}{u}\int_{-u}^{u}\left(1-\Re\varphi(t)\right)\mathrm{d}t,$$

so there is N with the left side below ε for $n\ge N$. By Lemma A.179, $\Pr(|X_n|\ge 2/u)\le\varepsilon$ for $n\ge N$. Each of the finitely many remaining variables $X_1,\dots,X_{N-1}$ is individually tight, its distribution function tending to 0 and 1 at the two ends, so there is K_0 with $\Pr(|X_n|>K_0)\le\varepsilon$ for $n<N$. Take $K=\max(2/u,K_0)$. □

This lemma is the whole reason the hypothesis of Theorem A.168 mentions the origin, and it shows the hypothesis cannot be dropped: the Cauchy-type variables $X_n=nY$ with Y standard Cauchy have $\varphi_n(t)=\mathrm{e}^{-n|t|}$, which converges pointwise to the function equal to 1 at $t=0$ and 0 elsewhere — not continuous at the origin — and the mass escapes to infinity, the distributions converging to nothing.

A.18.7 Proof of the theorem

Proof of Theorem A.168. *Derives Theorem A.168.*

By Lemma A.180 the family $\{X_n\}$ is tight.

Every subsequence has a convergent further subsequence with the same limit. Let (n_j) be any subsequence. By Helly's theorem (Theorem A.173) it has a further subsequence (n_{j_k}) along which $F_{n_{j_k}}\to F$ at every continuity point of some non-decreasing right-continuous $F:\mathbb{R}\to[0,1]$; by Lemma A.175 and tightness, F is a genuine distribution function. Let X be a random variable with distribution function F. Applying the Helly–Bray lemma (Lemma A.176) to the bounded continuous functions $x\mapsto\cos(tx)$ and $x\mapsto\sin(tx)$, for each fixed t, gives

$$\varphi_{n_{j_k}}(t)=\left\langle\cos\left(tX_{n_{j_k}}\right)\right\rangle+\mathrm{i}\left\langle\sin\left(tX_{n_{j_k}}\right)\right\rangle\;\longrightarrow\;\varphi_X(t).\tag{A.366}$$

But by hypothesis $\varphi_{n_{j_k}}(t)\to\varphi(t)$. Limits in $\mathbb{C}$ are unique, so $\varphi=\varphi_X$: the limit function *is* a characteristic function, which is the first assertion of the theorem. Moreover, by

Corollary A.178 the distribution function F is determined by φ alone, so *every* subsequential Helly limit obtained this way is the same function F.

Hence the whole sequence converges. Let x be a continuity point of F and suppose $F_n(x)$ does not converge to $F(x)$. Then there are $\eta > 0$ and a subsequence (n_j) with $\left|F_{n_j}(x) - F(x)\right| \geq \eta$ for every j. By the previous paragraph applied to (n_j) there is a further subsequence along which the distribution functions converge, at every continuity point of F and in particular at x, to F — contradicting the standing inequality. Therefore $F_n(x) \to F(x)$ at every continuity point of F, which is $X_n \to X$ in distribution. □

Corollary A.181 (The converse)**.** *If $X_n \to X$ in distribution then $\varphi_n(t) \to \varphi_X(t)$ for every t, and the limit is continuous everywhere.*

Rests on Lemma A.176 and Theorem A.168.

Proof. *Derives Corollary A.181.*

The first claim is Equation (A.366) read for the full sequence, the Helly–Bray lemma applying directly since $F_n \to F_X$ at continuity points by hypothesis. For continuity of φ_X: Equation (A.361) read with $u = X$, $v = 0$ and $t = h$ gives $\left|\mathrm{e}^{\mathrm{i}hX} - 1\right| \leq |h|\,|X|$, while the modulus of a difference of two unit complex numbers is at most 2, so $\left|\mathrm{e}^{\mathrm{i}(t+h)X} - \mathrm{e}^{\mathrm{i}tX}\right| = \left|\mathrm{e}^{\mathrm{i}hX} - 1\right| \leq \min(|hX|\,, 2)$ and hence $|\varphi_X(t+h) - \varphi_X(t)| \leq \langle \min(|hX|\,, 2)\rangle$, a bound independent of t that tends to 0 with h — by the same truncation as in Lemma 11.44: split the expectation at $|X| = K$, bound the inner part by $|h|\,K$ and the outer by $2\Pr(|X| > K)$, and choose K then h. So φ_X is in fact uniformly continuous. □

Remark A.182. Appendix A.18 discharges the proof obligation of Theorem 11.45, the one analytic input that Section 11.3.1 of Chapter 11 had to quote. With it, the derivation of the central limit theorem Theorem 11.46 in Section 11.3.2 is complete from the axioms of the chapter: Lemma 11.44 supplies the second-order expansion, Equation (11.36) the telescoping estimate, and this appendix the passage back from transforms to distributions. The same passage is the last step of Appendix A.19, and Theorem A.177 is the starting point of Appendix A.20. Two theorems of Lebesgue theory are assumed and are named in Remark A.171; nothing else is.

A.19 The Lindeberg–Feller Central Limit Theorem

This appendix proves Theorem 11.48 of Chapter 11: a triangular array of independent, individually negligible summands whose tails satisfy Lindeberg's condition has an asymptotically Gaussian normalised sum. It is the form of the central limit theorem the error theory of Chapter 2 actually needs, because the disturbances that perturb a measurement — a thermal drift, a vibration, a quantisation step, a reading error — are independent but certainly not identically distributed, so the Lindeberg–Lévy theorem Theorem 11.46 does not apply to them.

The argument is the characteristic-function argument of Section 11.3.2 carried out uniformly in the summand index. Three of its four ingredients are already in the chapter: the elementary properties of characteristic functions (Proposition 11.43), the exponential remainder bound Equation (11.31), and the telescoping product estimate Equation (11.36). The fourth is Lévy's continuity theorem, proved in Appendix A.18. Nothing else is assumed, and in particular the Lindeberg condition is shown here to imply the uniform asymptotic negligibility that the expansion needs — that implication is not an extra hypothesis.

A.19.1 Statement and notation

Theorem A.183 (Lindeberg–Feller)**.** *For each n let $X_{n,1}, \dots, X_{n,k_n}$ be independent random variables with $\langle X_{n,k} \rangle = 0$ and finite variances $\sigma_{n,k}^2 = \operatorname{var} X_{n,k}$, and put $s_n^2 = \sum_{k=1}^{k_n} \sigma_{n,k}^2$, assumed strictly positive. If for every $\varepsilon > 0$*

$$L_n(\varepsilon) \equiv \frac{1}{s_n^2} \sum_{k=1}^{k_n} \left\langle X_{n,k}^2 \, \mathbf{1}_{\{|X_{n,k}| > \varepsilon s_n\}} \right\rangle \longrightarrow 0 \qquad (n \to \infty)\,, \tag{A.367}$$

then $s_n^{-1} \sum_{k=1}^{k_n} X_{n,k} \to \mathcal{N}(0,1)$ in distribution.

Rests on Definitions 11.28 and 11.42 and Proposition 11.43.

It is convenient to normalise once and for all. Put

$$Y_{n,k} = \frac{X_{n,k}}{s_n}\,, \qquad \tau_{n,k}^2 = \left\langle Y_{n,k}^2 \right\rangle = \frac{\sigma_{n,k}^2}{s_n^2}\,, \qquad \sum_{k=1}^{k_n} \tau_{n,k}^2 = 1\,, \tag{A.368}$$

and write $\varphi_{n,k}$ for the characteristic function of $Y_{n,k}$. The event $\{|X_{n,k}| > \varepsilon s_n\}$ is the event $\{|Y_{n,k}| > \varepsilon\}$, so Equation (A.367) reads

$$L_n(\varepsilon) = \sum_{k=1}^{k_n} \left\langle Y_{n,k}^2 \, \mathbf{1}_{\{|Y_{n,k}| > \varepsilon\}} \right\rangle \longrightarrow 0 \qquad \text{for every } \varepsilon > 0\,. \tag{A.369}$$

Every quantity in Equation (A.368) is a pure number: the $X_{n,k}$ carry whatever SI unit the measurement error carries, and s_n carries the same one, so the ratio is dimensionless and so is the argument t of the characteristic functions below.

A.19.2 Lindeberg's condition implies uniform asymptotic negligibility

Lemma A.184 (Uniform asymptotic negligibility)**.** *Under Equation (A.369),*

$$\max_{1 \le k \le k_n} \tau_{n,k}^2 = \max_{1 \le k \le k_n} \frac{\operatorname{var} X_{n,k}}{s_n^2} \longrightarrow 0\,. \tag{A.370}$$

Rests on Equation (A.367).

Proof. *Derives Lemma A.184.*

Fix $\varepsilon > 0$ and k. Splitting the expectation at $|Y_{n,k}| = \varepsilon$ and bounding $Y_{n,k}^2$ by ε^2 on the inner piece,

$$\tau_{n,k}^2 = \left\langle Y_{n,k}^2 \, \mathbf{1}_{\{|Y_{n,k}| \le \varepsilon\}} \right\rangle + \left\langle Y_{n,k}^2 \, \mathbf{1}_{\{|Y_{n,k}| > \varepsilon\}} \right\rangle \le \varepsilon^2 + \left\langle Y_{n,k}^2 \, \mathbf{1}_{\{|Y_{n,k}| > \varepsilon\}} \right\rangle . \tag{A.371}$$

The last term is one summand of the non-negative sum $L_n(\varepsilon)$, hence at most $L_n(\varepsilon)$, and the bound is the same for every k:

$$\max_k \tau_{n,k}^2 \le \varepsilon^2 + L_n(\varepsilon)\,.$$

Letting $n \to \infty$ gives $\limsup_n \max_k \tau_{n,k}^2 \le \varepsilon^2$, and $\varepsilon > 0$ was arbitrary. □

This is Equation (11.39) of Chapter 11, proved. It is what licenses treating each factor of the product below as close to 1, and it is used twice: to know $1 - \tfrac{1}{2} t^2 \tau_{n,k}^2$ lies in $[0,1]$, and to control the sum of squares in Lemma A.187.

A.19.3 The uniform second-order expansion

Lemma 11.44 expands one characteristic function to second order, with a remainder $o(t^2)$ that depends on the distribution. Here there is a different distribution for every (n,k) and the remainders must be summed, so what is needed is a bound on the *total* remainder, uniform in the array. The Lindeberg condition is exactly what supplies it.

Lemma A.185 (Total remainder)**.** *For every $t \in \mathbb{R}$,*

$$\Delta_n(t) \equiv \sum_{k=1}^{k_n} \left| \varphi_{n,k}(t) - \left(1 - \tfrac{1}{2}t^2\tau_{n,k}^2\right) \right| \;\longrightarrow\; 0\,. \tag{A.372}$$

Rests on Equations (11.31) and (A.367).

Proof. *Derives Lemma A.185.*

Apply Equation (11.31) with $n = 2$ and $x = tY_{n,k}$:

$$\left| \mathrm{e}^{\mathrm{i}tY_{n,k}} - 1 - \mathrm{i}tY_{n,k} + \tfrac{1}{2}t^2Y_{n,k}^2 \right| \;\le\; \min\!\left(\tfrac{1}{6}\,|t|^3\,|Y_{n,k}|^3\,,\; t^2Y_{n,k}^2 \right).$$

Take expectations and use $|\langle Z\rangle| \le \langle |Z|\rangle$; since $\langle Y_{n,k}\rangle = 0$ and $\left\langle Y_{n,k}^2 \right\rangle = \tau_{n,k}^2$ the left side becomes the kth term of $\Delta_n(t)$, so

$$\left| \varphi_{n,k}(t) - 1 + \tfrac{1}{2}t^2\tau_{n,k}^2 \right| \;\le\; \left\langle \min\!\left(\tfrac{1}{6}\,|t|^3\,|Y_{n,k}|^3\,,\; t^2Y_{n,k}^2 \right) \right\rangle . \tag{A.373}$$

Fix $\varepsilon > 0$ and split the expectation at $|Y_{n,k}| = \varepsilon$, using a different branch of the minimum on each piece. Where $|Y_{n,k}| \le \varepsilon$ the first branch gives $\tfrac{1}{6}\,|t|^3\,|Y_{n,k}|^3 \le \tfrac{1}{6}\,|t|^3\,\varepsilon\,Y_{n,k}^2$; where $|Y_{n,k}| > \varepsilon$ the second gives $t^2Y_{n,k}^2$. Hence

$$\left| \varphi_{n,k}(t) - 1 + \tfrac{1}{2}t^2\tau_{n,k}^2 \right| \;\le\; \frac{\varepsilon\,|t|^3}{6}\,\tau_{n,k}^2 + t^2\left\langle Y_{n,k}^2\,\mathbf{1}_{\{|Y_{n,k}|>\varepsilon\}} \right\rangle . \tag{A.374}$$

From Equation (A.373) (split the expectation at $|Y_{n,k}| = \varepsilon$ and use one branch of the minimum on each piece).

Summing over k and using $\sum_k \tau_{n,k}^2 = 1$ from Equation (A.368) and the definition Equation (A.369),

$$\Delta_n(t) \;\le\; \frac{\varepsilon\,|t|^3}{6} + t^2 L_n(\varepsilon)\,. \tag{A.375}$$

For fixed t and ε the second term tends to 0, so $\limsup_n \Delta_n(t) \le \varepsilon\,|t|^3/6$; and $\varepsilon > 0$ was arbitrary. □

The contrast with Lemma 11.44 is worth stating plainly. There the remainder was $o(t^2)$ as $t \to 0$ for a *single* distribution, and the identically distributed case could rescale one such estimate n times. Here t is fixed and n grows, and the estimate Equation (A.375) is a statement about the array as a whole: the cubic branch of the minimum is used on the bulk of each summand and the quadratic branch on its tail, and Equation (A.367) is precisely the hypothesis that the tails contribute nothing in total.

A.19.4 Two product estimates

Lemma A.186 (Replacement)**.** *For every $t \in \mathbb{R}$ there is $N(t)$ such that for $n \ge N(t)$*

$$\left| \prod_{k=1}^{k_n} \varphi_{n,k}(t) - \prod_{k=1}^{k_n} \left(1 - \tfrac{1}{2}t^2\tau_{n,k}^2\right) \right| \;\le\; \Delta_n(t) \;\longrightarrow\; 0\,. \tag{A.376}$$

Rests on Equation (11.36) and Lemmas A.184 and A.185.

Proof. *Derives Lemma A.186.*

Set $a_k = \varphi_{n,k}(t)$ and $b_k = 1 - \frac{1}{2}t^2\tau_{n,k}^2$. By Proposition 11.43(i), $|a_k| \le 1$. For the b_k: by Lemma A.184 there is $N(t)$ with $\frac{1}{2}t^2 \max_k \tau_{n,k}^2 \le 1$ for $n \ge N(t)$, and then every b_k lies in $[0,1]$. The telescoping inequality Equation (11.36) applies to such factors and gives $|\prod a_k - \prod b_k| \le \sum_k |a_k - b_k|$, which is $\Delta_n(t)$ by Equation (A.372). □

Lemma A.187 (Exponentiation)**.** *For every $t \in \mathbb{R}$,*

$$\prod_{k=1}^{k_n} \left(1 - \tfrac{1}{2}t^2\tau_{n,k}^2\right) \longrightarrow \mathrm{e}^{-t^2/2}. \tag{A.377}$$

Rests on Equation (11.36), Lemma A.184, and Theorem 7.38.

Proof. *Derives Lemma A.187.*

Write $z_k = \frac{1}{2}t^2\tau_{n,k}^2 \ge 0$, so that $\sum_k z_k = \frac{1}{2}t^2$ by Equation (A.368) and $\max_k z_k \to 0$ by Lemma A.184. Take n large enough that $\max_k z_k \le 1$; then both $1 - z_k$ and e^{-z_k} lie in $[0,1]$ and Equation (11.36) applies:

$$\left|\prod_k (1 - z_k) - \prod_k \mathrm{e}^{-z_k}\right| \le \sum_k \left|1 - z_k - \mathrm{e}^{-z_k}\right|. \tag{A.378}$$

Taylor's theorem with Lagrange remainder (Theorem 7.38) applied to $z \mapsto \mathrm{e}^{-z}$ gives $\mathrm{e}^{-z} = 1 - z + \frac{1}{2}z^2\mathrm{e}^{-\xi}$ with ξ between 0 and z, so for $z \ge 0$ one has $|\mathrm{e}^{-z} - 1 + z| \le \frac{1}{2}z^2$. Hence

$$\sum_k \left|1 - z_k - \mathrm{e}^{-z_k}\right| \le \frac{1}{2}\sum_k z_k^2 \le \frac{1}{2}\left(\max_k z_k\right)\sum_k z_k = \frac{t^2}{4}\max_k z_k \longrightarrow 0,$$

the middle step bounding each term by $z_k^2/2$, factoring out the largest z_k and using $\sum_k z_k = t^2/2$; while $\prod_k \mathrm{e}^{-z_k} = \mathrm{e}^{-\sum_k z_k} = \mathrm{e}^{-t^2/2}$ exactly. □

A.19.5 Proof of the theorem

Proof of Theorem A.183. *Derives Theorem A.183.*

Write $T_n = s_n^{-1}\sum_k X_{n,k} = \sum_k Y_{n,k}$. The $Y_{n,k}$, $k = 1, \dots, k_n$, are independent, so Proposition 11.43(iii), extended from two factors to k_n by induction, gives

$$\varphi_{T_n}(t) = \prod_{k=1}^{k_n} \varphi_{n,k}(t). \tag{A.379}$$

Fix $t \in \mathbb{R}$. By the triangle inequality,

$$\left|\varphi_{T_n}(t) - \mathrm{e}^{-t^2/2}\right| \le \left|\prod_k \varphi_{n,k}(t) - \prod_k \left(1 - \tfrac{1}{2}t^2\tau_{n,k}^2\right)\right| + \left|\prod_k \left(1 - \tfrac{1}{2}t^2\tau_{n,k}^2\right) - \mathrm{e}^{-t^2/2}\right|,$$

whose first term tends to 0 by Lemma A.186 and whose second tends to 0 by Lemma A.187. Hence

$$\varphi_{T_n}(t) \longrightarrow \mathrm{e}^{-t^2/2} \qquad \text{for every } t \in \mathbb{R}. \tag{A.380}$$

From Equations (A.376), (A.377) and (A.379) (replace each factor by its quadratic approximation, then the product of those by the exponential of the sum).

The limit is continuous at $t = 0$, and it is the characteristic function of the standard Gaussian: as shown in the derivation of Theorem 11.46, the function $g(t) = \int \mathrm{e}^{itu}\mathrm{e}^{-u^2/2}\mathrm{d}u/\sqrt{2\pi}$ satisfies $g'(t) = -t\,g(t)$ with $g(0) = 1$, whence $g(t) = \mathrm{e}^{-t^2/2}$. Theorem A.168 therefore gives $T_n \to \mathcal{N}(0,1)$ in distribution. □

Corollary A.188 (Lindeberg–Lévy is the special case)**.** *Theorem 11.46 follows from Theorem A.183.*

Rests on Theorem A.183.

Proof. *Derives Corollary A.188.*

Let $X_1, X_2, \dots$ be independent and identically distributed with mean μ and variance $\sigma^2 \in (0, \infty)$, and set $k_n = n$, $X_{n,k} = X_k - \mu$. Then $\sigma_{n,k}^2 = \sigma^2$ and $s_n^2 = n\sigma^2$, so $Z_n = s_n^{-1} \sum_k X_{n,k}$ is the statistic of Equation (11.33). The Lindeberg sum is

$$L_n(\varepsilon) = \frac{n}{n\sigma^2} \left\langle (X-\mu)^2 \mathbf{1}_{\{|X-\mu| > \varepsilon\sigma\sqrt{n}\}} \right\rangle = \frac{1}{\sigma^2} \left\langle (X-\mu)^2 \mathbf{1}_{\{|X-\mu| > \varepsilon\sigma\sqrt{n}\}} \right\rangle ,$$

which tends to 0 as $n \to \infty$ because $\langle (X-\mu)^2 \rangle = \sigma^2$ is finite, a finite integral being one whose tail contribution vanishes — the same elementary fact used at Equation (11.32). The threshold $\varepsilon\sigma\sqrt{n}$ grows without bound, so the truncation level recedes and the tail expectation goes to zero for each fixed ε. □

Corollary A.189 (Lyapunov's condition)**.** *If there is $\delta > 0$ with*

$$\frac{1}{s_n^{2+\delta}} \sum_{k=1}^{k_n} \left\langle |X_{n,k}|^{2+\delta} \right\rangle \longrightarrow 0 , \tag{A.381}$$

then Equation (A.367) holds, and hence so does the conclusion of Theorem A.183.

Rests on Theorem A.183 and Equation (A.367).

Proof. *Derives Corollary A.189.*

On the event $|Y_{n,k}| > \varepsilon$ one has $1 < |Y_{n,k}|^\delta / \varepsilon^\delta$, so $Y_{n,k}^2 \mathbf{1}_{\{|Y_{n,k}| > \varepsilon\}} \le \varepsilon^{-\delta} |Y_{n,k}|^{2+\delta}$ pointwise. Taking expectations and summing over k,

$$L_n(\varepsilon) \le \frac{1}{\varepsilon^\delta} \sum_{k=1}^{k_n} \left\langle |Y_{n,k}|^{2+\delta} \right\rangle = \frac{1}{\varepsilon^\delta} \cdot \frac{1}{s_n^{2+\delta}} \sum_{k=1}^{k_n} \left\langle |X_{n,k}|^{2+\delta} \right\rangle ,$$

which tends to 0 for each fixed $\varepsilon > 0$ by Equation (A.381). □

Remark A.190 (What the theorem still does not say). The condition is sufficient and not necessary, and Chapter 11 exhibits both failures of the converse: summands equal to $\pm\sqrt{n}$ with probability $1/(2n)$ have vanishing variance shares yet Lindeberg sum 1 for every n, and adjoining one $\mathcal{N}(0, n)$ summand to n standard Gaussians breaks Equation (A.367) while leaving the normalised sum exactly $\mathcal{N}(0, 1)$. What Lemma A.184 establishes is the one implication the error theory uses — no single disturbance may carry a fixed fraction of the total variance — and it is an implication, not a converse: a dominant source violates Equation (A.367), but the absence of a dominant source does not by itself deliver a Gaussian. Feller's companion theorem, which closes the loop inside the negligible class, is not proved here [1446].

Remark A.191. Appendix A.19 discharges the proof obligation of Theorem 11.48, stated in Section 11.3.2 of Chapter 11 and used there to justify treating the aggregate of many small, non-identically distributed measurement disturbances as Gaussian — the licence on which the standard uncertainty of Chapter 2 rests. Two by-products are worth noting: Equation (11.39) of the chapter is Lemma A.184 here, proved rather than asserted, and Lyapunov's condition, which the chapter quotes, is Corollary A.189. The only input this appendix does not derive is Lévy's continuity theorem, which is Appendix A.18.

A.20 The Berry–Esseen Inequality

This appendix proves the uniform rate Equation (11.40) quoted in Remark 11.49 of Chapter 11: the Kolmogorov distance between the distribution of a standardised sum of n independent identically distributed variables and the standard Gaussian is at most a constant times $\rho/(\sigma^3\sqrt{n})$, where ρ is the third absolute central moment. The central limit theorem Theorem 11.46 is a limit statement and an uncertainty budget needs a rate; this is the rate, and it is what converts "the errors are asymptotically Gaussian" into a number a reader can check.

The proof has three parts, in the order Esseen gave them. First a *smoothing inequality*, which bounds the largest vertical gap between a distribution function and a smooth comparison function by an integral of the difference of their Fourier–Stieltjes transforms over a finite interval, plus a penalty for truncating the interval (Appendix A.20.3). Then an estimate of that difference for the case at hand, valid on $|t| \lesssim \sqrt{n}\,\sigma^3/\rho$ and carrying a Gaussian decay factor (Appendix A.20.4). Then the integration, which balances the two terms and fixes an admissible constant (Appendix A.20.5).

Notation. Throughout this appendix $\varphi(x) = \mathrm{e}^{-x^2/2}/\sqrt{2\pi}$ is the standard Gaussian density and Φ its distribution function, as in Definition 11.28; characteristic functions are written ψ, to keep the two apart. For a distribution function F we write $\psi_F(t) = \int \mathrm{e}^{\mathrm{i}tx}\,\mathrm{d}F(x)$, which is $\left\langle \mathrm{e}^{\mathrm{i}tX} \right\rangle$ for a variable X with that distribution function (Definition 11.42). The one analytic input is the inversion formula Theorem A.177 of Appendix A.18, and through it the two Lebesgue-theory statements named in Remark A.171; everything else below is derived.

A.20.1 Statement

Theorem A.192 (Berry–Esseen)**.** *Let $X_1, X_2, \dots$ be independent and identically distributed with mean μ, variance $\sigma^2 \in (0,\infty)$ and finite third absolute central moment $\rho = \left\langle |X-\mu|^3 \right\rangle$. Put $Z_n = (\sigma\sqrt{n})^{-1}\sum_{i=1}^{n}(X_i-\mu)$ and let F_n be its distribution function. Then for every $n \geq 1$*

$$\Delta_n \equiv \sup_{z\in\mathbb{R}} |F_n(z) - \Phi(z)| \;\leq\; \frac{C\rho}{\sigma^3\sqrt{n}}\,, \qquad C = 7.23\,. \tag{A.382}$$

Rests on Definitions 11.28 and 11.42 and Equation (11.31).

The constant produced here is honest but crude; Remark A.201 says what is known about the smallest admissible one and why this proof does not reach it. The quantity ρ/σ^3 is a pure number — both moments carry the cube of the SI unit of X — as it must be, since the left-hand side is a difference of probabilities.

A.20.2 The Fejér kernel

Lemma A.193 (A cosine integral)**.** *For every $a \in \mathbb{R}$,*

$$\int_{-\infty}^{\infty} \frac{1-\cos(ax)}{x^2}\,\mathrm{d}x = \pi\,|a|\,. \tag{A.383}$$

Rests on Lemma A.172 and Equation (7.28).

Proof. *Derives Lemma A.193.*

For $a = 0$ both sides vanish. For $a > 0$ the substitution $u = ax$ (Equation (7.27)) turns the left side into $a\int_{-\infty}^{\infty}(1-\cos u)\,u^{-2}\mathrm{d}u$, and the integrand is even, so it suffices to show $\int_0^{\infty}(1-\cos u)\,u^{-2}\mathrm{d}u = \pi/2$. Integrate by parts (Equation (7.28)) with $u^{-2}\mathrm{d}u = -\mathrm{d}\,(u^{-1})$:

$$\int_0^{\infty}\frac{1-\cos u}{u^2}\,\mathrm{d}u = \left[-\frac{1-\cos u}{u}\right]_0^{\infty} + \int_0^{\infty}\frac{\sin u}{u}\,\mathrm{d}u = 0 + \frac{\pi}{2}\,,$$

by Lemma A.172. Both boundary terms vanish: at infinity because the numerator is bounded by 2, and at zero because $1-\cos u \le u^2/2$. Oddness of $\cos(ax)$ in a — it is even — gives the case $a<0$ from the case $-a>0$. □

Lemma A.194 (The Fejér kernel and its transform)**.** *For $T>0$ define*

$$K_T(x)=\frac{1-\cos(Tx)}{\pi T x^2}\,, \tag{A.384}$$

extended by $K_T(0)=T/(2\pi)$. Then $K_T\ge 0$, K_T is even, $\int_{\mathbb{R}} K_T=1$, and

$$\int_{-\infty}^{\infty} \mathrm{e}^{\mathrm{i}tx} K_T(x)\,\mathrm{d}x=\begin{cases}1-\dfrac{|t|}{T} & |t|\le T\,,\\ 0 & |t|>T\,.\end{cases} \tag{A.385}$$

Moreover $\int_{|x|>\eta} K_T(x)\,\mathrm{d}x \le 4/(\pi T\eta)$ for every $\eta>0$.

Rests on Lemma A.193.

Proof. *Derives Lemma A.194.*

Non-negativity and evenness are immediate, and Equation (A.383) with $a=T$ gives $\int K_T=\pi T/(\pi T)=1$. For the tail bound use $1-\cos\le 2$, so that $K_T(x)\le 2/(\pi T x^2)$ and

$$\int_{|x|>\eta} K_T(x)\,\mathrm{d}x \;\le\; 2\int_{\eta}^{\infty}\frac{2}{\pi T x^2}\,\mathrm{d}x=\frac{4}{\pi T\eta}\,.$$

For Equation (A.385): the sine part of $\mathrm{e}^{\mathrm{i}tx}$ pairs with an even function and integrates to zero, so the transform is $\int\cos(tx)K_T(x)\mathrm{d}x$, which is real. Write the numerator of the integrand, $(1-\cos(Tx))\cos(tx)$, using the product formula $\cos A\cos B=\frac12[\cos(A-B)+\cos(A+B)]$:

$$(1-\cos(Tx))\cos(tx)=-(1-\cos(tx))+\tfrac12(1-\cos((T+t)x))+\tfrac12(1-\cos((T-t)x))\,, \tag{A.386}$$

the constants cancelling because $-1+\frac12+\frac12=0$. Dividing by πTx^2, integrating, and applying Equation (A.383) three times,

$$\int_{-\infty}^{\infty}\mathrm{e}^{\mathrm{i}tx}K_T(x)\,\mathrm{d}x=\frac{1}{\pi T}\left[-\pi|t|+\frac{\pi}{2}|T+t|+\frac{\pi}{2}|T-t|\right]. \tag{A.387}$$

From Equations (A.383) and (A.386) (divide by πTx^2 and integrate each of the three pieces).

For $|t|\le T$ the two moduli on the right are $T+t$ and $T-t$, so the bracket is $\pi(T-|t|)$ and the value is $1-|t|/T$. For $t>T$ they are $T+t$ and $t-T$, whose half-sum is $\pi t=\pi|t|$, and the bracket vanishes; the case $t<-T$ is the mirror image. □

A.20.3 Esseen's smoothing inequality

The inversion formula of Appendix A.18 recovers a distribution function from its transform. What is wanted here is the *difference* of two of them, at a single point, and in a form that needs no limit.

Lemma A.195 (Riemann–Lebesgue, continuous compactly supported case)**.** *Let $h:\mathbb{R}\to\mathbb{C}$ be continuous and vanish outside a bounded interval. Then $\int_{\mathbb{R}} h(t)\mathrm{e}^{-\mathrm{i}ta}\,\mathrm{d}t\to 0$ as $|a|\to\infty$.*

Rests on Theorem 7.25.

Proof. *Derives Lemma A.195.*

Let h vanish outside $[-T,T]$ and put $A(a)=\int_{\mathbb{R}} h(t)\mathrm{e}^{-\mathrm{i}ta}\mathrm{d}t$. Since $\mathrm{e}^{-\mathrm{i}(t+\pi/a)a}=-\mathrm{e}^{-\mathrm{i}ta}$, the substitution $t\mapsto t+\pi/a$ (Equation (7.27)) gives $A(a)=-\int_{\mathbb{R}} h(t-\pi/a)\mathrm{e}^{-\mathrm{i}ta}\mathrm{d}t$, so

$$2\,|A(a)|=\left|\int_{\mathbb{R}}\left[h(t)-h\Big(t-\frac{\pi}{a}\Big)\right]\mathrm{e}^{-\mathrm{i}ta}\,\mathrm{d}t\right| \;\le\; \int_{-T-\pi/|a|}^{T+\pi/|a|}\left|h(t)-h\Big(t-\frac{\pi}{a}\Big)\right|\mathrm{d}t\,.$$

The function h is uniformly continuous on $\mathbb{R}$ (Theorem 7.25 on a compact interval containing the support with room to spare, and $h \equiv 0$ outside), so the integrand tends to 0 uniformly and the interval length stays bounded. □

Lemma A.196 (Inversion for a difference)**.** *Let F_1, F_2 be distribution functions with transforms ψ_1, ψ_2, and suppose $h(t) = (\psi_1(t) - \psi_2(t))/(\mathrm{i}t)$, extended by its limit at $t = 0$, is continuous on $\mathbb{R}$ and vanishes outside $[-T, T]$. Then at every point x at which both F_1 and F_2 are continuous,*

$$F_1(x) - F_2(x) = -\frac{1}{2\pi} \int_{-T}^{T} \frac{\psi_1(t) - \psi_2(t)}{\mathrm{i}t} \, \mathrm{e}^{-\mathrm{i}tx} \, \mathrm{d}t \,. \tag{A.388}$$

Rests on Theorem A.177 and Lemma A.195.

Proof. *Derives Lemma A.196.*

Let $a < x$ be a common continuity point. Applying Equation (A.360) to F_1 and to F_2 and subtracting — both limits exist, so their difference is the limit of the difference — gives, for every $T' \geq T$,

$$[F_1(x) - F_1(a)] - [F_2(x) - F_2(a)] = \frac{1}{2\pi} \int_{-T'}^{T'} \left(\mathrm{e}^{-\mathrm{i}ta} - \mathrm{e}^{-\mathrm{i}tx} \right) h(t) \, \mathrm{d}t \,,$$

and since h vanishes outside $[-T, T]$ the integral does not depend on T' and no limit is needed. Split it into its two terms. By Lemma A.195 the term carrying $\mathrm{e}^{-\mathrm{i}ta}$ tends to 0 as $a \to -\infty$ through continuity points, while $F_1(a) \to 0$ and $F_2(a) \to 0$. What survives is Equation (A.388). □

Lemma A.197 (The transform is differentiable at the origin)**.** *If X has $\langle |X| \rangle < \infty$ and characteristic function ψ_X, then $\psi_X(t) = 1 + \mathrm{i}t \, \langle X \rangle + o(|t|)$ as $t \to 0$.*

Rests on Equation (11.31) and Definition 11.42.

Proof. *Derives Lemma A.197.*

Equation (11.31) at order one gives $\left| \mathrm{e}^{\mathrm{i}x} - 1 - \mathrm{i}x \right| \leq \min\left(x^2/2, \, 2\,|x|\right)$. Put $x = tX$, take expectations, use $|\langle Z \rangle| \leq \langle |Z| \rangle$ and divide by $|t|$:

$$\frac{|\psi_X(t) - 1 - \mathrm{i}t \, \langle X \rangle|}{|t|} \;\leq\; \left\langle \min\left(\tfrac{1}{2}\,|t|\, X^2, \; 2\,|X| \right) \right\rangle \;\leq\; \tfrac{1}{2}\,|t|\, K^2 + 2 \left\langle |X| \; \mathbf{1}_{\{|X| > K\}} \right\rangle ,$$

the last step splitting the expectation at $|X| = K$ and using one branch of the minimum on each piece, exactly as at Equation (11.32). Given $\varepsilon > 0$ choose K with the second term below $\varepsilon/2$ — possible because $\langle |X| \rangle$ is finite — and then $|t| < \varepsilon / K^2$. □

Theorem A.198 (Esseen's smoothing inequality)**.** *Let F be a distribution function and G a non-decreasing differentiable function with $G(-\infty) = 0$, $G(+\infty) = 1$ and $\sup_x G'(x) \leq m < \infty$; suppose both have a finite first absolute moment. Write ψ_F, ψ_G for their transforms and $\Delta = \sup_x |F(x) - G(x)|$. Then for every $T > 0$*

$$\Delta \;\leq\; \frac{1}{\pi} \int_{-T}^{T} \left| \frac{\psi_F(t) - \psi_G(t)}{t} \right| \mathrm{d}t + \frac{24\, m}{\pi T} \,. \tag{A.389}$$

Rests on Lemmas A.194 and A.196.

Proof. *Derives Theorem A.198.*

Write $H = F - G$, so $|H| \leq 1$ and $\Delta \leq 1$ is finite; if $\Delta = 0$ there is nothing to prove, and if the integral on the right is infinite the inequality is trivial, so assume both finite and $\Delta > 0$. Let W have density K_T, independently of everything else, and let F_T, G_T be the distribution functions of $U + W$ and $V + W$, where U has distribution function F and V

has G. Both are continuous, being convolutions with a density, and by Proposition 11.43(iii) and Equation (A.385) their transforms are $\psi_F \hat{K}_T$ and $\psi_G \hat{K}_T$ with $\hat{K}_T(t) = (1 - |t|/T)$ on $[-T, T]$ and 0 outside. Since K_T is even,

$$H_T(x) \equiv F_T(x) - G_T(x) = \int_{-\infty}^{\infty} H(x+s)\, K_T(s)\, \mathrm{d}s\,. \tag{A.390}$$

The transform side. The function $(\psi_F - \psi_G)\,\hat{K}_T/(\mathrm{i}t)$ is continuous — at $t = 0$ because Lemma A.197, applicable since both first absolute moments are finite, gives $\psi_F(t) - \psi_G(t) = \mathrm{i}t\,(\langle U\rangle - \langle V\rangle) + o(|t|)$, and at $t = \pm T$ because $\hat{K}_T$ vanishes there — and is supported in $[-T, T]$. So Lemma A.196 applies, and since $\left|\hat{K}_T\right| \le 1$,

$$\sup_x |H_T(x)| \;\le\; \frac{1}{2\pi} \int_{-T}^{T} \left| \frac{\psi_F(t) - \psi_G(t)}{t} \right| \mathrm{d}t\,. \tag{A.391}$$

The kernel side. Put $\eta = \Delta/(2m)$ and $\kappa = \int_{|s|>\eta} K_T(s)\,\mathrm{d}s$, so that $\kappa \le 4/(\pi T\eta) = 8m/(\pi T\Delta)$ by Lemma A.194. Let $\varepsilon \in (0, \Delta/2)$. Two cases, according to which sign of H realises the supremum.

Suppose first $\sup_x H(x) = \Delta$ and pick b with $H(b) > \Delta - \varepsilon$. For $y \ge b$ the mean value theorem (Theorem 7.35) gives $G(y) \le G(b) + m(y - b)$, while $F(y) \ge F(b)$; hence $H(y) \ge H(b) - m(y - b)$. Put $x_* = b + \eta$. For $|s| \le \eta$ the point $x_* + s$ lies at distance $\eta + s \in [0, 2\eta]$ to the right of b, so

$$H(x_* + s) \;\ge\; \Delta - \varepsilon - m\,(\eta + s) = \frac{\Delta}{2} - \varepsilon - ms \qquad (|s| \le \eta)\,. \tag{A.392}$$

Insert this in Equation (A.390). The term $-ms$ integrates to zero against the even kernel over the symmetric set $|s| \le \eta$; outside it, $H \ge -\Delta$. Therefore

$$H_T(x_*) \;\ge\; \left(\frac{\Delta}{2} - \varepsilon\right)(1 - \kappa) - \Delta\kappa \;\ge\; \frac{\Delta}{2} - \varepsilon - \frac{3\Delta}{2}\kappa \;\ge\; \frac{\Delta}{2} - \varepsilon - \frac{12\,m}{\pi T}\,. \tag{A.393}$$

From Equations (A.390) and (A.392) (split the convolution at $|s| = \eta$, use the wedge bound inside and $H \ge -\Delta$ outside, then insert $\kappa \le 8m/(\pi T\Delta)$).

If instead $\sup_x (-H(x)) = \Delta$, pick b with $H(b) < -\Delta + \varepsilon$ and put $x_* = b - \eta$. For $y \le b$ the same mean value theorem gives $G(y) \ge G(b) - m(b - y)$ and $F(y) \le F(b)$, so $H(y) \le H(b) + m(b - y)$; for $|s| \le \eta$ the point $x_* + s$ lies at distance $\eta - s \in [0, 2\eta]$ to the left of b and $H(x_* + s) \le -\Delta/2 + \varepsilon - ms$. The same two steps give $H_T(x_*) \le -\Delta/2 + \varepsilon + 12m/(\pi T)$.

In both cases $|H_T(x_*)| \ge \Delta/2 - \varepsilon - 12m/(\pi T)$. Combining with Equation (A.391), letting $\varepsilon \downarrow 0$ and multiplying by 2 gives Equation (A.389). □

A.20.4 The characteristic function of the standardised sum

Lemma A.199 (The standardised third moment is at least one)**.** *Let $\langle Y\rangle = 0$, $\langle Y^2\rangle = 1$ and $\beta = \left\langle |Y|^3 \right\rangle < \infty$. Then $\beta \ge 1$.*

Rests on Lemma 11.63.

Proof. *Derives Lemma A.199.*

The discriminant argument of Lemma 11.63, applied to the nowhere-negative quadratic $s \mapsto \langle (sV + W)^2\rangle$ without centring — which is all that proof uses, as Proposition 11.24 already records — gives $\langle VW\rangle^2 \le \langle V^2\rangle\,\langle W^2\rangle$ for any V, W of finite second moment. Take $V = |Y|^{1/2}$ and $W = |Y|^{3/2}$: $1 = \langle Y^2\rangle^2 \le \langle |Y|\rangle \left\langle |Y|^3 \right\rangle = \langle |Y|\rangle\,\beta$. Take $V = |Y|$, $W = 1$: $\langle |Y|\rangle^2 \le \langle Y^2\rangle = 1$. Combining, $1 \le \beta$. □

Lemma A.200 (Transform estimate)**.** *Let $Y, Y_1, Y_2, \dots$ be independent and identically distributed with $\langle Y\rangle = 0$, $\langle Y^2\rangle = 1$ and $\beta = \left\langle |Y|^3 \right\rangle < \infty$, and let $Z_n = n^{-1/2}\sum_{i=1}^{n} Y_i$. Then*

$$\left|\psi_{Z_n}(t) - \mathrm{e}^{-t^2/2}\right| \;\le\; \frac{\beta\,|t|^3}{2\sqrt{n}}\,\mathrm{e}^{-t^2/4} \qquad \text{for } |t| \le T_n = \frac{\sqrt{n}}{2\beta}\,. \tag{A.394}$$

Rests on Equation (11.31), Lemma A.199, and Proposition 11.43.

Proof. *Derives Lemma A.200.*

Write ψ for the common characteristic function of the Y_i and $s = t/\sqrt{n}$, so that $\psi_{Z_n}(t) = \psi(s)^n$ by Proposition 11.43(ii) and (iii). Fix t with $|t| \le T_n$; then $\beta\,|s| \le \frac{1}{2}$, and since $\beta \ge 1$ by Lemma A.199 also $|s| \le \frac{1}{2}$.

Step 1: the quadratic expansion. Equation (11.31) at order two, with $x = sY$, expectations taken and $\langle Y\rangle = 0$, $\langle Y^2\rangle = 1$ used, gives

$$\psi(s) = 1 + \omega\,, \qquad \omega = -\frac{s^2}{2} + r\,, \qquad |r| \le \frac{\beta\,|s|^3}{6}\,. \tag{A.395}$$

Since $\beta\,|s| \le \frac{1}{2}$ one has $\beta\,|s|^3/6 \le s^2/12$, so

$$|\omega| \;\le\; \frac{s^2}{2} + \frac{s^2}{12} = \frac{7s^2}{12} \;\le\; \frac{7}{48} \;<\; \frac{1}{2}\,. \tag{A.396}$$

In particular $\psi(s) \neq 0$, and $\psi(s)^n = \mathrm{e}^{n\ln\psi(s)}$ with the principal logarithm — for an integer power the branch is immaterial.

Step 2: the logarithm. For $|w| \le \frac{1}{2}$ the principal logarithm satisfies

$$|\ln(1+w) - w| = \left|\sum_{j\ge 2} \frac{(-1)^{j-1}w^j}{j}\right| \;\le\; \frac{|w|^2}{2}\sum_{j\ge 0}|w|^j = \frac{|w|^2}{2\,(1-|w|)} \;\le\; |w|^2\,. \tag{A.397}$$

Now $n\omega + \frac{1}{2}t^2 = nr$, because $ns^2 = t^2$, and $|nr| \le \beta\,|t|^3/(6\sqrt{n})$ by Equation (A.395). Also, using Equation (A.396) and then $|t|/n \le 1/(2\beta\sqrt{n}) \le \beta/(2\sqrt{n})$ — the last step being $1/\beta \le \beta$, valid since $\beta \ge 1$ —

$$n\,|\omega|^2 \;\le\; \frac{49}{144}\,\frac{t^4}{n} = \frac{49}{144}\,|t|^3\,\frac{|t|}{n} \;\le\; \frac{49}{288}\,\frac{\beta\,|t|^3}{\sqrt{n}}\,.$$

Adding, and using $\frac{1}{6} + \frac{49}{288} = \frac{97}{288} < \frac{1}{2}$,

$$\left|n\ln\psi(s) + \frac{t^2}{2}\right| \;\le\; \left|n\omega + \frac{t^2}{2}\right| + n\,|\ln(1+\omega) - \omega| \;\le\; \frac{\beta\,|t|^3}{2\sqrt{n}}\,. \tag{A.398}$$

From Equations (A.395) to (A.397) (add the cubic remainder of the expansion to the quadratic error of the logarithm, using $\beta\,|t| \le \sqrt{n}/2$).

Step 3: exponentiate. On $|t| \le T_n$,

$$\frac{\beta\,|t|^3}{2\sqrt{n}} = \frac{t^2}{2}\cdot\frac{\beta\,|t|}{\sqrt{n}} \;\le\; \frac{t^2}{2}\cdot\frac{1}{2} = \frac{t^2}{4}\,, \tag{A.399}$$

so by Equation (A.398) the real part of $n\ln\psi(s)$ is at most $-t^2/2 + t^2/4 = -t^2/4$, and the same bound holds trivially for $\Re\,(-t^2/2)$. For complex a, b,

$$\left|\mathrm{e}^{a} - \mathrm{e}^{b}\right| = \left|(a-b)\int_0^1 \mathrm{e}^{b+u(a-b)}\,\mathrm{d}u\right| \;\le\; |a-b|\;\mathrm{e}^{\max(\Re a,\,\Re b)}\,,$$

since $\Re\,(b + u(a-b)) = (1-u)\Re b + u\Re a$ is a convex combination. Taking $a = n\ln\psi(s)$ and $b = -t^2/2$ and inserting Equation (A.398) gives Equation (A.394). □

A.20.5 Integration, and the constant

Proof of Theorem A.192. *Derives Theorem A.192.*

Put $Y_i = (X_i - \mu)/\sigma$, so the Y_i are independent and identically distributed with mean 0, variance 1 and $\beta = \left\langle |Y|^3 \right\rangle = \rho/\sigma^3$, and $Z_n = n^{-1/2}\sum_i Y_i$ is the statistic of the theorem. Apply Theorem A.198 with $F = F_n$, $G = \Phi$ and $T = T_n = \sqrt{n}/(2\beta)$. The comparison function qualifies: Φ is non-decreasing and differentiable with $\Phi' = \varphi \le 1/\sqrt{2\pi}$, so $m = 1/\sqrt{2\pi}$; and both distributions have finite first moments, namely zero. Then, by Lemma A.200,

$$\Delta_n \;\le\; \frac{1}{\pi}\int_{-T_n}^{T_n} \frac{\beta t^2}{2\sqrt{n}}\, \mathrm{e}^{-t^2/4}\,\mathrm{d}t + \frac{24}{\pi\sqrt{2\pi}}\cdot\frac{2\beta}{\sqrt{n}}\,. \tag{A.400}$$

From Equations (A.389) and (A.394) (insert the transform estimate into the smoothing inequality at $T = T_n = \sqrt{n}/(2\beta)$).

Extend the first integral to all of $\mathbb{R}$, which only increases it, and evaluate it by the substitution $t = 2u$ together with the Gaussian moment $\int u^2\mathrm{e}^{-u^2}\mathrm{d}u = \sqrt{\pi}/2$ (Proposition 11.29, rescaled):

$$\int_{-\infty}^{\infty} t^2\mathrm{e}^{-t^2/4}\,\mathrm{d}t = 8\int_{-\infty}^{\infty} u^2\mathrm{e}^{-u^2}\,\mathrm{d}u = 4\sqrt{\pi}\,.$$

The first term of Equation (A.400) is therefore at most $(4\sqrt{\pi}/\pi)\,\beta/(2\sqrt{n}) = 2\beta/\sqrt{\pi n}$, and

$$\Delta_n \;\le\; \left(\frac{2}{\sqrt{\pi}} + \frac{48}{\pi\sqrt{2\pi}}\right)\frac{\beta}{\sqrt{n}} \;\le\; \frac{7.23\,\beta}{\sqrt{n}} = \frac{7.23\,\rho}{\sigma^3\sqrt{n}}\,, \tag{A.401}$$

since $2/\sqrt{\pi} = 1.1284$ and $48/\left(\pi\sqrt{2\pi}\right) = 6.0954$. That is Equation (A.382). Note that no step required n to be large: the inequality holds for every $n \ge 1$, being vacuous — because $\Delta_n \le 1$ always — until n exceeds about $52\beta^2$. □

Remark A.201 (On the constant). The value $C = 7.23$ derived here is admissible and is not sharp, and it is worth saying where the loss is. Almost all of it is in the smoothing inequality: of the two terms in Equation (A.401), the truncation penalty $24m/(\pi T)$ contributes 6.10 and the transform integral only 1.13. The factor 24 in Equation (A.389) comes from the crude estimate $1 - \cos \le 2$ used for the tail of the Fejér kernel and from the wedge construction's factor $\frac{3}{2}$; sharpening either changes the arithmetic but not the structure. The interval cannot simply be lengthened, because Equation (A.394) is proved only for $|t| \le \sqrt{n}/(2\beta)$ — beyond that the logarithm of $\psi(t/\sqrt{n})$ need not even be defined — so $T = T_n$ is the best this argument allows.

Determining the smallest admissible C is a separate literature and is *not* attempted here. Berry's paper [856] establishes finiteness, which is the qualitative content and all that Remark 11.49 needs; Esseen obtained the same result independently in the same period; and the sharpest published value for identically distributed summands is $C \le 0.4690$ [2238]. Since $\rho/\sigma^3 \ge 1$ always (Lemma A.199), no value of C below that can make the bound say anything at small n, which is the practical point Remark 11.49 draws.

Remark A.202. Appendix A.20 discharges the proof obligation of Equation (11.40), stated in Remark 11.49 of Chapter 11 as the rate that turns the central limit theorem into a usable statement about a finite sample. The consequences drawn there stand unchanged: the bound is uniform in z, so its *relative* accuracy is worst in the tails, exactly where a coverage factor $k = 3$ operates; and the $n^{-1/2}$ decay is slow enough that several hundred contributions are needed before the inequality itself certifies a few per cent. What this appendix adds is that both statements are now consequences of something proved, with an explicit constant, rather than of something quoted.

A.21 Wilks' Theorem in the Multi-Parameter Case

This appendix completes the derivation of Theorem 11.88 of Chapter 11 in k parameters with r constraints. The chapter's argument is correct at the level of the quadratic approximation and two of its steps are asserted rather than proved:

(i) the remainder in the k-dimensional Taylor expansion of the log-likelihood must be shown *uniform* on a neighbourhood of the true parameter that shrinks at rate $n^{-1/2}$, since the expansion is evaluated not at a fixed point but at two estimators that move with the data;

(ii) both estimators — the unconstrained one and the one constrained to Θ_0 — must be shown to lie in that neighbourhood with probability tending to one, since that is what licenses replacing the constraint surface Θ_0 by its tangent space at θ_0, the step written "$\Theta_0 \simeq \theta_0 + E$" at Equation (11.85).

Both are proved below, from exactly the regularity conditions (R1)–(R5) of Definition 11.59 and nothing stronger, and the chi-squared limit with r degrees of freedom is then assembled from them. The one-parameter case with a simple null needs none of this — there Θ_0 is a point, there is no surface to replace — which is why Chapter 11 carries that derivation in full and defers only this one.

A.21.1 Setting and notation

Let $X_1, \dots, X_n$ be independent and identically distributed with density $f(\,\cdot\,;\theta_0)$, let $\Theta \subseteq \mathbb{R}^k$ and let (R1)–(R5) hold at θ_0, read in k parameters: (R4) asks that $\theta \mapsto f(x;\theta)$ be three times continuously differentiable near θ_0 with the first two derivatives available under the integral, and (R5) that the information matrix $I = I_1(\theta_0)$ of Definition 11.60 be finite and positive definite and that a single integrable $M(x)$ dominate *every* third partial derivative $\partial^3 \ln f(x;\theta)/\partial\theta^a\partial\theta^b\partial\theta^c$ throughout a ball $\bar{B}(\theta_0, a_0) \subseteq \Theta$. Write $\lambda > 0$ for the smallest eigenvalue of I and $\|A\| = \sup_{\|\boldsymbol{v}\|=1} \|A\boldsymbol{v}\|$ for the operator norm of a matrix.

Put $\ell_n(\theta) = \sum_{i=1}^n \ln f(X_i;\theta)$ and

$$\boldsymbol{Z}_n = \frac{1}{\sqrt{n}}\,\nabla\ell_n(\theta_0)\,, \qquad J_n = \frac{1}{n}\,\nabla^2\ell_n(\theta_0)\,, \qquad \bar{M}_n = \frac{1}{n}\sum_{i=1}^n M(X_i)\,. \tag{A.402}$$

All three are averages of independent identically distributed terms: $\boldsymbol{Z}_n$ of the scores, whose common mean is zero and whose covariance is I (Lemma 11.61); J_n of the observation Hessians, whose common mean is $-I$ by Equation (11.48); and $\bar{M}_n$ of M, whose common mean $\bar{M} = \langle M \rangle$ is finite by (R5). The statistic is a pure number, the SI dimensions of θ cancelling in the likelihood ratio of Equation (11.80), and so is every quantity above: $\nabla\ell_n$ carries the reciprocal of the unit of θ and I its square, so the combinations formed below — $\boldsymbol{u}^{\mathsf{T}} I \boldsymbol{u}$ with $\boldsymbol{u} = \sqrt{n}(\theta - \theta_0)$, and $\boldsymbol{Z}_n^{\mathsf{T}} I^{-1} \boldsymbol{Z}_n$ — are dimensionless.

The two estimators are the local ones, defined exactly as Chapter 11 defines its root of the score equation. Fix $a_1 \in (0, a_0]$, to be chosen in Lemma A.211, and let

$$\hat{\theta}_n \in \arg\max_{\theta \in \bar{B}(\theta_0, a_1)} \ell_n(\theta)\,, \qquad \hat{\theta}_{0,n} \in \arg\max_{\theta \in \Theta_0 \cap \bar{B}(\theta_0, a_1)} \ell_n(\theta)\,. \tag{A.403}$$

Both maxima are attained: ℓ_n is continuous and both sets are closed and bounded, hence compact, so the extreme value theorem (Theorem 7.24) applies. Both sets contain θ_0, so

$$\ell_n(\hat{\theta}_n) \geq \ell_n(\theta_0) \qquad \text{and} \qquad \ell_n(\hat{\theta}_{0,n}) \geq \ell_n(\theta_0)\,, \tag{A.404}$$

the second because $\theta_0 \in \Theta_0$ by hypothesis. The statistic under study is $q = -2\left[\ell_n(\hat{\theta}_{0,n}) - \ell_n(\hat{\theta}_n)\right] \geq 0$.

The null set is a C^2 submanifold near θ_0, which is used in exactly one form and is therefore stated in that form.

Definition A.203 (The constraint surface)**.** Θ_0 is a C^2 *submanifold of dimension* $k-r$ *through* θ_0 *with tangent space* E when there are a linear subspace $E \subseteq \mathbb{R}^k$ with $\dim E = k-r$, a neighbourhood W of θ_0, an open $V \ni \mathbf{0}$ in E, and a twice continuously differentiable map $h : V \to E^\perp$ with $h(\mathbf{0}) = \mathbf{0}$ and $Dh(\mathbf{0}) = 0$, such that

$$\Theta_0 \cap W = \{\theta_0 + \boldsymbol{e} + h(\boldsymbol{e}) \mid \boldsymbol{e} \in V\} \,. \tag{A.405}$$

Rests on Definition 11.87.

Remark A.204 (Why the graph form, and not the constraint form). Theorem 11.88 states the hypothesis as "H_0 imposes r smooth, functionally independent constraints", i.e. Θ_0 is the level set $\{g(\theta) = \mathbf{0}\}$ of a C^2 map $g : \Theta \to \mathbb{R}^r$ with $Dg(\theta_0)$ of rank r. The equivalence of that description with Equation (A.405) is the implicit function theorem in several variables, which Chapter 13 records as owed rather than proved. This appendix therefore takes Definition A.203 as the hypothesis: it is the form the proof uses, it is one of the standard equivalent definitions of a submanifold, and adopting it keeps the argument free of a theorem the treatise has not yet built. A reader who has the implicit function theorem may read the two hypotheses as the same one.

A.21.2 What is quoted

Theorem A.205 (Weak law under integrability alone)**.** *Let* $W_1, W_2, \ldots$ *be independent and identically distributed with* $\langle |W| \rangle < \infty$*. Then* $n^{-1} \sum_{i=1}^n W_i \to \langle W \rangle$ *in probability [1894].*

Rests on Corollary 11.51.

Theorem A.206 (Cramér–Wold, and continuous mapping)**.** *Let* $\boldsymbol{W}_n, \boldsymbol{W}$ *be random vectors in* $\mathbb{R}^k$*. Then* $\boldsymbol{W}_n \to \boldsymbol{W}$ *in distribution if and only if* $\boldsymbol{a}^\mathsf{T}\boldsymbol{W}_n \to \boldsymbol{a}^\mathsf{T}\boldsymbol{W}$ *in distribution for every* $\boldsymbol{a} \in \mathbb{R}^k$*. Moreover, if* $\boldsymbol{W}_n \to \boldsymbol{W}$ *in distribution and* $g : \mathbb{R}^k \to \mathbb{R}$ *is continuous, then* $g(\boldsymbol{W}_n) \to g(\boldsymbol{W})$ *in distribution [1894].*

Rests on Definition 11.21 and Lemma 11.52.

Remark A.207 (What is quoted here). Three imports, all of them already relied on by Chapter 11 itself, and no more. Theorem A.205 is the weak law in the form that assumes only integrability; Corollary 11.51 is the Chebyshev form and needs a finite variance, which (R5) does not supply for the Hessian summands or for M — the chapter names this gap explicitly in the derivation of Theorem 11.67 and quotes the same source. Theorem A.206 is what promotes the scalar central limit theorem Theorem 11.46 to the vector statement $\boldsymbol{Z}_n \to \mathcal{N}(0, I)$ and lets a continuous function be applied under a limit in distribution; the chapter uses both silently in the k-parameter clause of Theorem 11.67 and proves the one-dimensional special case of the second at Equation (11.44). The third import is the implicit function theorem, and it is *avoided* rather than used, by taking Definition A.203 as the hypothesis (Remark A.204). Everything else below — the uniform remainder, the localisation of both estimators, the tangent-space replacement and the degrees of freedom — is derived here.

Lemma A.208 (The three averages)**.** $\|J_n + I\| \to 0$ *and* $\bar{M}_n \to \bar{M}$ *in probability, and* $\boldsymbol{Z}_n \to \mathcal{N}(0, I)$ *in distribution. In particular each component of* $\boldsymbol{Z}_n$*, and hence* $\|\boldsymbol{Z}_n\|$*, is bounded in probability.*

Rests on Lemma 11.61 and Theorems A.205 and A.206.

Proof. *Derives Lemma A.208.*

Each entry of J_n is the average of n independent copies of $\partial^2 \ln f(X;\theta_0)/\partial\theta^a\partial\theta^b$, integrable by (R4) with mean $-I_{ab}$ by Equation (11.48), so Theorem A.205 gives $J_n \to -I$

entrywise in probability; a matrix norm is a continuous function of finitely many entries, so $\|J_n + I\| \to 0$ in probability. The same theorem applied to M, integrable by (R5), gives the second claim.

For the third, fix $\boldsymbol{a} \in \mathbb{R}^k$, $\boldsymbol{a} \neq \mathbf{0}$. Then $\boldsymbol{a}^\mathsf{T} \boldsymbol{Z}_n = n^{-1/2} \sum_i \boldsymbol{a}^\mathsf{T} \boldsymbol{U}(\theta_0; X_i)$ with $\boldsymbol{U} = \nabla \ln f$ the score, a normalised sum of independent identically distributed variables with mean zero (Lemma 11.61) and variance $\boldsymbol{a}^\mathsf{T} I \boldsymbol{a}$, finite and strictly positive by (R5). Theorem 11.46 gives $\boldsymbol{a}^\mathsf{T} \boldsymbol{Z}_n \to \mathcal{N}(0, \boldsymbol{a}^\mathsf{T} I \boldsymbol{a})$, and Theorem A.206 converts this into $\boldsymbol{Z}_n \to \mathcal{N}(0, I)$. Boundedness in probability of each component is Equation (11.43), and $\|\boldsymbol{Z}_n\| \leq \sum_a |Z_n^a|$ is a finite sum of variables each bounded in probability. □

A.21.3 The uniform quadratic expansion

This is item (i). The content is not that a remainder exists — Taylor gives that at every fixed θ — but that a *single* random variable, not depending on θ, bounds it throughout the ball.

Lemma A.209 (Uniform third-order remainder)**.** *For every $\theta \in \bar{B}(\theta_0, a_0)$, writing $\delta = \theta - \theta_0$,*

$$\ell_n(\theta) = \ell_n(\theta_0) + \sqrt{n}\, \boldsymbol{Z}_n^\mathsf{T} \delta + \frac{n}{2}\, \delta^\mathsf{T} J_n \delta + R_n(\theta)\,, \qquad |R_n(\theta)| \;\leq\; \frac{n\, k^3}{6}\, \bar{M}_n\, \|\delta\|^3\,. \tag{A.406}$$

The bound is uniform in θ: apart from the explicit factor $\|\delta\|^3$ it involves only $\bar{M}_n$, which does not depend on θ.

Rests on Definition 11.59 and Theorem 7.38.

Proof. *Derives Lemma A.209.*

Fix θ and set $g(u) = \ell_n(\theta_0 + u\delta)$ for $u \in [0,1]$; the segment lies in $\bar{B}(\theta_0, a_0)$ by convexity of the ball, so g is three times continuously differentiable by (R4). Taylor's theorem with Lagrange remainder (Theorem 7.38) gives $g(1) = g(0) + g'(0) + \tfrac{1}{2} g''(0) + \tfrac{1}{6} g'''(\xi)$ for some $\xi \in (0,1)$. By the chain rule (Proposition 7.72),

$$g'(0) = \delta^\mathsf{T} \nabla \ell_n(\theta_0) = \sqrt{n}\, \boldsymbol{Z}_n^\mathsf{T} \delta\,, \qquad g''(0) = \delta^\mathsf{T} \nabla^2 \ell_n(\theta_0)\, \delta = n\, \delta^\mathsf{T} J_n \delta\,,$$

which are the first two displayed terms, and

$$g'''(\xi) = \sum_{a,b,c=1}^{k} \delta^a \delta^b \delta^c\, \frac{\partial^3 \ell_n}{\partial\theta^a \partial\theta^b \partial\theta^c}\, (\theta_0 + \xi\delta)\,. \tag{A.407}$$

Each third partial derivative of ℓ_n is a sum of n terms, one per observation, and (R5) bounds each of them by $M(X_i)$ throughout $\bar{B}(\theta_0, a_0)$ — in particular at the unknown intermediate point $\theta_0 + \xi\delta$, which is what makes the estimate independent of ξ and hence of θ. Since $|\delta^a| \leq \|\delta\|$ for each component and the sum Equation (A.407) has k^3 terms,

$$|g'''(\xi)| \;\leq\; k^3\, \|\delta\|^3 \sum_{i=1}^{n} M(X_i) = n\, k^3\, \bar{M}_n\, \|\delta\|^3\,,$$

and $R_n(\theta) = \tfrac{1}{6} g'''(\xi)$. □

Corollary A.210 (Uniform quadratic approximation on the $n^{-1/2}$ scale)**.** *Define, for $\boldsymbol{u} \in \mathbb{R}^k$,*

$$\Lambda_n(\boldsymbol{u}) = -2\, \boldsymbol{Z}_n^\mathsf{T} \boldsymbol{u} + \boldsymbol{u}^\mathsf{T} I\, \boldsymbol{u}\,. \tag{A.408}$$

Then for every $K > 0$ and every n with $K/\sqrt{n} \leq a_0$,

$$\sup_{\|\boldsymbol{u}\| \leq K} \left| -2 \left[\ell_n\!\left(\theta_0 + \frac{\boldsymbol{u}}{\sqrt{n}}\right) - \ell_n(\theta_0) \right] - \Lambda_n(\boldsymbol{u}) \right| \;\leq\; \epsilon_n(K)\,, \tag{A.409}$$

where $\epsilon_n(K) = K^2\, \|J_n + I\| + \tfrac{1}{3} k^3 K^3 \bar{M}_n / \sqrt{n}$ tends to 0 in probability.

Rests on Lemmas A.208 and A.209.

Proof. *Derives Corollary A.210.*

Put $\delta = \boldsymbol{u}/\sqrt{n}$ in Equation (A.406) and multiply by -2:

$$-2\left[\ell_n(\theta) - \ell_n(\theta_0)\right] = -2\boldsymbol{Z}_n^{\mathsf{T}}\boldsymbol{u} - \boldsymbol{u}^{\mathsf{T}} J_n \boldsymbol{u} - 2R_n(\theta)\,,$$

because $n\delta^{\mathsf{T}} J_n \delta = \boldsymbol{u}^{\mathsf{T}} J_n \boldsymbol{u}$ and $\sqrt{n}\boldsymbol{Z}_n^{\mathsf{T}}\delta = \boldsymbol{Z}_n^{\mathsf{T}}\boldsymbol{u}$. Subtracting Equation (A.408) leaves $-\boldsymbol{u}^{\mathsf{T}}(J_n + I)\,\boldsymbol{u} - 2R_n$, whose first part is at most $\|J_n + I\|\,\|\boldsymbol{u}\|^2$ in modulus and whose second is at most $\frac{1}{3}k^3\bar{M}_n\,\|\boldsymbol{u}\|^3/\sqrt{n}$ by Equation (A.406) with $\|\delta\| = \|\boldsymbol{u}\|/\sqrt{n}$. Both are increasing in $\|\boldsymbol{u}\|$, so the supremum over the ball is attained at the bound. That $\epsilon_n(K) \to 0$ in probability is Lemma A.208: the first term is K^2 times something tending to 0, and the second is $\bar{M}_n$, bounded in probability, times $\frac{1}{3}k^3K^3n^{-1/2} \to 0$. □

A.21.4 Localisation of both estimators

This is item (ii). Note that it is proved for *any* closed subset of the ball containing θ_0, so that the unconstrained and the constrained estimators are covered by one argument; nothing about the geometry of Θ_0 is used here.

Lemma A.211 (Root-n localisation)**.** *Choose $a_1 \in (0, a_0]$ with $\frac{1}{6}k^3\left(\bar{M}+1\right)a_1 \le \lambda/8$, and let $A \subseteq \bar{B}(\theta_0, a_1)$ be any closed set with $\theta_0 \in A$. Let $\hat{\theta}$ maximise ℓ_n over A. Then*

$$\Pr\!\left(\sqrt{n}\,\left\|\hat{\theta} - \theta_0\right\| \;\le\; \frac{4}{\lambda}\,\|\boldsymbol{Z}_n\|\right) \;\longrightarrow\; 1\,, \tag{A.410}$$

and consequently $\sqrt{n}\left\|\hat{\theta} - \theta_0\right\|$ is bounded in probability and $\hat{\theta} \to \theta_0$ in probability. In particular both estimators Equation (A.403) satisfy this.

Rests on Lemmas A.208 and A.209.

Proof. *Derives Lemma A.211.*

Write $\hat{\delta} = \hat{\theta} - \theta_0$ and $d = \left\|\hat{\delta}\right\| \le a_1$. Since $\theta_0 \in A$ we have $\ell_n(\hat{\theta}) \ge \ell_n(\theta_0)$, so Equation (A.406) gives

$$0 \;\le\; \sqrt{n}\,\boldsymbol{Z}_n^{\mathsf{T}}\hat{\delta} + \frac{n}{2}\,\hat{\delta}^{\mathsf{T}} J_n \hat{\delta} + R_n(\hat{\theta})\,. \tag{A.411}$$

Bound the three terms. The first is at most $\sqrt{n}\,\|\boldsymbol{Z}_n\|\,d$ by the Cauchy–Schwarz inequality for vectors. For the second, write $\hat{\delta}^{\mathsf{T}} J_n \hat{\delta} = -\hat{\delta}^{\mathsf{T}} I \hat{\delta} + \hat{\delta}^{\mathsf{T}}(J_n + I)\,\hat{\delta}$; the first piece is at most $-\lambda d^2$, since λ is the smallest eigenvalue of the positive-definite I, and the second is at most $\|J_n + I\|\,d^2$. The third is at most $\frac{1}{6}nk^3\bar{M}_n d^3$. Hence

$$\frac{n\lambda}{2}d^2 \;\le\; \sqrt{n}\,\|\boldsymbol{Z}_n\|\,d + \frac{n}{2}\,\|J_n + I\|\,d^2 + \frac{n\,k^3}{6}\bar{M}_n d^3\,. \tag{A.412}$$

From Equations (A.406) and (A.411) (bound the linear term by Cauchy–Schwarz, split the Hessian term into $-I$ plus its deviation, and insert the uniform remainder bound).

Let E_n be the event on which both $\|J_n + I\| \le \lambda/4$ and $\bar{M}_n \le \bar{M} + 1$; by Lemma A.208, $\Pr(E_n) \to 1$. On E_n, and using $d \le a_1$ with the choice of a_1,

$$\frac{n}{2}\,\|J_n + I\|\,d^2 \le \frac{n\lambda}{8}d^2\,, \qquad \frac{n\,k^3}{6}\bar{M}_n d^3 \le \left[\frac{k^3\left(\bar{M}+1\right)a_1}{6}\right] n\,d^2 \le \frac{n\lambda}{8}d^2\,.$$

Substituting in Equation (A.412) and cancelling $n\lambda d^2/4$ from both sides leaves $\frac{1}{4}n\lambda d^2 \le \sqrt{n}\,\|\boldsymbol{Z}_n\|\,d$; dividing by $\frac{1}{4}n\lambda d$ when $d > 0$ — and noting the conclusion is trivial when $d = 0$ — gives $\sqrt{n}\,d \le 4\,\|\boldsymbol{Z}_n\|/\lambda$, which is Equation (A.410). Boundedness in probability follows because $\|\boldsymbol{Z}_n\|$ is bounded in probability (Lemma A.208), and consistency because $\sqrt{n}d = O_P(1)$ forces $d \to 0$ in probability. □

A.21.5 Replacing the surface by its tangent space

Lemma A.212 (Second-order flatness)**.** *Under Definition A.203 there are $c_0 < \infty$ and $a_2 \in (0, a_1]$ such that*

1. *if $\theta \in \Theta_0$ and $\|\theta - \theta_0\| \le a_2$, then the orthogonal projection $\boldsymbol{w}$ of $\theta - \theta_0$ onto E satisfies $\|(\theta - \theta_0) - \boldsymbol{w}\| \le c_0 \|\theta - \theta_0\|^2$;*
2. *if $\boldsymbol{e} \in E$ and $\|\boldsymbol{e}\| \le a_2$, there is $\theta \in \Theta_0$ with $\|(\theta - \theta_0) - \boldsymbol{e}\| \le c_0 \|\boldsymbol{e}\|^2$.*

Rests on Definition A.203 and Theorem 7.38.

Proof. *Derives Lemma A.212.*

Choose $a_2 \in (0, a_1]$ small enough that the closed ball $\bar{B}(\theta_0, 2a_2)$ lies in W and that $\{\boldsymbol{e} \in E \mid \|\boldsymbol{e}\| \le 2a_2\} \subseteq V$; let $c_0 = \frac{1}{2} \sup \|D^2 h\|$ over that compact set, finite because h is twice *continuously* differentiable and the supremum of a continuous function on a compact set is attained (Theorem 7.24). Taylor's theorem applied to $u \mapsto h(u\boldsymbol{e})$ on $[0,1]$, with $h(\boldsymbol{0}) = \boldsymbol{0}$ and $Dh(\boldsymbol{0}) = 0$ killing the first two terms, gives

$$\|h(\boldsymbol{e})\| \;\le\; c_0 \|\boldsymbol{e}\|^2 \qquad \text{for } \|\boldsymbol{e}\| \le 2a_2 \,. \tag{A.413}$$

(ii) Take $\theta = \theta_0 + \boldsymbol{e} + h(\boldsymbol{e})$, which lies in Θ_0 by Equation (A.405); then $(\theta - \theta_0) - \boldsymbol{e} = h(\boldsymbol{e})$ and Equation (A.413) applies.

(i) Such a θ lies in W, so $\theta - \theta_0 = \boldsymbol{e} + h(\boldsymbol{e})$ for some $\boldsymbol{e} \in V$; the two summands are orthogonal, so $\boldsymbol{w} = \boldsymbol{e}$ and $\|\boldsymbol{e}\| \le \|\theta - \theta_0\| \le a_2$. Then $(\theta - \theta_0) - \boldsymbol{w} = h(\boldsymbol{e})$, and Equation (A.413) together with $\|\boldsymbol{e}\| \le \|\theta - \theta_0\|$ gives the bound. □

Lemma A.213 (The three minima)**.** *Write $\hat{\boldsymbol{u}} = \sqrt{n}(\hat{\theta}_n - \theta_0)$ and $\hat{\boldsymbol{u}}_0 = \sqrt{n}(\hat{\theta}_{0,n} - \theta_0)$. Then*

$$\Lambda_n(\hat{\boldsymbol{u}}) - \min_{\boldsymbol{u} \in \mathbb{R}^k} \Lambda_n(\boldsymbol{u}) \;\longrightarrow\; 0 \,, \qquad \Lambda_n(\hat{\boldsymbol{u}}_0) - \min_{\boldsymbol{e} \in E} \Lambda_n(\boldsymbol{e}) \;\longrightarrow\; 0 \,, \tag{A.414}$$

both in probability.

Rests on Corollary A.210 and Lemmas A.211 and A.212.

Proof. *Derives Lemma A.213.*

Since I is positive definite, Λ_n is a strictly convex quadratic; completing the square with $\boldsymbol{m} = I^{-1}\boldsymbol{Z}_n$,

$$\Lambda_n(\boldsymbol{u}) = (\boldsymbol{u} - \boldsymbol{m})^{\mathsf{T}} I \,(\boldsymbol{u} - \boldsymbol{m}) - \boldsymbol{Z}_n^{\mathsf{T}} I^{-1} \boldsymbol{Z}_n \,, \tag{A.415}$$

so the unconstrained minimum is attained at $\boldsymbol{m}$ and the minimum over the subspace E at the I-orthogonal projection $\boldsymbol{p}$ of $\boldsymbol{m}$ onto E. Both $\|\boldsymbol{m}\|$ and $\|\boldsymbol{p}\|$ are bounded in probability, being bounded linear images of $\boldsymbol{Z}_n$. Also Λ_n is Lipschitz on each ball: for $\|\boldsymbol{u}\|, \|\boldsymbol{u}'\| \le K$,

$$|\Lambda_n(\boldsymbol{u}) - \Lambda_n(\boldsymbol{u}')| \;\le\; L_n(K) \|\boldsymbol{u} - \boldsymbol{u}'\| \,, \qquad L_n(K) = 2\|\boldsymbol{Z}_n\| + 2K\|I\| \,, \tag{A.416}$$

which is bounded in probability for fixed K.

Fix $\varepsilon > 0$. By Lemma A.211 and the boundedness just noted, there is K such that with probability at least $1 - \varepsilon$ for all large n the four vectors $\hat{\boldsymbol{u}}, \hat{\boldsymbol{u}}_0, \boldsymbol{m}, \boldsymbol{p}$ all lie in $\bar{B}(\boldsymbol{0}, K)$; call that event A_n and intersect it with the event that $\epsilon_n(K+1) \le \varepsilon$, which also has probability approaching 1 by Corollary A.210. Work on the intersection, and abbreviate $D_n(\theta) = -2\,[\ell_n(\theta) - \ell_n(\theta_0)]$, so that Equation (A.409) reads $|D_n(\theta_0 + \boldsymbol{u}/\sqrt{n}) - \Lambda_n(\boldsymbol{u})| \le \varepsilon$ for every $\|\boldsymbol{u}\| \le K + 1$. The extra unit of radius is there because one auxiliary point below, the image in Θ_0 of the tangential minimiser, misses $\bar{B}(\boldsymbol{0}, K)$ by $O(n^{-1/2})$; all other points used lie in $\bar{B}(\boldsymbol{0}, K)$. Write $L_n = L_n(K+1)$ for the Lipschitz constant Equation (A.416) at that radius.

First limit. That $\Lambda_n(\hat{\boldsymbol{u}}) \geq \min_{\mathbb{R}^k} \Lambda_n$ is immediate. For the reverse, put $\theta_{\mathrm{m}} = \theta_0 + \boldsymbol{m}/\sqrt{n}$, which lies in $\bar{B}(\theta_0, a_1)$ once $K/\sqrt{n} \leq a_1$, so $\ell_n(\hat{\theta}_n) \geq \ell_n(\theta_{\mathrm{m}})$ and hence $D_n(\hat{\theta}_n) \leq D_n(\theta_{\mathrm{m}})$. Therefore

$$\Lambda_n(\hat{\boldsymbol{u}}) - \varepsilon \;\leq\; D_n(\hat{\theta}_n) \;\leq\; D_n(\theta_{\mathrm{m}}) \;\leq\; \Lambda_n(\boldsymbol{m}) + \varepsilon = \min_{\boldsymbol{u} \in \mathbb{R}^k} \Lambda_n(\boldsymbol{u}) + \varepsilon\,,$$

so the first difference in Equation (A.414) is at most 2ε on an event of probability approaching $1 - \varepsilon$.

Second limit. For the lower bound let $\boldsymbol{w}$ be the orthogonal projection of $\hat{\boldsymbol{u}}_0$ onto E. By Lemma A.212(i) applied to $\theta = \hat{\theta}_{0,n} \in \Theta_0$, whose distance to θ_0 is at most $K/\sqrt{n} \leq a_2$ for large n,

$$\|\hat{\boldsymbol{u}}_0 - \boldsymbol{w}\| = \sqrt{n}\,\left\|\left(\hat{\theta}_{0,n} - \theta_0\right) - \frac{\boldsymbol{w}}{\sqrt{n}}\right\| \;\leq\; \sqrt{n}\,c_0\left(\frac{K}{\sqrt{n}}\right)^2 = \frac{c_0 K^2}{\sqrt{n}}\,, \tag{A.417}$$

and $\|\boldsymbol{w}\| \leq \|\hat{\boldsymbol{u}}_0\| \leq K$, so Equation (A.416) gives $\Lambda_n(\hat{\boldsymbol{u}}_0) \geq \Lambda_n(\boldsymbol{w}) - L_n c_0 K^2/\sqrt{n} \geq \min_E \Lambda_n - L_n c_0 K^2/\sqrt{n}$.

For the upper bound apply Lemma A.212(ii) to $\boldsymbol{p}/\sqrt{n}$, of norm at most $K/\sqrt{n} \leq a_2$: there is $\theta_{\mathrm{p}} \in \Theta_0$ with $\|(\theta_{\mathrm{p}} - \theta_0) - \boldsymbol{p}/\sqrt{n}\| \leq c_0 K^2/n$, hence $\|\sqrt{n}\,(\theta_{\mathrm{p}} - \theta_0) - \boldsymbol{p}\| \leq c_0 K^2/\sqrt{n}$ and $\theta_{\mathrm{p}} \in \Theta_0 \cap \bar{B}(\theta_0, a_1)$ for large n. Since $\hat{\theta}_{0,n}$ maximises ℓ_n over that set, $D_n(\hat{\theta}_{0,n}) \leq D_n(\theta_{\mathrm{p}})$, and running the same three-step chain as before, then moving from $\sqrt{n}(\theta_{\mathrm{p}} - \theta_0)$ to $\boldsymbol{p}$ by Equation (A.416),

$$\Lambda_n(\hat{\boldsymbol{u}}_0) \;\leq\; \Lambda_n(\boldsymbol{p}) + 2\varepsilon + \frac{L_n c_0 K^2}{\sqrt{n}} = \min_{\boldsymbol{e} \in E} \Lambda_n(\boldsymbol{e}) + 2\varepsilon + \frac{L_n c_0 K^2}{\sqrt{n}}\,.$$

Both correction terms tend to 0 in probability, L_n being bounded in probability, and $\varepsilon > 0$ was arbitrary. □

A.21.6 The chi-squared limit

Theorem A.214 (Wilks, k parameters and r constraints)**.** *Let (R1)–(R5) hold at θ_0 in k parameters, let the sample be independent and identically distributed of size n, and let $\Theta_0 \ni \theta_0$ satisfy Definition A.203 with $\dim E = k - r$. Then the local likelihood-ratio statistic $q = -2\left[\ell_n(\hat{\theta}_{0,n}) - \ell_n(\hat{\theta}_n)\right]$ built from the estimators Equation (A.403) converges in distribution to χ^2_r.*

Rests on Lemmas 11.83 and A.213 and Theorem A.206.

Proof. *Derives Theorem A.214.*

Write D_n as in Lemma A.213, so that $q = D_n(\hat{\theta}_{0,n}) - D_n(\hat{\theta}_n)$ — the common reference value $\ell_n(\theta_0)$ cancels. By Corollary A.210 each D_n equals the corresponding Λ_n up to $\epsilon_n(K)$, and by Lemma A.213 each Λ_n equals the corresponding minimum up to a quantity tending to zero in probability. Hence

$$q = \min_{\boldsymbol{e} \in E} \Lambda_n(\boldsymbol{e}) - \min_{\boldsymbol{u} \in \mathbb{R}^k} \Lambda_n(\boldsymbol{u}) + o_P(1) = \min_{\boldsymbol{e} \in E} (\boldsymbol{e} - \boldsymbol{m})^{\mathsf{T}}\, I\, (\boldsymbol{e} - \boldsymbol{m}) + o_P(1)\,, \tag{A.418}$$

From Equations (A.414) and (A.415) (replace each statistic by the minimum of the quadratic form and cancel the common constant).

The second equality is Equation (A.415), whose additive constant $-\boldsymbol{Z}_n^{\mathsf{T}} I^{-1} \boldsymbol{Z}_n$ is the same in both minima and cancels.

Now substitute $\boldsymbol{V}_n = I^{1/2}\boldsymbol{m} = I^{-1/2}\boldsymbol{Z}_n$ and $S = I^{1/2}E$, where $I^{1/2}$ is any invertible matrix with $I^{1/2}\left(I^{1/2}\right)^{\mathsf{T}} = I$, symmetric here; the existence of one is the weak form of the

spectral theorem recorded in Remark 11.86. Since $I^{1/2}$ is invertible, $\dim S = \dim E = k - r$, and

$$\min_{\boldsymbol{e}\in E} (\boldsymbol{e}-\boldsymbol{m})^{\mathsf{T}}\, I\, (\boldsymbol{e}-\boldsymbol{m}) = \min_{\boldsymbol{s}\in S} \|\boldsymbol{s}-\boldsymbol{V}_n\|^2 = \|P\boldsymbol{V}_n\|^2 \;, \tag{A.419}$$

with P the orthogonal projector onto $S^{\perp}$, of dimension r: the nearest point of a subspace to a given vector is its orthogonal projection, and what is left over is the projection onto the orthogonal complement.

By Lemma A.208, $\boldsymbol{Z}_n \to \mathcal{N}(0, I)$ in distribution; applying Theorem A.206 to the linear map $\boldsymbol{z} \mapsto I^{-1/2}\boldsymbol{z}$ — for each $\boldsymbol{a}$, $\boldsymbol{a}^{\mathsf{T}} I^{-1/2}\boldsymbol{Z}_n \to \mathcal{N}(0, \boldsymbol{a}^{\mathsf{T}} I^{-1/2} I I^{-1/2}\boldsymbol{a}) = \mathcal{N}(0, \|\boldsymbol{a}\|^2)$ — gives $\boldsymbol{V}_n \to \boldsymbol{V} \sim \mathcal{N}(0, \mathbb{1})$ in distribution. The map $\boldsymbol{v} \mapsto \|P\boldsymbol{v}\|^2$ is continuous, so the continuous-mapping clause of Theorem A.206 gives $\|P\boldsymbol{V}_n\|^2 \to \|P\boldsymbol{V}\|^2$ in distribution, and $\|P\boldsymbol{V}\|^2 \sim \chi^2_r$ by Lemma 11.83. Finally, adding an $o_P(1)$ term does not change a limit in distribution, by the sum clause of Lemma 11.52. Hence $q \to \chi^2_r$. □

Remark A.215 (What "the" likelihood-ratio statistic means). Equation (11.80) defines q through the *global* suprema of the likelihood over Θ and over Θ_0, while Theorem A.214 is proved for the local maximisers Equation (A.403). The gap is the same one Remark 11.69 records for Theorem 11.67: identifying a consistent local maximiser with the global one is Wald's theorem [950], under conditions this treatise does not assume, and a likelihood with several local maxima can have a consistent root far from its highest peak at any finite n. Stating the theorem for the local statistic is therefore not a weakening introduced here — it is the same statement the chapter's one-parameter derivation proves, made explicit. The number r is unaffected: it is $\operatorname{codim} E$, a property of the constraint alone.

Remark A.216 (Where the two owed steps entered). It is worth marking the two places, because they are the whole content of this appendix. Uniformity — item (i) — is Equation (A.406): the remainder is bounded by $\frac{1}{6} n k^3 \bar{M}_n \|\delta\|^3$ with a coefficient that does not depend on θ, which is what (R5)'s single dominating function M buys and what a pointwise Taylor expansion would not. It is used at two moving points, $\hat{\theta}_n$ and $\hat{\theta}_{0,n}$, neither of which is known in advance; a θ-dependent remainder would say nothing about either. Localisation — item (ii) — is Equation (A.410): both estimators sit within $O_P(n^{-1/2})$ of θ_0, so the surface is only ever probed at distance $O(n^{-1/2})$, where Lemma A.212 bounds its departure from the tangent space by $O(n^{-1})$ — one order smaller, which after the $\sqrt{n}$ rescaling of Equation (A.417) is the $O(n^{-1/2})$ that vanishes. That is the honest content of writing $\Theta_0 \simeq \theta_0 + E$, and it is why second-order smoothness of the constraint, and not merely differentiability, is assumed.

Remark A.217. Appendix A.21 discharges the proof obligation left at Section 11.5.4 of Chapter 11. With it, Corollary 11.89 — one parameter of interest, any number of nuisance parameters, one degree of freedom — is a corollary of a proved theorem rather than of an argued one, and so is the practice it licenses: a collider search reads its significance off a one-degree-of-freedom distribution however many nuisance parameters describe the background and the detector [2172]. The two failure modes remain exactly as Remark 11.90 and Remark 11.91 describe them, and both are visible in the proof above: a parameter on the boundary violates (R3), so Equation (A.403) is no longer an interior maximisation and Lemma A.211 loses the two-sided estimate; a parameter unidentified under the null makes I singular, so $\lambda = 0$ and every step from Equation (A.412) onward fails at once.

A.22 Rice's Formula for the Expected Number of Upcrossings

This appendix proves Theorem 11.102 of Chapter 11: for a smooth Gaussian field of unit variance the expected number of upcrossings of a level z factorises into $\mathrm{e}^{-z^2/2}/(2\pi)$ times an integral of the standard deviation of the derivative, so that the level enters only

through a Gaussian factor. That factorisation is what the whole look-elsewhere machinery of Section 11.6 rests on: it is what makes Theorem 11.103 true, and hence what allows a search to count upcrossings at a low threshold in a few hundred simulated experiments and extrapolate to a threshold at which nothing could ever be simulated. The formula is section 3.3 of the second instalment of Rice's memoir on random noise [883]; the first instalment [877] carries the shot effect and the power spectra and not this.

The proof is in three moves. A purely deterministic counting identity expresses the number of upcrossings of a C^1 function as the limit of a normalised integral over the set where the function is near the level — Kac's device (Appendix A.22.3). The expectation of that integral factorises, because a field of constant variance is uncorrelated with its own derivative at each point, and for jointly Gaussian variables uncorrelated means independent (Appendix A.22.2). And the two elementary Gaussian integrals that remain are evaluated (Appendix A.22.5). The passage from the integral identity to its expectation is where Lebesgue theory enters, and it is the only thing quoted; it is stated precisely in Remark A.224.

A.22.1 Hypotheses and statement

Definition A.218 (The hypotheses)**.** Let $M = [m_1, m_2]$ be a compact interval and X a real-valued process on M satisfying:

(H1) *Gaussian, standardised*: every finite linear combination $\sum_j a_j X(n_j)$, $n_j \in M$, is Gaussian with mean zero; and the covariance function $r(n, n') = \langle X(n)X(n')\rangle$ satisfies $r(m, m) = 1$ for every $m \in M$.

(H2) *Smooth covariance*: r is twice continuously differentiable on $M \times M$.

(H3) *Smooth paths*: almost every sample path of X is continuously differentiable on M, and for each m the difference quotients $(X(m+h) - X(m))/h$ converge to $X'(m)$ in mean square as $h \to 0$.

(H4) *Non-degeneracy and non-tangency*: writing $\sigma_1(m)^2 = \operatorname{var} X'(m)$, the function σ_1 is continuous and strictly positive on M; and for the level z under consideration, almost surely there is no $m \in M$ with $X(m) = z$ and $X'(m) = 0$.

Rests on Definitions 11.28 and 11.100.

Theorem A.219 (Rice's formula)**.** *Under Definition A.218, the expected number of upcrossings of the level z by X on M, in the sense of Definition 11.100, is*

$$\langle N_z(X)\rangle = \frac{\mathrm{e}^{-z^2/2}}{2\pi} \int_{m_1}^{m_2} \sigma_1(m)\,\mathrm{d}m\,. \tag{A.420}$$

Rests on Definitions 11.100 and A.218.

The two sides carry the same SI dimension, namely none. The field is standardised, so X and the level z are pure numbers; the parameter m carries whatever unit the scanned quantity carries — in the application of Section 11.6 it is a mass — and X', being a derivative with respect to it, carries the reciprocal of that unit. So $\sigma_1(m)\,\mathrm{d}m$ is dimensionless, as a count must be. This is also the quickest check that no factor has been lost: the level enters only through $\mathrm{e}^{-z^2/2}$, which could carry no unit, and the geometry only through $\int \sigma_1\,\mathrm{d}m$, which is the total number of "independent looks" the scan contains.

A.22.2 The joint law of the field and its derivative

Lemma A.220 (At each point, field and derivative are independent Gaussians)**.** *Under (H1)–(H4), for each fixed $m \in M$ the pair $(X(m), X'(m))$ is jointly Gaussian with mean zero and covariance matrix* $\operatorname{diag}(1, \sigma_1(m)^2)$*. The two components are therefore independent, with joint density*

$$p_m(v, w) = \frac{\mathrm{e}^{-v^2/2}}{\sqrt{2\pi}} \cdot \frac{\mathrm{e}^{-w^2/(2\sigma_1(m)^2)}}{\sqrt{2\pi}\,\sigma_1(m)}\,. \tag{A.421}$$

Rests on Definition A.218 and Corollary A.178.

Proof. *Derives Lemma A.220.*

Joint Gaussianity. Fix $a, b \in \mathbb{R}$ and write $D_h = (X(m+h) - X(m))/h$, a linear combination of two values of X; by (H1) the variable $S_h = aX(m) + bD_h$ is Gaussian with mean zero, say $S_h \sim \mathcal{N}(0, v_h)$. Put $S = aX(m) + bX'(m)$. By (H3), $D_h \to X'(m)$ in mean square, so $S_h \to S$ in mean square and hence in probability, and therefore in distribution. Mean-square convergence also forces $v_h = \langle S_h^2 \rangle \to \langle S^2 \rangle = v$, since $\left| \langle S_h^2 \rangle^{1/2} - \langle S^2 \rangle^{1/2} \right| \le \langle (S_h - S)^2 \rangle^{1/2}$ by the triangle inequality for the second-moment norm. The characteristic function of S_h is $\mathrm{e}^{-v_h t^2/2}$ (Proposition 11.29 and the computation of the Gaussian transform in the derivation of Theorem 11.46), which converges to $\mathrm{e}^{-vt^2/2}$ for every t. By Corollary A.181 the characteristic function of S is that limit, and by Corollary A.178 S is therefore $\mathcal{N}(0, v)$. As a and b were arbitrary, the pair is jointly Gaussian.

The covariance vanishes. By the Cauchy–Schwarz inequality (Lemma 11.63, applied without centring, both variables having mean zero), $|\langle X(m)\,(D_h - X'(m))\rangle| \le \langle X(m)^2 \rangle^{1/2} \left\langle (D_h - X'(m))^2 \right\rangle^{1/2} \to 0$, so

$$\langle X(m) X'(m) \rangle = \lim_{h \to 0} \langle X(m) D_h \rangle = \lim_{h \to 0} \frac{r(m, m+h) - r(m, m)}{h} = \partial_2 r(m, m)\,, \tag{A.422}$$

where ∂_2 is the derivative in the second slot, which exists and is continuous by (H2). Now $r(m, m) = 1$ for every m by (H1); differentiating this identity in m by the chain rule (Proposition 7.72) gives $\partial_1 r(m, m) + \partial_2 r(m, m) = 0$, while r is symmetric, $r(n, n') = r(n', n)$, so $\partial_1 r(m, m) = \partial_2 r(m, m)$. Hence both vanish, and $\langle X(m) X'(m) \rangle = 0$ by Equation (A.422). Together with $\operatorname{var} X(m) = r(m, m) = 1$ and $\operatorname{var} X'(m) = \sigma_1(m)^2 > 0$ from (H4), the covariance matrix is $\operatorname{diag}(1, \sigma_1^2)$, which is invertible.

Independence. A jointly Gaussian pair with mean zero and invertible covariance Σ has density $(2\pi)^{-1} (\det \Sigma)^{-1/2} \exp\left(-\tfrac{1}{2} \boldsymbol{y}^{\mathsf{T}} \Sigma^{-1} \boldsymbol{y}\right)$; with Σ diagonal the quadratic form splits and the density factorises as Equation (A.421), which by Definition 11.25 is independence. □

The lemma is the structural heart of Equation (A.420) and is worth stating in words, because it is what Theorem 11.103 exploits: *constancy of the variance* is what makes field and derivative independent, and once they are, the level z can influence only the first factor of Equation (A.421) while the derivative supplies the same average slope at every level. Had the field not been standardised, the two would be correlated wherever $\mathrm{d} \operatorname{var} X / \mathrm{d}m \neq 0$ and no such factorisation would exist.

A.22.3 Kac's counting integral

The next lemma contains no probability at all. It is the observation that a transversal upcrossing contributes exactly 2δ to $\int \mathbf{1}_{\{|g-z|<\delta\}} (g')^+$, whatever δ is, while a downcrossing contributes nothing.

Lemma A.221 (Counting identity)**.** *Let $g : M \to \mathbb{R}$ be continuously differentiable and let $z \in \mathbb{R}$ satisfy $g(m_1) \neq z$, $g(m_2) \neq z$, and $g'(m) \neq 0$ at every m with $g(m) = z$. Then g*

has finitely many upcrossings of z, their number $N_z(g)$ in the sense of Definition 11.100 is finite, and there is $\delta_0(g) > 0$ with

$$\frac{1}{2\delta}\int_{m_1}^{m_2} \mathbf{1}_{\{|g(m)-z|<\delta\}}\,\big(g'(m)\big)^+\,\mathrm{d}m = N_z(g) \qquad \text{for every } 0<\delta<\delta_0(g)\,, \tag{A.423}$$

where $y^+ = \max(y,0)$. In particular the left side converges to $N_z(g)$ as $\delta \downarrow 0$.
Rests on Definition 11.100 and Theorems 7.24 and 7.43.

Proof. *Derives Lemma A.221.*

Finiteness. Let $Z = \{m \in M \mid g(m) = z\}$, a closed subset of the compact M and hence compact; by hypothesis it misses both endpoints. If $p \in Z$ then $g'(p) \neq 0$, and g' is continuous, so g is strictly monotone on a neighbourhood of p and takes the value z there only at p: every point of Z is isolated. A compact set all of whose points are isolated is finite — the singletons form an open cover with no proper subcover. Write $Z = \{p_1 < \cdots < p_J\}$, all interior to M.

A separating radius. For each j choose $\eta > 0$, the same for all j, small enough that the closed intervals $U_j = [p_j - \eta, p_j + \eta]$ are pairwise disjoint, contained in (m_1, m_2), and such that g' keeps the sign of $g'(p_j)$ throughout U_j; continuity of g' and finiteness of Z make this possible. On $M \setminus \bigcup_j (p_j - \eta, p_j + \eta)$ — a compact set on which $g - z$ does not vanish — the continuous function $|g - z|$ attains a strictly positive minimum μ (Theorem 7.24). Let $\delta_0 = \min\big(\mu,\ \min_j |g(p_j - \eta) - z|\,,\ \min_j |g(p_j + \eta) - z|\big)$, which is positive because g is strictly monotone on each U_j with $g(p_j) = z$.

The integral, for $\delta < \delta_0$. The set $A_\delta = \{m \in M \mid |g(m) - z| < \delta\}$ is contained in $\bigcup_j U_j$, since $\delta < \mu$. Fix j. On U_j the function g is strictly monotone and continuous, so $A_\delta \cap U_j$ is the open interval (α_j, β_j) whose endpoints are the two solutions of $g = z \mp \delta$ inside U_j; these exist and lie in the interior of U_j by the intermediate value theorem (Theorem 7.23) and the choice $\delta < \delta_0$.

If $g' > 0$ on U_j — an upcrossing at p_j, by Definition 11.100, since g passes from below z to above it there — then $(g')^+ = g'$ on U_j and, by the second fundamental theorem of calculus (Theorem 7.43),

$$\int_{\alpha_j}^{\beta_j} \big(g'(m)\big)^+\,\mathrm{d}m = g(\beta_j) - g(\alpha_j) = (z+\delta) - (z-\delta) = 2\delta\,. \tag{A.424}$$

If instead $g' < 0$ on U_j, then $(g')^+ = 0$ there and the contribution is 0; that is a downcrossing and is correctly not counted. Summing Equation (A.424) over the finitely many cells, the integral in Equation (A.423) equals 2δ times the number of j with $g'(p_j) > 0$, which is $N_z(g)$; dividing by 2δ gives the identity, with a value independent of δ. □

Remark A.222 (Why the hypotheses of the lemma are the hypotheses (H4)). The three conditions imposed on g are exactly what (H4) and the continuity of the one-dimensional Gaussian law provide for almost every path. That $X(m_i) \neq z$ almost surely is immediate: $X(m_i)$ is standard Gaussian and $\Pr(X(m_i) = z) = 0$ by Proposition 11.22. That no crossing is tangential is the second half of (H4), and it is assumed rather than derived — see Remark A.224.

A.22.4 Taking the expectation

Theorem A.223 (Tonelli and dominated convergence, as used here)**.** *Let $h(m,\omega) \geq 0$ be jointly measurable on $M \times \Omega$. Then $\omega \mapsto \int_M h(m,\omega)\mathrm{d}m$ and $m \mapsto \langle h(m,\cdot)\rangle$ are measurable and*

$$\Big\langle \int_M h(m,\cdot)\,\mathrm{d}m \Big\rangle = \int_M \langle h(m,\cdot)\rangle\,\mathrm{d}m\,, \tag{A.425}$$

both sides possibly infinite. And if $Y_\delta \to Y$ almost surely as $\delta \downarrow 0$ with $|Y_\delta| \le D$ for a single D with $\langle D\rangle < \infty$, then $\langle Y_\delta\rangle \to \langle Y\rangle$ [1894].
Rests on Definition 11.4.

Remark A.224 (What is quoted here). Two things, and they are the only ones.

First, Theorem A.223. Chapter 7 builds the Riemann–Darboux integral and no more, so neither Tonelli's theorem nor dominated convergence is available from anything earlier in this treatise; both belong to Lebesgue theory, and the same two statements are quoted for the same reason in Remark A.171. The interchange Equation (A.425) is unavoidable here: the object being averaged is an integral over M of a quantity that depends on the whole path, and there is no elementary truncation — of the kind used at Equation (11.32) to avoid dominated convergence in Lemma 11.44 — that reaches it. The dominated-convergence step is the passage from Equation (A.423), which holds path by path only for $\delta < \delta_0(g)$ with a threshold that depends on the path and has no positive lower bound over all paths, to a single limit under the expectation. The dominating variable is $D = \sup_{0<\delta<1} (2\delta)^{-1} \int_M \mathbf{1}_{\{|X-z|<\delta\}} (X')^+ \,\mathrm{d}m$, whose integrability is part of what is being assumed.

Second, the non-tangency half of (H4). It is stated as a hypothesis rather than derived. It is known to follow from $\sigma_1^2 > 0$ together with the smoothness already assumed, by an argument (Bulinskaya's lemma) that bounds the probability of the field being near z while its derivative is near 0 and requires the same Lebesgue theory; this treatise does not build it, and no elementary substitute is offered. It is not a vacuous assumption: a field with a genuine tangency at level z would touch the level without crossing it, and Lemma A.221 would fail on that path — the set $\{|g - z| < \delta\}$ would not be a finite union of monotone cells.

Everything else — the joint law Lemma A.220, the counting identity Lemma A.221, the two Gaussian integrals of Appendix A.22.5, and the assembly — is derived here.

A.22.5 Evaluation

Lemma A.225 (The mean positive part). *If $W \sim \mathcal{N}(0, \sigma^2)$ with $\sigma > 0$, then $\langle W^+\rangle = \sigma/\sqrt{2\pi}$.*
Rests on Definition 11.28 and Equation (7.27).

Proof. *Derives Lemma A.225.*
By Equation (11.20) and the substitution $w = \sigma y$ (Equation (7.27)),

$$\left\langle W^+ \right\rangle = \int_0^\infty w \, \frac{\mathrm{e}^{-w^2/(2\sigma^2)}}{\sqrt{2\pi}\,\sigma} \,\mathrm{d}w = \frac{\sigma}{\sqrt{2\pi}} \int_0^\infty y \, \mathrm{e}^{-y^2/2} \,\mathrm{d}y = \frac{\sigma}{\sqrt{2\pi}} \left[-\mathrm{e}^{-y^2/2}\right]_0^\infty = \frac{\sigma}{\sqrt{2\pi}} \,.$$

□

Lemma A.226 (The level factor). *Write $\varphi(v) = \mathrm{e}^{-v^2/2}/\sqrt{2\pi}$ for the standard Gaussian density. Then for every $z \in \mathbb{R}$ and $\delta > 0$ there is $\zeta_\delta \in [z - \delta, z + \delta]$ with*

$$\frac{1}{2\delta} \Pr(|X(m) - z| < \delta) = \varphi(\zeta_\delta) \,, \qquad |\varphi(\zeta_\delta) - \varphi(z)| \;\le\; \frac{\delta}{\sqrt{2\pi\mathrm{e}}} \,, \tag{A.426}$$

and the bound does not depend on m.
Rests on Definition 11.28 and Theorem 7.35.

Proof. *Derives Lemma A.226.*
By (H1) the variable $X(m)$ is standard Gaussian for every m, so $\Pr(|X(m) - z| < \delta) = \int_{z-\delta}^{z+\delta} \varphi(v)\mathrm{d}v$, independently of m. Since φ is continuous, the mean value theorem for integrals — apply Theorem 7.35 to the antiderivative Φ, whose derivative is φ by Proposition 11.22 —

gives $\int_{z-\delta}^{z+\delta}\varphi = 2\delta\,\varphi(\zeta_\delta)$ for some ζ_δ in the interval. Applying Theorem 7.35 once more, this time to φ itself, $|\varphi(\zeta_\delta)-\varphi(z)| \le \delta \sup_v |\varphi'(v)|$, and $\varphi'(v) = -v\varphi(v)$ has modulus maximised at $v = \pm 1$, where it equals $\mathrm{e}^{-1/2}/\sqrt{2\pi}$. □

Proof of Theorem A.219. *Derives Theorem A.219.*

By (H3) and Remark A.222, almost every sample path satisfies the hypotheses of Lemma A.221, so almost surely

$$N_z(X) = \lim_{\delta\downarrow 0} Y_\delta\,, \qquad Y_\delta = \frac{1}{2\delta}\int_{m_1}^{m_2} \mathbf{1}_{\{|X(m)-z|<\delta\}}\,\big(X'(m)\big)^+\,\mathrm{d}m\,. \tag{A.427}$$

Take expectations. The dominated-convergence clause of Theorem A.223 gives $\langle N_z(X)\rangle = \lim_{\delta\downarrow 0}\langle Y_\delta\rangle$, and the Tonelli clause — the integrand is non-negative — gives, for each fixed δ,

$$\langle Y_\delta\rangle = \frac{1}{2\delta}\int_{m_1}^{m_2} \Big\langle \mathbf{1}_{\{|X(m)-z|<\delta\}}\,\big(X'(m)\big)^+\Big\rangle\,\mathrm{d}m\,. \tag{A.428}$$

At each fixed m the indicator is a function of $X(m)$ alone and the positive part a function of $X'(m)$ alone, and those two are independent by Lemma A.220; so the expectation factorises, and by Lemmas A.225 and A.226,

$$\frac{1}{2\delta}\Big\langle \mathbf{1}_{\{|X(m)-z|<\delta\}}\,\big(X'(m)\big)^+\Big\rangle = \varphi(\zeta_\delta)\,\frac{\sigma_1(m)}{\sqrt{2\pi}}\,. \tag{A.429}$$

From Equations (A.421) and (A.428) (factorise the expectation at each m by independence, then evaluate the level factor and the mean positive part).

The point ζ_δ does not depend on m (Lemma A.226), so it comes outside the integral:

$$\langle Y_\delta\rangle = \frac{\varphi(\zeta_\delta)}{\sqrt{2\pi}}\int_{m_1}^{m_2}\sigma_1(m)\,\mathrm{d}m\,, \tag{A.430}$$

the integral being finite because σ_1 is continuous on the compact M (H4) and therefore bounded and Riemann integrable (Theorem 7.40). Letting $\delta\downarrow 0$ and using the uniform estimate of Equation (A.426),

$$\langle N_z(X)\rangle = \frac{\varphi(z)}{\sqrt{2\pi}}\int_{m_1}^{m_2}\sigma_1(m)\,\mathrm{d}m = \frac{\mathrm{e}^{-z^2/2}}{2\pi}\int_{m_1}^{m_2}\sigma_1(m)\,\mathrm{d}m\,,$$

since $\varphi(z)/\sqrt{2\pi} = \mathrm{e}^{-z^2/2}/(2\pi)$. That is Equation (A.420). □

Corollary A.227 (The stationary case)**.** *If in addition X is stationary, so that $r(n,n')$ depends only on $n-n'$, then σ_1 is the constant $\sqrt{\lambda_2}$ with $\lambda_2 = -r''(0)$, and*

$$\langle N_z(X)\rangle = \frac{L}{2\pi}\sqrt{\lambda_2}\,\mathrm{e}^{-z^2/2}\,, \qquad L = m_2 - m_1\,. \tag{A.431}$$

Rests on Theorem A.219.

Proof. *Derives Corollary A.227.*

With D_h as in Lemma A.220, the second-moment norm is continuous under mean-square convergence, so $\langle D_h D_{h'}\rangle \to \langle X'(m)^2\rangle$ as $h,h'\to 0$. On the other hand

$$\langle D_h D_{h'}\rangle = \frac{r(m+h,m+h') - r(m+h,m) - r(m,m+h') + r(m,m)}{h\,h'}\,, \tag{A.432}$$

a second-order difference quotient of the twice continuously differentiable r, which converges to $\partial_1\partial_2 r(m,m)$. Hence $\sigma_1(m)^2 = \partial_1\partial_2 r(m,m)$ in general. Now write $r(n,n') = \varrho(n-n')$ with ϱ twice continuously differentiable by (H2) and $\varrho(0)=1$; then $\partial_1 r = \varrho'(n-n')$ and $\partial_2\partial_1 r = -\varrho''(n-n')$, so $\sigma_1(m)^2 = -\varrho''(0) = \lambda_2$, independent of m, and the integral in Equation (A.420) is $L\sqrt{\lambda_2}$. □

Remark A.228. Appendix A.22 discharges the proof obligation of Theorem 11.102 in Section 11.6.2 of Chapter 11, the last of the results that section had to import. With it, the chain the look-elsewhere effect rests on is complete: Davies' bound Theorem 11.101 was already derived there from the intermediate value theorem and Markov's inequality; Theorem 11.103 — the exponential level dependence $\langle N_u \rangle = \langle N_{u_0} \rangle \, \mathrm{e}^{-(u-u_0)/2}$, which is what lets a search estimate a trials factor from upcrossings counted at a one-sigma threshold — follows from Equation (A.420) at $z = \sqrt{u}$; and Corollary 11.105 follows from those two. What is assumed and not proved is named in Remark A.224: two theorems of Lebesgue theory, and the absence of tangential crossings. The extension of Theorem 11.103 to a scan over several parameters remains, as Remark 11.104 says, reported and not derived — and nothing in this treatise uses it.

A.23 The Hilbert–Schmidt Theorem for Compact Self-Adjoint Operators

This appendix proves Theorem 12.44 of Chapter 12: a compact self-adjoint operator on a Hilbert space has an orthonormal system of eigenvectors, with real eigenvalues accumulating only at 0, in terms of which the operator is a norm- convergent sum of rank-one pieces. It is the one infinite-dimensional theorem that reproduces the finite-dimensional spectral theorem Theorem 5.75 without weakening any of its conclusions, and it is the theorem Hilbert proved for symmetric integral kernels [388] and Schmidt recast in the language used here [338].

Everything below rests on material already available: the numerical-radius formula $\|A\| = \sup_{\|x\|=1} |\langle x|Ax\rangle|$ (Proposition 12.43), Bessel's inequality (Proposition 12.27), the projection theorem (Theorem 12.18), and the equivalence of compactness and sequential compactness in a metric space (Theorem 6.31). No weak topology is used; the closing Remark A.236 says precisely what the standard weak-compactness argument would have supplied and why the elementary route replaces it.

A.23.1 Statement

Theorem A.229 (Hilbert–Schmidt)**.** *Let $\mathcal{H} \neq \{0\}$ be a Hilbert space and let $A \in \mathcal{B}(\mathcal{H})$ be compact and self-adjoint (Definition 12.41). Then there is a finite or countable orthonormal system $\{e_n\}$ in $\mathcal{H}$ and real numbers $\lambda_n \neq 0$ with $|\lambda_1| \geq |\lambda_2| \geq \cdots$ such that*

$$Ax = \sum_n \lambda_n \, \langle e_n|x\rangle \; e_n \,, \qquad \forall\, x \in \mathcal{H} \,, \tag{A.433}$$

the series converging in the norm of $\mathcal{H}$. If the system is infinite then $\lambda_n \longrightarrow 0$. Every eigenspace belonging to a non-zero eigenvalue is finite dimensional, $Ae_n = \lambda_n e_n$, and $\|A\| = \max_n |\lambda_n|$ when $A \neq 0$. Finally

$$\mathcal{H} = \ker A \oplus \overline{\mathit{span}\,\{e_n\}} \,, \tag{A.434}$$

so that adjoining any orthonormal basis of $\ker A$ *to $\{e_n\}$ produces an orthonormal basis of $\mathcal{H}$ consisting of eigenvectors of A.*

Rests on Definition 12.41, Proposition 12.43, and Theorem 12.30.

The proof occupies the rest of the section: the sequential form of compactness (Appendix A.23.2), the attainment of the supremum and the first eigenvector (Appendix A.23.3), the recursion (Appendix A.23.4), and the passage to the limit (Appendix A.23.5).

A.23.2 Compactness in sequential form

Lemma A.230 (Sequential characterisation)**.** *$A \in \mathcal{B}(\mathcal{H})$ is compact if and only if every bounded sequence (x_n) in $\mathcal{H}$ admits a subsequence (x_{n_k}) for which (Ax_{n_k}) converges in $\mathcal{H}$.*
Rests on Definition 12.41 and Theorem 6.31.

Proof. *Derives Lemma A.230.*

Suppose A is compact and let $\|x_n\| \le c$ for all n; we may assume $c > 0$. The vectors Ax_n/c lie in the image of the closed unit ball, hence in the set $K = \overline{A\{x \mid \|x\| \le 1\}}$, which is compact by hypothesis. A compact subset of the metric space $\mathcal{H}$ is sequentially compact (Theorem 6.31), so some subsequence Ax_{n_k}/c converges in K, and therefore Ax_{n_k} converges.

Conversely, assume the sequential property and let (y_m) be a sequence in K. Each y_m is a limit of points Ax with $\|x\| \le 1$, so we may choose x_m with $\|x_m\| \le 1$ and $\|y_m - Ax_m\| < 1/m$. By hypothesis some Ax_{m_k} converges, and then y_{m_k} converges to the same limit, which lies in the closed set K. Hence K is sequentially compact, hence compact by Theorem 6.31. □

Lemma A.231 (Restriction to an invariant closed subspace)**.** *Let A be compact and self-adjoint and let $M \subseteq \mathcal{H}$ be a closed subspace with $AM \subseteq M$. Then M is a Hilbert space, and the restriction $A|_M$ is a compact self-adjoint operator on M with $\|A|_M\| \le \|A\|$. Moreover $AM^\perp \subseteq M^\perp$.*
Rests on Lemma A.230, Theorem 12.18, and Definition 12.41.

Proof. *Derives Lemma A.231.*

A closed subspace of a complete metric space is complete, so M is a Hilbert space with the inherited inner product. Symmetry of $A|_M$ is inherited, and by Proposition 12.42 a symmetric operator defined on all of the Hilbert space M is self-adjoint there. Compactness is Lemma A.230: a bounded sequence in M is a bounded sequence in $\mathcal{H}$, so (Ax_n) has a convergent subsequence, whose limit lies in the closed set M. The norm bound is immediate, the supremum being taken over a smaller set. For the last claim, let $y \in M^\perp$ and $z \in M$; then $Az \in M$, so $\langle z|Ay\rangle = \langle Az|y\rangle = 0$, and $Ay \in M^\perp$. □

A.23.3 The supremum is attained: the first eigenvector

This is the step Chapter 12 left open. The numerical-radius formula Equation (12.26) exhibits $\|A\|$ as a supremum; for a compact operator the supremum is a maximum, and the maximising vector is an eigenvector.

Lemma A.232 (Attainment)**.** *Let $A \in \mathcal{B}(\mathcal{H})$ be compact and self-adjoint with $A \neq 0$. Then there are $e \in \mathcal{H}$ with $\|e\| = 1$ and $\lambda \in \mathbb{R}$ with $|\lambda| = \|A\|$ such that $Ae = \lambda e$.*
Rests on Propositions 12.42 and 12.43 and Lemma A.230.

Proof. *Derives Lemma A.232.*

By Proposition 12.43 there are unit vectors x_n with

$$|\langle x_n|Ax_n\rangle| \longrightarrow \|A\| \,. \tag{A.435}$$

Each number $\langle x_n|Ax_n\rangle$ is real, because A is self-adjoint (Proposition 12.42). A real sequence whose absolute values converge to $\|A\|$ has a subsequence converging to $+\|A\|$ or to $-\|A\|$: infinitely many of its terms are non-negative or infinitely many are negative, and along the corresponding indices the absolute value carries the sign. Relabel, and let

$$\langle x_n|Ax_n\rangle \longrightarrow \lambda\,, \qquad \lambda \in \mathbb{R}\,, \qquad |\lambda| = \|A\| \neq 0\,. \tag{A.436}$$

Expand, using λ real, $\|x_n\| = 1$, and $\langle Ax_n|x_n\rangle = \langle x_n|Ax_n\rangle$:

$$\|Ax_n - \lambda x_n\|^2 = \|Ax_n\|^2 - 2\lambda\,\langle x_n|Ax_n\rangle + \lambda^2\,. \tag{A.437}$$

Now $\|Ax_n\| \le \|A\| = |\lambda|$, so the right-hand side of Equation (A.437) is at most $2\lambda^2 - 2\lambda\,\langle x_n|Ax_n\rangle$, which tends to 0 by Equation (A.436). Hence

$$Ax_n - \lambda x_n \longrightarrow 0\,. \tag{A.438}$$

This much uses only self-adjointness; it says that λ is an *approximate* eigenvalue. Compactness converts the approximation into an eigenvector.

The sequence (x_n) is bounded, so by Lemma A.230 there is a subsequence with $Ax_{n_k} \longrightarrow y$ for some $y \in \mathcal{H}$. Since $\lambda \neq 0$ we may write

$$x_{n_k} = \frac{1}{\lambda}\Big(Ax_{n_k} - \big(Ax_{n_k} - \lambda x_{n_k}\big)\Big) \longrightarrow \frac{y}{\lambda} =: e\,,$$

by Equation (A.438). The norm is continuous (Corollary 12.5), so $\|e\| = \lim \|x_{n_k}\| = 1$; and A is continuous (Proposition 12.36), so $Ax_{n_k} \longrightarrow Ae$. But $Ax_{n_k} \longrightarrow y = \lambda e$. Limits in a metric space are unique, so $Ae = \lambda e$. □

A.23.4 The recursion

Lemma A.233 (Construction of the system)**.** *Let A be compact and self-adjoint. There are a finite or countable orthonormal system $\{e_n\}$ and real numbers $\lambda_n \neq 0$ with $Ae_n = \lambda_n e_n$ and $|\lambda_1| \ge |\lambda_2| \ge \cdots$, such that, writing $\mathcal{H}_1 = \mathcal{H}$ and*

$$\mathcal{H}_{N+1} = \{e_1, \dots, e_N\}^{\perp}\,, \qquad A_{N+1} = A|_{\mathcal{H}_{N+1}}\,, \tag{A.439}$$

one has $\|A_{N+1}\| = |\lambda_{N+1}|$ at every stage at which the construction continues, and the construction stops at stage N exactly when $A_N = 0$, i.e. when $\mathcal{H}_N \subseteq \ker A$.

Rests on Lemmas A.231 and A.232 and Theorem 12.18.

Proof. *Derives Lemma A.233.*

Set $\mathcal{H}_1 = \mathcal{H}$ and $A_1 = A$. Suppose $\mathcal{H}_N$ and A_N have been defined, with $\mathcal{H}_N$ a closed A-invariant subspace and $A_N = A|_{\mathcal{H}_N}$ compact and self-adjoint on it (Lemma A.231). If $A_N = 0$ the construction stops, and then every $x \in \mathcal{H}_N$ has $Ax = 0$. If $A_N \neq 0$, apply Lemma A.232 inside the Hilbert space $\mathcal{H}_N$: it produces a unit vector $e_N \in \mathcal{H}_N$ and a real λ_N with $|\lambda_N| = \|A_N\| \neq 0$ and $Ae_N = A_N e_N = \lambda_N e_N$.

The vector e_N lies in $\mathcal{H}_N$, hence is orthogonal to $e_1, \dots, e_{N-1}$, so the system stays orthonormal. Put $\mathcal{H}_{N+1} = \mathcal{H}_N \cap \{e_N\}^{\perp} = \{e_1, \dots, e_N\}^{\perp}$, which is closed (Proposition 12.17). It is A-invariant: for $x \in \mathcal{H}_{N+1}$ and $j \le N$,

$$\langle e_j|Ax\rangle = \langle Ae_j|x\rangle = \lambda_j^{*}\,\langle e_j|x\rangle = \lambda_j\,\langle e_j|x\rangle = 0\,, \tag{A.440}$$

using self-adjointness and $\lambda_j \in \mathbb{R}$; and $Ax \in \mathcal{H}_N$ because $\mathcal{H}_N$ is invariant. Finally $\|A_{N+1}\| \le \|A_N\|$ because A_{N+1} is a restriction of A_N, whence $|\lambda_{N+1}| \le |\lambda_N|$; the construction therefore delivers a non-increasing sequence of moduli, and it is exactly the statement $\|A_N\| = |\lambda_N|$ that Lemma A.232 supplies at each stage. □

Lemma A.234 (The eigenvalues tend to zero, with finite multiplicity)**.** *If the construction of Lemma A.233 does not stop, then $\lambda_n \longrightarrow 0$. Moreover, for every $\lambda \neq 0$ the eigenspace $\ker(A - \lambda\mathbb{1})$ is finite dimensional.*

Rests on Lemmas A.230 and A.233.

Proof. *Derives Lemma A.234.*

Both statements follow from one computation. Let (f_n) be an orthonormal sequence with $Af_n = \nu_n f_n$. For $n \neq m$, orthogonality gives

$$\|Af_n - Af_m\|^2 = \|\nu_n f_n - \nu_m f_m\|^2 = |\nu_n|^2 + |\nu_m|^2\,. \tag{A.441}$$

Eigenvalues. Apply this to $f_n = e_n$, $\nu_n = \lambda_n$. If (λ_n) does not tend to 0 there are $\varepsilon > 0$ and infinitely many indices with $|\lambda_n| \geq \varepsilon$; along them Equation (A.441) gives $\|Ae_n - Ae_m\|^2 \geq 2\varepsilon^2$, so (Ae_n) has no Cauchy subsequence, hence no convergent subsequence. Since (e_n) is bounded, this contradicts Lemma A.230. As the moduli are non-increasing, $\lambda_n \longrightarrow 0$.

Multiplicity. If $\ker(A - \lambda\mathbb{1})$ were infinite dimensional for some $\lambda \neq 0$, Gram–Schmidt (Proposition 12.23) would produce an infinite orthonormal sequence (f_n) inside it, all with $\nu_n = \lambda$, and Equation (A.441) would give $\|Af_n - Af_m\|^2 = 2\,|\lambda|^2 > 0$: the same contradiction. □

A.23.5 Passage to the limit

Proof of Theorem A.229. *Derives Theorem A.229.*

Let $\{e_n\}$, $\{\lambda_n\}$ be the system of Lemma A.233. Fix $x \in \mathcal{H}$ and put

$$x_N = x - \sum_{n=1}^{N} \langle e_n | x \rangle \; e_n \,. \tag{A.442}$$

Then $\langle e_j | x_N \rangle = \langle e_j | x \rangle - \langle e_j | x \rangle = 0$ for $j \leq N$, so $x_N \in \mathcal{H}_{N+1}$, and Bessel's inequality (Proposition 12.27) gives

$$\|x_N\|^2 = \|x\|^2 - \sum_{n=1}^{N} |\langle e_n | x \rangle|^2 \leq \|x\|^2 \,. \tag{A.443}$$

Applying A to Equation (A.442) and using $Ae_n = \lambda_n e_n$,

$$Ax - \sum_{n=1}^{N} \lambda_n \, \langle e_n | x \rangle \; e_n = Ax_N = A_{N+1} x_N \,, \tag{A.444}$$

the last equality because $x_N \in \mathcal{H}_{N+1}$. Therefore, by Lemma A.233 and Equation (A.443),

$$\left\| Ax - \sum_{n=1}^{N} \lambda_n \, \langle e_n | x \rangle \; e_n \right\| \leq \|A_{N+1}\| \; \|x_N\| \leq |\lambda_{N+1}| \; \|x\| \,. \tag{A.445}$$

If the construction stops at stage N then $A_N = 0$ and Equation (A.444) already gives Equation (A.433) as a finite sum. If it does not stop, $|\lambda_{N+1}| \longrightarrow 0$ by Lemma A.234, so the right-hand side of Equation (A.445) tends to 0 and Equation (A.433) holds with convergence in norm. The eigenvalue relation $Ae_n = \lambda_n e_n$, the ordering of the moduli and the finiteness of the non-zero eigenspaces are Lemmas A.233 and A.234. For $A \neq 0$, $\|A\| = \|A_1\| = |\lambda_1| = \max_n |\lambda_n|$, the maximum being attained because the moduli decrease.

It remains to prove Equation (A.434). Write $M = \overline{\operatorname{span}\{e_n\}}$, a closed subspace, so that $\mathcal{H} = M \oplus M^\perp$ by Theorem 12.18. If $x \in M^\perp$ then $\langle e_n | x \rangle = 0$ for every n, and Equation (A.433) gives $Ax = 0$: thus $M^\perp \subseteq \ker A$. Conversely if $Ax = 0$ then for every n,

$$0 = \langle e_n | Ax \rangle = \langle Ae_n | x \rangle = \lambda_n \, \langle e_n | x \rangle \;,$$

and $\lambda_n \neq 0$ forces $\langle e_n | x \rangle = 0$, so $x \in M^\perp$; hence $\ker A = M^\perp$, which is Equation (A.434). Every vector of $\ker A$ is an eigenvector with eigenvalue 0, so an orthonormal basis of $\ker A$ adjoined to $\{e_n\}$ is an orthonormal system of eigenvectors whose closed span is $M \oplus \ker A = \mathcal{H}$: an orthonormal basis of $\mathcal{H}$ in the sense of Definition 12.29. □

Remark A.235 (Where the orthonormal basis of the kernel comes from). The last sentence of Theorem A.229 needs an orthonormal basis of the closed subspace $\ker A$, and that is the only point at which the theorem is not constructive. If $\mathcal{H}$ is separable — the case of every

physical application, and the standing assumption of Theorem 12.33 — so is $\ker A$, and Gram–Schmidt applied to a countable dense set produces the basis (Corollary 12.24). For a non-separable $\mathcal{H}$ the existence of an orthonormal basis of $\ker A$ is a maximality statement proved with Zorn's lemma (Chapter 3); the system $\{e_n\}$ itself, on which the whole content of the theorem rests, is always countable and always constructed, never chosen.

Remark A.236 (What the weak topology would have bought, and why it is not needed). The route usually taken to Lemma A.232 [1481] passes through two statements about the weak topology, neither of which this treatise develops: that the closed unit ball of a Hilbert space is weakly sequentially compact, so that a maximising sequence has a weakly convergent subsequence $x_n \rightharpoonup e$; and that a compact operator carries weakly convergent sequences to norm convergent ones, so that $Ax_n \longrightarrow Ae$ and the supremum is attained at e. Both are true and both are proved in [1481], chapter VI.

The proof given above needs neither. The reason is Equation (A.438): self-adjointness alone forces the maximising sequence to satisfy $Ax_n - \lambda x_n \longrightarrow 0$ in *norm*, and once that is known the sequential form of compactness, Lemma A.230, is enough to extract a genuine eigenvector — the vector e is recovered from Ax_{n_k} by dividing by $\lambda \neq 0$, not by any weak limit. The argument therefore quotes nothing beyond Proposition 12.43 and Theorem 6.31, and Chapter 12 may drop the reservation with which Theorem 12.44 was first stated.

Remark A.237. Appendix A.23 discharges the proof obligation of Theorem 12.44 (Section 12.3.1). The theorem is what makes the integral operators Equation (12.28) of Chapter 10 — the Green functions of a boundary-value problem — carry a discrete spectrum of modes with a complete set of eigenfunctions, and it is the exact infinite-dimensional counterpart of Equation (5.105). It is also the last point at which the counterpart is exact: Example 12.56 exhibits a bounded self-adjoint operator, not compact, with no eigenvector at all, and the repair for that case is the projection-valued measure of Appendix A.24.

A.24 The Spectral Theorem for a Bounded Self-Adjoint Operator

This appendix proves Theorem 12.59 of Chapter 12, in both of the forms stated there: the existence and uniqueness of a projection-valued measure E on $\mathbb{R}$, supported on $\sigma(A)$, with $A = \int_{\sigma(A)} \lambda \, \mathrm{d}E(\lambda)$; and the unitary equivalence of A, on a separable Hilbert space, with multiplication by a bounded real function on a finite measure space. It is the theorem three of the quantum postulates of Chapter 77 are statements about (Remark 12.63), and it is the replacement, forced by Example 12.56, for the eigenbasis that Theorem 5.75 supplies in finite dimension.

The route is the classical one of von Neumann [664, 706] in the arrangement of Reed and Simon [1481]: first the polynomial calculus and the identity $\|p(A)\| = \sup_{\sigma(A)} |p|$, which is what makes the construction possible at all; then the continuous calculus, obtained by completing the polynomials in the supremum norm; then, for each pair of vectors, a complex measure on $\sigma(A)$; then the extension of the calculus to bounded Borel functions, whose values on indicator functions are the projections $E(\Omega)$; and finally the multiplication form. Two classical theorems are used and are not proved in this treatise — Stone–Weierstrass and Riesz–Markov. Each is stated precisely where it is used, and Remark A.251 collects them.

Throughout, $A \in \mathcal{B}(\mathcal{H})$ is self-adjoint, $\mathcal{H} \neq \{0\}$, and $\sigma(A) \subseteq \mathbb{R}$ is compact and non-empty (Theorems 12.54 and 12.55). We write $C(\sigma(A))$ for the continuous complex functions on $\sigma(A)$ with the supremum norm $\|f\|_\infty = \sup_{\lambda \in \sigma(A)} |f(\lambda)|$, and $B(\sigma(A))$ for the bounded Borel functions with the same norm.

A.24.1 Statement

Theorem A.238 (Spectral theorem, both forms)**.** *Let $A \in \mathcal{B}(\mathcal{H})$ be self-adjoint. Then:*

1. *there is exactly one projection-valued measure E on $\mathbb{R}$ (Definition 12.58) with $E(\mathbb{R} \setminus \sigma(A)) = 0$ and*
$$\langle x | Ay \rangle = \int_{\sigma(A)} \lambda \, \langle x | \mathrm{d}E(\lambda) y \rangle \,, \qquad \forall\, x, y \in \mathcal{H} \,, \tag{A.446}$$
and every $B \in \mathcal{B}(\mathcal{H})$ commuting with A commutes with every $E(\Omega)$;
2. *if $\mathcal{H}$ is separable there are a measure space (M, μ) with $\mu(M) < \infty$, a bounded real measurable function a on M, and a unitary $U : \mathcal{H} \longrightarrow L^2(M, \mu)$ with*
$$(UAU^{-1} f)(m) = a(m)\, f(m) \,, \qquad \forall\, f \in L^2(M, \mu) \,. \tag{A.447}$$

Rests on Definition 12.58, Theorem 12.55, and Proposition 12.43.

A.24.2 The polynomial calculus

For a polynomial $p(z) = \sum_{k=0}^{d} c_k z^k$ with complex coefficients write $p(A) = \sum_k c_k A^k \in \mathcal{B}(\mathcal{H})$, with $A^0 = \mathbb{1}$, and let $\bar{p}(z) = \sum_k c_k^* z^k$. Since $A^\dagger = A$, Equation (12.24) gives $p(A)^\dagger = \bar{p}(A)$.

Lemma A.239 (The norm of a self-adjoint operator lies in its spectrum)**.** *Let $B \in \mathcal{B}(\mathcal{H})$ be self-adjoint. Then $\|B\| \in \sigma(B)$ or $-\|B\| \in \sigma(B)$; consequently*
$$\|B\| = \sup_{\lambda \in \sigma(B)} |\lambda| \,. \tag{A.448}$$

Rests on Propositions 12.43 and 12.52 and Definition 12.49.

Proof. *Derives Lemma A.239.*

If $B = 0$ then $\sigma(B) = \{0\}$ by Theorem 12.54 and Proposition 12.52 and the claim is trivial, so let $B \neq 0$. Exactly as in Equation (A.436), choose unit vectors x_n with $\langle x_n | B x_n \rangle \longrightarrow \lambda$ where $\lambda \in \mathbb{R}$ and $|\lambda| = \|B\|$; this is possible by Proposition 12.43 and because $\langle x_n | B x_n \rangle$ is real (Proposition 12.42). Then, as in Equation (A.437),
$$\|(B - \lambda \mathbb{1}) x_n\|^2 = \|B x_n\|^2 - 2\lambda \, \langle x_n | B x_n \rangle + \lambda^2 \leq 2\lambda^2 - 2\lambda \, \langle x_n | B x_n \rangle \longrightarrow 0 \,. \tag{A.449}$$
If $B - \lambda \mathbb{1}$ had a bounded inverse R we would get $1 = \|x_n\| \leq \|R\| \, \|(B - \lambda \mathbb{1}) x_n\| \longrightarrow 0$, which is false; so $\lambda \in \sigma(B)$ with $|\lambda| = \|B\|$. Since $\sigma(B)$ is contained in the disc of radius $\|B\|$ (Proposition 12.52), Equation (A.448) follows. □

Lemma A.240 (Spectral mapping for polynomials)**.** *For every polynomial p and every $A \in \mathcal{B}(\mathcal{H})$,*
$$\sigma(p(A)) = p(\sigma(A)) = \{ p(\lambda) \mid \lambda \in \sigma(A) \} \,. \tag{A.450}$$

Rests on Definition 12.49 and Proposition 12.37.

Proof. *Derives Lemma A.240.*

If p is constant, $p \equiv c$, then $p(A) = c\mathbb{1}$ and both sides are $\{c\}$ (using $\sigma(A) \neq \varnothing$, Theorem 12.54). Otherwise let $\mu \in \mathbb{C}$ and factor the non-constant polynomial $p(z) - \mu$ over $\mathbb{C}$ (Theorem 8.19):
$$p(z) - \mu = c \prod_{j=1}^{d} (z - \alpha_j) \,, \qquad c \neq 0 \,, \tag{A.451}$$
so that, substituting A and using that polynomials in A commute,
$$p(A) - \mu \mathbb{1} = c \prod_{j=1}^{d} (A - \alpha_j \mathbb{1}) \,. \tag{A.452}$$

If every factor is invertible, so is the product, and $\mu \in \rho(p(A))$. Conversely suppose the product $T = \prod_j (A - \alpha_j \mathbb{1})$ is invertible and fix j. Its inverse T^{-1} commutes with A — from $TA = AT$ one gets $AT^{-1} = T^{-1}A$ on multiplying by T^{-1} on both sides — hence with every factor. Writing $S_j = \prod_{k \neq j} (A - \alpha_k \mathbb{1})$ we have $T = (A - \alpha_j \mathbb{1}) S_j = S_j (A - \alpha_j \mathbb{1})$, so

$$(A - \alpha_j \mathbb{1})\, S_j T^{-1} = \mathbb{1} = T^{-1} S_j\, (A - \alpha_j \mathbb{1})\,,$$

and $A - \alpha_j \mathbb{1}$ is invertible with inverse $S_j T^{-1} = T^{-1} S_j$. Therefore $\mu \in \sigma(p(A))$ if and only if some $\alpha_j \in \sigma(A)$; and by Equation (A.451) the α_j are exactly the roots of $p - \mu$, so this happens exactly when $\mu = p(\lambda)$ for some $\lambda \in \sigma(A)$. □

Proposition A.241 (The polynomial calculus is isometric)**.** *For every polynomial p and every self-adjoint $A \in \mathcal{B}(\mathcal{H})$,*

$$\|p(A)\| = \sup_{\lambda \in \sigma(A)} |p(\lambda)| = \|p\|_\infty\,. \tag{A.453}$$

Rests on Lemmas A.239 and A.240 and Proposition 12.39.

Proof. *Derives Proposition A.241.*

The operator $p(A)^\dagger p(A) = (\bar{p}\, p)(A)$ is self-adjoint, and $\bar{p}\, p$ is a polynomial. By the C^* identity Equation (12.25), then Lemma A.239 applied to it, then Lemma A.240,

$$\|p(A)\|^2 = \|(\bar{p}\, p)(A)\| = \sup_{\mu \in \sigma((\bar{p}\, p)(A))} |\mu| = \sup_{\lambda \in \sigma(A)} |\bar{p}(\lambda)\, p(\lambda)| = \sup_{\lambda \in \sigma(A)} |p(\lambda)|^2\,, \tag{A.454}$$

the last step because $\sigma(A) \subseteq \mathbb{R}$ (Theorem 12.55), so that $\bar{p}(\lambda) = p(\lambda)^*$ there. □

A.24.3 The continuous calculus

Theorem A.242 (Stone–Weierstrass; quoted)**.** *Let K be a compact Hausdorff space and let $\mathcal{A} \subseteq C(K)$ be a subalgebra that contains the constants, separates the points of K, and is closed under complex conjugation. Then $\mathcal{A}$ is dense in $C(K)$ for the supremum norm. For $K \subseteq \mathbb{R}$ compact the polynomials form such a subalgebra, and the statement reduces to the classical Weierstrass approximation theorem quoted in Remark 12.1.*

Rests on Definition 6.9.

Proposition A.243 (Continuous functional calculus)**.** *There is exactly one map $\Phi : C(\sigma(A)) \longrightarrow \mathcal{B}(\mathcal{H})$ that is linear, multiplicative, sends $1 \longmapsto \mathbb{1}$ and $\lambda \longmapsto A$, and is continuous for $\|\cdot\|_\infty$ and the operator norm. It satisfies, writing $f(A) = \Phi(f)$,*

$$\|f(A)\| = \|f\|_\infty\,, \qquad f(A)^\dagger = \bar{f}(A)\,, \qquad f \geq 0 \implies f(A) \geq 0\,, \tag{A.455}$$

and $f(A)$ commutes with every bounded operator commuting with A.

Rests on Propositions 12.61 and A.241 and Theorem A.242.

Proof. *Derives Proposition A.243.*

Well defined on polynomials. If two polynomials agree on $\sigma(A)$ their difference q has $\|q\|_\infty = 0$, so $q(A) = 0$ by Equation (A.453): the map $p|_{\sigma(A)} \longmapsto p(A)$ depends only on the restriction, and it is isometric.

Extension. The polynomials restricted to the compact set $\sigma(A) \subseteq \mathbb{R}$ are dense in $C(\sigma(A))$ by Theorem A.242. An isometric linear map defined on a dense subspace of a normed space, with values in the complete space $\mathcal{B}(\mathcal{H})$ (Proposition 12.37), extends uniquely to an isometry of the closure: given f, choose polynomials p_n with $\|p_n - f\|_\infty \longrightarrow 0$; then $\|p_n(A) - p_m(A)\| = \|p_n - p_m\|_\infty$ makes $(p_n(A))$ Cauchy, and its limit $\Phi(f)$ is independent of the approximating sequence by the same identity. Linearity and multiplicativity pass to

the limit because addition and multiplication are continuous in a Banach algebra (Proposition 12.37), and the first identity of Equation (A.455) is the limit of Equation (A.453). Taking adjoints term by term — legitimate because the adjoint is isometric (Proposition 12.39) — gives $\Phi(f)^\dagger = \Phi(\bar{f})$.

Positivity. If $f \geq 0$ on $\sigma(A)$ then $g = \sqrt{f}$ is continuous and real, so $\Phi(f) = \Phi(g)^2 = \Phi(g)^\dagger \Phi(g)$ is positive by Proposition 12.42(iv).

Commutation. If $BA = AB$ then B commutes with every polynomial in A, hence with the norm limits $\Phi(f)$.

Uniqueness is Proposition 12.61, already proved in the chapter. □

A.24.4 The spectral measures

Theorem A.244 (Riesz–Markov; quoted)**.** *Let K be a compact metric space. For every bounded linear functional ℓ on $C(K)$ there is exactly one regular complex Borel measure ν on K with*

$$\ell(f) = \int_K f \, \mathrm{d}\nu \,, \qquad \forall\, f \in C(K) \,, \tag{A.456}$$

and $\|\ell\|$ equals the total variation $|\nu|(K)$. If $\ell(f) \geq 0$ whenever $f \geq 0$, then ν is a positive measure and $\|\ell\| = \nu(K) = \ell(1)$. Regularity carries with it that $C(K)$ is dense in $L^2(K, \nu)$ for every positive finite Borel measure ν.

Rests on Definition 6.9.

Proposition A.245 (The measures $\mu_{x,y}$)**.** *For $x, y \in \mathcal{H}$ there is a unique regular complex Borel measure $\mu_{x,y}$ on $\sigma(A)$ with*

$$\langle x | f(A)\, y \rangle = \int_{\sigma(A)} f \, \mathrm{d}\mu_{x,y} \,, \qquad \forall\, f \in C(\sigma(A)) \,. \tag{A.457}$$

The assignment is linear in y, antilinear in x, obeys $\mu_{y,x} = \mu_{x,y}^*$ and $|\mu_{x,y}|(\sigma(A)) \leq \|x\|\,\|y\|$; and $\mu_x := \mu_{x,x}$ is a positive measure with $\mu_x(\sigma(A)) = \|x\|^2$.

Rests on Proposition A.243 and Theorems 12.46 and A.244.

Proof. *Derives Proposition A.245.*

The map $f \longmapsto \langle x | f(A) y \rangle$ is linear on $C(\sigma(A))$ and bounded, since by Equation (12.1) and Equation (A.455)

$$|\langle x | f(A) y \rangle| \leq \|x\|\, \|f(A)\|\, \|y\| = \|f\|_\infty \, \|x\|\, \|y\| \,. \tag{A.458}$$

Theorem A.244 supplies a unique regular complex Borel measure $\mu_{x,y}$ satisfying Equation (A.457), with $|\mu_{x,y}|(\sigma(A)) \leq \|x\|\,\|y\|$ by the norm statement there. Linearity in y and antilinearity in x hold for the functionals and therefore, by the uniqueness in Theorem A.244, for the measures. For the conjugation rule,

$$\left(\int f \, \mathrm{d}\mu_{x,y} \right)^* = \langle f(A) y | x \rangle = \left\langle y \middle| f(A)^\dagger x \right\rangle = \left\langle y \middle| \bar{f}(A) x \right\rangle = \int \bar{f} \, \mathrm{d}\mu_{y,x} \,,$$

and since $f \longmapsto \bar{f}$ exhausts $C(\sigma(A))$, uniqueness gives $\mu_{y,x} = \mu_{x,y}^*$. Finally, if $f \geq 0$ then $\langle x | f(A) x \rangle \geq 0$ by the positivity in Equation (A.455), so μ_x is a positive measure, and taking $f = 1$ in Equation (A.457) gives $\mu_x(\sigma(A)) = \langle x | x \rangle = \|x\|^2$. □

A.24.5 The Borel calculus

Proposition A.246 (Bounded Borel functional calculus)**.** *There is a unique map $g \longmapsto g(A)$ from $B(\sigma(A))$ to $\mathcal{B}(\mathcal{H})$ extending Φ and satisfying*

$$\langle x | g(A)\, y \rangle = \int_{\sigma(A)} g \, \mathrm{d}\mu_{x,y} \,, \qquad \forall\, x, y \in \mathcal{H} \,. \tag{A.459}$$

It is linear, multiplicative, satisfies $g(A)^\dagger = \bar{g}(A)$ and $\|g(A)\| \le \|g\|_\infty$, and $g(A)$ commutes with every bounded operator commuting with A.

Rests on Propositions A.243 and A.245 and Theorem 12.46.

Proof. *Derives Proposition A.246.*

Existence of the operator. Fix $g \in B(\sigma(A))$ and consider

$$b_g(x,y) = \int_{\sigma(A)} g \, \mathrm{d}\mu_{x,y} \,, \qquad |b_g(x,y)| \le \|g\|_\infty \, |\mu_{x,y}|\,(\sigma(A)) \le \|g\|_\infty \, \|x\| \, \|y\| \,,$$

which by Proposition A.245 is antilinear in x and linear in y. For fixed x the map $y \longmapsto b_g(x,y)$ is a bounded linear functional, so by Theorem 12.46 there is a unique vector $w(x)$ with $b_g(x,y) = \langle w(x)|y\rangle$; the map $x \longmapsto w(x)$ is linear — antilinearity in the first slot on both sides — and bounded by $\|g\|_\infty$. Its adjoint in the sense of Theorem 12.38 is the operator we call $g(A)$, so that Equation (A.459) holds with $\|g(A)\| \le \|g\|_\infty$. For continuous g the formula reproduces Equation (A.457), so the map extends Φ, and it is unique because Equation (A.459) determines all matrix elements. Linearity in g and $g(A)^\dagger = \bar{g}(A)$ follow from Equation (A.459) and $\mu_{y,x} = \mu_{x,y}^*$.

Multiplicativity, first step. Let $f \in C(\sigma(A))$ and $x, y \in \mathcal{H}$. For every $h \in C(\sigma(A))$,

$$\int h \, \mathrm{d}\mu_{x,f(A)y} = \langle x|h(A)f(A)y\rangle = \langle x|(hf)(A)y\rangle = \int hf \, \mathrm{d}\mu_{x,y} \,,$$

using multiplicativity of the continuous calculus. The two regular measures $\mu_{x,f(A)y}$ and $f\,\mu_{x,y}$ therefore integrate every continuous function alike, so they are equal by the uniqueness in Theorem A.244. Consequently, for $g \in B(\sigma(A))$,

$$\langle x|g(A)f(A)y\rangle = \int g \, \mathrm{d}\mu_{x,f(A)y} = \int gf \, \mathrm{d}\mu_{x,y} = \langle x|(gf)(A)y\rangle \,, \tag{A.460}$$

i.e. $g(A)f(A) = (gf)(A)$ for g Borel and f continuous. Taking adjoints in Equation (A.460) and replacing (f,g) by $(\bar{f},\bar{g})$ gives $f(A)g(A) = (fg)(A)$ as well.

Multiplicativity, second step. Now let $g \in B(\sigma(A))$ be fixed. For every $h \in C(\sigma(A))$, by the step just proved,

$$\int h \, \mathrm{d}\mu_{x,g(A)y} = \langle x|h(A)g(A)y\rangle = \langle x|(hg)(A)y\rangle = \int hg \, \mathrm{d}\mu_{x,y} \,,$$

so $\mu_{x,g(A)y} = g\,\mu_{x,y}$ by uniqueness again. Hence for any two bounded Borel g, g',

$$\langle x|g'(A)g(A)y\rangle = \int g' \, \mathrm{d}\mu_{x,g(A)y} = \int g'g \, \mathrm{d}\mu_{x,y} = \langle x|(g'g)(A)y\rangle \,. \tag{A.461}$$

Commutation. Let $BA = AB$. By Proposition A.243, B commutes with $f(A)$ for every continuous f, so for such f

$$\int f \, \mathrm{d}\mu_{B^\dagger x,y} = \left\langle B^\dagger x \middle| f(A)y \right\rangle = \langle x|Bf(A)y\rangle = \langle x|f(A)By\rangle = \int f \, \mathrm{d}\mu_{x,By} \,,$$

whence $\mu_{B^\dagger x,y} = \mu_{x,By}$, and evaluating Equation (A.459) on both sides gives $\langle x|Bg(A)y\rangle = \langle x|g(A)By\rangle$ for every Borel g. □

A.24.6 The projection-valued measure

Proof of Theorem A.238, part (1): existence. *Derives Theorem A.238.*

For a Borel set $\Omega \subseteq \mathbb{R}$ let χ_Ω be its indicator function, restricted to $\sigma(A)$, and put

$$E(\Omega) = \chi_\Omega(A) \,. \tag{A.462}$$

This is a bounded operator by Proposition A.246.

Projections. $\chi_\Omega^2 = \chi_\Omega$ and $\bar{\chi}_\Omega = \chi_\Omega$, so $E(\Omega)^2 = E(\Omega) = E(\Omega)^\dagger$: each $E(\Omega)$ is a projection in the sense of Proposition 12.21.

Normalisation and multiplicativity. $\chi_\varnothing = 0$ and $\chi_{\mathbb{R}} = 1$ on $\sigma(A)$ give $E(\varnothing) = 0$ and $E(\mathbb{R}) = \mathbb{1}$; also $E(\mathbb{R} \setminus \sigma(A)) = 0$, since that indicator vanishes identically on $\sigma(A)$, which is the support statement. And $\chi_{\Omega_1 \cap \Omega_2} = \chi_{\Omega_1}\chi_{\Omega_2}$ gives $E(\Omega_1 \cap \Omega_2) = E(\Omega_1)E(\Omega_2)$ by Equation (A.461).

Countable additivity. Finite additivity is linearity of the calculus: for disjoint Ω_1, Ω_2, $\chi_{\Omega_1 \cup \Omega_2} = \chi_{\Omega_1} + \chi_{\Omega_2}$. For a disjoint sequence $\{\Omega_n\}$ with union Ω, write $S_N = \sum_{n \le N} E(\Omega_n) = E(\bigcup_{n \le N} \Omega_n)$, so that $E(\Omega) - S_N = E(\Omega_{>N})$ with $\Omega_{>N} = \bigcup_{n>N} \Omega_n$. Since $E(\Omega_{>N})$ is a projection,

$$\|E(\Omega)x - S_N x\|^2 = \langle x | E(\Omega_{>N}) x \rangle = \mu_x(\Omega_{>N}) = \sum_{n>N} \mu_x(\Omega_n)\,, \tag{A.463}$$

using Equation (A.459) with $g = \chi_{\Omega_{>N}}$ and the countable additivity of the ordinary positive measure μ_x. The series $\sum_n \mu_x(\Omega_n) = \mu_x(\Omega) \le \|x\|^2$ converges, so its tail tends to 0, and Equation (12.36) holds. Thus E is a projection-valued measure in the sense of Definition 12.58.

It represents A. Taking $g = \chi_\Omega$ in Equation (A.459) identifies the complex measure of Definition 12.58 with the measure of Proposition A.245: $\langle x | E(\Omega) y \rangle = \mu_{x,y}(\Omega)$. Hence, taking $f(\lambda) = \lambda$ in Equation (A.457) — the continuous calculus assigns A to that function — we obtain Equation (A.446). The commutation statement is the last part of Proposition A.246. □

Lemma A.247 (Integration against a projection-valued measure)**.** *Let F be any projection-valued measure on $\mathbb{R}$ supported on a compact set K, and for $g \in B(K)$ define $\int g \,\mathrm{d}F$ by $\langle x | (\int g \,\mathrm{d}F) y \rangle = \int g \,\mathrm{d}\langle x | F y \rangle$. Then $g \longmapsto \int g \,\mathrm{d}F$ is linear and multiplicative.*

Rests on Definition 12.58 and Theorem 12.46.

Proof. *Derives Lemma A.247.*

Exactly as in Proposition A.246, the sesquilinear form is bounded by $\|g\|_\infty \|x\| \|y\|$ — the total variation of $\langle x | F(\cdot) y \rangle$ is at most $\|x\| \|y\|$, by the Cauchy–Schwarz inequality applied to $\langle x | F(\Omega) y \rangle = \langle F(\Omega) x | F(\Omega) y \rangle$ over a partition — so the operator exists, and linearity is clear. For multiplicativity, note first that for simple functions $g = \sum_i c_i \chi_{\Omega_i}$ and $g' = \sum_j c'_j \chi_{\Omega'_j}$ the property $F(\Omega)F(\Omega') = F(\Omega \cap \Omega')$ gives

$$\left(\int g \,\mathrm{d}F\right)\left(\int g' \,\mathrm{d}F\right) = \sum_{i,j} c_i c'_j \, F(\Omega_i \cap \Omega'_j) = \int g g' \,\mathrm{d}F\,.$$

A bounded Borel function is a uniform limit of simple Borel functions — partition the disc of radius $\|g\|_\infty$ into finitely many Borel pieces of diameter $< \varepsilon$ and take preimages — and $\|\int g \,\mathrm{d}F\| \le \|g\|_\infty$, so both sides pass to the uniform limit. □

Proof of Theorem A.238, part (1): uniqueness. *Derives Theorem A.238.*

Let E and E' both satisfy Equation (A.446) and be supported on $\sigma(A)$, and write $\nu_{x,y}, \nu'_{x,y}$ for the associated complex measures. By Lemma A.247, $\int \lambda^n \,\mathrm{d}E = (\int \lambda \,\mathrm{d}E)^n = A^n$ for every $n \ge 0$, and likewise for E'; hence

$$\int_{\sigma(A)} p \,\mathrm{d}\nu_{x,y} = \langle x | p(A) y \rangle = \int_{\sigma(A)} p \,\mathrm{d}\nu'_{x,y}$$

for every polynomial p. The polynomials are dense in $C(\sigma(A))$ (Theorem A.242) and both measures are finite, so the two integrate every continuous function alike; by the uniqueness in Theorem A.244, $\nu_{x,y} = \nu'_{x,y}$. Taking Ω Borel and x, y arbitrary gives $\langle x | E(\Omega) y \rangle = \langle x | E'(\Omega) y \rangle$, i.e. $E = E'$. □

A.24.7 The multiplication form

Definition A.248 (Cyclic vector and cyclic subspace)**.** For $x \in \mathcal{H}$ the *cyclic subspace* generated by x is

$$\mathcal{H}_x = \overline{\{f(A)\,x \mid f \in C(\sigma(A))\}}\,, \tag{A.464}$$

a closed A-invariant subspace containing $x = 1(A)x$. The vector x is *cyclic* for A if $\mathcal{H}_x = \mathcal{H}$.

Rests on Proposition A.243 and Theorem 12.18.

Lemma A.249 (The cyclic case)**.** *Let $x \neq 0$ be cyclic for A. Then there is a unitary $U : \mathcal{H} \longrightarrow L^2(\sigma(A), \mu_x)$ with $Uf(A)x = f$ for every $f \in C(\sigma(A))$, and*

$$(UAU^{-1}h)(\lambda) = \lambda\, h(\lambda)\,, \qquad \forall\, h \in L^2(\sigma(A), \mu_x)\,. \tag{A.465}$$

Rests on Definition A.248, Proposition A.245, and Theorem A.244.

Proof. *Derives Lemma A.249.*

For $f \in C(\sigma(A))$, using Equation (A.455) and Equation (A.457),

$$\|f(A)x\|^2 = \Big\langle x \Big| \bar{f}(A)f(A)x \Big\rangle = \Big\langle x \Big| (|f|^2)(A)x \Big\rangle = \int_{\sigma(A)} |f|^2 \,\mathrm{d}\mu_x = \|f\|^2_{L^2(\mu_x)}\,, \tag{A.466}$$

so $f(A)x \longmapsto f$ is a well-defined linear isometry from the dense subspace $\{f(A)x\}$ of $\mathcal{H}$ onto the subspace $C(\sigma(A))$ of $L^2(\sigma(A), \mu_x)$ — well defined because $f(A)x = g(A)x$ forces $\|f - g\|_{L^2(\mu_x)} = 0$ by Equation (A.466). Its target is dense by the regularity statement of Theorem A.244, and both spaces are complete, so the isometry extends to a unitary U (a densely defined isometry with dense range extends to a surjective isometry by taking limits, and Equation (12.3) then gives preservation of the inner product). Finally, for f continuous, $UAf(A)x = U(\lambda f)(A)x = \lambda f = \lambda \cdot (Uf(A)x)$, which is Equation (A.465) on a dense subspace; both sides are bounded, so it holds everywhere. □

Lemma A.250 (Decomposition into cyclic subspaces)**.** *Let $\mathcal{H}$ be separable and A self-adjoint. Then there are finitely or countably many non-zero vectors x_n such that the cyclic subspaces $\mathcal{H}_{x_n}$ are mutually orthogonal and*

$$\mathcal{H} = \bigoplus_n \mathcal{H}_{x_n}\,. \tag{A.467}$$

Rests on Definitions 12.32 and A.248 and Proposition 12.87.

Proof. *Derives Lemma A.250.*

Let $\{y_j\}_{j\in\mathbb{N}}$ be dense in $\mathcal{H}$ (Definition 12.32). Construct the x_n recursively. Put $K_0 = \mathcal{H}$. Given mutually orthogonal cyclic subspaces $\mathcal{H}_{x_1}, \dots, \mathcal{H}_{x_{n-1}}$, let K_{n-1} be the orthogonal complement of their sum. Each $\mathcal{H}_{x_i}$ is A-invariant, and A is self-adjoint, so K_{n-1} is A-invariant too (Lemma A.231), and it is closed. If $K_{n-1} = \{0\}$, stop. Otherwise let $j(n)$ be the least index with $P_{K_{n-1}} y_j \neq 0$ — such an index exists, since otherwise every y_j would lie in $K_{n-1}^{\perp}$ and, by density and closedness, so would every vector, forcing $K_{n-1} = \{0\}$ — and set $x_n = P_{K_{n-1}} y_{j(n)}$, $\mathcal{H}_{x_n} \subseteq K_{n-1}$.

By construction $j(1) < j(2) < \cdots$, because $P_{K_{n-1}} y_j = 0$ for every $j < j(n)$ not already used means $y_j \in \mathcal{H}_{x_1} \oplus \cdots \oplus \mathcal{H}_{x_{n-1}}$, while $y_{j(n)} =$ (its part in that sum) $+ x_n$ also lies in $\mathcal{H}_{x_1} \oplus \cdots \oplus \mathcal{H}_{x_n}$. Hence every y_j lies in $\bigoplus_n \mathcal{H}_{x_n}$, whose closure is therefore all of $\mathcal{H}$; that closure is the internal direct sum of Proposition 12.87, which is Equation (A.467). If instead the recursion stops because $K_{n-1} = \{0\}$, the sum is already $\mathcal{H}$. □

Proof of Theorem A.238, part (2). *Derives Theorem A.238.*

Take the decomposition Equation (A.467) and write A_n for the restriction of A to $\mathcal{H}_{x_n}$, a bounded self-adjoint operator on that Hilbert space for which x_n is cyclic, with $\sigma(A_n) \subseteq \sigma(A)$

and with the same functional calculus (the calculus of A leaves $\mathcal{H}_{x_n}$ invariant). Lemma A.249 gives unitaries $U_n : \mathcal{H}_{x_n} \longrightarrow L^2(\sigma(A), \mu_n)$, $\mu_n = \mu_{x_n}$, carrying A into multiplication by λ.

Let M be the disjoint union of countably many copies of $\sigma(A)$, the nth copy written $\sigma(A) \times \{n\}$, and define on it the measure

$$\mu(\Omega \times \{n\}) = c_n \, \mu_n(\Omega) \,, \qquad c_n = \frac{2^{-n}}{\|x_n\|^2} \,, \tag{A.468}$$

so that, by Proposition A.245, $\mu(M) = \sum_n c_n \, \|x_n\|^2 = \sum_n 2^{-n} \leq 1 < \infty$. Define $a(\lambda, n) = \lambda$, a bounded real measurable function on M because $\sigma(A)$ is compact and real. The map

$$U\Big(\sum_n v_n\Big)\Big|_{\sigma(A)\times\{n\}} = c_n^{-1/2} \, U_n v_n \,, \qquad v_n \in \mathcal{H}_{x_n} \,, \tag{A.469}$$

is unitary from $\mathcal{H}$ onto $L^2(M, \mu)$: on the nth block it is an isometry from $\mathcal{H}_{x_n}$ onto $L^2(\sigma(A), c_n \mu_n)$, because $\int \left| c_n^{-1/2} h \right|^2 \, c_n \mathrm{d}\mu_n = \int |h|^2 \, \mathrm{d}\mu_n$, and $L^2(M, \mu)$ is by construction the orthogonal direct sum of those blocks (Proposition 12.85). Since multiplication by λ is unaffected by the constant $c_n^{-1/2}$, Equation (A.465) gives Equation (A.447), which completes the proof of Theorem A.238 and, with it, of Theorem 12.59. □

Remark A.251 (What is quoted here). Two classical theorems enter the proof and are not derived in this treatise; every other step above is carried out from Chapter 12 and its predecessors.

- Theorem A.242 (Stone–Weierstrass) is used twice: to extend the polynomial calculus to $C(\sigma(A))$, and in the uniqueness argument. Only the special case of a compact subset of $\mathbb{R}$, where it is the Weierstrass approximation theorem, is ever needed; that theorem is already declared as quoted in Remark 12.1 and is used there for Proposition 12.61.

- Theorem A.244 (Riesz–Markov) is the representation of a bounded functional on $C(K)$ by a regular complex Borel measure, together with the uniqueness of that measure and the density of $C(K)$ in $L^2(K, \nu)$. It is a theorem of measure theory, and this treatise develops no measure theory (Remark 12.1); it is what converts the operator inequality Equation (A.458) into a *measure*, and there is no route to a projection-valued measure that avoids it. Statement and proof: [1481], chapter IV.

Nothing else is assumed. In particular the polynomial identity Equation (A.453) — the step that makes the whole construction possible, and the one a reader should check first — rests only on the C^* identity Equation (12.25) and the numerical-radius formula Equation (12.26), both proved in the chapter.

Remark A.252. Appendix A.24 discharges the proof obligation of Theorem 12.59 (Section 12.4.2). The projection-valued measure it constructs is what Definition 12.60 integrates against, so the functional calculus $f(A)$ of the chapter — unique by Proposition 12.61 — now exists as well as being unique; Proposition A.246 is that existence statement for bounded Borel f. The theorem is used again in Appendix A.25, where the unbounded case is derived from it and the exponential $\exp(-\mathrm{i}Ht/\hbar)$ is defined by Equation (A.459), and in Appendix A.27, whose direct-integral decomposition is Lemma A.250 read fibrewise. Physically it is Remark 12.63: the support of E is the set of possible measured values, and $\|E(\Omega)\psi\|^2$ is the Born probability.

A.25 Stone's Theorem on One-Parameter Unitary Groups

This appendix proves the two halves of Theorem 12.66 (Chapter 12) that Proposition 12.67 left open: that the domain

$$D(H)=\left\{x\in\mathcal{H}\;\middle|\;\lim_{t\to0}\frac{U(t)x-x}{t}\ \text{exists in }\mathcal{H}\right\},\qquad Hx=\mathrm{i}\hbar\lim_{t\to0}\frac{U(t)x-x}{t},\tag{A.470}$$

is dense and that H is self-adjoint on it, not merely symmetric; and the converse, that every self-adjoint operator — bounded or not — exponentiates to a strongly continuous one-parameter unitary group. Together with Proposition 12.67 this establishes the bijection asserted by Theorem 12.66, which is what makes the two halves of the abstract Schrödinger equation Equation (12.48) equivalent statements [707].

Units are carried explicitly, as everywhere in this treatise. The group parameter t has the unit s, the generator H the unit J, and $\hbar$ the unit J s, so that $Ht/\hbar$ is a pure number; the energy scale $\varepsilon>0$ introduced in Appendix A.25.5 likewise has the unit J, and the spectral variable λ is an energy. The smoothing function φ of Appendix A.25.3 has the unit 1/s, so that $\int\varphi(t)\,\mathrm{d}t$ is dimensionless.

A.25.1 Statement

Theorem A.253 (Stone)**.** *Let $\{U(t)\}_{t\in\mathbb{R}}$ be a strongly continuous one-parameter unitary group on a Hilbert space $\mathcal{H}$ (Definition 12.64). Then the domain Equation (A.470) is dense and H is self-adjoint on it. Conversely, if H is any self-adjoint operator on $\mathcal{H}$ (Definition 12.72), then $U(t)=\exp(-\mathrm{i}Ht/\hbar)$, defined by the functional calculus of Proposition A.246 applied to the projection-valued measure of Proposition A.262, is a strongly continuous one-parameter unitary group whose generator in the sense of Equation (A.470) is exactly H. The two constructions are mutually inverse.*

Rests on Definition 12.64, Proposition 12.67, and Theorem A.238.

A.25.2 Vector-valued integrals

The smoothing argument needs to integrate a continuous $\mathcal{H}$-valued function. Nothing more than the Riemann integral is required, and it is built exactly as on the line.

Lemma A.254 (Riemann integral of a continuous curve)**.** *Let $G\colon[a,b]\longrightarrow\mathcal{H}$ be continuous. Then the Riemann sums of G over tagged partitions converge, as the mesh tends to 0, to a vector $\int_a^b G(t)\,\mathrm{d}t\in\mathcal{H}$, and*

$$\left\langle w\middle|\int_a^b G(t)\,\mathrm{d}t\right\rangle=\int_a^b\langle w|G(t)\rangle\,\mathrm{d}t\,,\qquad\left\|\int_a^b G(t)\,\mathrm{d}t\right\|\le\int_a^b\|G(t)\|\,\mathrm{d}t\,,\tag{A.471}$$

for every $w\in\mathcal{H}$. If $B\in\mathcal{B}(\mathcal{H})$ then $B\int_a^b G=\int_a^b BG$.

Rests on Definition 12.2 and Proposition 12.4.

Proof. *Derives Lemma A.254.*

G is uniformly continuous on the compact interval $[a,b]$: the Heine–Cantor argument of Theorem 7.25 uses only that the target is a metric space, and $\mathcal{H}$ is one. So given $\eta>0$ there is $\delta>0$ with $\|G(t)-G(s)\|<\eta$ whenever $|t-s|<\delta$. Two tagged partitions of mesh $<\delta$ have a common refinement, and comparing each with the refinement bounds the difference of their Riemann sums by $2\eta(b-a)$; the sums therefore form a Cauchy net, which converges because $\mathcal{H}$ is complete (Definition 12.2). Both identities in Equation (A.471) hold for Riemann sums — the first by linearity of the inner product in its second slot, the second by the triangle inequality — and pass to the limit, the first by continuity of the inner product (Proposition 12.4). The same argument gives $B\int G=\int BG$ for a bounded B. □

A.25.3 The domain is dense

Lemma A.255 (Smoothed vectors lie in the domain)**.** *Let U be a strongly continuous one-parameter unitary group, let $\varphi\colon \mathbb{R} \longrightarrow \mathbb{R}$ be continuously differentiable with support in a compact interval, and for $x \in \mathcal{H}$ put*

$$x_\varphi = \int_{\mathbb{R}} \varphi(t)\, U(t)x \,\mathrm{d}t\,. \tag{A.472}$$

Then $x_\varphi \in D(H)$ and

$$H\, x_\varphi = -\mathrm{i}\hbar \int_{\mathbb{R}} \varphi'(t)\, U(t)x \,\mathrm{d}t = -\mathrm{i}\hbar\, x_{\varphi'}\,. \tag{A.473}$$

Rests on Lemma A.254, Definition 12.64, and Equation (A.470).

Proof. *Derives Lemma A.255.*

The integrand is continuous, by strong continuity of U and continuity of φ, and vanishes outside a compact interval, so Lemma A.254 defines x_φ. Using $U(s)U(t) = U(t+s)$ and the substitution $t \longmapsto t - s$ — a translation, which the Riemann integral of Lemma A.254 respects because it acts on tagged partitions by translation —

$$U(s)\, x_\varphi = \int_{\mathbb{R}} \varphi(t)\, U(t+s)x \,\mathrm{d}t = \int_{\mathbb{R}} \varphi(t-s)\, U(t)x \,\mathrm{d}t\,. \tag{A.474}$$

Hence, for $s \neq 0$,

$$\frac{U(s)x_\varphi - x_\varphi}{s} = \int_{\mathbb{R}} \frac{\varphi(t-s) - \varphi(t)}{s}\, U(t)x \,\mathrm{d}t\,. \tag{A.475}$$

By the mean value theorem, $[\varphi(t-s)-\varphi(t)]/s = -\varphi'(t-\theta s)$ for some $\theta = \theta(t,s) \in (0,1)$, and φ' is continuous with compact support, hence uniformly continuous; so $[\varphi(\cdot - s) - \varphi]/s \longrightarrow -\varphi'$ uniformly as $s \to 0$, with all supports inside one fixed compact interval $[a,b]$ of length ℓ once $|s| \leq 1$. The second estimate of Equation (A.471) and $\|U(t)x\| = \|x\|$ then give

$$\left\| \frac{U(s)x_\varphi - x_\varphi}{s} + \int_{\mathbb{R}} \varphi'(t) U(t)x \,\mathrm{d}t \right\| \leq \ell\, \|x\| \sup_t \left| \frac{\varphi(t-s) - \varphi(t)}{s} + \varphi'(t) \right| \longrightarrow 0\,.$$

So the limit in Equation (A.470) exists and equals $-x_{\varphi'}$; multiplying by $\mathrm{i}\hbar$ gives Equation (A.473). □

Proposition A.256 (Density)**.** *$D(H)$ is dense in $\mathcal{H}$.*

Rests on Lemma A.255 and Definition 12.64.

Proof. *Derives Proposition A.256.*

For $n \in \mathbb{N}$ define

$$\varphi_n(t) = \frac{15\, n}{16} \left(1 - n^2 t^2\right)^2 \quad \text{for } |t| \leq \frac{1}{n}\,, \qquad \varphi_n(t) = 0 \ \text{ otherwise}\,. \tag{A.476}$$

Each φ_n is continuously differentiable — at $t = \pm 1/n$ both φ_n and φ_n' vanish, so the pieces match — non-negative, supported in $[-1/n, 1/n]$, and normalised: substituting $u = nt$,

$$\int_{\mathbb{R}} \varphi_n(t) \,\mathrm{d}t = \frac{15}{16} \int_{-1}^{1} \left(1 - u^2\right)^2 \mathrm{d}u = \frac{15}{16} \cdot \frac{16}{15} = 1\,,$$

a pure number, as it must be: φ_n carries the unit $1/\mathrm{s}$ and $\mathrm{d}t$ the unit s.

Fix $x \in \mathcal{H}$. Since $\int \varphi_n = 1$,

$$\|x_{\varphi_n} - x\| = \left\| \int_{\mathbb{R}} \varphi_n(t) \big(U(t)x - x\big) \mathrm{d}t \right\| \leq \sup_{|t| \leq 1/n} \|U(t)x - x\|\,,$$

by Equation (A.471) and non-negativity of φ_n. The right-hand side tends to 0 as $n \to \infty$, by strong continuity of U at $t = 0$ (Definition 12.64). Each x_{φ_n} lies in $D(H)$ by Lemma A.255, so x is a limit of vectors of $D(H)$. □

A.25.4 The generator is closed and self-adjoint

Lemma A.257 (Integrated form of the equation of motion)**.** *For $x \in D(H)$ and every t,*

$$U(t)x - x = -\frac{\mathrm{i}}{\hbar}\int_0^t U(r)\,Hx\,\mathrm{d}r\,. \tag{A.477}$$

Rests on Proposition 12.67 and Lemma A.254.

Proof. *Derives Lemma A.257.*

Fix $w \in \mathcal{H}$ and let $g(r) = \langle w|U(r)x\rangle$. By Equation (12.46) the curve $r \longmapsto U(r)x$ is differentiable in norm with derivative $-\mathrm{i}\hbar^{-1}U(r)Hx$, so g is differentiable with $g'(r) = -\mathrm{i}\hbar^{-1}\langle w|U(r)Hx\rangle$, which is continuous in r. The fundamental theorem of calculus (Theorem 7.43) and the first identity of Equation (A.471) give

$$\langle w|U(t)x - x\rangle = g(t) - g(0) = \int_0^t g'(r)\,\mathrm{d}r = \left\langle w\middle| -\frac{\mathrm{i}}{\hbar}\int_0^t U(r)Hx\,\mathrm{d}r\right\rangle .$$

As w is arbitrary, Equation (5.31) gives Equation (A.477). □

Proposition A.258 (The generator is closed)**.** *H is a closed operator (Definition 12.70).*
Rests on Lemma A.257 and Equation (A.470).

Proof. *Derives Proposition A.258.*

Let $x_n \in D(H)$ with $x_n \longrightarrow x$ and $Hx_n \longrightarrow z$. Each term of Equation (A.477) converges: the left side to $U(t)x - x$, since $U(t)$ is bounded; and the right side to $-\mathrm{i}\hbar^{-1}\int_0^t U(r)z\,\mathrm{d}r$, because

$$\left\|\int_0^t U(r)(Hx_n - z)\mathrm{d}r\right\| \le |t|\;\|Hx_n - z\| \longrightarrow 0\,.$$

Hence $U(t)x - x = -\mathrm{i}\hbar^{-1}\int_0^t U(r)z\,\mathrm{d}r$ for every t. Dividing by $t \neq 0$ and using continuity of $r \longmapsto U(r)z$ at $r = 0$,

$$\left\|\frac{1}{t}\int_0^t U(r)z\,\mathrm{d}r - z\right\| \le \sup_{|r|\le|t|}\|U(r)z - z\| \longrightarrow 0\,,$$

so the limit Equation (A.470) exists for x and equals $-\mathrm{i}\hbar^{-1}z$ before multiplication by $\mathrm{i}\hbar$. That is, $x \in D(H)$ and $Hx = z$: the graph is closed. □

Proposition A.259 (The generator is self-adjoint)**.** *H is self-adjoint on $D(H)$.*
Rests on Propositions 12.67, A.256 and A.258.

Proof. *Derives Proposition A.259.*

H is densely defined (Proposition A.256) and symmetric (Equation (12.45)), so $H \subseteq H^\dagger$ and the adjoint exists. Let $\varepsilon > 0$ be an energy.

Step 1: $\ker(H^\dagger \mp \mathrm{i}\varepsilon) = \{0\}$. Let $y \in D(H^\dagger)$ with $H^\dagger y = \mathrm{i}\varepsilon y$, fix $x \in D(H)$, and put $f(t) = \langle y|U(t)x\rangle$. By Proposition 12.67, $U(t)x \in D(H)$ and the curve is differentiable, so

$$f'(t) = \left\langle y\middle| -\frac{\mathrm{i}}{\hbar}H\,U(t)x\right\rangle = -\frac{\mathrm{i}}{\hbar}\left\langle H^\dagger y\middle|U(t)x\right\rangle = -\frac{\mathrm{i}}{\hbar}\langle \mathrm{i}\varepsilon y|U(t)x\rangle = -\frac{\varepsilon}{\hbar}f(t)\,, \tag{A.478}$$

where the second equality is Equation (12.50) and the third uses the antilinearity Equation (5.36), which turns $\mathrm{i}\varepsilon$ in the first slot into $-\mathrm{i}\varepsilon$ and cancels one factor of i against the prefactor. Hence $f(t) = f(0)\,\mathrm{e}^{-\varepsilon t/\hbar}$. But $|f(t)| \le \|y\|\,\|U(t)x\| = \|y\|\,\|x\|$ for all $t \in \mathbb{R}$, while $\mathrm{e}^{-\varepsilon t/\hbar} \longrightarrow \infty$ as $t \longrightarrow -\infty$; so $f(0) = \langle y|x\rangle = 0$. As x ranges over the dense set $D(H)$, $y = 0$. The case $H^\dagger y = -\mathrm{i}\varepsilon y$ is the same with $t \to +\infty$.

Step 2: $\mathrm{im}(H \pm \mathrm{i}\varepsilon) = \mathcal{H}$. For $x \in D(H)$, symmetry makes the cross terms cancel:

$$\|(H \pm \mathrm{i}\varepsilon)x\|^2 = \|Hx\|^2 + \varepsilon^2\,\|x\|^2 \ge \varepsilon^2\,\|x\|^2\,. \tag{A.479}$$

If $(H+\mathrm{i}\varepsilon)x_n \longrightarrow u$ then, by Equation (A.479) applied to differences, both (x_n) and (Hx_n) are Cauchy; H is closed (Proposition A.258), so $x_n \longrightarrow x \in D(H)$ with $(H+\mathrm{i}\varepsilon)x = u$. The image is therefore closed. It is also dense: exactly as in Equation (12.53), $y \perp \mathrm{im}(H+\mathrm{i}\varepsilon)$ means $\langle y|Hx\rangle = \langle \mathrm{i}\varepsilon y|x\rangle$ for all $x \in D(H)$, i.e. $y \in \ker(H^\dagger - \mathrm{i}\varepsilon) = \{0\}$ by Step 1. A dense closed subspace is everything, and likewise for $H - \mathrm{i}\varepsilon$.

Step 3. Let $y \in D(H^\dagger)$. By Step 2 there is $x \in D(H)$ with $(H-\mathrm{i}\varepsilon)x = (H^\dagger - \mathrm{i}\varepsilon)y$. Since $H \subseteq H^\dagger$, this reads $(H^\dagger - \mathrm{i}\varepsilon)(y-x) = 0$, so $y - x = 0$ by Step 1 and $y = x \in D(H)$. Hence $D(H^\dagger) = D(H)$ and $H = H^\dagger$. □

A.25.5 The converse: exponentiating a self-adjoint operator

The converse needs a projection-valued measure for an operator that is in general unbounded, and Theorem A.238 supplies one only for bounded operators. The gap is closed by the Cayley transform: the unbounded H is traded for a *unitary* operator V, for which the construction of Appendix A.24 goes through with three changes displayed below, and the measure is then transported back along an explicit Möbius map.

Lemma A.260 (Cayley transform of a self-adjoint operator)**.** *Let H be self-adjoint and let $\varepsilon > 0$ be an energy. Then $H \pm \mathrm{i}\varepsilon$ maps $D(H)$ bijectively onto $\mathcal{H}$, the operator*

$$V = (H - \mathrm{i}\varepsilon)(H + \mathrm{i}\varepsilon)^{-1} \tag{A.480}$$

is unitary, $\ker(\mathbb{1} - V) = \{0\}$*, and*

$$(H+\mathrm{i}\varepsilon)^{-1} = \frac{\mathbb{1} - V}{2\mathrm{i}\varepsilon}\,, \qquad D(H) = \mathrm{im}\,(\mathbb{1} - V)\ . \tag{A.481}$$

Rests on Propositions 12.73 and A.259 and Definition 12.72.

Proof. *Derives Lemma A.260.*

The identity Equation (A.479) holds for any symmetric H, so $H \pm \mathrm{i}\varepsilon$ is injective with $\|(H \pm \mathrm{i}\varepsilon)x\| \geq \varepsilon\,\|x\|$; and H is closed (Proposition 12.73), so, exactly as in Step 2 of Proposition A.259, the image is closed. It is dense because $\big(\mathrm{im}(H \pm \mathrm{i}\varepsilon)\big)^\perp = \ker(H^\dagger \mp \mathrm{i}\varepsilon) = \ker(H \mp \mathrm{i}\varepsilon) = \{0\}$, the middle equality being $H = H^\dagger$ and the last one Equation (A.479) again. Hence $\mathrm{im}(H \pm \mathrm{i}\varepsilon) = \mathcal{H}$ and $H \pm \mathrm{i}\varepsilon$ is a bijection of $D(H)$ onto $\mathcal{H}$. Thus V is defined on all of $\mathcal{H}$, and by Equation (A.479)

$$\|V(H+\mathrm{i}\varepsilon)x\| = \|(H-\mathrm{i}\varepsilon)x\| = \|(H+\mathrm{i}\varepsilon)x\|\ ,$$

so V is isometric; its image is $\mathrm{im}(H - \mathrm{i}\varepsilon) = \mathcal{H}$, so it is unitary. Writing $u = (H+\mathrm{i}\varepsilon)x$,

$$(\mathbb{1} - V)u = (H+\mathrm{i}\varepsilon)x - (H-\mathrm{i}\varepsilon)x = 2\mathrm{i}\varepsilon\, x\,, \tag{A.482}$$

which is Equation (A.481) — both the formula for the inverse and, since x runs over $D(H)$ as u runs over $\mathcal{H}$, the identification of $\mathrm{im}(\mathbb{1} - V)$ with $D(H)$. If $Vu = u$ then Equation (A.482) gives $x = 0$, hence $u = (H+\mathrm{i}\varepsilon)x = 0$. □

Proposition A.261 (Spectral theorem for a unitary operator)**.** *Let $V \in \mathcal{B}(\mathcal{H})$ be unitary and let $\mathbb{T} = \{z \in \mathbb{C} \mid |z| = 1\}$. Then $\sigma(V) \subseteq \mathbb{T}$, and there is a unique projection-valued measure F on $\mathbb{T}$, supported on $\sigma(V)$, with $V = \int z\,\mathrm{d}F(z)$; the associated bounded Borel calculus $g \longmapsto g(V)$ has all the properties of Proposition A.246.*

Rests on Theorem A.238 and Propositions 12.52 and A.246.

Proof. *Derives Proposition A.261.*

The construction of Appendix A.24 is repeated with Laurent polynomials $q(z) = \sum_{k=-m}^{m} c_k z^k$ in place of polynomials, $q(V) = \sum_k c_k V^k$ with $V^{-1} = V^\dagger$. Three steps need a

new argument; everything after them — Propositions A.245 and A.246 and the construction and uniqueness of the projection-valued measure in Appendix A.24.6 — uses only that Φ is an isometric, multiplicative, conjugation-preserving map on $C(K)$ for a compact $K \subseteq \mathbb{C}$, and applies word for word.

(a) The spectrum lies on the circle. $\|V\| = 1$, so $\sigma(V)$ lies in the closed unit disc (Proposition 12.52). For $|z| < 1$ write $V - z\mathbb{1} = V(\mathbb{1} - zV^{-1})$; since $\|zV^{-1}\| = |z| < 1$ the bracket is invertible by the geometric series of Proposition 12.52 and V is invertible, so $z \in \rho(V)$.

(b) Spectral mapping. Fix $\nu \in \mathbb{C}$ and put $r(z) = z^m(q(z) - \nu)$, an ordinary polynomial. Then $r(V) = V^m(q(V) - \nu\mathbb{1})$ with V^m invertible, so $q(V) - \nu\mathbb{1}$ is invertible exactly when $r(V)$ is, i.e. exactly when $0 \notin \sigma(r(V)) = r(\sigma(V))$ (Lemma A.240). Since $z \neq 0$ on $\sigma(V) \subseteq \mathbb{T}$, $r(z) = 0$ there means $q(z) = \nu$; hence $\sigma(q(V)) = q(\sigma(V))$.

(c) The norm identity. With $\bar{q}(z) = \sum_k c_k^* z^{-k}$ one has $q(V)^\dagger = \bar{q}(V)$, and on $\mathbb{T}$, where $z^{-1} = z^*$, $\bar{q}(z) = q(z)^*$. So $(\bar{q}\,q)(V)$ is self-adjoint and, by Equation (12.25), Lemma A.239 and (b),

$$\|q(V)\|^2 = \|(\bar{q}\,q)(V)\| = \sup_{z \in \sigma(V)} |q(z)|^2 \,. \tag{A.483}$$

Laurent polynomials restricted to the compact set $\sigma(V)$ form a subalgebra of $C(\sigma(V))$ that contains the constants, is closed under conjugation (by (c)) and separates points (the function z does), so Theorem A.242 makes it dense; with Equation (A.483) this yields the isometric continuous calculus, and the rest is Appendix A.24 unchanged. □

Proposition A.262 (Spectral theorem for an unbounded self-adjoint operator)**.** *Let H be self-adjoint. There is a projection-valued measure E on $\mathbb{R}$ such that, writing $\mu_x(\Omega) = \langle x|E(\Omega)x\rangle$,*

$$D(H) = \left\{ x \in \mathcal{H} \;\middle|\; \int_{\mathbb{R}} \lambda^2 \,\mathrm{d}\mu_x(\lambda) < \infty \right\}, \qquad \langle y|Hx\rangle = \int_{\mathbb{R}} \lambda \,\langle y|\mathrm{d}E(\lambda)x\rangle \tag{A.484}$$

for $x \in D(H)$, $y \in \mathcal{H}$. For bounded Borel g the operator $g(H) = \int g\,\mathrm{d}E$ is bounded with $\|g(H)\| \leq \|g\|_\infty$, and $g \longmapsto g(H)$ is linear, multiplicative and $*$-preserving.

Rests on Lemma A.260 and Propositions A.246 and A.261.

Proof. *Derives Proposition A.262.*

Let V be the Cayley transform Equation (A.480) and F its projection-valued measure (Proposition A.261). Write

$$w(z) = \frac{1-z}{2\mathrm{i}\varepsilon}, \qquad h(z) = \mathrm{i}\varepsilon\,\frac{1+z}{1-z} \quad (z \neq 1), \tag{A.485}$$

so that $(H + \mathrm{i}\varepsilon)^{-1} = w(V)$ by Equation (A.481).

h is real, and $F(\{1\}) = 0$. For $|z| = 1$, $z \neq 1$, multiply numerator and denominator by $1 - z^*$:

$$\frac{1+z}{1-z} = \frac{(1+z)(1-z^*)}{|1-z|^2} = \frac{z - z^*}{|1-z|^2} = \frac{2\mathrm{i}\,\mathrm{Im}\,z}{|1-z|^2}, \tag{A.486}$$

so $h(z) = -2\varepsilon\,\mathrm{Im}\,z/\,|1-z|^2 \in \mathbb{R}$, with the unit J. Since $w\chi_{\{1\}} = 0$ identically, multiplicativity gives $w(V)F(\{1\}) = 0$; but $w(V)$ is injective, so $F(\{1\}) = 0$.

The measure. Define $E(\Omega) = F(h^{-1}(\Omega))$ for Borel $\Omega \subseteq \mathbb{R}$. Preimages respect complements, intersections and countable unions, so E inherits every clause of Definition 12.58 from F, with $E(\mathbb{R}) = F(\mathbb{T} \setminus \{1\}) = \mathbb{1}$. By construction μ_x is the image of μ_x^F under h, so $\int (g \circ h)\,\mathrm{d}\mu_x^F = \int g\,\mathrm{d}\mu_x$ for every Borel $g \geq 0$ or bounded, and $g(H) := (g \circ h)(V)$ is the calculus claimed.

The domain. A direct computation on $\mathbb{T}$, using $|1 \pm z|^2 = 2 \pm 2\operatorname{Re} z$, gives the identity that makes the transport work:

$$|w(z)|^{-2} = \frac{4\varepsilon^2}{2 - 2\operatorname{Re} z} = \varepsilon^2 \frac{2 + 2\operatorname{Re} z}{2 - 2\operatorname{Re} z} + \varepsilon^2 = |h(z)|^2 + \varepsilon^2 \,. \tag{A.487}$$

Now $D(H) = \operatorname{im} w(V)$ by Equation (A.481), and

$$\operatorname{im} w(V) = \left\{ x \;\middle|\; \int_{\mathbb{T}} |w|^{-2} \, \mathrm{d}\mu_x^F < \infty \right\} . \tag{A.488}$$

Indeed, if $x = w(V)u$ then $\mu_x^F = |w|^2 \, \mu_u^F$ — because $\langle x | F(\Omega) x \rangle = \langle u | (\bar{w} \chi_\Omega w)(V) u \rangle$ — so $\int |w|^{-2} \, \mathrm{d}\mu_x^F = \|u\|^2 < \infty$. Conversely, if the integral is finite put $g_n = w^{-1} \chi_{\{|w| \geq 1/n\}}$, a bounded Borel function, and $u_n = g_n(V)x$; then $\|u_n - u_m\|^2 = \int |g_n - g_m|^2 \, \mathrm{d}\mu_x^F \longrightarrow 0$ by dominated convergence (Remark 12.1), the dominating function being $|w|^{-2}$, and $w(V)u_n = \chi_{\{|w| \geq 1/n\}}(V)x \longrightarrow x$ because $F(\{w = 0\}) = F(\{1\}) = 0$. Hence $x \in \operatorname{im} w(V)$. Combining Equations (A.487) and (A.488) with $\mu_x^F(\mathbb{T}) = \|x\|^2$,

$$\int_{\mathbb{T}} |w|^{-2} \, \mathrm{d}\mu_x^F = \int_{\mathbb{R}} \lambda^2 \, \mathrm{d}\mu_x(\lambda) + \varepsilon^2 \, \|x\|^2 \,,$$

so the two finiteness conditions agree and the first half of Equation (A.484) holds.

The action. Let $x = w(V)u \in D(H)$. Then, by Equation (A.481),

$$Hx = (H + \mathrm{i}\varepsilon)x - \mathrm{i}\varepsilon x = u - \mathrm{i}\varepsilon \, \frac{\mathbb{1} - V}{2\mathrm{i}\varepsilon} \, u = \frac{\mathbb{1} + V}{2} \, u \,. \tag{A.489}$$

On the other side, put $h_n = h \, \chi_{\{|h| \leq n\}}$, a bounded Borel function, so that $h_n(H) = \int_{|\lambda| \leq n} \lambda \, \mathrm{d}E$. Since $h_n w \longrightarrow hw$ pointwise on $\mathbb{T} \setminus \{1\}$ with $|h_n w| \leq |hw| = |1 + z| \, / 2 \leq 1$, dominated convergence gives

$$h_n(H) \, x = (h_n w)(V) \, u \longrightarrow (hw)(V) \, u = \frac{\mathbb{1} + V}{2} \, u = Hx \,,$$

because $h(z)w(z) = (1 + z)/2$ by Equation (A.485). Pairing with y and passing to the limit gives the second half of Equation (A.484); the integral converges absolutely because $\int |\lambda| \; \mathrm{d} \, |\mu_{y,x}| \leq \|y\| \, \big(\int \lambda^2 \mathrm{d}\mu_x \big)^{1/2}$, by Cauchy–Schwarz on the partition sums. □

Proof of Theorem A.253, converse half. *Derives Theorem A.253.*

Let H be self-adjoint, E its projection-valued measure (Proposition A.262), and for $t \in \mathbb{R}$ put

$$U(t) = \exp\left(-\frac{\mathrm{i}Ht}{\hbar} \right) := f_t(H) \,, \qquad f_t(\lambda) = \mathrm{e}^{-\mathrm{i}\lambda t/\hbar} \,, \tag{A.490}$$

which is legitimate because $|f_t| = 1$: the exponent $\lambda t/\hbar$ is dimensionless, λ being an energy.

Unitary, and a group. $f_t \bar{f}_t = 1$ and $f_t f_s = f_{t+s}$, $f_0 = 1$, so multiplicativity and the $*$-property of the calculus give $U(t)^\dagger U(t) = U(t) U(t)^\dagger = \mathbb{1}$ and Equation (12.41).

Strong continuity. For $x \in \mathcal{H}$,

$$\|U(t)x - x\|^2 = \int_{\mathbb{R}} \left| \mathrm{e}^{-\mathrm{i}\lambda t/\hbar} - 1 \right|^2 \mathrm{d}\mu_x(\lambda) \longrightarrow 0 \qquad (t \to 0) \,, \tag{A.491}$$

by dominated convergence (Remark 12.1): the integrand tends to 0 pointwise and is bounded by the constant 4, which is μ_x-integrable because $\mu_x(\mathbb{R}) = \|x\|^2$.

The generator is H. Let $x \in D(H)$. Then

$$\left\| \frac{U(t)x - x}{t} + \frac{\mathrm{i}}{\hbar} Hx \right\|^2 = \int_{\mathbb{R}} \left| \frac{\mathrm{e}^{-\mathrm{i}\lambda t/\hbar} - 1}{t} + \frac{\mathrm{i}\lambda}{\hbar} \right|^2 \mathrm{d}\mu_x(\lambda) \,, \tag{A.492}$$

whose integrand tends to 0 pointwise and is bounded by $4\lambda^2/\hbar^2$, since $\left|e^{i\theta}-1\right| \le |\theta|$ for real θ; that bound is μ_x-integrable exactly because $x \in D(H)$ (Equation (A.484)). Dominated convergence makes Equation (A.492) tend to 0, so x lies in the domain Equation (A.470) of the generator G of U, with $Gx = Hx$. Thus $H \subseteq G$. But G is self-adjoint by Proposition A.259 and H is self-adjoint by hypothesis, so

$$G = G^\dagger \subseteq H^\dagger = H \subseteq G\,,$$

the middle inclusion because taking adjoints reverses inclusions. Hence $G = H$: a self-adjoint operator has no proper symmetric extension. □

Proposition A.263 (The two constructions are inverse)**.** *If U and W are strongly continuous one-parameter unitary groups with the same generator H, then $U = W$. Consequently $H \longmapsto \exp(-iHt/\hbar)$ and $U \longmapsto H$ are mutually inverse bijections between the self-adjoint operators on $\mathcal{H}$ and the strongly continuous one-parameter unitary groups on $\mathcal{H}$.*

Rests on Propositions 12.67 and A.259 and Theorem A.253.

Proof. *Derives Proposition A.263.*

Fix $x \in D(H)$ and t, and set $g(s) = W(t-s)U(s)x$ for $s \in [0,t]$. By Proposition 12.67, $U(s)x \in D(H)$ and both curves are differentiable, so the product rule — legitimate because each factor is differentiable in norm and W is isometric — gives

$$\frac{dg}{ds} = W(t-s)\left(-\frac{i}{\hbar}H\right)U(s)x + \left(+\frac{i}{\hbar}H\right)W(t-s)\,U(s)x = 0\,,$$

since H commutes with $W(t-s)$ on $D(H)$ (again Proposition 12.67). Hence g is constant: $W(t)x = g(0) = g(t) = U(t)x$. As $D(H)$ is dense (Proposition A.256) and both operators are bounded, $U(t) = W(t)$.

For the bijection: Propositions A.256 and A.259 show that every group has a self-adjoint generator, and Theorem A.253 that every self-adjoint operator is the generator of the group Equation (A.490); the paragraph just proved shows that no group is the exponential of two different self-adjoint operators, since the generator is recovered from the group by Equation (A.470). □

Remark A.264 (What is quoted here)*.* The direct half — Propositions A.256, A.258 and A.259 — quotes nothing at all: it uses the Riemann integral of Lemma A.254, built here, and the scalar fundamental theorem of calculus (Theorem 7.43).

The converse inherits the two quoted inputs of Appendix A.24 — Stone–Weierstrass (Theorem A.242) and Riesz–Markov (Theorem A.244) — through Proposition A.261, and in addition uses the dominated convergence theorem of Lebesgue integration three times: in Equation (A.488), in Equation (A.491) and in Equation (A.492). That theorem is already declared as quoted in Remark 12.1, where the same declaration covers the completeness of L^2. The passage from the bounded spectral theorem to the unbounded one is *not* quoted: it is carried out in Lemma A.260 and Propositions A.261 and A.262, and the algebra that makes it work — $(\mathbb{1}-V)/(2i\varepsilon) = (H+i\varepsilon)^{-1}$ and $|w|^{-2} = |h|^2 + \varepsilon^2$ — is displayed in full.

Remark A.265*.* Appendix A.25 discharges the proof obligation of Theorem 12.66 (Section 12.4.3), of which Proposition 12.67 had proved the elementary part. What the theorem buys the physics is stated in Remark 12.68: the equivalence of the differential and the integrated Schrödinger equation Equation (12.48), and the reason a Hamiltonian must be self-adjoint rather than merely symmetric — symmetry gives no unitary group, hence no conserved probability. That is not a technicality, and Example 12.82 is the proof: there the generator has no self-adjoint extension at all, so by Proposition A.263 there is no unitary dynamics to be had, a point settled in general by Theorem 12.80 and Appendix A.26, where the Cayley transform used above is developed for an arbitrary closed symmetric operator.

A.26 Von Neumann's Criterion for Self-Adjoint Extensions

This appendix proves Theorem 12.80 of Chapter 12: a closed symmetric operator is self-adjoint exactly when both deficiency indices vanish; it admits self-adjoint extensions exactly when the two indices are equal; and the extensions are then in bijective correspondence with the unitary maps from one deficiency subspace to the other. The proof is von Neumann's [664], through the Cayley transform, which converts a closed symmetric operator into an isometry between closed subspaces and a self-adjoint operator into a unitary — so that the extension problem for operators becomes the extension problem for isometries, where it is a matter of counting dimensions. The two examples the criterion was made for, momentum on an interval and momentum on a half-line, are recovered in Appendix A.26.6 as corollaries, with the one-parameter family of boundary conditions Equation (12.55) produced explicitly from the unitary parameter.

Throughout, A is a densely defined closed symmetric operator (Definitions 12.70 and 12.72) and $\mu > 0$ is a fixed number carrying the same SI dimension as A, so that $A \pm \mathrm{i}\mu$ is dimensionally consistent, as in Definition 12.79; for the momentum operator of Appendix A.26.6, μ is a momentum in $\mathrm{kg\,m/s}$. The deficiency subspaces and indices are those of Equation (12.53),

$$K_{\pm} = \ker\left(A^{\dagger} \mp \mathrm{i}\mu\right) = \left(\mathrm{im}(A \pm \mathrm{i}\mu)\right)^{\perp}, \qquad n_{\pm} = \dim K_{\pm}\,, \tag{A.493}$$

where dim means the cardinality of an orthonormal basis.

A.26.1 Statement

Theorem A.266 (von Neumann)**.** *Let A be a closed symmetric operator with deficiency indices (n_+, n_-). Then*

1. *A is self-adjoint if and only if $n_+ = n_- = 0$;*
2. *the self-adjoint extensions of A are in bijective correspondence with the unitary maps $W : K_+ \longrightarrow K_-$, the extension A_W attached to W being*

$$D(A_W) = D(A) \oplus \{k - Wk \mid k \in K_+\}\,, \qquad A_W(x + k - Wk) = Ax + \mathrm{i}\mu\,(k + Wk)\,, \tag{A.494}$$

   the sum of subspaces being direct; such maps exist if and only if $n_+ = n_-$, and when $n_+ = n_- = n < \infty$ they form a family parametrised by $\mathrm{U}(n)$;
3. *if $n_+ \neq n_-$ there is no self-adjoint extension.*

Rests on Definitions 12.72, 12.78 and 12.79.

A.26.2 The basic identity

Lemma A.267 (Isometry of $A \pm \mathrm{i}\mu$, and closed range)**.** *For every $x \in D(A)$,*

$$\|(A \pm \mathrm{i}\mu)x\|^2 = \|Ax\|^2 + \mu^2\,\|x\|^2\,, \tag{A.495}$$

so $A \pm \mathrm{i}\mu$ is injective with $\|(A \pm \mathrm{i}\mu)x\| \geq \mu\,\|x\|$, and $\|(A + \mathrm{i}\mu)x\| = \|(A - \mathrm{i}\mu)x\|$. If A is closed, the subspaces $\mathrm{im}(A \pm \mathrm{i}\mu)$ are closed, so that

$$\mathcal{H} = \mathrm{im}(A + \mathrm{i}\mu) \oplus K_+ = \mathrm{im}(A - \mathrm{i}\mu) \oplus K_-\,. \tag{A.496}$$

Rests on Definitions 12.72 and 12.79 and Theorem 12.18.

Proof. *Derives Lemma A.267.*

Expanding and using $\langle Ax|x\rangle = \langle x|Ax\rangle$, which is symmetry, the two cross terms cancel:

$$\|(A \pm \mathrm{i}\mu)x\|^2 = \|Ax\|^2 \pm \mathrm{i}\mu \langle Ax|x\rangle \mp \mathrm{i}\mu \langle x|Ax\rangle + \mu^2 \|x\|^2 = \|Ax\|^2 + \mu^2 \|x\|^2 ,$$

the sign of the third term coming from the antilinearity Equation (5.36) of the first slot. Both consequences are immediate. For closedness of the image, let $(A + \mathrm{i}\mu)x_n \longrightarrow u$. Applying Equation (A.495) to differences shows that both (x_n) and (Ax_n) are Cauchy, hence convergent, say $x_n \longrightarrow x$ and $Ax_n \longrightarrow y$; since A is closed, $x \in D(A)$ and $Ax = y$, so $u = (A + \mathrm{i}\mu)x$ lies in the image. Equation (A.496) is then the projection theorem Theorem 12.18 together with Equation (A.493). □

Lemma A.268 (The indices do not depend on μ)**.** *For a closed symmetric A the numbers $n_\pm$ are the same for every $\mu > 0$.*

Rests on Lemma A.267 and Definition 12.79.

Proof. *Derives Lemma A.268.*

Write $K_+(\mu) = \ker(A^\dagger - \mathrm{i}\mu)$ and suppose $\dim K_+(\nu) < \dim K_+(\mu)$ for two positive μ, ν of the same dimension. Then there is a non-zero $u \in K_+(\mu) \cap K_+(\nu)^\perp$: otherwise the orthogonal projection onto $K_+(\nu)$ would be injective on $K_+(\mu)$, and its adjoint — the projection onto $K_+(\mu)$ restricted to $K_+(\nu)$ — would have dense range in $K_+(\mu)$, forcing $\dim K_+(\mu) \leq \dim K_+(\nu)$.

By Equations (A.493) and (A.496), $K_+(\nu)^\perp = \mathrm{im}(A + \mathrm{i}\nu)$, so $u = (A + \mathrm{i}\nu)x$ for some $x \in D(A)$; and $A^\dagger u = \mathrm{i}\mu u$. Hence, using Equation (12.50) and Equation (5.36),

$$\|u\|^2 = \langle u|(A + \mathrm{i}\nu)x\rangle = \left\langle A^\dagger u \middle| x \right\rangle + \mathrm{i}\nu \langle u|x\rangle = \mathrm{i}\,(\nu - \mu)\,\langle u|x\rangle \ . \tag{A.497}$$

But Equation (A.495) gives $\|u\| \geq \nu \|x\|$, so $|\langle u|x\rangle| \leq \|u\| \|x\| \leq \|u\|^2 / \nu$ by Equation (12.1), and Equation (A.497) forces $\|u\|^2 \leq |\nu - \mu| \ \|u\|^2 / \nu$, i.e. $|\nu - \mu| \geq \nu$. So whenever $|\nu - \mu| < \nu$ no such u exists and $\dim K_+(\mu) \leq \dim K_+(\nu)$; exchanging the roles of μ and ν, the two dimensions are equal whenever $|\nu - \mu| < \min(\mu, \nu)$. The function $\mu \longmapsto n_+(\mu)$ is therefore locally constant on the connected set $(0, \infty)$, hence constant (Theorem 6.14). The argument for K_- is the same with i replaced by $-\mathrm{i}$. □

A.26.3 The Cayley transform

Definition A.269 (Cayley transform)**.** The *Cayley transform* of a closed symmetric operator A is the map

$$V_A \colon \mathrm{im}(A + \mathrm{i}\mu) \longrightarrow \mathrm{im}(A - \mathrm{i}\mu)\,, \qquad V_A\,(A + \mathrm{i}\mu)x = (A - \mathrm{i}\mu)x\,, \quad x \in D(A)\,. \tag{A.498}$$

Rests on Lemma A.267 and Definition 12.79.

Proposition A.270 (Properties of the transform)**.** *V_A is a well-defined linear isometry of the closed subspace $K_+^\perp = \mathrm{im}(A + \mathrm{i}\mu)$ onto the closed subspace $K_-^\perp = \mathrm{im}(A - \mathrm{i}\mu)$. Moreover $\mathbb{1} - V_A$ is injective on $K_+^\perp$, its image is $D(A)$ up to the factor $2\mathrm{i}\mu$,*

$$(\mathbb{1} - V_A)\,(A + \mathrm{i}\mu)x = 2\mathrm{i}\mu\, x\,, \qquad (\mathbb{1} + V_A)\,(A + \mathrm{i}\mu)x = 2\,Ax\,, \tag{A.499}$$

and consequently A is recovered from V_A by

$$D(A) = \mathrm{im}\,(\mathbb{1} - V_A)\ , \qquad A = \mathrm{i}\mu\,(\mathbb{1} + V_A)\,(\mathbb{1} - V_A)^{-1}\ . \tag{A.500}$$

Rests on Definition A.269 and Lemma A.267.

Proof. *Derives Proposition A.270.*

$A + \mathrm{i}\mu$ is injective on $D(A)$ (Lemma A.267), so every $u \in \mathrm{im}(A + \mathrm{i}\mu)$ is $(A + \mathrm{i}\mu)x$ for exactly one x and Equation (A.498) defines $V_A u$ unambiguously; linearity is inherited from that of A. Isometry is the second consequence in Lemma A.267, $\|V_A u\| = \|(A - \mathrm{i}\mu)x\| = \|(A + \mathrm{i}\mu)x\| = \|u\|$, and the image is $\mathrm{im}(A - \mathrm{i}\mu)$ by construction. Both subspaces are closed and are the orthogonal complements of $K_\pm$, by Equation (A.496).

The two identities Equation (A.499) are immediate: $(A + \mathrm{i}\mu)x - (A - \mathrm{i}\mu)x = 2\mathrm{i}\mu x$ and $(A + \mathrm{i}\mu)x + (A - \mathrm{i}\mu)x = 2Ax$. The first shows that $(\mathbb{1} - V_A)u = 0$ forces $x = 0$, hence $u = 0$: injectivity; that $\mathrm{im}(\mathbb{1} - V_A) = D(A)$, since x runs over $D(A)$ as u runs over $K_+^\perp$; and, dividing the second identity by the first, Equation (A.500). □

A.26.4 From an isometry back to an operator

Lemma A.271 (Injectivity of $\mathbb{1} - V$ for any isometric extension)**.** *Let V be an isometry of a closed subspace of $\mathcal{H}$ into $\mathcal{H}$ extending V_A. Then* $\ker(\mathbb{1} - V) = \{0\}$.

Rests on Proposition A.270 and Definition 12.72.

Proof. *Derives Lemma A.271.*

An isometry preserves inner products, by the polarization identity Equation (12.3) applied on its domain. Let $Vz = z$ and let $u \in K_+^\perp$ be arbitrary. Then

$$\langle z|(\mathbb{1} - V)\, u\rangle = \langle z|u\rangle - \langle z|Vu\rangle = \langle z|u\rangle - \langle Vz|Vu\rangle = 0\,,$$

using $Vz = z$ in the third step. By Equation (A.499), $(\mathbb{1} - V)u = (\mathbb{1} - V_A)u$ ranges over $2\mathrm{i}\mu\, D(A)$, which is dense because A is densely defined. Hence $z \perp \mathcal{H}$ and $z = 0$. □

Lemma A.272 (The operator attached to an isometry)**.** *Let V be an isometry of a closed subspace $D(V)$ onto a closed subspace, with* $\ker(\mathbb{1} - V) = \{0\}$ *and* $\mathrm{im}(\mathbb{1} - V)$ *dense. Then*

$$D(B) = \mathrm{im}\,(\mathbb{1} - V)\,, \qquad B\,(\mathbb{1} - V)\,z = \mathrm{i}\mu\,(\mathbb{1} + V)\,z \tag{A.501}$$

defines a densely defined symmetric operator B whose Cayley transform is V. If V extends V_A then B extends A.

Rests on Proposition A.270, Lemma A.271, and Definition 12.72.

Proof. *Derives Lemma A.272.*

B is well defined and single valued because $\mathbb{1} - V$ is injective, and linear because V is; its domain is dense by hypothesis.

Symmetry. Let $z, z' \in D(V)$ and put $x = (\mathbb{1} - V)z$, $y = (\mathbb{1} - V)z'$, so $Bx = \mathrm{i}\mu(\mathbb{1} + V)z$ and $By = \mathrm{i}\mu(\mathbb{1} + V)z'$. Using $\langle Vz|Vz'\rangle = \langle z|z'\rangle$ and the antilinearity of the first slot, which turns the prefactor $\mathrm{i}\mu$ into $-\mathrm{i}\mu$,

$$\langle Bx|y\rangle = -\mathrm{i}\mu\Big[\langle z|z'\rangle - \langle z|Vz'\rangle + \langle Vz|z'\rangle - \langle Vz|Vz'\rangle\Big] = -\mathrm{i}\mu\Big[\langle Vz|z'\rangle - \langle z|Vz'\rangle\Big]\,, \tag{A.502}$$

while, the prefactor now sitting in the second slot,

$$\langle x|By\rangle = +\mathrm{i}\mu\Big[\langle z|z'\rangle + \langle z|Vz'\rangle - \langle Vz|z'\rangle - \langle Vz|Vz'\rangle\Big] = -\mathrm{i}\mu\Big[\langle Vz|z'\rangle - \langle z|Vz'\rangle\Big]\,. \tag{A.503}$$

So $\langle Bx|y\rangle = \langle x|By\rangle$ for all $x, y \in D(B)$.

Its Cayley transform is V. From Equation (A.501),

$$(B + \mathrm{i}\mu)x = \mathrm{i}\mu\,(\mathbb{1} + V)\,z + \mathrm{i}\mu\,(\mathbb{1} - V)\,z = 2\mathrm{i}\mu\,z\,, \qquad (B - \mathrm{i}\mu)x = 2\mathrm{i}\mu\,Vz\,,$$

so $\mathrm{im}(B + \mathrm{i}\mu) = D(V)$, $\mathrm{im}(B - \mathrm{i}\mu) = \mathrm{im}\,V$, and V_B sends $2\mathrm{i}\mu z$ to $2\mathrm{i}\mu Vz$: that is, $V_B = V$.

Extension. If $V \supseteq V_A$ then, by Equation (A.499), $D(B) = \mathrm{im}(\mathbb{1} - V) \supseteq \mathrm{im}(\mathbb{1} - V_A) = D(A)$, and on $D(A)$ the prescription Equation (A.501) is Equation (A.499) itself, so B agrees with A there. □

Proposition A.273 (Self-adjoint means unitary)**.** *A closed symmetric operator A is self-adjoint if and only if its Cayley transform is unitary on all of $\mathcal{H}$, that is, if and only if $n_+ = n_- = 0$.*

Rests on Proposition A.270, Lemma A.267, and Definition 12.72.

Proof. *Derives Proposition A.273.*

Suppose $A = A^\dagger$. Then $K_\pm = \ker(A^\dagger \mp \mathrm{i}\mu) = \ker(A \mp \mathrm{i}\mu) = \{0\}$ by Equation (A.495), so $n_\pm = 0$ and, by Equation (A.496), V_A is an isometry of $\mathcal{H}$ onto $\mathcal{H}$: unitary.

Conversely suppose $n_+ = n_- = 0$, i.e. $\mathrm{im}(A \pm \mathrm{i}\mu) = \mathcal{H}$. Let $y \in D(A^\dagger)$. There is $x \in D(A)$ with $(A - \mathrm{i}\mu)x = (A^\dagger - \mathrm{i}\mu)y$, and since $A \subseteq A^\dagger$ this reads $(A^\dagger - \mathrm{i}\mu)(y - x) = 0$, i.e. $y - x \in K_+ = \{0\}$. Hence $y = x \in D(A)$, so $D(A^\dagger) = D(A)$ and A is self-adjoint. This is part (1) of Theorem A.266. □

A.26.5 Proof of the criterion

Proof of Theorem A.266, parts (2) and (3). *Derives Theorem A.266.*

From an extension to a unitary. Let $B \supseteq A$ be self-adjoint. By Proposition A.273 its Cayley transform V_B is unitary on $\mathcal{H}$, and it extends V_A: indeed $\mathrm{im}(A + \mathrm{i}\mu) \subseteq \mathrm{im}(B + \mathrm{i}\mu)$ and, on that subspace, $V_B(A + \mathrm{i}\mu)x = (B - \mathrm{i}\mu)x = (A - \mathrm{i}\mu)x$. A unitary carrying the closed subspace $K_+^\perp$ onto $K_-^\perp$ carries the orthogonal complement onto the orthogonal complement, so $W = V_B|_{K_+}$ is a unitary map $K_+ \longrightarrow K_-$.

From a unitary to an extension. Conversely let $W : K_+ \longrightarrow K_-$ be unitary and define, using the decompositions Equation (A.496),

$$V_W\,(u + k) = V_A u + W k\,, \qquad u \in K_+^\perp\,,\ k \in K_+\,. \tag{A.504}$$

Both summands on the right are orthogonal — $V_A u \in K_-^\perp$ and $Wk \in K_-$ — so $\|V_W(u+k)\|^2 = \|u\|^2 + \|k\|^2$ and V_W is an isometry of $\mathcal{H}$; its image is $K_-^\perp \oplus K_- = \mathcal{H}$, so V_W is unitary. By Lemma A.271, $\mathbb{1} - V_W$ is injective, and its image is dense because

$$\mathrm{im}\,(\mathbb{1} - V_W)^\perp = \ker\left(\mathbb{1} - V_W^\dagger\right) = \ker\,(\mathbb{1} - V_W) = \{0\}\ ,$$

where the middle equality holds because for a unitary V_W the relations $V_W z = z$ and $V_W^\dagger z = z$ are equivalent. So Lemma A.272 applies: it produces a densely defined symmetric $A_W \supseteq A$ whose Cayley transform is the unitary V_W, and A_W is therefore self-adjoint by Proposition A.273.

The formula Equation (A.494). Write $z = u + k$ with $u = (A + \mathrm{i}\mu)x$, $x \in D(A)$. Then, by Equations (A.499) and (A.504),

$$(\mathbb{1} - V_W)\,z = 2\mathrm{i}\mu\,x + k - Wk\,, \qquad \mathrm{i}\mu\,(\mathbb{1} + V_W)\,z = \mathrm{i}\mu\,(2Ax + k + Wk)\ ,$$

so, dividing by $2\mathrm{i}\mu$ and renaming $k/(2\mathrm{i}\mu)$ as k — which is a bijection of the subspace K_+, and W is linear — Equation (A.501) becomes exactly Equation (A.494). The sum there is direct: if $x + k - Wk = 0$ then applying $\mathbb{1} - V_W$ backwards, i.e. using injectivity on $2\mathrm{i}\mu x = (\mathbb{1} - V_W)u$ and $k - Wk = (\mathbb{1} - V_W)k$, gives $u + k = 0$ with $u \perp k$, hence $u = k = 0$.

The correspondence is bijective. The two constructions are inverse to each other: from A_W one recovers $V_{A_W} = V_W$ (Lemma A.272) and hence $W = V_W|_{K_+}$; and from a self-adjoint $B \supseteq A$ one gets $W = V_B|_{K_+}$, whose associated operator has Cayley transform V_B and therefore equals B, since B is determined by V_B through Equation (A.500).

Counting. A unitary map $K_+ \longrightarrow K_-$ exists if and only if the two spaces have orthonormal bases of the same cardinality — given such bases, the induced map is unitary; conversely a unitary carries a basis to a basis — that is, if and only if $n_+ = n_-$. If $n_+ \neq n_-$ there is none, and by the first paragraph a self-adjoint extension would produce one: this is part (3). When $n_+ = n_- = n < \infty$, fixing orthonormal bases of $K_\pm$ identifies the unitary maps with the matrix group $\mathrm{U}(n)$, a transitive and free action of $\mathrm{U}(n)$ on the set of extensions. □

A.26.6 The two worked cases

Both examples of Chapter 12 use the same differential expression $P = -\mathrm{i}\hbar\,\mathrm{d}/\mathrm{d}x$ of Equation (12.54), and both use the boundary form Equation (12.57), which for absolutely continuous φ, ψ with $\varphi', \psi' \in L^2$ reads

$$\left\langle \varphi \middle| P^\dagger \psi \right\rangle - \left\langle P^\dagger \varphi \middle| \psi \right\rangle = -\mathrm{i}\hbar\,(\varphi(L)^*\psi(L) - \varphi(0)^*\psi(0))\,, \tag{A.505}$$

an integration by parts legitimate for absolutely continuous functions (Theorem 7.43); on $[0,\infty)$ the term at L is replaced by a limit at infinity, which vanishes for L^2 functions with L^2 derivative. As Chapter 12 records, $P^\dagger$ is the same differential expression on the maximal domain — absolutely continuous ψ with $\psi' \in \mathcal{H}$ and no boundary condition [1481].

Corollary A.274 (Momentum on $[0,L]$: the circle of extensions)**.** *Let $\mathcal{H} = L^2([0,L])$ and let P be Equation (12.54) on the domain D_0 of continuously differentiable functions vanishing at both endpoints. Then $n_+ = n_- = 1$; every P_θ of Equation (12.55) is self-adjoint; these are all the self-adjoint extensions; and the unitary parameter $Wk_+ = \mathrm{e}^{\mathrm{i}\alpha}k_-$ of Theorem A.266 corresponds to the boundary phase*

$$\mathrm{e}^{\mathrm{i}\theta} = \frac{q - \mathrm{e}^{\mathrm{i}\alpha}}{1 - q\,\mathrm{e}^{\mathrm{i}\alpha}}\,, \qquad q = \mathrm{e}^{-\mu L/\hbar} \in (0,1)\,, \tag{A.506}$$

a bijection of the circle onto the circle.

Rests on Theorem A.266, Example 12.81, and Equation (12.55).

Proof. *Derives Corollary A.274.*

Indices. This is the computation of Example 12.81: the equations $P^\dagger\psi = \pm\mathrm{i}\mu\psi$ have the one-dimensional solution spaces spanned by

$$k_+(x) = N_+\mathrm{e}^{-\mu x/\hbar}\,, \qquad k_-(x) = N_-\mathrm{e}^{+\mu x/\hbar}\,, \tag{A.507}$$

both square integrable on the compact interval, so $n_+ = n_- = 1$ and Theorem A.266 gives a family of extensions parametrised by U(1). Normalising, $N_+^{-2} = \int_0^L \mathrm{e}^{-2\mu x/\hbar}\mathrm{d}x = (\hbar/2\mu)\,(1-q^2)$ and $N_-^{-2} = (\hbar/2\mu)\,(q^{-2}-1)$, whence

$$N_- = q\,N_+\,. \tag{A.508}$$

Each P_θ is self-adjoint. Symmetry on D_θ is Equation (A.505): for $\varphi, \psi \in D_\theta$, $\varphi(L)^*\psi(L) = \mathrm{e}^{-\mathrm{i}\theta}\mathrm{e}^{\mathrm{i}\theta}\varphi(0)^*\psi(0) = \varphi(0)^*\psi(0)$ and the right-hand side vanishes. For the converse inclusion let $y \in D(P_\theta^\dagger)$. Since $D_0 \subseteq D_\theta$, y belongs to the maximal domain $D(P^\dagger)$ and $P_\theta^\dagger y = P^\dagger y$; so Equation (A.505) with $\varphi = y$ must vanish for every $\psi \in D_\theta$:

$$0 = y(L)^*\psi(L) - y(0)^*\psi(0) = \psi(0)\left(y(L)^*\mathrm{e}^{\mathrm{i}\theta} - y(0)^*\right)\,.$$

Choosing $\psi(x) = 1 + (\mathrm{e}^{\mathrm{i}\theta} - 1)x/L$, which lies in D_θ and has $\psi(0) = 1$, gives $y(L)^*\mathrm{e}^{\mathrm{i}\theta} = y(0)^*$, i.e. $y(L) = \mathrm{e}^{\mathrm{i}\theta}y(0)$ and $y \in D_\theta$. Hence $D(P_\theta^\dagger) = D_\theta$ and P_θ is self-adjoint.

There are no others. Let B be a self-adjoint extension of P. Then $P \subseteq B = B^\dagger \subseteq P^\dagger$, so $D(B)$ lies in the maximal domain and Equation (A.505) vanishes on $D(B) \times D(B)$. Taking $\varphi = \psi$ gives $|\psi(L)|^2 = |\psi(0)|^2$ for every $\psi \in D(B)$: the image $S \subseteq \mathbb{C}^2$ of the boundary map $\psi \longmapsto (\psi(0), \psi(L))$ is a subspace isotropic for the hermitian form $|b|^2 - |a|^2$, which has signature $(1,1)$, so $\dim S \leq 1$. If $\dim S = 1$, say $S = \mathbb{C}\,(1, \mathrm{e}^{\mathrm{i}\theta})$, then $D(B) \subseteq D_\theta$, i.e. $B \subseteq P_\theta$; taking adjoints reverses the inclusion, so $P_\theta = P_\theta^\dagger \subseteq B^\dagger = B$ and $B = P_\theta$. If $S = \{0\}$ then $D(B)$ is contained in D_θ for *every* θ, so $B \subseteq P_\theta$ and the same argument gives $B = P_\theta$ — contradicting $S = \{0\}$, since the domain of P_θ contains $\psi(x) = 1 + (\mathrm{e}^{\mathrm{i}\theta} - 1)x/L$, whose boundary values are not both zero. So every self-adjoint extension is one of the P_θ.

Matching the parameters. Let $Wk_+ = \mathrm{e}^{\mathrm{i}\alpha}k_-$ and let A be the closure of P, a closed symmetric operator with the same adjoint and the same deficiency subspaces — the defining condition Equation (12.50) for $A^\dagger$ extends from D_0 to its graph closure by continuity of the inner product. By Equation (A.494), every element of $D(A_W)$ is $\psi = \psi_0 + c\,(k_+ - \mathrm{e}^{\mathrm{i}\alpha}k_-)$ with $\psi_0 \in D(A)$ and $c \in \mathbb{C}$. Every $\psi_0 \in D(A)$ vanishes at both endpoints: if $\psi_n \in D_0$ converges to ψ_0 in the graph norm then, for absolutely continuous ϕ on $[0, L]$,

$$|\phi(x)| \le \frac{1}{L}\int_0^L |\phi| + \int_0^L |\phi'| \le L^{-1/2}\,\|\phi\| + L^{1/2}\,\|\phi'\|\,, \tag{A.509}$$

— average $\phi(x) = \phi(y) + \int_y^x \phi'$ over y and use Equation (12.1) — so graph convergence implies uniform convergence and $\psi_0(0) = \lim \psi_n(0) = 0$, likewise at L. Therefore the boundary values of ψ come from the second term alone: by Equations (A.507) and (A.508),

$$\psi(0) = c\,N_+\left(1 - \mathrm{e}^{\mathrm{i}\alpha}q\right)\,, \qquad \psi(L) = c\,N_+\left(q - \mathrm{e}^{\mathrm{i}\alpha}\right)\,,$$

using $k_+(L) = N_+ q$ and $k_-(L) = N_- q^{-1} = N_+$. The denominator $1 - \mathrm{e}^{\mathrm{i}\alpha}q$ never vanishes because $q < 1$, and

$$\left|q - \mathrm{e}^{\mathrm{i}\alpha}\right|^2 = q^2 - 2q\cos\alpha + 1 = \left|1 - q\,\mathrm{e}^{\mathrm{i}\alpha}\right|^2\,, \tag{A.510}$$

so the ratio $\psi(L)/\psi(0)$ is a phase, which is Equation (A.506). Hence $D(A_W) \subseteq D_\theta$ with that θ, and since both operators are self-adjoint, $A_W = P_\theta$ by the adjoint argument used above. Finally $z \longmapsto (q - z)/(1 - qz)$ is a Möbius transformation with $|q| < 1$; Equation (A.510) shows it maps the unit circle into itself, and it is injective, so it is a bijection of the circle: as α runs once around, so does θ, and the U(1) of Theorem A.266 is exactly the circle of boundary conditions Equation (12.55). □

Corollary A.275 (Momentum on $[0, \infty)$: no extension)**.** *Let $\mathcal{H} = L^2([0, \infty))$ and let P be Equation (12.54) on the continuously differentiable functions of compact support in $(0, \infty)$. Then $(n_+, n_-) = (1, 0)$ and P has no self-adjoint extension.*

Rests on Theorem A.266 and Example 12.82.

Proof. *Derives Corollary A.275.*

The solutions of $P^\dagger\psi = \pm\mathrm{i}\mu\psi$ are again $\psi(x) = C\mathrm{e}^{\mp\mu x/\hbar}$; on the half-line the decaying one is square integrable, with $\|\psi\|^2 = |C|^2\,\hbar/(2\mu)$, and the growing one is not, so $n_+ = 1$ and $n_- = 0$ (Example 12.82). By part (3) of Theorem A.266 — there is no unitary map from a one-dimensional space onto $\{0\}$ — there is no self-adjoint extension. By Proposition A.263 there is therefore no strongly continuous unitary group whose generator is a momentum on the half-line, which is the statement that probability cannot be conserved under translations that push it off the end of the half-line (Remark 12.83). □

Remark A.276 (What is quoted here)*.* The criterion itself — Lemma A.267 through Theorem A.266 — quotes nothing: every step is carried out from the definitions of Section 12.5 and the projection theorem. Two facts are imported in the worked cases of Appendix A.26.6, both of them classical real analysis rather than operator theory. First, that the adjoint of P on either interval is the same differential expression on the maximal domain of absolutely continuous functions with square-integrable derivative; this is stated without proof in Example 12.81 as well, with the reference [1481], and identifying it requires the du Bois-Reymond lemma on weak derivatives. Second, that integration by parts Equation (A.505) is valid for absolutely continuous functions, which is Theorem 7.43 applied to the product. Neither is needed for Theorem A.266.

Remark A.277*.* Appendix A.26 discharges the proof obligation of Theorem 12.80 (Section 12.5.2), and with Corollaries A.274 and A.275 it completes the two examples that section is built around — in particular the assertion of Example 12.81 that D_θ exhausts the

possibilities, which is proved above by the isotropic-subspace count and not merely asserted. Read with Appendix A.25, the criterion is the precise statement of what Remark 12.77 calls the physics of a domain: the deficiency indices decide whether a symmetric differential expression admits a unitary dynamics at all, and when they are equal and non-zero it is the boundary condition — the ring, or the ring threaded by a flux — that selects one, the mathematics offering the whole $\mathrm{U}(n)$ and choosing nothing.

A.27 The Nuclear Spectral Theorem of Gelfand and Maurin

This appendix proves Theorem 12.107 of Chapter 12 — that a self-adjoint operator acting continuously on the test space of a Gelfand triple possesses a complete set of generalized eigenvectors — and says exactly what the proof assumes. It is the theorem that licenses the completeness relation $\int |\lambda\rangle\langle\lambda| \, \mathrm{d}\mu(\lambda) = \mathbb{1}$ of Remark 12.108, and with it Dirac's formalism [646] in the form physics actually uses it. The result is due to Gelfand and his collaborators [1276], where it appears in volume 4 of *Generalized Functions*; Maurin obtained it independently at about the same time, and the theorem carries both names.

The architecture has three stages, and only the second imports anything. *First*, the spectral theorem of Appendices A.24 and A.25 is read as a *direct-integral* decomposition: $\mathcal{H}$ is realised as a space of square-integrable fields $\lambda \longmapsto \hat{x}(\lambda)$ over the spectrum, in which A acts by multiplication by λ. At that stage the assignment $x \longmapsto \hat{x}(\lambda)$ is defined only up to a μ-null set, and only as a map of equivalence classes: for a *fixed* λ it is not a map on $\mathcal{H}$ at all, so there are no eigenvectors yet, generalized or otherwise. *Second*, nuclearity of the test space is used — and this is the only import — to produce, for μ-almost every λ, a genuine *continuous* map $\Phi \longrightarrow \mathcal{H}_\lambda$ that is a version of the fibre map. *Third*, each vector in the fibre is paired with that map, giving a continuous linear functional on Φ, and the multiplication form of A makes it a generalized eigenvector of eigenvalue λ; the isometry of the first stage, read fibrewise, is the completeness relation.

A.27.1 Hypotheses and statement

The standing hypotheses of Definition 12.103 are made explicit here, because the proof uses each of them.

Definition A.278 (Countably Hilbert nuclear space)**.** A *countably Hilbert space* is a vector space Φ whose topology is given by an increasing sequence of norms $\|\cdot\|_1 \le \|\cdot\|_2 \le \cdots$, each coming from an inner product, and which is complete for the resulting metric; Φ_p denotes the Hilbert space completion of Φ in $\|\cdot\|_p$. It is *nuclear* if for every p there is $q \ge p$ such that the canonical map $\Phi_q \longrightarrow \Phi_p$ is nuclear, that is, of the form $u \longmapsto \sum_k s_k \, \langle a_k|u\rangle \, b_k$ with $\sum_k |s_k| < \infty$ and $\{a_k\}$, $\{b_k\}$ orthonormal.
Rests on Definitions 12.2 and 12.103.

Theorem A.279 (Gelfand–Maurin)**.** *Let $\Phi \subseteq \mathcal{H} \subseteq \Phi'$ be a Gelfand triple (Definition 12.103) in which $\mathcal{H}$ is separable and Φ is a separable countably Hilbert nuclear space, densely and continuously embedded in $\mathcal{H}$. Let A be self-adjoint on $\mathcal{H}$ and map Φ continuously into itself. Then there exist a finite Borel measure μ on $\sigma(A)$, separable Hilbert spaces $\mathcal{H}_\lambda$ and, for μ-almost every λ, a continuous linear map $\Lambda_\lambda \colon \Phi \longrightarrow \mathcal{H}_\lambda$ such that*

1. *$\Lambda_\lambda(A\varphi) = \lambda \, \Lambda_\lambda(\varphi)$ for every $\varphi \in \Phi$ and μ-almost every λ;*
2. *for every $\xi \in \mathcal{H}_\lambda$ the functional $F_{\lambda,\xi}(\varphi) = \langle \xi | \Lambda_\lambda \varphi \rangle_{\mathcal{H}_\lambda}$ belongs to Φ' and is a generalized eigenvector of A with eigenvalue λ (Definition 12.105);*
3. *writing $\{\xi_n\}$ for an orthonormal basis of $\mathcal{H}_\lambda$ and $F_{\lambda,n} = F_{\lambda,\xi_n}$,*

$$\langle \varphi | \psi \rangle = \int_{\sigma(A)} \sum_n F_{\lambda,n}(\varphi)^* \, F_{\lambda,n}(\psi) \, \mathrm{d}\mu(\lambda) \,, \qquad \forall \, \varphi, \psi \in \Phi \,. \tag{A.511}$$

When the spectrum of A is simple — when $\mathcal{H}$ has a single cyclic vector — every $\mathcal{H}_\lambda$ is one dimensional, the sum in Equation (A.511) has one term, and the identity is Equation (12.69) exactly as stated in Chapter 12.

Rests on Definitions 12.103 and 12.105 and Theorem A.238.

A.27.2 The direct integral

Proposition A.280 (Direct-integral form of the spectral theorem)**.** *Let A be self-adjoint on a separable $\mathcal{H}$, with projection-valued measure E (Theorem A.238 and Proposition A.262). There are a finite Borel measure μ on $\mathbb{R}$, supported on $\sigma(A)$, and an isometry*

$$J\colon \mathcal{H} \longrightarrow \Big\{ \textit{fields } \lambda \longmapsto \hat{x}(\lambda) \in \ell^2(\mathbb{N}) \Big\}\,, \qquad \|x\|^2 = \int_{\mathbb{R}} \|\hat{x}(\lambda)\|_{\ell^2}^2 \,\mathrm{d}\mu(\lambda)\,, \tag{A.512}$$

such that for $x \in D(A)$ one has $\widehat{Ax}(\lambda) = \lambda\,\hat{x}(\lambda)$ for μ-almost every λ.

Rests on Theorem A.238, Lemma A.250, and Proposition A.262.

Proof. *Derives Proposition A.280.*

Cyclic decomposition. The construction of Lemma A.250 applies verbatim with the bounded Borel calculus of Proposition A.246 — or, for unbounded A, of Proposition A.262 — in place of the continuous one: it used only that the cyclic subspaces $\mathcal{H}_n = \overline{\{g(A)x_n \mid g \text{ bounded Borel}\}}$ are A-invariant with A-invariant orthogonal complements, and that $\mathcal{H}$ is separable. So $\mathcal{H} = \bigoplus_n \mathcal{H}_n$ with each x_n cyclic in $\mathcal{H}_n$.

Each block. As in Lemma A.249, $\|g(A)x_n\|^2 = \int |g|^2 \,\mathrm{d}\mu_n$ with $\mu_n(\Omega) = \langle x_n | E(\Omega) x_n\rangle$, so $g(A)x_n \longmapsto g$ extends to a unitary $U_n\colon \mathcal{H}_n \longrightarrow L^2(\mathbb{R},\mu_n)$ — the bounded Borel functions are dense in $L^2(\mu_n)$, since the simple functions already are — and $U_n A U_n^{-1}$ is multiplication by λ.

One measure. Put $\mu = \sum_n 2^{-n}\,\|x_n\|^{-2}\,\mu_n$, a Borel measure with $\mu(\mathbb{R}) \le 1$, supported on $\sigma(A)$ because every μ_n is. Each μ_n is absolutely continuous with respect to μ, so the Radon–Nikodym theorem (Remark A.284) provides densities $\rho_n = \mathrm{d}\mu_n/\mathrm{d}\mu \ge 0$.

The isometry. For $x = \sum_n v_n$ with $v_n \in \mathcal{H}_n$ write $h_n = U_n v_n \in L^2(\mu_n)$ and define

$$\hat{x}(\lambda) = \Big(\sqrt{\rho_n(\lambda)}\; h_n(\lambda) \Big)_{n\in\mathbb{N}} \in \ell^2(\mathbb{N})\,. \tag{A.513}$$

Then, exchanging sum and integral by monotone convergence (Remark 12.1),

$$\int_{\mathbb{R}} \|\hat{x}(\lambda)\|_{\ell^2}^2 \,\mathrm{d}\mu = \sum_n \int_{\mathbb{R}} |h_n|^2\,\rho_n \,\mathrm{d}\mu = \sum_n \int_{\mathbb{R}} |h_n|^2 \,\mathrm{d}\mu_n = \sum_n \|v_n\|^2 = \|x\|^2\,,$$

which is Equation (A.512); in particular $\hat{x}(\lambda)$ lies in $\ell^2(\mathbb{N})$ for μ-almost every λ. Since A acts on each block as multiplication by λ, and multiplication commutes with the fibrewise rescaling by $\sqrt{\rho_n}$, $\widehat{Ax}(\lambda) = \lambda\hat{x}(\lambda)$ almost everywhere for $x \in D(A)$. □

The map J is the whole content of the spectral theorem written fibrewise, and it is also the whole of the difficulty: $\hat{x}$ is an equivalence class of fields modulo μ-null sets, so the expression $\hat{x}(\lambda)$ for one fixed λ has no meaning, and there is nothing yet that could be evaluated on a test function.

A.27.3 What nuclearity buys

Theorem A.281 (Nuclear spaces embed by Hilbert–Schmidt maps; quoted)**.** *Let Φ be a countably Hilbert nuclear space (Definition A.278) continuously embedded in a Hilbert space $\mathcal{H}$. Then there is an index q such that the embedding extends to a* Hilbert–Schmidt *map $J_q\colon \Phi_q \longrightarrow \mathcal{H}$, that is, one for which*

$$\sum_k \|e_k\|_{\mathcal{H}}^2 < \infty \tag{A.514}$$

for one, hence for every, orthonormal basis $\{e_k\}$ *of* Φ_q.
Rests on Definition A.278.

The Schwartz triple Equation (12.66) is the case to keep in mind: $\mathcal{S}(\mathbb{R})$ is countably Hilbert for the norms built from the harmonic-oscillator Hermite expansion, and Equation (A.514) holds there because the Hermite coefficients of a Schwartz function decay faster than any power.

Proposition A.282 (The fibre maps are continuous on Φ)**.** *Under the hypotheses of Theorem A.279 there are, for* μ*-almost every* λ*, a constant* $C(\lambda) < \infty$ *and a linear map* $\Lambda_\lambda \colon \Phi_q \longrightarrow \ell^2(\mathbb{N})$ *with*

$$\|\Lambda_\lambda \varphi\|_{\ell^2} \le C(\lambda)\, \|\varphi\|_q\,, \qquad \forall\, \varphi \in \Phi_q\,, \tag{A.515}$$

such that for each fixed $\varphi \in \Phi$ *one has* $\Lambda_\lambda \varphi = \hat{\varphi}(\lambda)$ *for* μ*-almost every* λ*. In particular* Λ_λ *is continuous for the topology of* Φ.
Rests on Theorem A.281 and Proposition A.280.

Proof. *Derives Proposition A.282.*
Let q and $\{e_k\}$ be as in Theorem A.281. Applying Equation (A.512) to each e_k and summing,

$$\int_{\mathbb{R}} \left(\sum_k \|\hat{e}_k(\lambda)\|_{\ell^2}^2 \right) \mathrm{d}\mu(\lambda) = \sum_k \|e_k\|_{\mathcal{H}}^2 < \infty\,, \tag{A.516}$$

the exchange of sum and integral being monotone convergence for a series of non-negative terms (Remark 12.1). A non-negative function with finite integral is finite almost everywhere, so

$$C(\lambda)^2 = \sum_k \|\hat{e}_k(\lambda)\|_{\ell^2}^2 < \infty \qquad \text{for } \mu\text{-almost every } \lambda\,. \tag{A.517}$$

This is the entire role of nuclearity: without Equation (A.514) the left-hand side of Equation (A.516) is a divergent series and Equation (A.517) says nothing.

Fix such a λ. For $\varphi \in \Phi_q$ expand $\varphi = \sum_k c_k e_k$ with $c_k = \langle e_k | \varphi \rangle_q$ and $\sum_k |c_k|^2 = \|\varphi\|_q^2$ (Theorem 12.30), and put

$$\Lambda_\lambda \varphi = \sum_k c_k\, \hat{e}_k(\lambda)\,. \tag{A.518}$$

The series converges absolutely in $\ell^2(\mathbb{N})$, since by Cauchy–Schwarz

$$\sum_k |c_k|\, \|\hat{e}_k(\lambda)\| \le \Big(\sum_k |c_k|^2 \Big)^{1/2} \Big(\sum_k \|\hat{e}_k(\lambda)\|^2 \Big)^{1/2} = C(\lambda)\, \|\varphi\|_q\,,$$

which is also Equation (A.515). Linearity is clear.

It remains to identify $\Lambda_\lambda \varphi$ with the fibre of φ. Fix $\varphi \in \Phi$ and let $S_N = \sum_{k \le N} c_k e_k$. Then $S_N \longrightarrow \varphi$ in Φ_q, hence in $\mathcal{H}$ because the embedding is bounded, and J is isometric, so

$$\int_{\mathbb{R}} \big\| \hat{S}_N(\lambda) - \hat{\varphi}(\lambda) \big\|^2 \, \mathrm{d}\mu(\lambda) = \|S_N - \varphi\|_{\mathcal{H}}^2 \longrightarrow 0\,.$$

A sequence converging in $L^2(\mu)$ has a subsequence converging μ-almost everywhere (Remark A.284), so along it $\hat{S}_N(\lambda) \longrightarrow \hat{\varphi}(\lambda)$ for almost every λ. But $\hat{S}_N(\lambda)$ is the Nth partial sum of Equation (A.518), which converges to $\Lambda_\lambda \varphi$ for every λ satisfying Equation (A.517). Limits are unique, so $\Lambda_\lambda \varphi = \hat{\varphi}(\lambda)$ almost everywhere. Finally $\|\cdot\|_q$ is one of the norms defining the topology of Φ, so Equation (A.515) is continuity on Φ. □

A.27.4 Generalized eigenvectors, and completeness

Proof of Theorem A.279. *Derives Theorem A.279.*

Take μ, $\mathcal{H}_\lambda = \ell^2(\mathbb{N})$ and Λ_λ from Propositions A.280 and A.282.

(1) The eigenvalue relation. Since A maps Φ into Φ, in particular $\Phi \subseteq D(A)$, and Proposition A.280 gives, for each fixed $\varphi \in \Phi$,

$$\Lambda_\lambda(A\varphi) = \widehat{A\varphi}(\lambda) = \lambda\,\hat{\varphi}(\lambda) = \lambda\,\Lambda_\lambda\varphi \qquad \text{for } \mu\text{-almost every } \lambda\,, \tag{A.519}$$

the exceptional null set depending on φ. Let $\{\varphi_j\}$ be dense in Φ, which exists because Φ is separable, and let Z be the union of the countably many exceptional sets attached to the φ_j together with the null set outside which Equation (A.517) holds; Z is μ-null. For $\lambda \notin Z$ the two maps $\varphi \longmapsto \Lambda_\lambda(A\varphi)$ and $\varphi \longmapsto \lambda\Lambda_\lambda\varphi$ are continuous on Φ — the first because A is continuous from Φ to Φ and Λ_λ is continuous on Φ, the second by Equation (A.515) — and they agree on the dense set $\{\varphi_j\}$, hence everywhere. This is (1), now with one null set for all φ at once.

(2) The functionals. For $\lambda \notin Z$ and $\xi \in \mathcal{H}_\lambda$ put $F_{\lambda,\xi}(\varphi) = \langle \xi | \Lambda_\lambda\varphi\rangle$. It is linear in φ, because Λ_λ is linear and the inner product is linear in its second slot (Equation (5.34)), and continuous, since $|F_{\lambda,\xi}(\varphi)| \le \|\xi\|\, C(\lambda)\, \|\varphi\|_q$ by Equation (12.1) and Equation (A.515); so $F_{\lambda,\xi} \in \Phi'$ (Definition 12.103). By (1) and the reality of λ,

$$F_{\lambda,\xi}(A\varphi) = \langle \xi | \Lambda_\lambda(A\varphi)\rangle = \langle \xi | \lambda\Lambda_\lambda\varphi\rangle = \lambda\, F_{\lambda,\xi}(\varphi)\,,$$

which is Equation (12.68): $F_{\lambda,\xi}$ is a generalized eigenvector of A with eigenvalue λ.

(3) Completeness. Polarising the isometry Equation (A.512) — by Equation (12.3), an isometry of Hilbert spaces preserves inner products — gives, for $\varphi, \psi \in \Phi$,

$$\langle \varphi | \psi \rangle_{\mathcal{H}} = \int_{\mathbb{R}} \Big\langle \hat{\varphi}(\lambda) \Big| \hat{\psi}(\lambda) \Big\rangle_{\ell^2}\, \mathrm{d}\mu(\lambda)\,. \tag{A.520}$$

Let $\{\xi_n\}$ be the standard orthonormal basis of $\ell^2(\mathbb{N})$, the same for every λ, and $F_{\lambda,n} = F_{\lambda,\xi_n}$. Parseval's identity Equation (12.20) in the fibre reads

$$\Big\langle \hat{\varphi}(\lambda) \Big| \hat{\psi}(\lambda) \Big\rangle = \sum_n \langle \hat{\varphi}(\lambda) | \xi_n \rangle \Big\langle \xi_n \Big| \hat{\psi}(\lambda) \Big\rangle = \sum_n F_{\lambda,n}(\varphi)^*\, F_{\lambda,n}(\psi)\,,$$

using $\Lambda_\lambda\varphi = \hat{\varphi}(\lambda)$ almost everywhere and $\langle \hat{\varphi} | \xi_n\rangle = \langle \xi_n | \hat{\varphi}\rangle^* = F_{\lambda,n}(\varphi)^*$. Substituting into Equation (A.520) gives Equation (A.511). Since μ is supported on $\sigma(A)$, the integral may be written over $\sigma(A)$.

Simple spectrum. If a single cyclic vector generates $\mathcal{H}$ the decomposition of Proposition A.280 has one block, $\ell^2(\mathbb{N})$ is replaced by $\mathbb{C}$, and Equation (A.511) collapses to $\langle \varphi | \psi \rangle = \int F_\lambda(\varphi)^* F_\lambda(\psi)\, \mathrm{d}\mu$, which is Equation (12.69). □

Example A.283 (Momentum on the line)**.** For the Schwartz triple Equation (12.66) and $A = P = -\mathrm{i}\hbar\,\mathrm{d}/\mathrm{d}x$, the spectrum is simple, μ may be taken to be Lebesgue measure on $\mathbb{R}$ in the variable p, and $\Lambda_p\varphi$ is the Fourier transform Equation (12.67), so that $F_p = F_p$ of Proposition 12.106. Statement (2) of Theorem A.279 is then the computation already carried out there, and Equation (A.511) is the Plancherel identity of Chapter 17. The plane waves are a complete set of generalized eigenvectors of the momentum, and no one of them is a state.

Rests on Theorem A.279, Proposition 12.106, and Example 12.104.

Remark A.284 (What is quoted here). This is the one long proof of Chapter 12 that rests on a theory the treatise does not build, and the reader is owed a precise account of where.

- Theorem A.281 — that a countably Hilbert nuclear space embeds in $\mathcal{H}$ through some Hilbert–Schmidt map — is *assumed*. It is the definition of nuclearity (Definition A.278) plus the elementary fact that the composition of a nuclear map with a bounded one is Hilbert–Schmidt, but the theory of nuclear spaces itself, including the proof that $\mathcal{S}(\mathbb{R})$ is nuclear, is not developed anywhere in this treatise. Reference of record: [1276], volume 4, chapter I. Everything that nuclearity is used for is Equations (A.516) and (A.517) and nothing else — which is why the architecture above is worth having even though the input is quoted: the reader can see exactly how much is being bought, and how little.

- Three standard theorems of measure theory are used: the Radon–Nikodym theorem, in Proposition A.280; the monotone convergence theorem, twice; and the fact that a sequence convergent in L^2 has an almost-everywhere convergent subsequence. The treatise develops no measure theory and says so in Remark 12.1, where the convergence theorems are already declared.

- The spectral theorem is *not* quoted: the direct integral of Proposition A.280 is built from Appendix A.24 for bounded A and from Proposition A.262 for unbounded A — the momentum operator of Example A.283 is the unbounded case.

- Two hypotheses of Theorem A.279 are suppressed in the chapter's statement Theorem 12.107 and are used here: separability of $\mathcal{H}$, without which the cyclic decomposition need not be countable, and separability of Φ, without which the single null set of Equation (A.519) cannot be assembled. Both hold for the Schwartz triple. A third point of honesty: for a spectrum of multiplicity greater than one the completeness relation carries the sum over n displayed in Equation (A.511), which Equation (12.69) suppresses; the two agree exactly when the spectrum is simple.

Nothing above claims more. In particular the theorem does not say that the $F_{\lambda,n}$ are unique, nor that every generalized eigenvector arises this way, nor that μ is canonical — only its measure class is — and no use made of the theorem in this treatise requires any of those.

Remark A.285. Appendix A.27 discharges the proof obligation of Theorem 12.107 (Section 12.6.3). What it licenses is the working rule of Remark 12.108: a ket belonging to a point of continuous spectrum is an element of Φ', the pairing $\langle\lambda|\varphi\rangle$ is the number $F_\lambda(\varphi)$ for a test function φ, and the "normalisation" $\langle\lambda|\lambda'\rangle = \delta(\lambda-\lambda')$ is shorthand for Equation (A.511) — an identity between functionals, never between numbers. Proposition 12.102 is the proof that no other reading is available, and Example A.283 is the case every scattering calculation of Chapter 86 silently uses.

A.28 The Implicit Function Theorem

This appendix proves the one input that Theorem 13.59 of Chapter 13 takes from multivariable calculus and that Chapter 7 does not state: where the derivative of a system of equations with respect to one block of variables is invertible, the system can be solved locally for that block as a differentiable function of the remaining variables, and the solution is as smooth as the system. It is the theorem that turns a level set into a graph, and through the regular value theorem it is what makes a sphere, a hyperboloid, a constraint surface or a mass shell a manifold at all.

What is assumed as already available is exactly the several-variable differential calculus of Section 7.10.2: partial derivatives and the gradient (Definition 7.65), the class C^1 (Definition 7.66), differentiability at a point with the uniqueness of the differential (Definitions 7.67 and 7.70), the theorem that a C^1 map is differentiable (Theorem 7.68),

the chain rule (Proposition 7.72), the one-variable mean value theorem (Theorem 7.35), the Cauchy criterion (Theorem 7.8) and the geometric series (Proposition 7.46). *No* fixed-point theorem is imported: the contraction is carried out explicitly, in the manner of the Picard iteration of Theorem 9.8, with the geometric estimate written out. Nothing else is quoted — see Remark A.295.

Throughout, $|\cdot|$ is the Euclidean length (Equation (6.12)) and, for a real matrix A,

$$\|A\| = \left(\sum_{i,j} (A_{ij})^2 \right)^{1/2} , \qquad |Av| \le \|A\|\,|v| , \tag{A.521}$$

by the Cauchy–Schwarz inequality of Chapter 5 applied row by row. Points of $\mathbb{R}^m \times \mathbb{R}^n$ are written (x, y) with $x \in \mathbb{R}^m$, $y \in \mathbb{R}^n$; for a map F into $\mathbb{R}^n$ we write

$$(D_x F)^i{}_j = \frac{\partial F^i}{\partial x^j} , \qquad (D_y F)^i{}_j = \frac{\partial F^i}{\partial y^j} , \tag{A.522}$$

the first an $n \times m$ matrix, the second an $n \times n$ matrix.

A.28.1 Statement

Theorem A.286 (Implicit function theorem)**.** *Let $A \subseteq \mathbb{R}^m \times \mathbb{R}^n$ be open, let $F : A \longrightarrow \mathbb{R}^n$ be of class C^k with $k \ge 1$, and let $(a, b) \in A$ satisfy*

$$F(a, b) = 0 , \qquad \det\left[D_y F(a, b) \right] \neq 0 . \tag{A.523}$$

Then there are open sets $W \subseteq \mathbb{R}^m$ with $a \in W$ and $V \subseteq \mathbb{R}^n$ with $b \in V$, satisfying $W \times V \subseteq A$, and a map $h : W \longrightarrow V$ such that

$$\{ (x, y) \in W \times V \mid F(x, y) = 0 \} = \{ (x, h(x)) \mid x \in W \} , \qquad h(a) = b . \tag{A.524}$$

The map h is unique: it is the only map $W \longrightarrow V$ whose graph is the zero set. It is of class C^k, and

$$Dh(x) = - \left[D_y F(x, h(x)) \right]^{-1} D_x F(x, h(x)) , \qquad x \in W . \tag{A.525}$$

If F is smooth, so is h.

Rests on Theorem 7.68, Proposition 7.72, and Definition 7.67.

The proof is in four movements: the equation is recast as a fixed-point problem whose iteration contracts (Appendix A.28.2); the iteration is run and its limit shown to be the unique solution (Appendix A.28.3); the solution is shown Lipschitz and then differentiable, with Equation (A.525) (Appendix A.28.4); and the smoothness is bootstrapped to C^k there as well. Appendix A.28.5 draws the two corollaries the treatise uses.

A.28.2 The contraction

Lemma A.287 (The Newton map contracts)**.** *Under the hypotheses of Theorem A.286, put*

$$C = \left[D_y F(a, b) \right]^{-1} , \qquad T(x, y) = y - C\, F(x, y) . \tag{A.526}$$

Then there are $r > 0$ and $\rho \in (0, r]$ such that, writing $\overline{B}_r$ for closed balls, $\overline{B}_\rho(a) \times \overline{B}_r(b) \subseteq A$ and:

1. *for every $y \in \overline{B}_r(b)$ and $x \in \overline{B}_\rho(a)$, $F(x, y) = 0$ if and only if $T(x, y) = y$;*
2. *$|T(x, y) - T(x, y')| \le \frac{1}{2}\,|y - y'|$ for all $y, y' \in \overline{B}_r(b)$ and $x \in \overline{B}_\rho(a)$;*

3. $|T(x,b)-b| \le r/4$ *for every* $x \in \overline{B}_\rho(a)$;

4. $T(x,\cdot)$ *maps* $\overline{B}_r(b)$ *into itself; and*

5. $\det[D_y F(x,y)] \neq 0$ *throughout* $\overline{B}_\rho(a) \times \overline{B}_r(b)$.

Rests on Equation (A.523), Theorem 7.35, and Definition 7.66.

Proof. *Derives Lemma A.287.*

C exists by Equation (A.523). Assertion (1) is immediate from Equation (A.526): $T(x,y) = y$ says $C\,F(x,y) = 0$, and C is invertible, so this says $F(x,y) = 0$.

Differentiating Equation (A.526) in y,

$$D_y T(x,y) = \mathbb{1} - C\,D_y F(x,y)\,, \tag{A.527}$$

which vanishes at (a,b) by the definition of C. The entries of $D_y F$ are continuous, because F is C^1 (Definition 7.66), hence so are those of $D_y T$ and so is $\det[D_y F]$. Choose $r > 0$ with $\overline{B}_r(a) \times \overline{B}_r(b) \subseteq A$ and, by that continuity together with $D_y T(a,b) = 0$ and $\det[D_y F(a,b)] \neq 0$, small enough that

$$\|D_y T(x,y)\| \le \frac{1}{2\sqrt{n}}\,, \qquad \det[D_y F(x,y)] \neq 0\,, \tag{A.528}$$

on the whole of $\overline{B}_r(a) \times \overline{B}_r(b)$. That is assertion (5).

For (2), fix x and y, y' in the convex set $\overline{B}_r(b)$. Applying Theorem 7.35 to $\lambda \longmapsto T^i\,(x, y' + \lambda(y - y'))$ on $[0,1]$ gives $\theta_i \in (0,1)$ with

$$T^i(x,y) - T^i(x,y') = \nabla_y T^i(x,\xi_i) \cdot (y - y')\,, \qquad \xi_i = y' + \theta_i(y - y') \in \overline{B}_r(b)\,,$$

so that $|T^i(x,y) - T^i(x,y')| \le \|D_y T(x,\xi_i)\|\ |y - y'| \le |y - y'|\,/(2\sqrt{n})$, the row length being at most the whole matrix norm Equation (A.521). Squaring and summing the n components gives (2).

For (3): $T(a,b) = b$ because $F(a,b) = 0$, and $x \longmapsto T(x,b)$ is continuous, so there is $\rho \in (0,r]$ with $|T(x,b) - b| \le r/4$ for $|x - a| \le \rho$.

For (4), combine (2) and (3): for $y \in \overline{B}_r(b)$ and $|x - a| \le \rho$,

$$|T(x,y) - b| \le |T(x,y) - T(x,b)| + |T(x,b) - b| \le \frac{|y-b|}{2} + \frac{r}{4} \le \frac{3r}{4} < r\,. \tag{A.529}$$

□

A.28.3 Existence and uniqueness of the implicit map

Lemma A.288 (The iteration converges)**.** *With* r, ρ *as in Lemma A.287, fix* $x \in \overline{B}_\rho(a)$ *and define*

$$y_0 = b\,, \qquad y_{j+1} = T(x, y_j)\,. \tag{A.530}$$

Then every y_j *lies in* $\overline{B}_r(b)$*, the sequence converges to a limit* $h(x)$ *with*

$$|h(x) - b| \le \frac{r}{2}\,, \tag{A.531}$$

and $h(x)$ *is the unique point of* $\overline{B}_r(b)$ *with* $F(x, h(x)) = 0$.

Rests on Lemma A.287, Theorem 7.8, and Proposition 7.46.

Proof. *Derives Lemma A.288.*

The iterates stay in $\overline{B}_r(b)$ by Equation (A.529) and induction. By assertion (2) of Lemma A.287,

$$|y_{j+1} - y_j| = |T(x, y_j) - T(x, y_{j-1})| \le \frac{1}{2} |y_j - y_{j-1}| \le \cdots \le 2^{-j} |y_1 - y_0| \le 2^{-j} \frac{r}{4}, \tag{A.532}$$

the last step by assertion (3). For $l > j$ the triangle inequality (Proposition 7.3) and the geometric series (Proposition 7.46) give

$$|y_l - y_j| \le \sum_{s=j}^{l-1} |y_{s+1} - y_s| \le \frac{r}{4} \sum_{s \ge j} 2^{-s} = \frac{r}{2^{j+1}},$$

so each of the n coordinate sequences is a Cauchy sequence of reals and converges (Theorem 7.8); call the limit $h(x)$, which lies in the closed set $\overline{B}_r(b)$. Letting $l \to \infty$ with $j = 0$ in the display gives $|h(x) - b| \le r/2$, which is Equation (A.531). Since $T(x, \cdot)$ is continuous (indeed Lipschitz, by assertion (2)), passing to the limit in Equation (A.530) gives $T(x, h(x)) = h(x)$, i.e. $F(x, h(x)) = 0$ by assertion (1).

Uniqueness in $\overline{B}_r(b)$: if y and y' both satisfy $F(x, \cdot) = 0$ there, both are fixed points of $T(x, \cdot)$, and assertion (2) gives $|y - y'| \le \frac{1}{2} |y - y'|$, hence $y = y'$. □

Corollary A.289 (The zero set is a graph)**.** *Put $W = B_\rho(a)$ and $V = B_r(b)$, the* open *balls. Then $W \times V \subseteq A$, $h(W) \subseteq V$, $h(a) = b$, and Equation (A.524) holds; moreover h is the only map $W \longrightarrow V$ whose graph is the zero set of F in $W \times V$.*

Rests on Lemma A.288.

Proof. *Derives Corollary A.289.*

$h(x) \in V$ by Equation (A.531), since $r/2 < r$; and $h(a) = b$ because $y \equiv b$ is then a fixed point, unique by Lemma A.288. If $(x, y) \in W \times V$ has $F(x, y) = 0$ then $y \in \overline{B}_r(b)$, so $y = h(x)$ by the uniqueness clause; conversely $F(x, h(x)) = 0$ for every $x \in W$. That is Equation (A.524). Any other map $g : W \longrightarrow V$ with the same graph would satisfy $F(x, g(x)) = 0$ with $g(x) \in \overline{B}_r(b)$, hence $g = h$. □

A.28.4 Continuity, differentiability and the derivative formula

Lemma A.290 (h is Lipschitz)**.** *There is $K \ge 0$ with*

$$|h(x) - h(x')| \le K \, |x - x'|, \qquad x, x' \in W. \tag{A.533}$$

In particular h is continuous.

Rests on Lemma A.288 and Theorem 7.35.

Proof. *Derives Lemma A.290.*

The entries of $D_x F$ are continuous, hence bounded on the compact set $\overline{B}_\rho(a) \times \overline{B}_r(b)$ (Theorem 7.24); let μ bound $\|D_x F\|$ there. Exactly as in step (2) of Lemma A.287, the mean value theorem along the segment from x' to x — which lies in the convex ball $\overline{B}_\rho(a)$ — gives

$$|F(x, y) - F(x', y)| \le \sqrt{n}\, \mu \, |x - x'|, \qquad y \in \overline{B}_r(b). \tag{A.534}$$

Now, using that $h(x)$ and $h(x')$ are fixed points of $T(x, \cdot)$ and $T(x', \cdot)$,

$$\begin{aligned} |h(x) - h(x')| &= |T(x, h(x)) - T(x', h(x'))| \\ &\le |T(x, h(x)) - T(x, h(x'))| + |T(x, h(x')) - T(x', h(x'))| \\ &\le \frac{1}{2} |h(x) - h(x')| + \|C\| \, |F(x, h(x')) - F(x', h(x'))|, \end{aligned}$$

the last term because $T(x, y) - T(x', y) = -C\,[F(x, y) - F(x', y)]$. Absorbing the first term on the left and inserting Equation (A.534) gives Equation (A.533) with $K = 2\sqrt{n}\, \mu \, \|C\|$. □

Lemma A.291 (h is differentiable, with the stated derivative)**.** *h is differentiable at every $x \in W$ and its differential is Equation (A.525); the right-hand side of Equation (A.525) is continuous on W, so h is C^1.*

Rests on Lemma A.290, Theorem 7.68, and Definition 7.67.

Proof. *Derives Lemma A.291.*

Fix $x \in W$, write $y = h(x)$, and let $s \in \mathbb{R}^m$ be small enough that $x + s \in W$. Put

$$\Delta = h(x+s) - h(x)\,, \qquad \text{so} \qquad |\Delta| \le K\,|s|$$

by Equation (A.533). Since F is C^1 it is differentiable at (x, y) (Theorem 7.68), and its differential is the pair of blocks Equation (A.522) (Definition 7.70); so by Equation (7.45) there is a function ε with $|\varepsilon(s,\Delta)| \,/\, (|s| + |\Delta|) \longrightarrow 0$ and

$$0 = F(x+s,\, y+\Delta) - F(x,y) = D_xF(x,y)\,s + D_yF(x,y)\,\Delta + \varepsilon(s,\Delta)\,, \tag{A.535}$$

both values of F vanishing by Equation (A.524). Because $|\Delta| \le K\,|s|$, the remainder obeys $|\varepsilon| \le (1+K)\,|s| \cdot |\varepsilon| \,/ (|s| + |\Delta|)$, so it is $o(|s|)$. The matrix $D_yF(x,y)$ is invertible by assertion (5) of Lemma A.287, so solving Equation (A.535) for Δ,

$$\Delta = -\,[D_yF(x,y)]^{-1}\,D_xF(x,y)\,s - [D_yF(x,y)]^{-1}\,\varepsilon\,. \tag{A.536}$$

The second term is $o(|s|)$ as well, the matrix being a fixed one. Hence $h(x+s) - h(x) - \left(-\,[D_yF]^{-1}\,D_xF\right) s = o(|s|)$, which by Definition 7.67 says that h is differentiable at x with the differential Equation (A.525); the differential being unique, no other candidate exists.

Continuity: the entries of $[D_yF]^{-1}$ are, by Cramer's rule (Chapter 5), quotients of polynomials in the entries of D_yF by the determinant, which does not vanish on $\overline{B}_\rho(a) \times \overline{B}_r(b)$; those entries are continuous, and so is h (Lemma A.290), so the composite $x \longmapsto -\,[D_yF(x,h(x))]^{-1}\,D_xF(x,h(x))$ is continuous. By Definition 7.66, h is C^1. □

Proof of Theorem A.286. *Derives Theorem A.286.*

Corollary A.289 supplies W, V, h, Equation (A.524) and the uniqueness; Lemma A.291 supplies Equation (A.525) and the class C^1. It remains to raise the smoothness. Write

$$Dh(x) = G(x,h(x))\,, \qquad G(x,y) = -\,[D_yF(x,y)]^{-1}\,D_xF(x,y)\,. \tag{A.537}$$

If F is C^k then D_xF and D_yF are C^{k-1}, and so is $[D_yF]^{-1}$, its entries being quotients of polynomials in C^{k-1} functions with non-vanishing denominator; hence G is C^{k-1}. We prove by induction on j that h is C^j for $1 \le j \le k$. The case $j = 1$ is Lemma A.291. Suppose h is C^j with $j < k$. Then $x \longmapsto (x, h(x))$ is C^j, and G is C^{k-1} with $k - 1 \ge j$; a composition of a C^j map with a C^j map is C^j, because by the chain rule Equation (7.52) each first partial derivative of the composite is a sum of products of first partial derivatives of the two factors, and an induction on j carries this to order j. So Dh is C^j by Equation (A.537), that is, h is C^{j+1}. After $k-1$ steps h is C^k. If F is smooth the argument applies for every k, so h is smooth. □

A.28.5 The two consequences the treatise uses

Corollary A.292 (Inverse function theorem)**.** *Let $U \subseteq \mathbb{R}^n$ be open, $f : U \longrightarrow \mathbb{R}^n$ of class C^k with $k \ge 1$, and $\alpha \in U$ with $\det [Df(\alpha)] \neq 0$. Then there are open sets $U_0 \subseteq U$ with $\alpha \in U_0$ and $V_0 \subseteq \mathbb{R}^n$ with $f(\alpha) \in V_0$ such that f maps U_0 bijectively onto V_0, the inverse $g : V_0 \longrightarrow U_0$ is C^k, and*

$$Dg(v) = \left[Df(g(v))\right]^{-1}\,. \tag{A.538}$$

Rests on Theorem A.286 and Proposition 7.72.

Proof. *Derives Corollary A.292.*

Apply Theorem A.286 to

$$\Phi : \mathbb{R}^n \times U \longrightarrow \mathbb{R}^n , \qquad \Phi(v,u) = v - f(u) ,$$

at the point $(f(\alpha),\alpha)$, where $\Phi = 0$ and $D_u\Phi = -Df(\alpha)$ is invertible. It supplies open sets $V_0 \ni f(\alpha)$ and $V \ni \alpha$ and a C^k map $g : V_0 \longrightarrow V$ whose graph is the zero set of Φ in $V_0 \times V$; that is,

$$\text{for } (v,u) \in V_0 \times V : \qquad f(u) = v \iff u = g(v) . \tag{A.539}$$

Put $U_0 = V \cap f^{-1}(V_0)$, open because f is continuous, and note $\alpha \in U_0$. If $u \in U_0$ then $(f(u),u) \in V_0 \times V$, so $u = g(f(u))$ by Equation (A.539): f is injective on U_0. If $v \in V_0$ then $g(v) \in V$ and $f(g(v)) = v \in V_0$, so $g(v) \in U_0$ and $v \in f(U_0)$: f maps U_0 onto V_0, with g as its two-sided inverse. Finally, differentiating $g \circ f = \mathrm{id}$ on U_0 by the chain rule Equation (7.52) gives $Dg(f(u))Df(u) = \mathbb{1}$, which is Equation (A.538) at $v = f(u)$. □

Corollary A.293 (Solving one scalar equation for one coordinate)**.** *Let $A \subseteq \mathbb{R}^n$ be open, $F : A \longrightarrow \mathbb{R}$ of class C^k with $k \geq 1$, and let $P \in A$ satisfy $F(P) = c$ and $\partial F/\partial x^n(P) \neq 0$. Write $P = (P', P^n)$ with $P' \in \mathbb{R}^{n-1}$. Then there are an open set $W \subseteq \mathbb{R}^{n-1}$ containing P' and an open interval I containing P^n, with $W \times I \subseteq A$, and a C^k function $\varsigma : W \longrightarrow I$ with $\varsigma(P') = P^n$ such that, inside $W \times I$,*

$$F\left(x^1,\dots,x^n\right) = c \quad \iff \quad x^n = \varsigma\left(x^1,\dots,x^{n-1}\right) , \tag{A.540}$$

and

$$\frac{\partial \varsigma}{\partial x^i}\left(x'\right) = -\left.\frac{\partial F/\partial x^i}{\partial F/\partial x^n}\right|_{(x',\varsigma(x'))} , \qquad i = 1,\dots,n-1 . \tag{A.541}$$

Rests on Theorem A.286.

Proof. *Derives Corollary A.293.*

Apply Theorem A.286 with $m = n-1$, target dimension 1, and $G(x',x^n) = F(x',x^n) - c$ at the point (P',P^n): $G = 0$ there, and D_yG is the 1×1 matrix $\partial F/\partial x^n(P) \neq 0$, whose determinant is itself. The theorem returns W, an open ball $V \subseteq \mathbb{R}$ — that is, an open interval I — and ς of class C^k with Equation (A.524), which is Equation (A.540). Equation (A.525) reads, for 1×1 blocks, $D\varsigma = -\left(\partial F/\partial x^n\right)^{-1}\left(\partial F/\partial x^1,\dots,\partial F/\partial x^{n-1}\right)$, which is Equation (A.541). □

Example A.294 (The sphere, made explicit)**.** Take $n = 3$ and $F(x,y,z) = x^2 + y^2 + z^2$, $c = R^2 > 0$, the level set of Example 13.61. At a point of the sphere with $z \neq 0$ one has $\partial F/\partial z = 2z \neq 0$, so Corollary A.293 applies with the whole of $\mathbb{R}^3$ as A; the function it produces is the one the chapter writes down by hand, $\varsigma(x,y) = +\sqrt{R^2 - x^2 - y^2}$ on the northern hemisphere, and Equation (A.541) returns $\partial\varsigma/\partial x = -x/z$ and $\partial\varsigma/\partial y = -y/z$, which is what differentiating the explicit square root gives. The point of the corollary is that the same conclusion holds when no explicit solution can be written: at a point of the sphere with $z = 0$ one of the other two partial derivatives is non-zero, and the corollary — applied after relabelling the coordinates — produces a graph there too. If all three partial derivatives could vanish on the level set, no such chart would be guaranteed; that is exactly the regularity hypothesis of Theorem 13.59, and on the sphere it fails only at the origin, which is not on the level set.

Rests on Corollary A.293 and Example 13.61.

A.28.6 Reading the result

Remark A.295 (Nothing is quoted here). This section imports no theorem that the treatise does not prove. In particular it does not use a fixed-point theorem: the Banach contraction principle is not in this book, and rather than quote it the iteration Equation (A.530) is run explicitly and its convergence read off from the geometric estimate Equation (A.532) and the Cauchy criterion Theorem 7.8 — the same device, and the same estimate, by which Theorem 9.8 constructs the solution of an initial value problem. The only other analytic inputs are the mean value theorem Theorem 7.35, used twice to convert a bound on a derivative into a Lipschitz bound; the theorem that a C^1 map is differentiable (Theorem 7.68), used once to expand F to first order in Equation (A.535); and the chain rule Proposition 7.72. From linear algebra, only the invertibility criterion $\det \neq 0$ and Cramer's rule are used.

Remark A.296 (Both hypotheses are needed, and the conclusion is local). The invertibility of $D_y F(a,b)$ cannot be dropped. On $\mathbb{R}\times\mathbb{R}$, $F(x,y)=y^2-x$ has $F(0,0)=0$ and $\partial F/\partial y(0,0)=0$; the zero set near the origin is the parabola $x=y^2$, which is not the graph of any function of x — two solutions for $x>0$, none for $x<0$. The conclusion is also irreducibly local: $F(x,y)=x^2+y^2-1$ on $\mathbb{R}\times\mathbb{R}$ satisfies the hypotheses at $(0,1)$, and the implicit function $\varsigma(x)=\sqrt{1-x^2}$ exists only for $|x|<1$ and cannot be continued past $x=\pm1$, where $\partial F/\partial y$ vanishes. Finally, the smoothness of h can be no better than that of F: taking $m=n=1$ and $F(x,y)=y-\phi(x)$ with ϕ of class C^k but not C^{k+1} makes $h=\phi$.
Rests on Theorem A.286.

Remark A.297. Appendix A.28 discharges the derivation owed at Remark 13.60 of Chapter 13. The statement used there is Corollary A.293: in the proof of the regular value theorem Theorem 13.59 a chart is chosen in which $\partial F/\partial x^n \neq 0$ at the point, and Equation (A.540) is exactly the assertion Equation (13.146) that the level set meets the coordinate box in the graph of a smooth h — from which the chapter reads off the chart $u \longmapsto (u, h(u))$ of the hypersurface. The regular value theorem in turn underlies Example 13.61 and Definition 13.58 and every later construction of a submanifold by one equation. The inverse function theorem Corollary A.292, proved here as a companion, is what licenses a change of chart whenever a Jacobian determinant is non-zero, and is used in that role in Appendix A.29.

A.29 The General Stokes Theorem for Differential Forms

This appendix proves the theorem that Equation (13.231) of Chapter 13 is an instance of: for a compact oriented n-manifold M with boundary and a smooth $(n-1)$-form ω on it,

$$\int_M \mathrm{d}\omega = \int_{\partial M} \omega\,. \tag{A.542}$$

It is the single statement of which Green's theorem (Theorem 7.99), the classical Stokes theorem (Theorem 7.100), Gauss's theorem (Theorem 7.101) and the antisymmetric-tensor form Equation (13.231) are the low-dimensional faces, and Remark 7.102 names it as the formulation the treatise was still owed.

There is no circularity to create. Chapter 7 proves its three classical theorems directly from the fundamental theorem of calculus over simple regions and does not lean on the present section; the present section does not use them. What it does use from Chapter 7 is the multiple integral (Definition 7.93), the three properties of it collected as declared inputs in Remark 7.96 — integrability of a continuous function, additivity, and reduction to an iterated integral — and the fundamental theorem of calculus (Theorem 7.43). From Chapter 13 it uses the whole exterior calculus: Definitions 13.98, 13.102 and 13.103, Proposition 13.100, and Equation (13.246). From this appendix it uses the pullback of a k-form (Definition A.70 and Lemma A.71) and the inverse function theorem (Corollary A.292). One input is *quoted*,

the change-of-variables formula for multiple integrals; it is stated precisely as Theorem A.303 and discussed in Remark A.316.

A.29.1 Manifolds with boundary

Definition A.298 (Half-space; smoothness on it)**.** The *closed half-space* is

$$\mathbb{H}^n = \left\{ x = (x^1, \dots, x^n) \in \mathbb{R}^n \mid x^n \le 0 \right\}, \qquad \partial\mathbb{H}^n = \{ x \in \mathbb{H}^n \mid x^n = 0 \}, \tag{A.543}$$

carrying the subspace topology of $\mathbb{R}^n$ (Definition 6.1). A map defined on a subset $S \subseteq \mathbb{H}^n$ that is open in $\mathbb{H}^n$ is called *smooth* if it extends to a smooth map on some open subset of $\mathbb{R}^n$ containing S; all partial derivatives are then defined at points of $\partial\mathbb{H}^n$ as well, and take there the values of the one-sided limits, so that every identity of the differential calculus of Section 7.10.2 continues to hold on S.

Rests on Definitions 6.1 and 7.66.

Definition A.299 (Manifold with boundary)**.** An *n-manifold with boundary* is defined exactly as in Definition 13.48, with one change: the charts $\varphi : U \longrightarrow \varphi(U)$ of the atlas (Definition 13.44) are homeomorphisms onto subsets of $\mathbb{H}^n$ open in $\mathbb{H}^n$, rather than onto open subsets of $\mathbb{R}^n$, and the transition maps are smooth in the sense of Definition A.298. A point $P \in M$ is a *boundary point* if $\varphi(P) \in \partial\mathbb{H}^n$ for some chart around it, and an *interior point* otherwise; the set of boundary points is written ∂M.

Rests on Definitions 13.44, 13.48 and A.298.

Lemma A.300 (The boundary is well defined, and is a manifold)**.** *No point is a boundary point in one chart and an interior point in another. Moreover ∂M, with the charts obtained by dropping the last coordinate of a boundary chart, is an $(n-1)$-manifold without boundary.*

Rests on Definition A.299 and Corollary A.292.

Proof. *Derives Lemma A.300.*
